Proceedings of the

Fifth International Joint Conference on

Autonomous Agents

and

Multiagent Systems

Future University-Hakodate, Japan
May 8-12, 2006

Edited by

Peter Stone, Gerhard Weiss

Table of Contents

INTRODUCTION..... **xxi**
INDUSTRY TRACK INTRODUCTION..... **xxiv**
CONFERENCE OFFICIALS..... **xxv**
SENIOR PROGRAM COMMITTEE..... **xxvii**
PROGRAM COMMITTEE..... **xxviii**
AUXILIARY REVIEWERS..... **xxxi**
INDUSTRY TRACK OFFICIALS..... **xxxiii**
SPONSORSHIP AND SUPPORT..... **xxxiv**

Invited Talks **1**

Towards Emergence of Communication: A Cognitive Developmental Robotics Approach 3
Minoru Asada
Making Strong Business Case for Multiagent Technology 10
Steve S. Benfield Jim Hendrickson, Daniel Galanti

SESSION: Simulation and modeling..... **17**

Full papers:
Agent Interface Enhancement: Making Multiagent Graphical Models Accessible..... 19
Yang Xiang, Kun Zhang
Power and Negotiation - Lessons from Agent-Based Participatory Simulations..... 27
Paul Guyot, Alexis Drogoul, Shinichi Honiden
RPD-Enabled Agents Teaming with Human for Multi-Context Decision Making..... 34
Xiaocong Fan, Bingjun Sun, Shuang Sun, Michael McNeese, John Yen
Camera-based Observation of Football Games for Analyzing Multi-agent Activities..... 42
Michael Beetz, Suat Gedikli, Bernhard Kirchlechner, Alexis Maldonado
Modeling one Human Decision-Maker with a Multi-Agent System: the CODAGE approach..... 50
Jean-Daniel Kant, Samuel Thiriot
Efficient Agent-Based Models for Non-Genomic Evolution..... 58
Nachi Gupta, Adrian Agogino, Kagan Tumer
Cognitive Agents Based Simulation for Decisions Regarding Human Team Composition..... 65
Bruno Gonçalves, Sofia Esteves, António Lopes, Luís Botelho

Performance of Pheromone Model for Predicting Traffic Congestion……..……..... 73
Yasushi Ando, Osamu Masutani, Hirotoshi Iwasaki, Yoshiaki Fukazawa, Shinichi Honiden
Modeling Agents and Interactions in Agricultural Economics……..... 81
Daisuke Torii, Toru Ishida, Francois Bousquet
Learnable Behavioural Model for Autonomous Virtual Agents: Low-Level Learning……..... 89
Toni Conde, Daniel Thalmann
A Flexible Framework for Representing Personality in Agents……..... 97
André Campos, Emanuel Santos, Anne Canuto, Rodrigo Soares, João Alchieri

Short papers:

Emotion-based Norm Enforcement and Maintenance in Multi-Agent Systems: Foundations and Petri Net Modeling……..... 105
Julia Fix, Christian von Scheve, Daniel Moldt
An Agent-Based Simulation of Pedestrian Dynamics: from Lane Formation to Auditorium Evacuation..... 108
Marcelo Toyama, Ana Bazzan, Roberto da Silva
Modeling Uncertain Domains with Polyagents……..... 111
Van Parunak, Sven Brueckner
TEAKS: Simulation of Human Performance at Work to Support Team Configuration……..... 114
Juan Martínez-Miranda, Arantza Aldea, Rene Bañares-Alcántara, Matias Alvarado
Modelling Dynamics of Cognitive Agents by Higher-Order Potentialities……..... 117
Tibor Bosse, Jan Treur
Approaches for Resolving the Dilemma between Model Structure Refinement and Parameter Calibration in Agent-Based Simulations……..... 120
Manuel Fehler, Franziska Klugl, Frank Puppe
Multiagent Simulation Meets the Real World……..... 123
Toru Ishida
Congestion Tolls as Utility Alignment Between Agent and System Optimum……..... 126
Ana Bazzan, Robert Junges
Agent-based modeling of human education data……..... 129
Yuqing Tang, Simon Parsons, Elizabeth Sklar
Study of Social Consciousness in Stochastic Agent-Based Simulations: Application to Supply Chains..... 132
Thierry Moyaux, Brahim Chaib-draa, Sophie D'Amours

SESSION: Logics for agent systems 135

Full papers:

Complexity and Succinctness of Public Announcement Logic……..... 137
Carsten Lutz
A complete and decidable security-specialised logic and its application to the TESLA protocol…….. 145
Alessio Lomuscio, Bożena Woźna
On the Logic of Coalitional Games……..... 153
Thomas Ågotnes, Wiebe van der Hoek, Michael Wooldridge
Model checking knowledge, strategies, and games in multi-agent systems……..... 161
Franco Raimondi, Alessio Lomuscio
Model Checking for Multivalued Logic of Knowledge and Time……..... 169
Wojciech Penczek, Beata Konikowska
Temporal Qualitative Coalitional Games……..... 177
Thomas Ågotnes, Wiebe van der Hoek, Michael Wooldridge
Reasoning about Action and Cooperation……..... 185
Luigi Sauro, Jelle Gerbrandy, Wiebe van der Hoek, Michael Wooldridge
Logics for Propositional Control……..... 193
Jelle Gerbrandy
On the Complexity of Practical ATL Model Checking……..... 201
Wiebe van der Hoek, Alessio Lomuscio, Michael Wooldridge
Knowing How to Play: Uniform Choices in Logics of Agency……..... 209
Andreas Herzig, Nicolas Troquard

Short paper:

Verifying space and time requirements for resource-bounded agents……..... 217
Natasha Alechina, Piergiorgio Bertoli, Chiara Ghidini, Mark Jago, Brian Logan, Luciano Serafini
The Interpreted System Model of Knowledge, Belief, Desire and Intention……..... 220
Kaile Su, Xiangyu Luo, Abdul Sattar, Mehmet Orgun
Operationalisation of Norms for Usage in Electronic Institutions……..... 223
Huib Aldewereld, Andrés García-Camino, Frank Dignum, Pablo Noriega, Juan Antonio Rodríguez-Aguilar, Carles Sierra
Mutual Enrichment Through Nested Belief Change……..... 226
Laurent Perrussel, Jean-Marc Thévenin, Thomas Meyer
An Architecture of a Normative System……..... 229
Guido Boella, Leendert van der Torre
What Agents Can Achieve under Incomplete Information……..... 232
Wojtek Jamroga, Thomas Ågotnes
Flexible agent protocols via temporal and resource-based reasoning……..... 235
Duc Pham, James Harland

Run-Time Model Checking of Interaction and Deontic Models for Multi-Agent Systems……..... 238
Nardine Osman, Dave Robertson, Christopher Walton
Modeling mental states in the analysis of multiagent systems requirements……..... 241
Alexei Lapouchnian, Yves Lespérance
A Stochastic Language for Modeling Opponent Agents……..... 244
Gerardo Simari, Amy Sliva, Dana Nau, Venkatramanan Subrahmanian

SESSION: Agent planning and search 247

Full papers:

Decentralized planning under uncertainty for teams of communicating agents……..... 249
Matthijs Spaan, Geoffrey J. Gordon, Nikos Vlassis
Integrating Parallel Interactions into Cooperative Search……..... 257
Efrat Manisterski, David Sarne, Sarit Kraus
A Multi-Agent System that Facilitates Scientific Publications Search……..... 265
Aliaksandr Birukou, Enrico Blanzieri, Paolo Giorgini
Security in multiagent systems by policy randomization……..... 273
Praveen Paruchuri, Milind Tambe, Fernando Ordóñez, Sarit Kraus
Real-Time Adaptive A*……..... 281
Sven Koenig, Maxim Likhachev
Winning back the cup for distributed POMDPs: Planning over continuous belief spaces……..... 289
Pradeep Varakantham, Ranjit Nair, Milind Tambe, Makoto Yokoo
Resource Allocation Among Agents with Preferences Induced by Factored MDPs……..... 297
Dmitri Dolgov, Edmund Durfee
Multi-Agent Based Peer-to-Peer Information Retrieval Systems With Concurrent Search Sessions……..... 305
Haizheng Zhang, Victor Lesser
A Hierarchical Approach to Efficient Reinforcement Learning in Deterministic Domains……..... 313
Carlos Diuk, Michael Littman, Alexander Strehl

Short papers:

A Smart Home Agent for plan recognition……..... 320
Bruno Bouchard, Abdenour Bouzouane, Sylvain Giroux
Exploring Sensor Networks using Mobile Agents……..... 323
Daniel Massaguer, Chien-Liang Fok, Nalini Venkatasubramanian, Gruia-Catalin Roman, Chenyang Lu
Stochastic Planning for Weakly-Coupled Distributed Agents……..... 326
AnYuan Guo, Victor Lesser

Dynamic Cooperation Using Resource Based Planning……..... 329
Utku Erdoğdu, Faruk Polat
Real-Time Target Evaluation Search……..... 332
Cagatay Undeger, Faruk Polat
Organizational Self-Design in Semi-dynamic Environments……..... 335
Sachin Kamboj, Keith Decker
A Decision-Theoretic Approach to File Consistency in Constrained Peer-to-Peer Device Networks……..338
David Roberts, Sooraj Bhat, Charles Isbell, Brian Cooper, Jeffrey S. Pierce
Solving POMDPs Using Quadratically Constrained Linear Programs……..... 341
Christopher Amato, Daniel S. Bernstein, Shlomo Zilberstein

SESSION: Argumentation and negotiation 345

Full papers:

An Argumentation-based Approach for Practical Reasoning……..... 347
Iyad Rahwan, Leila Amgoud
Predicting partner's behaviour in agent negotiation……..... 355
Jakub Brzostowski, Ryszard Kowalczyk
Tractable Negotiation in Tree-structured Domains……..... 362
Yann Chevaleyre, Ulle Endriss, Nicolas Maudet
Predicting People's Bidding Behavior in Negotiation……..... 370
Ya'akov Gal, Avi Pfeffer
Support-based Distributed Search……..... 377
Peter Harvey, Chee Fon Chang, Aditya Ghose
Adaptive Agent Negotiation via Argumentation……..... 384
Antonis Kakas, Pavlos Moraitis
Monotonic Concession Protocols for Multilateral Negotiation……..... 392
Ulle Endriss
Negotiating using Rewards……..... 400
Sarvapali Ramchurn, Carles Sierra, Lluis Godo, Nick Jennings

Short papers:

Negotiation Coalitions in Group-Choice Multi-Agent Systems……..... 408
Tom Wanyama, Behrouz Far
Negotiation-based coalitions in the physical world……..... 411
Majid Ali Khan, Ladislau Bölöni
A formal model for designing dialogue strategies……..... 414

Leila Amgoud, Nabil Hameurlain

A Scalable Method for Online Learning of Non-linear Preferences Based on Anonymous Negotiation Data 417

D.J.A. Somefun, J.A. La Poutré

Towards Formal Model of Adversarial Action in Multi-Agent Systems……..... 420

Michal Pěchouček, Jan Tožička, Martin Rehák

Negotiating Efficient Outcomes over Multiple Issues……..... 423

Sabyasachi Saha, Sandip Sen

Managing Social Influences through Argumentation-Based Negotiation……..... 426

Nishan Karunatillake, Nick Jennings, Iyad Rahwan, Sarvapali Ramchurn

An expressive approach to fuzzy constraint based agent purchase negotiation……..... 429

Miguel López-Carmona, Juan R. Velasco

Symbolic Negotiation Revisited……..... 432

Peep Küngas, Mihhail Matskin

A Multi-Issue Negotiation Protocol among Competitive Agents and its Extension to A Nonlinear Utility Negotiation Protocol……..... 435

Takayuki Ito, Mark Klein

SESSION: Robotics..... 439

Full papers:

Multi-Robot Learning with Particle Swarm Optimization……..... 441

Jim Pugh, Alcherio Martinoli

Multi-Model Motion Tracking under Multiple Team Member Actuators……..... 449

Gu Yang, Manuela Veloso

Multi-Agent Strategic Modeling in a Robotic Soccer Domain……..... 457

Andraz Bezek, Matjaz Gams, Ivan Bratko

On the Response of EMT-based Control to Interacting Targets and Models……..... 465

Zinovi Rabinovich, Jeffrey Rosenschein

Multiple UAV Task Allocation using Negotiation……..... 471

P.B. Sujit, Arpita Sinha, Debasish Ghose

Short papers:

Distributed Automatic Target Recognition Using Multi-Agent UAV Swarms……..... 479

Prithviraj Dasgupta

Action Awareness - Enabling Agents to Optimize, Transform, and Coordinate Plans……..... 482

Freek Stulp, Michael Beetz

Programming Modular Robots with the TOTA Middleware……..... 485

Marco Mamei, Franco Zambonelli

RADIC - A Generic Component for the Integration of Existing Reactive and Deliberative Layers..... 488

Matthias Scheutz, James Kramer

A Constraint Optimization Framework for Fractured Robot Teams……..... 491

Mary Koes, Katia Sycara, Illah Nourbakhsh

SESSION: Computational complexity in agent systems 495

Full papers:

Junta Distributions and the Average-Case Complexity of Manipulating Elections……..... 497

Ariel Procaccia, Jeffrey Rosenschein

The Communication Complexity of Coalition Formation Among Autonomous Agents……..... 505

Ariel Procaccia, Jeffrey Rosenschein

The Cost of Social Agents……..... 513

Guido Governatori, Antonino Rotolo, Vineet Padmanabhan

Failures of the VCG Mechanism in Combinatorial Auctions and Exchanges……..... 521

Vincent Conitzer, Tuomas Sandholm

Agent Interaction in Distributed MDPs and its Implications on Complexity……..... 529

Jiaying Shen, Raphen Becker, Victor Lesser

A Technique for Reducing Normal Form Games to Compute a Nash Equilibrium……..... 537

Vincent Conitzer, Tuomas Sandholm

Short papers:

Information-theoretic approaches to branching in search……..... 545

Andrew Gilpin, Tuomas Sandholm

The complexity of model checking concurrent programs against CTLK specifications……..... 548

Alessio Lomuscio, Franco Raimondi

SESSION: Cooperation and coordination 551

Full papers:

Distributed Navigation in an Unknown Physical Environment……..... 553

Arnon Gilboa, Ariel Felner, Amnon Meisels

Accident or Intention: That Is the Question (in the Noisy Iterated Prisoner's Dilemma)……..... 561

Tsz-Chiu Au, Dana Nau

On using Multi-agent Systems in Playing Board Games……..... 569

Stefan Johansson

Solution Sets for DCOPs and Graphical Games……..... 577
Jonathan Pearce, Rajiv Maheswaran, Milind Tambe
Towards Autonomous Mobile Agents with Emergent Migration Behaviour……..... 585
Tino Schlegel, Peter Braun, Ryszard Kowalczyk
Artifacts for Time-Aware Agents……..... 593
Cédric Dinont, Emmanuel Druon, Philippe Mathieu, Patrick Taillibert
Total Performance by Local Agent Selection Strategies in Multi-Agent Systems……..... 601
Toshiharu Sugawara, Satoshi Kurihara, Toshio Hirotsu, Kensuke Fukuda, Shinya Sato, Osamu Akashi
Effect of joining decisions on peer clusters……..... 609
Stéphane Airiau, Sandip Sen, Prithviraj Dasgupta
History-based Traffic Control……..... 616
Gabriel Balan, Sean Luke
Communication Management Using Abstraction in Distributed Bayesian Networks……..... 622
Jiaying Shen, Victor Lesser
Toward an Understanding of the Impact of SoftwarePersonal Assistants on Human Organizations……..... 630
Steven Okamoto, Paul Scerri, Katia Sycara
Robust Recognition of Physical Team Behaviors Using Spatio-temporal Models……..... 638
Gita Sukthankar, Katia Sycara
How Autonomy Oriented Computing (AOC) Tackles a Computationally Hard Optimization Problem…… 646
Xiao-Feng Xie, Jiming Liu
Social Coordination without Communication in Multi-Agent Territory Exploration Tasks……..... 654
Paul Schermerhorn, Matthias Scheutz
Analyzing characteristics of task structures to develop GPGP coordination mechanisms……..... 662
Wei Chen, Keith Decker

Short papers:

Norm-Oriented Programming of Electronic Institutions……..... 670
Andres García-Camino, Juan Antonio Rodríguez-Aguilar, Carles Sierra, Wamberto Vasconcelos
Learning to Identify Winning Coalitions in the PAC Model……..... 673
Ariel Procaccia, Jeffrey Rosenschein
A Deployed Multi-Agent Framework for Distributed Energy Applications……..... 676
Geoff James, Dave Cohen, Robert Dodier, Glenn Platt, Doug Palmer
Behaviosites: A Novel Paradigm for Affecting Distributed Behavior……..... 679
Amit Shabtay, Zinovi Rabinovich, Jeffrey Rosenschein
How can agent know the global information without close coordination?..... 682
Satoshi Kurihara, Kensuke Fukuda, Shinya Sato, Toshiharu Sugawara
Strategic voting when aggregating partially ordered preferences……..... 685

Francesca Rossi, Maria Silvia Pini, Kristen Brent Venable, Toby Walsh

Role-Based Semantics for Agent Communication……..... 688

Guido Boella, Rossana Damiano, Joris Hulstijn, Leendert van der Torre

Teaching New Teammates……..... 691

Doran Chakraborty, Sandip Sen

SESSION: Learning and evolution 695

Full papers:

Efficient agents for Cliff Edge environments with a large set of decision options……..... 697

Ron Katz, Sarit Kraus

A Novel Method for Automatic Strategy Acquisition in N-player Non-zero-sum Games……..... 705

Steve Phelps, Marek Marcinkiewicz, Simon Parsons, Peter McBurney

Robust Game Play Against Unknown Opponents……..... 713

Nathan Sturtevant, Michael Bowling

Probabilistic Policy Reuse in a Reinforcement Learning Agent……..... 720

Fernando Fernández, Manuela Veloso

Learning from Induced Changes in Opponent (Re)Actions in Multi-Agent Games……..... 728

Pieter Jan't Hoen, Sander Bohte, Han La Poutré

Learning the Required Number of Agents for Complex Tasks……..... 736

Sébastien Paquet, Brahim Chaib-draa

Extensive Games with Possibly Unaware Players……..... 744

Joseph Halpern, Leandro Rêgo

Learning against multiple opponents……..... 752

Thuc Vu, Rob Powers, Yoav Shoham

Selecting Informative Actions Improves Cooperative Multiagent Learning……..... 760

Liviu Panait, Sean Luke

The Use of Agents in Human Learning Systems……..... 767

Elizabeth Sklar, Debbie Richards

Reinforcement Learning for Declarative Optimization-Based Drama Management……..... 775

Mark Nelson, David Roberts, Charles Isbell, Michael Mateas

Short papers:

Learning to Cooperate in Multi-Agent Social Dilemmas……..... 783

Enrique Munoz de Cote, Andrea Bonarini, Alessandro Lazaric, Marcello Restelli

An Adaptive Plan-Based Dialogue Agent: Integrating Learning into a BDI Architecture…….. 786

Anh Nguyen, Wayne Wobcke

Multi-agent Reinforcement Learning Algorithm to Handle Beliefs of Other Agents' Policies and Embedded Beliefs……..... 789
Takaki Makino, Kazuyuki Aihara
Rule Value Reinforcement Learning for Cognitive Agents…..... 792
Chris Child, Kostas Stathis
Learning Executable Agent Behaviors from Observation……..... 795
Andrew Guillory, Hai Nguyen, Tucker Balch, Charles Isbell
RV $_{\sigma(t)}$: A unifying approach to performance and convergence in online multiagent learning……..... 798
Bikramjit Banerjee, Jing Peng
Lenient Learners in Cooperative Multiagent Systems……..... 801
Liviu Panait, Keith Sullivan, Sean Luke
Can Good Learners Always Compensate for Poor Learners?..... 804
Keith Sullivan, Liviu Panait, Gabriel Balan, Sean Luke
Learning Regularities with a Constructivist Agent……..... 807
Filipo Perotto, Luís Otávio Álvares
Improving Reinforcement Learning with Context Detection……..... 810
Bruno C. da Silva, Eduardo W. Basso, Filipo S. Perotto, Ana L.C. Bazzan, Paulo M. Engel
Software agents that learn through observation……..... 813
Jaçanã Machado, Luís Botelho

SESSION: Task and resource allocation 817

Full papers:

Resource Selection Games with Unknown Number of Players……..... 819
Itai Ashlagi, Dov Monderer, Moshe Tennenholtz
Adaptive Distributed Resource Allocation and Diagnostics Using Cooperative Information-Sharing Strategies……..... 826
Partha Dutta, Nick Jennings, Luc Moreau
Forming Efficient Agent Groups for Completing Complex Tasks……..... 834
Efrat Manisterski, Esther David, Sarit Kraus, Nick Jennings
Gradient Field-Based Task Assignment in an AGV Transportation System……..... 842
Danny Weyns, Nelis Boucké, Tom Holvoet
Learning the Task Allocation Game……..... 850
Sherief Abdallah, Victor Lesser
Continuous Refinement of Agent Resource Estimates……..... 858
David Morley, Karen Myers, Neil Yorke-Smith
How Equitable Is Rational Negotiation?..... 866

Sylvia Estivie, Yann Chevaleyre, Ulle Endriss, Nicolas Maudet

Mathematical Programming for Deliberation Scheduling in Time-limited Domains……..... 874

Jianhui Wu, Edmund Durfee

Optimal Decision-Making With Minimal Waste: Strategyproof Redistribution of VCG Payments……..... 882

Ruggiero Cavallo

Short papers:

Distributed Lagrangean Relaxation Protocol for the Generalized Mutual Assignment Problem……..... 890

Katsutoshi Hirayama

Auctioning Transformable Goods……..... 893

Andrea Giovannucci, Juan Antonio Rodríguez-Aguilar, Jesús Cerquides

SESSION: Ontologies and web services 897

Full papers:

ANEMONE: An effective minimal ontology negotiation environment……..... 899

Jurriaan van Diggelen, Robbert-Jan Beun, Frank Dignum, Rogier van Eijk, John-Jules Meyer

Agents for e-Business Applications……..... 907

Alessandro Negri, Agostino Poggi, Michele Tomaiuolo, Paola Turci

Automated Semantic Web Service Discovery with OWLS-MX……..... 915

Matthias Klusch, Benedikt Fries, Mahboob Alam Khalid, Katia Sycara

Ontology-Guided Learning to Improve Communication between Groups of Agents……..... 923

Mohsen Afsharchi, Behrouz Far, Jörg Denzinger

A Context-Aware Approach for Service Selection Using Ontologies……..... 931

Murat Şensoy, Pinar Yolum

Short papers:

TANDEM - a Design Method for Integrating Web Services into Multi-Agent Systems……..... 939

Steve Goschnick, Sandrine Balbo, Leon Sterling, Christine Sun

Reconciling Ontological Differences by Assistant Agents……..... 943

Kendall Lister, Leon Sterling, Kuldar Taveter

Formalizing Typicality of Objects and Context-sensitivity in Ontologies ……..... 946

Ching-Man Au Yeung, Ho-fung Leung

Service-Oriented and Autonomous Distribution and Provision of Multimedia Contents ……..... 949

Fuyuki Ishikawa, Nobukazu Yoshioka, Shinichi Honiden

Deriving Axioms Across Ontologies……..... 952

Dejing Dou, Drew McDermott

Web Presentation System using RST Events……..... 955
Arturo Nakasone, Helmut Prendinger, Mitsuru Ishizuku

SESSION: Believable agents 959

Full papers:

Learning Empathy: A Data-Driven Framework for Modeling Empathetic Companion Agents……. 961
Scott McQuiggan, James Lester

Embodied mobile agents……..... 969
Bill Tomlinson, Man Lok Yau, Eric Baumer

U-DIRECTOR: A Decision-Theoretic Narrative Planning Architecture for Storytelling Environments..... 977
Bradford Mott, James Lester

Evaluating a Computational Model of Social Causality and Responsibility……..... 985
Wenji Mao, Jon Gratch

Short papers:

A Model of Emotions for Situated Agents……..... 993
Van Parunak, Robert Bisson, Sven Brueckner, Robert Matthews, John Sauter

Balancing the needs of players and spectators in agent-based commentary systems……..... 996
Daniel Fielding, Brian Logan, Steve Benford

SESSION: Architectures: BDI and MDPs 999

Full papers:

Hierarchical Planning in BDI Agent Programming Languages: A Formal Approach……..... 1001
Sebastian Sardina, Lavindra de Silva, Lin Padgham

Modular BDI Architecture…….…….…….…..... 1009
Peter Novák, Jürgen Dix

Awareness as a vital ingredient of teamwork……..... 1017
Barbara Dunin-Kęplicz, Rineke Verbrugge

Exact Solutions of Interactive POMDPs Using Behavioral Equivalence……..... 1025
Bharanee Rathnasabapathy, Prashant Doshi, Piotr Gmytrasiewicz

On Proactivity and Maintenance Goals…….....1033
Simon Duff, James Harland, John Thangarajah

On the relationship between MDPs and the BDI architecture……..... 1041
Gerardo Simari, Simon Parsons

Short papers:

Modelling Situations in Intelligent Agents……..... 1049

John Thangarajah, Lin Padgham, Sebastian Sardina

Beliefs, Desires and Intentions Through the Environment……..... 1052

Tom Holvoet, Paul Valckenaers

User Defined Monitoring Strategies for BDI Agent Programs……..... 1055

Timothy William Cleaver, Abdul Sattar, Raihana Ferdous

Mixed-integer Linear Programming for Transition-independent Decentralized MDPs……..... 1058

Jianhui Wu, Edmund Durfee

SESSION: Scalability, security, and performance analysis 1061

Full papers:

Performance Analysis of Untraceability Protocols for Mobile Agents Using an Adaptable Framework……. 1063

Rafał Leszczyna, Janusz Górski

Scalable and Reliable Data Delivery in Mobile Ad Hoc Sensor Networks……..... 1071

Bin Yu, Paul Scerri, Katia Sycara, Yang Xu, Michael Lewis

Efficient Agent-Based Cluster Ensembles……..... 1079

Adrian Agogino, Kagan Tumer

ReAgents: Behavior-based Remote Agents and Their Performance……..... 1087

Eugene Hung, Joseph Pasquale

Short papers:

MLBP: MAS for Large-Scale Biometric Pattern Recognition……..... 1095

Ram Meshulam, Shulamit Reches, Aner Yarden, Sarit Kraus

Using Queuing Theory to Predict Organizational Metrics……..... 1098

Bryan Horling, Victor Lesser

Agent Dependability as an Architectural Issue……..... 1101

Peter C. Lockemann, Jens Nimis

Quorum Sensing on Mobile Ad-Hoc Networks**……**..... 1104

Maxim Peysakhov, Chris Dugan, Jay Modi, William Regli

Performance Evaluation of Open-Source Multiagent Platforms……..... 1107

Luis Mulet, Jose Miguel Such, Juan Miguel Alberola, Vicent Botti, Agustin Espinosa, Ana Garcia, Andres Terrasa

Structural Evaluation of Agent Organizations……..... 1110

Davide Grossi, Frank Dignum, Virginia Dignum, Mehdi Dastani, Lambèr Royakkers

Comparing Market and Token-Based Coordination……..... 1113

Yang Xu, Paul Scerri, Katia Sycara, Michael Lewis

SAgent: A Security Framework for JADE……..... 1116

Vandana Gunupudi, Stephen Tate

Coordinating simple and unreliable agents……..... 1119

Kagan Tumer

The Emergence of Global Properties from Local Interactions……..... 1122

Daniel Yamins

SESSION: Auctions and electronic markets 1125

Full papers:

Sequences of Take-It-or-Leave-It Offers: Near-Optimal Auctions Without Full Valuation Revelation……1127

Tuomas Sandholm, Andrew Gilpin

False-name-proof Combinatorial Auction Protocol: Groves Mechanism with Submodular Approximation…….1135

Makoto Yokoo, Toshihiro Matsutani, Atsushi Iwasaki

Reducing Price Fluctuation in Continuous Double Auctions through Pricing Policy and Shout Improvement….1143

Jinzhong Niu, Simon Parsons, Elizabeth Sklar, Kai Cai

Instantiating the Contingent Bids Model of Truthful Interdependent Value Auctions……..... 1151

Takayuki Ito, David Parkes

Designing a Successful Trading Agent for Supply Chain Management……..... 1159

Minghua He, Alex Rogers, Xudong Luo, Nicholas R. Jennings

Reducing Costly Information Acquisition in Auctions……..... 1167

Kate Larson

Computationally Efficient and Revenue Optimized Auctioneer's Strategy for Expanding Auctions…… 1175

Onn Shehory, Eran Dror

A Robust Combinatorial Auction Mechanism against Shill Bidders……..... 1183

Tokuro Matsuo, Takayuki Ito, Robert Day, Toramatsu Shintani

Mertacor: A Successful Autonomous Trading Agent……..... 1191

Panos Toulis, Dionisis Kehagias, Pericles Mitkas

Short papers:

A Comparison between mechanisms for Sequential Compute Resource Auctions……..... 1199

Andrew Byde

Robust Mechanisms for Information Elicitation……..... 1202

Aviv Zohar, Jeffrey Rosenschein

A Comparative Study of Sequential and Simultaneous Auctions……..... 1205

Shaheen Fatima

Competing Sellers in Online Markets: Reserve Prices, Shill Bidding, and Auction Fees……..... 1208
Enrico Gerding, Alex Rogers, Rajdeep Dash, Nick Jennings
Evaluating Bidding Strategies for Simultaneous Auctions……..... 1211
Teddy Candale, Sandip Sen

SESSION: Trust and reputation 1215

Full papers:
Certified Reputation: How an Agent Can Trust a Stranger……..... 1217
Trung Dong Huynh, Nick Jennings, Nigel R. Shadbolt
Trust and Honour in Information-based Agency……..... 1225
Carles Sierra, John Debenham
Using CHI-Scores to Reward Honest Feedback from Repeated Interactions……..... 1233
Radu Jurca, Boi Faltings
Learning Trust Strategies in Reputation Exchange Networks……..... 1241
Karen Fullam, K. Suzanne Barber
Monopolising Markets by Exploiting Trust……..... 1249
Sandip Sen, Dipyaman Banerjee

Short papers:
Developing a Composite Trust Model for Multi-agent Systems……..... 1257
Xiaoqing Zheng, Zhaohui Wu, Huajun Cheng, Yuxin Mao
Trust-based Agent Community for Collaborative Recommendation……..... 1260
Jianshu Weng, Chunyan Miao, Angela Goh, Zhiqi Shen, Robert Gay
Learning to commit in repeated games……..... 1263
Stéphane Airiau, Sandip Sen
Effect of deceptive referrals on system stability……..... 1266
Ikpeme Erete, Teddy Candale, Sandip Sen

SESSION: Agent programming 1269

Full papers:
Goal-Oriented Modularity in Agent Programming……..... 1271
M. Birna van Riemsdijk, Mehdi Dastani, John-Jules Meyer, Frank de Boer

Short papers:
Prototyping 3APL in the Maude Term Rewriting Language……..... 1279

M. Birna van Riemsdijk, Frank de Boer, Mehdi Dastani, John-Jules Meyer

A Jabber-based Multi-Agent System Platform……..... 1282

Miguel Escrivá Gregori, Javier Palanca Cámara, Gustavo Aranda Bada, Ana Garcia, Vicente Julian, Vicent Botti

Goal Types in Agent Programming……..... 1285

Mehdi Dastani, M. Birna van Riemsdijk, John-Jules Meyer

Belief Revision for AgentSpeak Agents……..... 1288

Natasha Alechina, Rafael Bordini, Jomi Fred Hübner, Mark Jago, Brian Logan

Plan Patterns for Declarative Goals in AgentSpeak……..... 1291

Jomi Fred Hübner, Rafael Bordini, Michael Wooldridge

A Service-Oriented Language for Programming Mobile Agents……..... 1294

Hervé Paulino, Luís Lopes

ActorNet: An Actor Platform for Wireless Sensor Networks……..... 1297

YoungMin Kwon, Sundresh Sameer, Kirill Mechitov, Gul Agha

SESSION: Agent-oriented engineering and methodologies 1301

Full papers:

Integrating Agent-Oriented Methodologies with UML-AT……..... 1303

Rubén Fuentes-Fernandez, Jorge Gómez-Sanz, Juan Pavón

Short papers:

Designing Agent Chips……..... 1311

Insu Song, Guido Governatori

Multiagent Systems as Software Architecture……..... 1314

Danny Weyns, Tom Holvoet, Kurt Schelfthout

Automated Analysis and Verification of Agent Behavior……..... 1317

Tibor Bosse, Dung Lam, K. Suzanne Barber

The hidden dangers of experimenting in distributed AI……..... 1320

Annika Smit, Masja Kempen, André Meyer, Niek Wijngaards

Agent-Community based Peer-to-Peer Information Retrieval - an Evaluation……..... 1323

Tsunenori Mine, Akihiro Kogo, Makoto Amamiya

An Overview of Business Process Adaptations via Protocols……..... 1326

Nirmit Desai, Amit Chopra, Munindar Singh

Multi-agent based Community Computing System Development with the Model Driven Architecture…….. 1329

Yuna Jung, Jungtae Lee, Minkoo Kim

Enhancing Agent-Oriented Models with Aspects……..... 1332

Alessandro Garcia, Christina Chavez, Ricardo Choren

SESSION: Agent communication 1335

Full papers:

On the Semantics of Conditional Commitment……..... 1337

Shakil Khan, Yves Lespérance

Contextualizing Commitment Protocols……..... 1345

Amit Chopra, Munindar Singh

A Utility based sensing and communication model for a glacial sensor network……..... 1353

Paritosh Padhy, Rajdeep Dash, Kirk Martinez, Nick Jennings

Specifying and Resolving Preferences Among Agent Interaction Patterns……..... 1361

Ashok Mallya, Munindar Singh

Short papers:

An Ontology of Social Control Tools……..... 1369

Philippe Pasquier, Roberto Flores, Brahim Chaib-draa

Modelling the Links Between Social Commitments and Individual Intentions……..... 1372

Philippe Pasquier, Brahim Chaib-draa

The MAPa Language of Agent Dialogues……..... 1375

MaríaAdela Grando, Christopher Walton

Convergence Analysis for Collective Vocabulary Development……..... 1378

Jun Wang, Les Gasser, Jim Houk

Learning a Common Language Through an Emergent Interaction Topology……..... 1381

Samarth Swarup, Kiran Lakkaraju, Les Gasser

Organizational Petri Nets for Protocol Design and Enactment……..... 1384

Stéphanie Combettes, Chihab Hanachi, Christophe Sibertin-Blanc

SESSION: Optimization and constraint processing 1387

Full papers:

Nogood-based Asynchronous Distributed Optimization (ADOPT-ng)……..... 1389

Marius Silaghi, Makoto Yokoo

MDPOP: Faithful Distributed Implementation of Efficient Social Choice Problems……..... 1397

Adrian Petcu, Boi Faltings, David Parkes

Examining DCSP Coordination Tradeoffs……..... 1405

Michael Benisch, Norman Sadeh

Multiply-Constrained Distributed Constraint Optimization……..... 1413
Emma Bowring, Milind Tambe, Makoto Yokoo

Short papers:

The DynCOAA Algorithm for Dynamic Constraint Optimization Problems……..... 1421
Koenraad Mertens, Tom Holvoet, Yolande Berbers
Experimental analysis of privacy loss in DCOP algorithms……..... 1424
Rachel Greenstadt, Jonathan Pearce, Emma Bowring, Milind Tambe
No-Commitment Branch and Bound Search for Distributed Constraint Optimization……..... 1427
Anton Chechetka, Katia Sycara
An Agent Based General Solution Model For the Course Timetabling Problem……..... 1430
Yan Yang, Raman Paranjape, Luigi Benedicenti
Hierarchical Variable Ordering for Distributed Constraint Optimization……..... 1433
John Davin, Jay Modi

Demonstration Session..... 1437

SESSION 1

SeSAm: Implementation of Agent-Based Simulation Using Visual Programming..... 1439
F. Klugl, R. Herrler, M. Fehler
CSC: Criticality-Sensitive Coordination..... 1441
Pedro Szekely , Marcel Becker , Stephen Fitzpatrick , Gergely Gati , David Hanak , Jing Jin , Gabor Karsai , Rajiv T. Maheswaran , Bob Neches , Craig M. Rogers , Romeo Sanchez , Chris van Buskirk
Synergistic Integration of Agent Technologies for Military Simulation 1443
Sean Owens, Paul Scerri, Robin Glinton, Bin Yu, Katia Sycara
Asynchronous Chess Competition 1445
Nathaniel Gemelli, Robert Wright, James Lawton, Andrew Boes
Deployment of A-globe Multi-Agent Platform 1447
David Sislak, Martin Rehák, Michal Pěchouček, Dušan Pavlíček
UAV Airspace Management System UAMS 1449
Regis Vincent, Osher Yagdar, Andrew Agno
Multi-Agent Coordination and Control Testbed for planning and scheduling strategies 1451
Paul Verstraete, Paul Valckenaers, Hendrik Van Brussel, Karuna Hadeli, Bart Saint Germain
A Texas Hold'em poker player based on automated abstraction and real-time equilibrium computation 1453
Andrew Gilpin, Tuomas Sandholm

SESSION 2

Decision-Making Support for Maritime Business..... 1455
Jonathan Himoff

Participatory, Embodied, Multi-Agent Simulation..... 1457
Paulo Blikstein, William Rand, Uri Wilensky

CONOISE-G: Agent-Based Virtual Organisations..... 1459
Jigar Patel, W.T. Luke Teacy, Nicholas R. Jennings, Michael Luck, Stuar t Chalmers, Nir Oren, Timothy J. Norman, Alun Preece, Peter M. D. Gray, Gareth Shercliff, Patrick J. Stockreisser, Jianhua Shao, W. Alex Gray, Nick J. Fiddian, Simon Thompson

Automated Argument System based on Logic of Multiple-Valued Argumentation..... 1461
Toshiko Wakaki, Takanori Mukai, Hiromitsu Miyashita, Hajime Sawamura, Kumiko Matsunaga, Taro Fukumoto, Katsumi Nitta

Computational Mechanism Design for Multi-Sensor Information Fusion..... 1463
A. Rogers, R.K. Dash, N.R. Jennings, S. Reece, S. Roberts

Component Agent Framework for domain-Experts (CAFnE) Toolkit..... 1465
Gaya Jayatilleke John Thangarajah Lin Padgham Michael Winikoff

Conflict Negotiation Among Personal Calendar Agents..... 1467
Pauline M. Berry, Cory Albright, Emma Bowring, Ken Conley, Kenneth Nitz, Jonathan P. Pearce, Bart Peintner, Shahin Saadati, Milind Tambe, *Tomás Uribe, Neil Yorke-Smith*

Synthetic Humans in Emergency Response Drills..... 1469
Daniel Massaguer, Vidhya Balasubramanian, Sharad Mehrotra, Nalini Venkatasubramanian

ITSUMO : an Intelligent Transportation System for Urban Mobility..... 1471
Bruno Castro da Silva, Rober t Junges , Denise de Oliveira, Ana L.C. Bazzan

***Industry Track*..... 1473**

SESSION: IT1

Towards a Reference Model for Intelligent Agent Systems..... 1475
Pragnesh Jay Modi, Spiros Mancoridis, William M. Mongan, William Regli, Israel Mayk

Automating Deep Space Network Scheduling and Conflict Resolution 1483
Mark D. Johnston, Bradley J. Clement

Using Multiagent Teams to Improve the Training of Incident Commanders..... 1490
Nathan Schurr, Pratik Patil, Fred Pighin, Milind Tambe

Autonomous Agents for Air-Traffic Deconfliction..... 1498
Michal Pěchouček, David Sislak, , Dušan Pavlíček, Miroslav Uller

SESSION: IT2

Automating Supply Chain Negotiations using Autonomous Agents: a Case Study in Transportation Logistics.. 1506
Sander van der Putten, Valentin Robu, Han La Poutré, Annemiek Jorritsma, Margo Gal

Multi-Agent Logistics i-Scheduler for Road Transportation..... 1514
Jonathan Himoff, George Rzevski, Petr Skobelev

Commercializing a Multiagent-Supported Collaborative System..... 1522
Leen-Kiat Soh, Hong Jiang

SESSION: IT3

The Role of Agents in Enterprise System Management..... 1530
Onn Shehory

Implantable Medical Devices as Agents and Part of Multiagent Systems..... 1534
Touby Drew, Maria Gini

A Hotel Information System implementation using MAS technology……..... 1542
Armando Robles P., Pablo Noriega B.V., Marco Julio Robles P., Hector Hernandez T., Victor Soto Ramírez, Edgar Gutierrez S.

Commercial Applications of Agents: Lessons, Experiences and Challenges..... 1549
Roxana A. Belecheanu, Steve Munroe, Michael Luck, Tim Miller, Peter McBurney

SESSION: IT4

A Computer-Supported Cooperative Learning System with Multiagent Intelligence..... 1556
Leen-Kiat Soh, Nobel Khandaker, Xuliu Liu, Hong Jiang

Deploying a Personalized Time Management Agent..... 1564
Pauline Berry, Ken Conley, Melinda Gervasio, Bart Peintner, Tomás Uribe, Neil Yorke-Smith

Utility-based Collaboration among Autonomous Agents for Resource Allocation in Data Centers..... 1572
Rajarshi Das, Ian N. Whalley, Jeffrey O. Kephart

ACTIVE: Agile Coordinator Testbed Integrated Virtual Environment..... 1580
G. Emami, J. Cheng, D. Cornwell, M. Feldhousen, C. Long, V. Malhotra, I. Starnes, L. Kerschberg, A. Brodsky, X. Zhang

***Author Index*..... 1588**

INTRODUCTION

The spread of Internet connectivity and advancement of computer hardware increases the power of information technologies to perform practical services in many areas of our everyday life. Agent technologies play essential roles in the design of service-oriented systems such as computer-mediated collaboration, education and training, electronic commerce, information retrieval, and data mining.

Agents and multiagent systems also provide a new way of thinking--conceptualizing performance elements as autonomous changes the paradigm for analyzing problems, designing systems, and dealing with complexity, distribution, and interactivity. Concept of agents and multiagent architecture are shaping landscapes of basic research areas including social simulation, games, pervasive and ubiquitous computing, robotics, and user interfaces.

The Autonomous Agents and Multiagent Systems (AAMAS) conference series brings together researchers from around the world to share the latest advances in the field. It was initiated in 2002 as a merger of three highly successful related events: the International Conference on Autonomous Agents (AGENTS), the International Conference on Multi-Agent Systems (ICMAS), and the International Workshop on Agent Theories, Architectures, and Languages (ATAL). The AAMAS conference series provides a single, high-profile forum for research in the theory and practice of autonomous agents and multiagent systems. AAMAS 2002, the first of the series, was held in Bologna, followed by AAMAS 2003 in Melbourne, AAMAS 2004 in New York, and AAMAS 2005 in Utrecht. AAMAS 2006 is held in Hakodate, Japan.

The five-day event consists of 6 tutorials, 32 workshops, a main conference track, a separate industry paper track with 15 papers, demonstration sessions with 17 demonstrations, an exhibition, and a doctoral mentoring program with 24 students. These and other conference elements are the result of great efforts on the part of many dedicated volunteers. We are grateful to all the AAMAS-06 conference officials and those who worked with them to put together such a successful research meeting.

AAMAS 2006 received 553 submissions for the main conference. Each paper was reviewed by at least three program committee members (guided by a senior program committee member). 127 papers were accepted as full 8-page papers, and an additional 123 were accepted as short 3-page papers (acceptance rates of 23.0% for full papers and 45.2% overall).

Several innovations were added to this year's conference program and review process. In order to make the review process more interactive, authors were given the opportunity to respond to their reviews prior to the discussion phase and final decisions. In many cases, the reviews, and sometimes the decisions, were altered as a result. In addition, we introduced awards for "best program committee member" and "best senior program committee member" in recognition of the exceptional time and effort contributed by our program committee.

At the conference itself, for the first time, the emphasis was on poster presentations as the main form of technical exchange. All accepted papers were presented at poster sessions, with just about half of the full papers presented orally in two parallel tracks. The oral presentations were chosen primarily so as to provide a broad representative of the accepted papers. The goal of this format was to allow for more focused oral sessions while maximizing the opportunity for one-on-one detailed technical exchanges at the posters.

From among this year's complete program, the following papers were selected as nominees for the best paper and best student paper awards:

Resource Selection Games with Unknown Number of Players
Itai Ashlagi, Dov Monderer, Moshe Tennenholtz

Optimal Decision-Making With Minimal Waste: Strategyproof Redistribution of VCG Payments
Ruggiero Cavallo

A Technique for Reducing Normal Form Games to Compute a Nash Equilibrium
Vincent Conitzer, Tuomas Sandholm

Instantiating the Contingent Bids Model of Truthful Interdependent Value Auctions
Takayuki Ito, David Parkes

Automated Semantic Web Service Discovery with OWLS-MX
Matthias Klusch, Benedikt Fries, Mahboob Alam Khalid, Katia Sycara

Learning Empathy: A Data-Driven Framework for Modeling Empathetic Companion Agents
Scott McQuiggan, James Lester

Toward an Understanding of the Impact of Software Personal Assistants on Human Organizations
Steven Okamoto, Paul Scerri, Katia Sycara

A complete and decidable security-specialised logic and its application to the TESLA protocol
Bozena Wozna, Alessio Lomuscio

The program chairs would like to thank all of the PC and SPC members for their hard work putting together this year's program. Overall, the reviews were quite detailed and the reviewers were very responsive in the discussion phase, often carefully considering the author responses and altering reviews accordingly. From among the group, a few PC members stand out as having written particularly detailed reviews and providing constructive, helpful feedback both to the authors and to the program chairs. These individuals have been nominated for the best PC member award:

Gal Kaminka
Barbara Keplicz
David Parkes
Simon Parsons
Jeff Rosenschein

Additionally, a few SPC members stand out as leading particularly useful discussions and providing useful input back to the authors and the program chairs. These individuals have been nominated for the best SPC member award:

Vincent Conitzer
Luke Hunsberger
Shaul Markovitch
Karl Tuyls
Danny Weyns

Congratulations (and thank you!) to all of the nominees.

Hideyuki Nakashima and Michael Wellman (general chairs)
Peter Stone and Gerhard Weiss (program chairs)

March 2006

INDUSTRY TRACK INTRODUCTION

Agents and multi-agent systems have a role to play in commercial computing and this role will grow. Today the world is interconnected, tomorrow the world will only be more so. This loosely coupled distributed environment is exactly the environment for which agents were created. In parallel with this growth of networked computation is an increase in the sophistication that we, as users, personal or business, expect from our software systems. If it has a processor, we want it connected to the world and doing something useful for us. Agent frameworks, algorithms, or methodologies that support flexible, dynamic, intelligent, or autonomous management of information or resources are potentially commercial discriminators today and are assuredly future discriminators. The agent paradigm can and will make a difference and have impact on commercial computing.

The AAMAS industry track is a special track at the AAMAS conference that runs in parallel with the regular AAMAS scientific track. The track is dedicated to fostering commercial, or real world, impact for agent technologies. The track features presentations, panels, invited talks, and demonstrations from industrial participants, giving them an opportunity to showcase the state of the art in agent technology. The industry track aims to foster mutually beneficial links between those engaged in foundational scientific research and those working to make autonomous agents and multi-agent systems a commercial reality.

This year's track follows on the successful industry track held at AAMAS05 in Utrecht, the Netherlands. The AAMAS05 track featured 15 high quality papers, an invited talk by Dr. Mark Greaves of DARPA (Defense Advanced Research Projects Agency), and a panel chaired by Dr. Tom Wagner on Developing Impact for Agents. The AAMAS05 papers discussed the application of agent technology to commercial problems, presented case studies, or assessed technology adoption issues. The selection of papers at AAMAS05 was competitive and the best papers were reported in the IEEE Journal of Intelligent Systems.

This year the conference features 15 high quality papers that present applications of multi-agent systems or discuss deployment related aspects of agent technology. Authors include leaders from research and academe but also commercial stakeholders and key decision makers from agent oriented software companies. Specific application areas include the use of agents in space exploration and defense, logistics and supply chain management, medical applications and enterprise information systems. This year's papers also present more technical applications in coordination, collaboration and multi-agent learning. The proceedings also include the lessons, experiences and challenges generated during the operation of AgentLink III – a Co-ordination Action funded by the European Union for Agent Based Computing. The AAMAS06 invited speaker is Steve Benfield of Agentis Software. The industry panel is chaired by Dr. Brad Clement of NASA JPL.

We are glad to see continued strong interest in the industry track. Agents can and will have impact, and it is our job as a community to foster this impact.

Tom Wagner and Michal Pechoucek (Industry Track Co-Chairs) March 2006

CONFERENCE OFFICIALS

General Chairs

- Hideyuki Nakashima, Future University - Hakodate, Japan
- Michael Wellman, University of Michigan, USA

Program Chairs

- Peter Stone, The University of Texas at Austin, USA
- Gerhard Weiss, Technical University Munich, Germany

Local Organization Chair

- Ei-ichi Osawa, Future University - Hakodate, Japan

Local Treasurer

- Hitoshi Matsubara, Future University - Hakodate, Japan

Finance Chair

- Liz Sonenberg, University of Melbourne, Australia

Workshops Chair

- Jiming Liu, Hong Kong Baptist University, China

Tutorials Chair

- Yves Lesperance, York University, Canada

Demos Chairs

- Ana Lucia C. Bazzan, Universidade Federal do Rio Grande do Sul, Brasil
- Regis Vincent, SRI International, USA

Industry Track Chairs

- Michal Pechoucek, Gerstner Laboratory and Czech Technical University, CZ
- Tom Wagner, Defense Advanced Research Projects Agency (DARPA), USA

Doctoral Mentoring Co-chairs

- Ahlem Ben Hassine, NICT, Japan
- Toru Ishida, Kyoto University, Japan

Publicity Chair

- Chengqi Zhang, University of Technology, Australia

Sponsorship Chairs

- **Europe:** Steven Willmott, Universitat Politecnica de Catalunya, Spain
- **East Asia:** Akihiko Ohsuga, Toshiba Co., Japan
- **US & Canada:** Van Parunak, Altarum Institute, USA

Publications Chair

- Takayuki Ito, Nagoya Institute of Technology, Japan

Student Scholarship Chairs

- Eduardo Alonso, City University, London, UK
- Sandip Sen, University of Tulsa, USA

Exhibits Chair

- Keiji Suzuki, Future University - Hakodate, Japan

SENIOR PROGRAM COMMITTEE

- Elisabeth Andre, Germany
- Tucker Balch, USA
- Mike Bowling, Canada
- Monique Calisti, Switzerland
- Keith Decker, USA
- Marie DesJardins, USA
- Virginia Dignum, The Netherlands
- Jurgen Dix, Germany
- Edmund Durfee, USA
- Maria Gini, USA
- Paolo Giorgini, Italy
- Amy Greenwald, USA
- Brian Henderson-Sellers, Australia
- Adele Howe, USA
- Gal Kaminka, Israel
- Barbara Keplicz, Poland
- Sven Koenig, USA
- Sarit Kraus, Israel
- Kate Larson, Canada
- Kevin Leyton-Brown, Canada
- Alessio Lomuscio, University College London, UK
- Maja Mataric, USA
- Nicolas Maudet, France
- Itsuki Noda, Japan
- Lin Padgham, Australia
- Ana Paiva, Portugal
- David Parkes, USA
- Simon Parsons, USA
- Michal Pechoucek, Czech Republic
- Joelle Pineau, Canada
- Daniel Polani, UK
- David Pynadath, USA
- Martin Riedmiller, Germany
- Jeff Rosenschein, Israel
- Paul Rybski, USA
- Jaime Sichman, Brazil
- Carles Sierra, Spain
- Betsy Sklar, USA
- Tomoichi Takahashi, Japan
- Kagan Tumer, USA
- Mike Wooldridge, UK
- Franco Zambonelli, Italy

PROGRAM COMMITTEE

- Adrian Agogino, USA
- Thomas Ågotnes, UK
- H. Levent Akin, Turkey
- Klaus-Dieter Althoff, Germany
- Leila Amgoud, France

Invited Talks

Towards Emergence of Communication: A Cognitive Developmental Robotics Approach

Minoru Asada
JST ERATO Asada Synergistic Intelligence Project and Dept. of Adaptive Machine Systems
Graduate School of Eng., Osaka University, Suita, Osaka 565-0871, Japan
asada@jeap.org

ABSTRACT

This paper presents an introduction of the JST ERATO Asada Synergistic Intelligence Project (hereafter, SI) and its preliminary studies on emergence of communication. The project aims at building cognitive developmental artificial agents (humanoids), understanding natural agents (humans), and their mutual feedbacks. The project consists of four groups: (1) Physio-SI: whole body dynamic motions such as walking, running, and jumping, (2) Perso-SI: cognitive developmental robotics including body image, imitation, and language communication, (3) Socio-SI: emergence of communication and society by androids, and (4) SI-mechanism: neuroscientific supports for Physio, Perso, and Socio-SIs. As a preliminary study, vowel acquisition based on visual and auditory mutual imitation is given. It aims at modelling mother-infant interaction in vowel acquisition based on the findings in infant studies, such as lip shape imitation and bias from mother's vocalization onto the infant auditory perception.

1. INTRODUCTION

The recent advances in information and robot technology (in short, IRT) enable us to build humanoid robots that have a large number of DoFs and various kinds of many sensors. Human-like motions are realized on these robots, and the shape and appearance have become closer and closer to us. [12, 4].

However, the current robotics lacks the faculties of language communication with ordinary people and of intelligent behavior generation in various situations such as at home. The fundamental relationship between humans and robots would become more important since these robots would be introduced into our lives in near future, and therefore the mechanisms of adaptation and development of both humans and robots should be taken into account in order to find the correct direction of the technology in future.

"Synergistic Intelligence (hereafter, SI)," the title of JST (Japan Science and Technology Agency) ERATO (Exploratory Research for Advanced Technology) Asada project, emerges intelligent behaviours through the interaction with environment including humans. Synergistic effects with brain science, neuroscience, cognitive science, and developmental psychology are expected. SI is one approach to a new discipline called "Humanoid Science" that aims at providing a new way of understanding ourselves and a new design theory of humanoids through mutual feedback between the design of human-like robots and human-related science.

"Humanoid Science" under which a variety of researchers from robotics, AI, brain science, cognitive science, psychology and so on are seeking for new understanding of ourselves by constructivist approaches, that is expected to produce many applications.

SI adopts a methodology called "Cognitive Developmental Robotics" (hereafter, CDR) [1] that consists of the design of self-developing structures inside the robot's brain, and the environmental design: how to set up the environment so that the robots embedded therein can gradually adapt themselves to more complex tasks in more dynamic situations. Unstructured terrains are opponents for adaptive walkers to negotiate with in order to generate dynamic motions. The caregiver's behaviour to a robot is one environmental design issue since parents, teachers, and other adults adapt themselves to the needs of children according to each child's level of maturity and the particular relationship they have developed with that child.

One of the most formidable issues in SI is "Nature vs. Nurture": to what extent should we embed the structure, and to what extent should we expect the development triggered by the environment? A symbolic issue is " Language Acquisition. "How can robots emerge the symbol in the social context? What is the essential element in this process?

This paper presents an introduction of SI and its preliminary studies on emergence of communication. The project aims at building cognitive developmental artificial agents (humanoids), understanding natural agents (humans), and their mutual feedbacks (see Fig.1). The project consists of four groups: (1) Physio-SI: whole body dynamic motions such as walking, running, and jumping, (2) Perso-SI: cognitive developmental robotics including body image, imitation, and language communication, (3) Socio-SI: emergence of communication and society by androids, and (4) SI-mechanism: neuroscientific supports for Physio, Perso, and Socio-SIs. As a preliminary study, vowel acquisition based on visual and auditory mutual imitation is given. It aims at modelling mother-infant interaction in vowel acquisition based on the findings in infant studies, such as lip

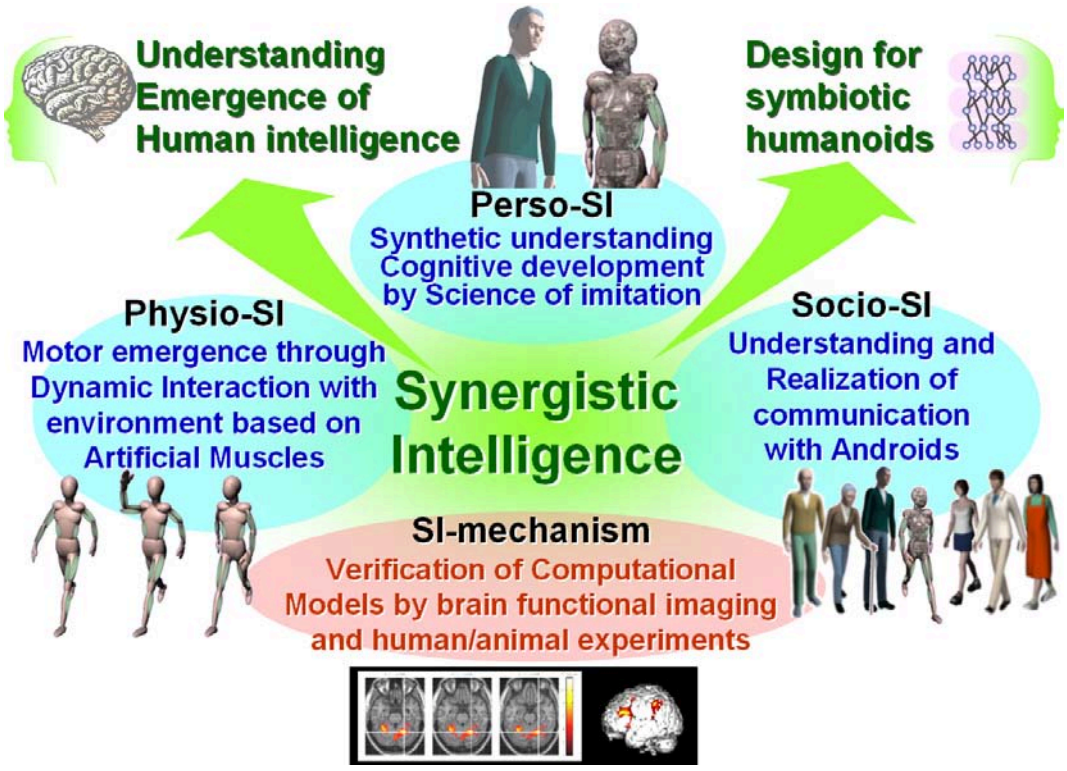

Figure 1: An overview of Synergistic Intelligence Project

shape imitation and bias from mother's vocalization onto the infant auditory perception.

2. AN OVERVIEW OF SI

In this project, we will establish a new discipline that explains the essential relationship between humans and robots in future symbiotic society. Systematic and continuous modelling of " embodiment, " " autonomy, " and " sociality " from a viewpoint of emergence and development will be performed, and constructivism will be shown by realizing these models on real robots. Fundamental principles for adaptive and developable robots will be revealed and may contribute to human society.

An expected goal is realization of three years old humanoid that can show the capabilities of 1) seamless transition among running, jumping, walking, and stop, and whole body motion such as rope skipping, 2) naming game with toy playing and novel behavior generation from imitation, and 3) self-expression, attention, and conversation. The rest of this section gives overviews of four groups of SI.

2.1 Physically Synergistic Intelligence

Physio-SI in short, aims at understanding emergence of human intelligence from dynamic connection between body structure and environment with artificial muscles.

The agent behavior is determined by not only its dynamics but also environmental one if its compliance is comparable to that of the environment. This interaction may help the agent to be adaptive and robust against changes of the environment, which cannot be taken for the rigid agents with high-ratio geared motors. In this project, we utilize such physical interactions to realize dynamic skills such as walking, jumping, and running, and try to figure out the methodology to emerge synergistic intelligence:

- **Walking on uneven terrains utlizing antagonistic driven legs:** By utilizing flexibility provided by antagonistic driven legs and ballistics of the body, we will derive a methodology to realize adaptive walking on uneven terrains Preliminary results are shown in [11].
- **Realization of dynamic behaviors:** We will realize dynamic behaviors such as jumping and running by utlizing compliance and dymamic power provided by the antagonistic drive.
- **Smooth transition between dynamic behaviors:** We will propose a framework to deal with different modes of locomotion, walking and running, and develop a "Motor Skill Emerging Humanoid" that can realize these locomotion modes.
- **Cognitive approach to locomotion:** From the standpoint of building a Motor SKill Emerging Humanoid, we approach to the synergistic intelligence mechanisms and will understand the foundation of emergence of dynamic behaviors.

2.2 Interpersonally-Synergistic Intelligence

Fusing together the capabilities of real world behavior and communication will be the critical step towards the truly humanoid robot intelligence. Interpersonally-Synergistic Intelligence group (Perso-SI in short) aims at constructing

synthetic robotic models that account for the process of cognitive development starting from bodily movements of fetuses and reaching rich meaningful communication of infants. This will bridge the research of the other two groups, namely, Physio-Synergistic Intelligence and Socio-Synergistic Intelligence.

Our developmental cognitive model would account for (but not limited to) the following cognitive functionalities:

1. Acquisition of brain internal representation of self body through whole body sensory-motor learning,
2. Learning about objects and tools,
3. Emergence and development of behavior imitation,
4. Concept/imagery formation by abstraction of behaviors, and
5. Fusing together the behavior concepts/imitation with interactions through gestures, vocalizations, and facial expressions.

Some of our models will be based on the neuroscientific models provided by the Synergistic Intelligence Mechanisms group; The model of object manipulation for topic 2, imitation learning for topic 3, and motor imagery for topic 4.

Two of the hardware platforms required for the above research are; (a) whole-body sensory-motor learning robot, and (b) behavior imitation learning robot. We will develop these robots and use them for the above described research on cognitive models. Robot (a) will have a whole body tactile sensing skin and whole body motion capabilities, and will be used for experiments such as body image acquisition by sensory integration learning. Robot (b) will emphasize object manipulation capabilities and their integration with audio-visual sensing, and will be used for experiments on imitation learning, concept acquisition, and fusing with communication. In addition, we will construct (c) a computer simulation of sensory-motor learning of fetuses, in order to carry out learning experiments and model validation for very early stages of sensory-motor learning.

2.3 Socially Syngenetic intelligence

This group studies developmental mechanisms of communication and evaluations of intelligence based on human subjects and the human society. We, humans, anthropomorphize the object for conversation. This is an essential human ability and a hint for investigating principles of communicative and intelligent machines by engineering and scientific approaches. This idea guides us to a new cross-interdisciplinary framework called Android Science [4]. In this framework, we tackle the following issues

- Development of Man-Made Man (M3: M cube): In order to realize robots that can be accepted by the human society, we need to develop a human-like robot. The robot developed in this project is different from other robot-like humanoids and very humanlike androids (**??**). The robot M3 is going to have about 50 pneumatic actuators, soft skin covering the whole body, and various humanlike sensors with a child size.
- Mechanisms for establishing social relationships with humans: We, humans, have various interactive behaviors for establishing fundamental relationships with others as humans, for example eye movement while looking at each other, personal distance, shard attention, synchronized movement while interacting, and reactions with tactile sensation. These human behaviors are precisely measured and the numerical models are developed [5]. Then, these programmable models of the behaviors are going to be implemented into M3.
- Constructive approach for understanding social mechanisms of humans and robots: We are going to implement more complicated and social behaviors to the robot that has the fundamental relationships with humans. This is the constructive approach [3] that starts from the basic elements and gradationally implements more complex behaviors. Finally, we acquire knowledge on what is a human and what is the human society by using the develop robot.

2.4 Synergistic Intelligence Mechanism

SI-Mech in short, will conduct the following three issues:

1. study of neural correlates of interactive control mechanism between hands and objects,
2. investigation of the brain mechanism of imitation and imaging, and
3. construction of an acquisition model for fundamental functions of communication.

In study of neural correlates of interactive control mechanism between hands and objects, we will use tracing of line drawing tasks under various conditions to identify the neural circuits involved in smooth manipulation of hands and objects. We will also clarify the relationship between some motor and mental disorders and the neural substrates. Furthermore, Nagai et al. [7] indicated that patients with Williams syndrome can trace the drawings of objects, but can not copy them. To investigate this dissociation between tracing and copying, we will use functional imaging and neuropsychological methods to clarify the difference in brain regions involved in these behaviors.

On the other hand, mechanisms of prediction and imitation play important roles in acquiring functions of communication. Imazu et al. [2] studied neural correlates of tool (chopstick) use with functional neuroimaging and revealed the following finding: actual use of chopstick activates the right cerebellum, whereas pantomiming and imagery of chopstick use activate the left inferior parietal lobule. This result suggests that different neural networks are involved in actual use, and pantomime and imagery of tool use. This could explain the dissociation observed in patients with ideomotor apraxia: they unable to pantomime with tools, despite their ability to manipulate tools actually.

For the purpose of 'the investigation of the brain mechanism of imitation and imaging', we will first examine those of action in the human brain with functional MRI. Second we will make a research on both the deficit and the learning process of action imitation of autistic children who have communication deficits, modeling the relationship between action imitation and communication function. In addition, we are going to compare the aforesaid study of William's syndrome with that of the autism and clarify the essence of communication function.

Furthermore, the 'motor sequence prediction learning hypothesis' on the basis of the brain imaging studies as well as the anatomical ones has been proposed. There are two main assumptions in the hypothesis. First, it is assumed that the functions of left BA44 and BA45 in Broca's area differ from each other; left BA45 is involved in motor sequence prediction and left BA44 is implicated in motor sequence generation, interacting with the basal ganglia respectively. Second, left BA45 makes contact with the temporal lobe through long-distance association fibers to integrate semantic and syntactic information. Finally, in terms of 'the construction of an acquisition model for fundamental functions of communication', we plan to construct an acquisition model through brain imaging studies based on the 'motor sequence prediction learning hypothesis'.

3. VOWEL ACQUISITION BASED ON VISUAL AND AUDITORY MUTUAL IMITATION

A preliminary study of SI is briefly described, which attempts to model mother-infant interaction in vowel acquisition. A pioneering constructivist approach to building a robot that reproduces a developmental process of infants' vowel acquisition has been conducted by Yoshikawa et al. [13] inspired by the observation in infant study. They have constructed a mother-infant interaction model with robot learning capability and parrot-like teaching by caregiver. However, the robot has not listened his/her own voice, therefore nor actively explored more natural vowels similar to the caregiver.

The study presented in this section extends the previous work in the following manners seeking for more natural interaction. First, a lip is added to the robot to imitate the lip shape of the caregiver in order to accelerate the learning process by constraining the initial exploration area in the formant space which is a well-known sound feature space to distinguish vowels [9]. From the lip shape imitation, the initial locations of vowels are obtained. Second, the pentagon the caregiver's vowels construct in the formant space is utilized as the desired vowels for the robot by shifting this pentagon to the centroid of the initial vowel locations of the robot. Third, mutual imitation between the robot and the caregiver is introduced in order to obtain more natural vowels hypothesizing that the caregiver imitates the robot voice but unconsciously the imitated voice is close to one of his/her own vowels. Through this process, the desired positions specified at the second step are gradually shifted, expecting to more natural ones.

3.1 Vowel imitation based on mother-infant interatction model

An overview of the whole system is shown in Fig. 2 where a vocal robot with articulation and auditory functions interacts with a caregiver who shows lip shape to the robot, and both imitate their voices each other. We slightly modified the vocal robot in [13] by adding the lip structure that has two degrees of freedom corresponding to opening/closing in horizontally and vertically. The shape change of the vocal tract is controlled by four motors instead of five ones in the previous work.

The caregiver has two roles: the first one is to show the lip shape to the robot so that it can imitate the lip shape

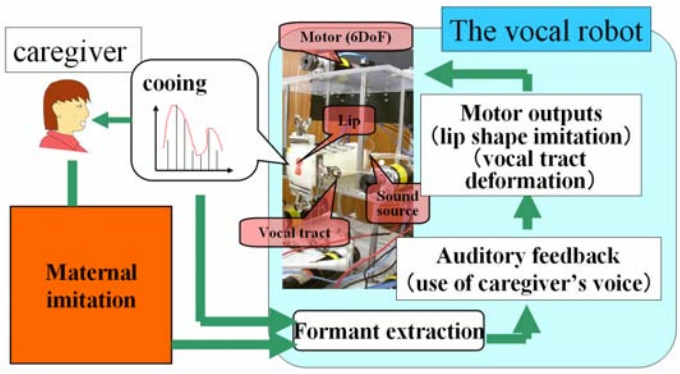

Figure 2: An overview of the whole system

since there are some evidences on the relationship between the lip shape and the vowel utterance. Carre [10] shows the formant changes owing to opening/closing of the lip by his simulation. Patterson and Werker [8] found that the infants have knowledge on the relationship between the lip shape and phoneme. Then, we assume that the robot can imitate the lip shape corresponding to each vowel from the caregiver to initialize its vowels in the formant space for further exploration.

The second one is maternal imitation, that is, imitation of the robot voices. Since the robot also imitates the caregiver's imitation, mutual imitation is expected to lead the robot voices to more natural one. The implicit assumption behind this process is that the caregiver tries to imitate the robot voices, but unconsciously his or her voices are close to his or her own vowels owing to the embodiment (sensorimotor constraint). As a result, the robot voices gradually change to more natural ones.

The vocal robot has six degrees of freedom, two of which are for lip opening/closing. First, we examine the utterance capability of the robot. The motor command is normalized into three levels 0 (free, no deformation), 0.5 (middle), and 1.0 (the maximum deformation), therefore we have 729 (3^6) utterrances. Among them, we picked up 711 utterrances after removing unstable onses.

Next, the effect of the lip shape is examined, that is, two of six DoFs corresponding lip opening/closing is fixed to imitate the human lip shape, and other four DoFs are combined (81 utterances, 3^4). Fig.3 shows the formant distribution of the robot utterances when the lip shape is imitated. The top row indicates the formant distributions of utterances when the lip shape is fixed to imitate that of human's vowel utternaces /a/, /i/, /u/, /e/, and /o/, respectively. The bottom row shows the lip shapes of human and the robot, respectively.

The number of utterances constrained by lip shape is 394 (11 unstable utterances are removed) from 711 without the constraint. This tells that by lip shape imitation, the number of candidates for vowel utterances can be reduced to 55%.

3.2 Learning to acquire more natural vowels through mutual imitation

From the above discussion, the exploration process to find more natural vowel utterance seems easy since the robot can

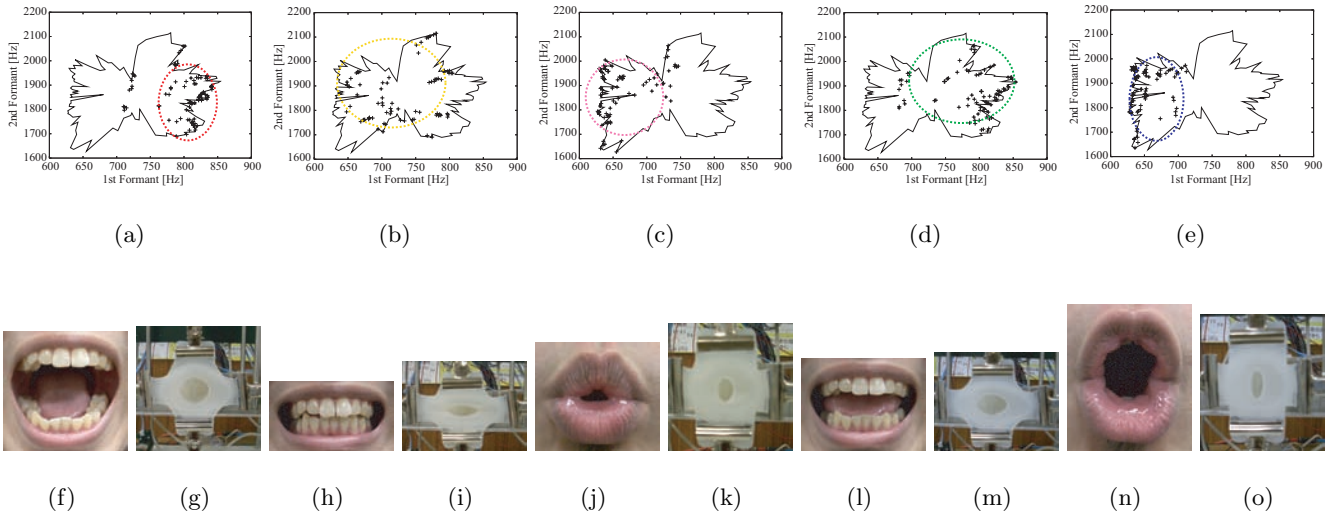

Figure 3: Formant distribution of the utterances (top: /a/, /i/, /u/, /e/, /o/) from lip shape imitation (bottom)

follow the trajectory between its initial position (L/j/, j=a, i, u, e, or o) to the desired vowel position (C/j/', j=a, i, u, e, or o) under the condition that the lip shape is fixed. However, there is no guarantee that the desired vowels can be heard as natural ones. Then, we introduce mutual imitation to shift the desired position so that the robot can acquire more natural ones by hypothesizing that the caregiver's imitation is biased by his/her own sensorimotor constraint, that is, embodiment, and therefore unconsciously implies the direction of natural utterance in the formant space.

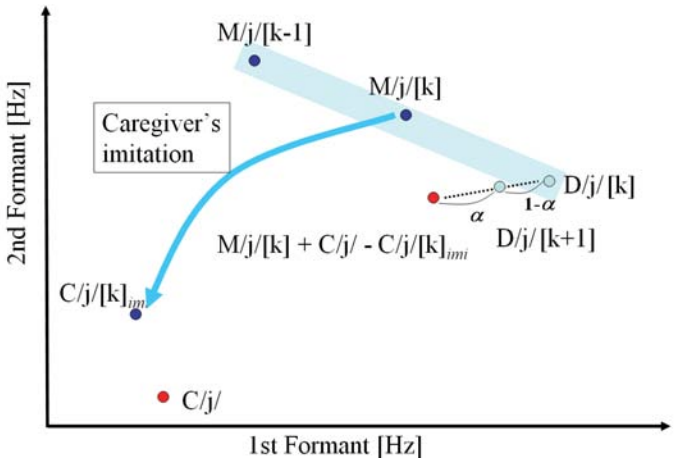

Figure 4: Mutual imitation process on the formant space

Fig.4 explains how mutual imitation can improve the robot utterance. Let D/j/[k], M/j/[k], C/j/[k]$_{imi}$ (i=a, i, u, e, or o) be the desired position, the current position and the utterance that caregiver imitates at the time=k, respectively. Initially, D/j/[0] = C/j/' and M/j/[0] = L/j/, and C/j/ is the caregiver's original vowel.

1. The robot finds the the current position M/j/[k] on the trajectory between M/j/[k-1] and D/j/[k], and utters this position to the caregiver.
2. The caregiver imitates the robot utterance M/j/[k], but the imitated utterance C/j/[k]$_{imi}$ is close to his/her own vowel C/j/ owing to the sensorimotor constraint.
3. A difference vector from C/j/[k]$_{imi}$ to C/j/ is supposed to indicate the direction to more natural vowel utternace.
4. Then, the desired position of the utterance is set at the position M/j/[k] + C/j/ - C/j/[k]$_{imi}$ from the current position.
5. To avoid a big change, a new desired position D/j/[k+1] is set as follows: D/j/[k+1] = α D/j/[k] + (1-α) (M/j/[k] + C/j/ - C/j/[k]$_{imi}$).
6. Repeat the above process until M/j/ does not change (often, due to the limit of the utterance capability).

We apply the learning algorithm to the real robot and a caregiver with α = .7. Here, we stop the learning at the 500th step since almost no changes happened in the robot utterance. Fig.5 shows the results of all vowels where thin folded lines of D/j/ indicate how they are modified according to the mutual imitation. The initial D/j/s are shown as nodes of a pentagon connected by dotted black lines and the final ones as nodes of a pentagon connected by dotted yellow-green lines. The acquired vowels are shown as nodes of a pentagon connected by dotted sky-blue lines. The initial nodes are black and the final ones colored. The human vowels are shown as larger marks such as +, *, and so on, while the robot ones as smaller ones.

Since it is difficult to show how natural the robot utterances are, we prepared the robot utterances without mutual

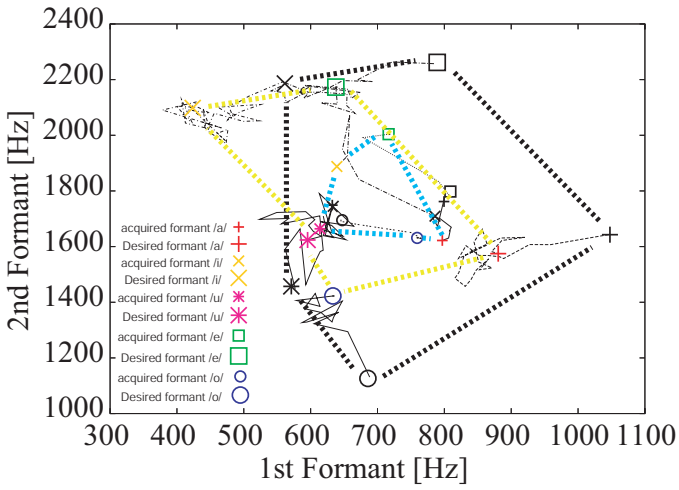

Figure 5: Desired and acquired vowels by a robot at the learning step 500

imitation, that is, the robot acquired the vowels supposing the initial desired positions D/j/[0] untl the end of learning, and asked about 40 naive people (no knowledge on vowel learning). As a result, 70% agreed that the utterances with mutual imitation are more natural than that without mutual imitation.

3.3 Discussion

Currently, we emulated the lip shape imitation by hand. In a real situation, the robot should capture the caregiver's face through its TV camera and extract the lip shape information. Then, it should send the motor commands to imitate the observed lip shape. To do that, the robot should know the correspondence between the body parts such as eyes, nose, and lip, and also how to control its body part, in this case lip motion. Neonatal imitation tells us such a capability [6] though it has been controversy. However, its mechanism has not been revealed yet. Development of boy representation and motor control is one of the key issues in cognitive developmental robotics, and we will attack this problem in near future.

Another issue is how the caregiver behaviors affect the learning results. In this paper, the number of the caregiver is just one, but we have not recorded how he responded (imitated) to the robot. The analysis of such interaction data would be helpful to understand the developmental process of vowel acquisition, and also to build the design policy of the learning robots.

In our study, we adopted the following hypotheses that the lip shape information helps the infant's vowel acquisition and that the caregiver's imitation tends to similar to his/her own vowels. Based on these, we build the interaction model and showed the experimental results. The verification for these hypotheses is not complete. Collaboration with infant study and developmental psychology seems necessary not only to verify them but also to refine or modify the model.

4. CONCLUSION

The brief introdcution of SI project is given and one preliminary study was shown toward emergence of communication. More studies on body representation, imitation, and symbol emergence will be done in our project and hopefully, we like to build a humanoid that can show intelligent, adaptive behaviors including dynamic motions such as runnig and junmping, conversation skill though poor utterance, and facial expression to communicate with us.

5. ACKNOWLEDGMENTS

First of all, the author appreciates the group leaders of the project: Profs. Hiroshi Ishiguro and Koh Hosoda at Osaka University, Prof. Toshio Inui at Kyoto University, and Prof. Yasuo Kuniyoshi at University of Tokyo for the invaluable discussion with them. Next, Dr. Yuichiro Yoshikawa and Mr. Katsushi Miura are appreciated for their preparation of the paper on the preliminary study.

ABSTRACT
In this paper, we describe lessons learned in commercializing and implementing agent-based systems in real-world business situations. Most notably we discuss gains in programmer productivity achieved by using AdaptivEnterprise, a commercial IDE and J2EE runtime engine based on BDI agents. In a wide range of complex business applications, we show that the use of BDI technology incorporated within an enterprise-level architecture can improve overall developer productivity by an average 350%. For java coding alone, the increase in productivity was over 500%. In competitive bids for large scale enterprise applications, AdaptivEnterprise was able to reduce total cost of ownership between two- and three-fold. In addition, the agent approach allowed the business to change and extend solutions quickly and helped bridge the gap between the business side and IT development.

Categories and Subject Descriptors
I.2.11 [**Artificial Intelligence**]: Distributed Artificial Intelligence – *multiagent systems*.

General Terms

Keywords
Agentis, AdaptivEnterprise, Function Point Analysis

1. INTRODUCTION
Agentis Software offers a commercial environment and methodology, called AdaptivEnterprise, for implementing agent-oriented goal-seeking applications. To date, Agentis has either implemented or assisted customers in implementing 15 applications. Of these, 13 are currently in production and two are pending deployment.

AdaptivEnterprise is both an IDE for building agents as well as a Java runtime engine for deploying the agents in a scalable, reliable, and secure manner. AdaptivEnterprise deploys agents in a pure J2EE-environment and has been commercially available for several years.

2. MAJOR LESSONS LEARNED
Agentis has learned several major lessons in commercializing agent technology. They are:

- Agent technology is applicable to a wide range of industry problems;
- The primary business value of agent technology is reduced complexity;
- Agent technology provides compelling ROI and productivity improvement;
- Designing with agents is easier for business analysts than conventional technologies;
- An iterative methodology is critical to building successful Agent-Oriented Systems; and
- IT Programmers can easily make the transition from pure Object-Orientation to Agent-Orientation

3. AGENT TECHNOLOGY IS APPLICABLE TO A WIDE RANGE OF INDUSTRY PROBLEMS
Our solution, AdaptivEnterprise, is currently in use in a wide variety of applications across a range of industries including logistics, finance, energy, telephony, transportation, and housing administration.

The range of implemented applications includes:

- Datacenter compliance and monitoring (Sarbanes-Oxley Compliance)

4. REDUCING COMPLEXITY: THE #1 VALUE OF AGENTS

The most common theme throughout these applications is that they are "hard" to build. All are complex and are not the typical transactional applications that corporate IT groups normally build. Many of these applications are more typically delivered as customizable packages by third-party vendors. However, these applications have complex requirements and enough "exceptions" to make implementing an off-the-shelf package unfeasible without significant customization efforts.

Another common theme of these applications is change. Requirements for these applications change very rapidly and in often complex ways. New services and pricing schemes are added, companies are merged, government regulations change, etc. The ability to be able to quickly add or change functionality is critical. Because major control logic is abstracted in an agent-based system, adding and changing functionality is very easy.

These applications are also event and exception driven. That is, the system needs to respond to ongoing events and exceptions. Because the response to an event can vary depending on the current state of the system, the loosely coupled nature of agent control logic (processes) makes event and exception processing much simpler to code.

Finally, speed to market has been critical in the applications we've been involved in. Given the mission critical nature of these projects, there are serious financial and business implications involved in getting these applications completed. The reason many of our customers adopted Agent technology is that they were looking for a faster and easier way to get these applications built. Some projects were awarded to Agentis because we promised to deliver the application quickly, not because the customer understood Agent-based systems.

5. MEASURING ROI FOR PROJECTS

While the technical reasons for using agents might be apparent for various situations, in business settings, Return on Investment (ROI) is a primary decision criterion. Businesses will take a chance on a technology through a proof-of-concept project (POC) without regard for ROI but, for real implementations, the ROI must be compelling. Agent technologies are not pervasive in businesses and are foreign to many IT departments. In addition, there is a good bit of confusion about what agents are.

Measuring true ROI is complicated—and can be expensive to measure in full detail. In addition, it is sometimes hard to isolate the ROI of agent technology itself because many factors go into the success and the total cost of a project, including software licenses, analysis and design, testing, GUI construction, server infrastructure, project management, consulting/labor costs, etc.

Likewise, one cannot compare the ROI of two projects and assume the one with the lowest ROI was the most successful. Projects differ in complexity, internal politics, purpose, stakeholders and, of course, core functionality. Even two projects with similar functionality can have vastly different ROIs because of factors external to the products/languages used, such as changing requirements, ineffective management, etc.

However imprecise ROI measurements tend to be, there are several generally accepted measures of a project's "success". The first is productivity—how productive was the IT staff at implementing the solution versus other technology choices or development teams? The second is cost—how much did the project cost versus alternative estimates?

Given the fact that the applications that agents are best at solving tend to be complex critical applications, the expected ROI should be high. One specific project resulted in a 173% ROI and is detailed at the end of this paper.

5.1 Estimating Agent Productivity with Function Point Analysis

Function Point Analysis (FPA) is a technique published in 1979 by Allan J. Albrecht to measure the "size" of a software application and predict the level of effort associated with building it.

A Function Point (FP), according to the International Function Point Users Group (IFPUG.org), is a unit of "system functionality" measured from a functional, or user, point of view. It is independent of the computer language, development methodology, technology or capability of the project team used to develop the application.

According to IFPUG:

- FPA can be used to size software applications accurately. Sizing is an important component in determining productivity (outputs/inputs).
- Function Points can be counted by different people, at different times, to obtain the same measure within a reasonable margin of error.
- Function Points can be used to determine whether a tool, a language, or an environment is more productive when compared with others.

Because FPA is a fairly objective methodology for analyzing software complexity, it is useful for measuring

the productivity of differing software teams, methodologies, frameworks, and languages.

One of Agentis' customers, a large international logistics firm, uses FPA as a standard for measuring projects and IT productivity. Recently, they performed an analysis of their Agent-Oriented projects to determine whether to increase the role of Agents in the organization.

Based on six applications encompassing a total of 7,356 function points (FP) and 10 person-years of development, AdaptivEnterprise delivered an average of 2.11 function points per day for each fully completed project. Average productivity for all other non-agent-based Java projects within the organization is 0.45 FP per day.

Based on this analysis, agent-oriented methodology, architecture, and development delivered a 368% improvement in overall project productivity. (2.11 FP Actual/0.45 FP Expected)

Improvements on specific projects ranged from a high of 513% improvement to a low of 273% improvement. The largest single project had 3,850 FP and the smallest project had 304 FP.

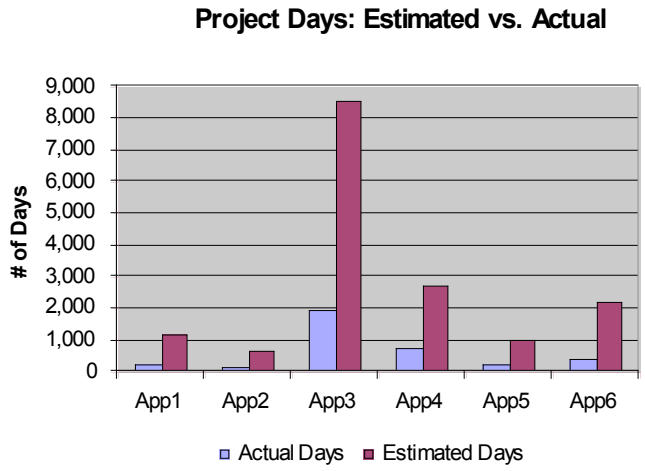

Figure 1: Estimated vs. Actual Project Days

5.2 Agent-Orientation's Effect on Coding

All the FP numbers presented to this point have been for the complete project—which includes requirements gathering, analysis and design, testing, and implementation. When Agent-oriented development is compared at a pure coding level, the productivity improvements are even greater.

Since AdaptivEnterprise is a 100% pure Java and J2EE solution, we compared the agent-based applications against other Java applications in the organizations. The historical average FP coding productivity for the organization's Java developers is 0.95 FP/day.

We only have coding metrics for four of the projects and their mean coding productivity with AdaptivEnterprise was 4.97FP/day. This represents a 423% improvement (4.97FP / 0.95 Average Java FP) over the standard for the organization.

Finally, a non-FP related data point is provided by an application for another customer involving a migration of an existing COBOL workflow application with 120,000 lines of code. The application was re-engineered into a Java-based system with seven agents in less than three months with two full-time and one part-time developer.

6. DESIGNING WITH AGENTS IS EASIER FOR BUSINESS ANALYSTS

How do you take a business process and map it into software? This is a central problem that business is still striving to solve in application development. Translating requirements into a working system is as much a science as it is an art. Humans who work with business processes speak one language while programmers and systems analysts speak another. IT staff are much more concerned with wiring specific systems and functions together to form a specific process. Business analysts describe roles, patterns, workflows, and decision trees.

We have found that by discussing systems in terms of data, goals, and plans, the conceptual modeling of systems becomes much easier. First, the terminology is easier for both IT and business to understand. Agent analysis lends itself very well to iterative requirements gathering. Just as it is easy to code new plans to an existing Agent-based application, it is also easier to add new plans during the conceptual phase of an application. Likewise, moving from the conceptual phase of analysis to the concrete design phase is aided because agent-oriented analysis produces goals and plans that can then be specifically designed and coded as discrete work elements.

At Agentis, we've used a modified version of the Rational Unified Process along with agile development techniques such as Scrum or XP. As pointed out previously, time to market is important with these applications. Because of that, a classic waterfall or even a strict RUP-based UML modeling approach is not always possible or desirable for these projects.

6.1 Agility Is Critical

A typical situation that we encountered was a rapid escalation in the problem space. Many organizations that are introduced to Agents for the first time are a bit skeptical. To mitigate any possible risks involved with bringing Agent-technology on board, many projects start as smaller proofs-of-concept and are quickly escalated into full-blown formal projects once Agent technology and concepts are proven.

Besides being able to tackle complex problems, Agentis' experience is also one of agility. Agent-based approaches allow us to respond very quickly to changes in the

requirements of a system and to changes to systems currently in production. For example, the application that covers 3,850 function points started life as a 350+ function point application. The benefits of the system were immediately seen by the customer and the application quickly escalated into a major, mission-critical endeavor. Because the BDI agent-model scales easily, it was fairly straightforward to move the system from a small effort to a large one—more agents were added along with more goals and more plans.

Several customers have stated that agent-oriented methodology coupled with a GUI design environment for building agents facilitated RAD capabilities with their complex systems—something that was previously not thought possible, since RAD tends to be associated with smaller systems with more CRUD (Create, Read, Update, Delete) transaction functionality.

6.2 Agent Technology Must Play Well With Others

Both the methodology as well as the actual implementation of an agent-based system must "play well with others". At minimum, a system will need to interact with an existing relational (SQL) database—most likely by storing long running state & transaction information.

Many organizations are moving toward Service Oriented Architecture (SOA) by implementing standard language and platform neutral mechanisms for exposing computing resources through WSDL or SOAP. At minimum, the agent system must be able to consume SOAP-based web services and provide agent-based web services to other systems via web services standards.

Likewise, organizations are also starting to use BPEL as a process model definition and execution environment. Agents must be able to call BPEL processes and BPEL processes must be able to invoke agents.

Having an Agent technology based on J2EE or .NET mitigates most of these integration concerns at a code level. Having GUI and IDE support for these interactions is critical for productivity.

6.3 Agent Technology Can Be Used By IT Programmers

Agentis normally helps customers build their first application. In cases of large applications, a third-party integrator might be brought in to provide programming resources. Projects are normally led by Agentis staff with extensive agent experience. However, most of the coding is done by "normal" Java developers. Agentis has trained over 100 developers in the AdaptivEnterprise product and all of our customers have taken over the maintenance of their applications with several of them continuing to build new applications with no direct input from Agentis.

Typical developer training is three days of classroom training on the product and 1½ days on the methodology. We have added concept courses for the Business Analyst and Architects. Developers can be productive after the training and proficient in 4 to 6 weeks of project work.

7. CASE STUDIES

7.1 Multi-Jurisdiction Tax Application for a Large Energy Company

Collection of sales and use tax is complicated because each city, municipality, county, and state has their own taxation policies. In addition, many large corporations are given tax breaks and have specific agreements in place with various government agencies covering the types of items that are taxable and at which special rate. Finally, because the customer in this case is an energy utility, many special taxation rules apply that are above and beyond typical use tax calculations.

The customer had acquired an existing tax package and had spent almost 18 months of time and several millions of dollars implementing and customizing the application. However, the tax package was unable to provide accurate tax information because of the complexities involved and required heavy user intervention, resulting in large amounts of overtime pay spent to ensure the tax calculations were correct. Agentis was brought in to help fix the problem.

The customer was attracted to the speed of development that Agentis promised as well as the goal and plan nature of the agent architecture which was easy for the customer to understand. Likewise, speed of application maintenance and change was critical. Tax laws and regulations change constantly across many tax jurisdictions. The agent-oriented application allows them to add and modify tax calculation plans very easily.

Between overtime spending, maintenance spending on the discontinued tax application, and ability to meet quality of service requirements of the government, the customer saved just under $6 million in direct costs and administrative revenue for collecting & administrating the taxes.

ROI for Tax Application	
Direct Savings & Revenue Stream	$5,812,000
Project Costs	$ 1,171,000
Useful Life	5 Years
Net Present Value	$ 2,005,555
ROI	173.06%

Overall the ROI on the project was calculated at 173% over five years resulting in an internal rate of return of 43%. In

addition to the cost savings, the customer can now offer value-added services to their customers such as tax reduction strategies, etc. In addition, the new system provides an audit trail for additional Sarbanes-Oxley (SOX) compliance.

The project was so successful that the customer has contacted Agentis on how the two companies can become closer strategic partners for further application development.

7.2 Global Package Tracking, Tracing, and Recovery

The customer is a global logistics and shipping company handling billions of packages a year. As the organization grows and acquires other logistics firms, a global solution was needed to handle package tracking, tracing, and recovery. As packages move through the system, millions of events are generated which change the state of the system and of individual shipments.

The application was designed to handle up to 7,500 concurrent users over 100 countries and needed to handle over 10,000 traces per day. A trace is a physical trace of a shipment—not just a check on 'where is my package'. Many times a trace results in people physically looking for a shipment or entering details about the shipment and its current status: examples include being detained for customs, weather delays, transit strikes, etc. Because of this, human intervention is usually required in the process as well as timely communication to the customer on the shipment status. To support this complex workflow scenario, the system supports the following:

- Role-based and team-based workflow;
- Integration to existing enterprise services for authorization and authentication, shipment searching, customer location and service level agreements;
- Real-time subscription to changes in physical location and workflow state;
- Automatic workflow task allocation to most suitable Customer Service Representative (CSR) and most suitable team; and
- Extensive workflow monitoring: notifications, alerts, reminders, state change markers.

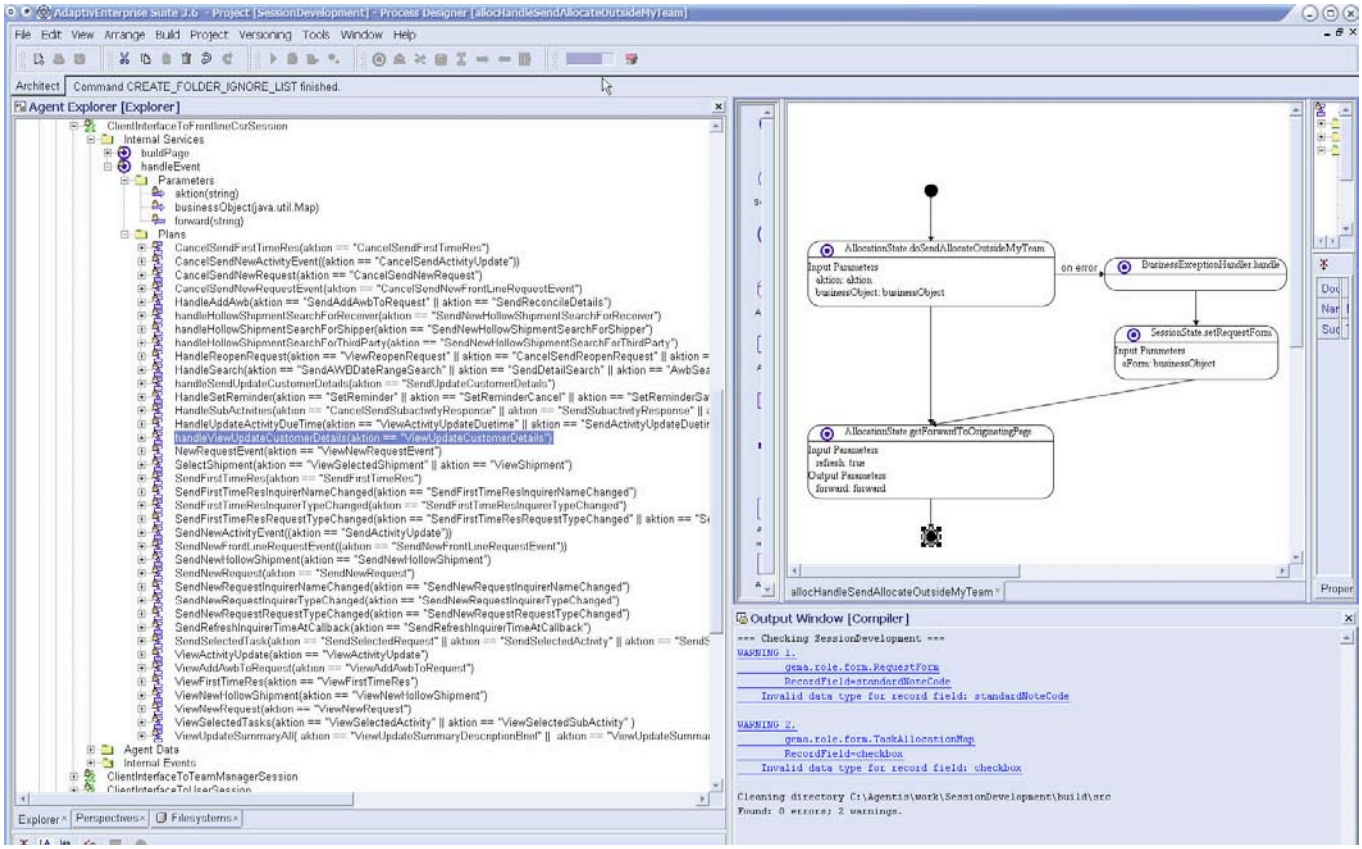

Figure 2: An event-handling agent with 37 possible executable plans.

The system is currently deployed to over 30 CPUs serving almost 3,000 concurrent users.

Business benefits, as stated by the customer, are:

- Reduced cost of operations because of automation of tasks and increased call center throughput;
- Enterprise-level adaptability because of agent reuse and flexibility and SOA implementation; and
- New platform for customer self-service as well as new service delivery channels

The reasons the customer chose Agentis/Agent Technology were:

- Full BDI/Goal Directed Agent Framework
  - 100% J2EE solution; use of EJBs, MDBs, JMS
  - Both synchronous and asynchronous inter-agent communication
- Extreme adaptability through Agents
  - Low lifecycle costs: maintenance is adaptation
  - Unprecedented application longevity
- Agents are EJBs
  - Enterprise friendly and very scalable
- Visual Agent Development Environment
  - Oriented toward Business Analysts
  - Comprehensive develop/test/deploy environment

The system was competitively bid with the customer. The total implementation costs to date are roughly $6MM. Other competitive solutions using a combination of packaged software along with customization had a estimated total ownership cost of $15MM to $25MM. The customer was able to get the functionality that they wanted in half the time they wanted at less than half the cost.

8. Summary

Agent technology is ready for mainstream corporate use and can be successfully commercialized. It has proven itself to be highly reliable and scalable and also well suited for complex business applications involving many moving parts, fast changing requirements, and tight timelines. Agent-based solutions have been used many times to solve problems customers thought were not solvable—at least not within any reasonable timeframe or budget constraints.

However, pure agent technology is not enough. The technology must be presented in a way that "typical" programmers can understand and use—and it must integrate into their current development efforts.

Likewise, a proven methodology that addresses the needs of business analysts as well as developers is also required.

Agent Interface Enhancement: Making Multiagent Graphical Models Accessible

Yang Xiang

zhangk@uoguelph.ca

ABSTRACT

Multiagent probabilistic reasoning with multiply sectioned Bayesian networks requires interfacing agent subnets (the modeling task) subject to a set of conditions. To specify the interfaces such that they are both valid and efficient is non-trivial. We present multiagent interface enhancement that relieves agent designers from the burden of model efficiency so that multiagent graphical models become more accessible.

Agent-Based Modeling, Cooperation and Coordination Among Agents, Graphical Models, MSBNs, Multiagent Architectures, Uncertain Reasoning

1. INTRODUCTION

Built upon the success of Bayesian Networks (BNs) [4], multiply sectioned Bayesian networks (MSBNs) [7] provide a rigorous framework for reasoning about uncertain domains in cooperative multiagent systems (MASs). Each agent holds its partial perspective (a subnet over a subdomain) of a domain, reasons autonomously as well as through limited communication with other agents. From a few high level requirements, (1) exact probabilistic measure of agent belief, (2) agent communication by belief over small sets of shared variables, (3) a simpler agent organization, (4) DAG domain structuring, and (5) joint belief admitting agents' belief on private variables and combining their beliefs on shared variables, it has been shown [9] that the resultant representation of a cooperative multiagent system is an MSBN.

To ensure autonomous, exact and efficient inference, subnets in an MSBN must satisfy a set of representational constraints. This is the modeling task. Specification of such a multiagent graphical model that is both valid and efficient is non-trivial and places a major burden on MAS designers. A key factor in modeling is the specification of agent interfaces, which are subject to hypertree, d-sepset, privacy, and sparse linkage tree conditions (to be introduced below). The main contribution of this work is a method to automate interface modeling so that MAS designers are relieved from the burden of model efficiency (the sparse linkage tree condition) and partially from the burden of privacy. The direct consequence is the simplification of modeling task and the improved accessibility of the MSBN framework to MAS designers.

2. THE ENHANCEMENT APPROACH

Before agents can aid graphical modeling, the MAS has to be created. We assume that for any large domain where an MAS is to be built, there is a natural subdomain division reasonably obvious to the human agent designers. The natural division divides the domain into overlapping subdomains, one for each agent, and thus forms the initial agent interfaces. For instance, in equipment diagnosis [7], each subsystem forms a natural subdomain and its input from and output to another subsystem form the interface between the two. In supply chain collaborative design [8], each component to be designed by a supplier forms a natural subdomain. The initial interfaces, however, may not support efficient inference. We let agents cooperate to enhance interfaces to improve efficience. Not requiring initial interfaces to be efficient removes the burden from agent designers and eases their modeling task.

One of the advantages of the MSBN framework is that once the modeling of MSBN-based MAS is complete, internal details of each agent (its subnet) is kept private throughout model verification, model compilation, and run-time inference. As we are now dealing with multiagent modeling, it is necessary to relax this privacy constraint *slightly* (but not completely). Each subnet is built by its agent designer. We assume that the designer can classify variables in the subnet into three sets: private, public, and preferably private. The *private* set should be kept so absolutely. The *public* set is included in the initial agent interface. The *preferably private* set is initially private, but the agent is allowed to make some elements public if it believes that the disclosure improves inference efficience. The agent is required, however, to keep the disclosed subset as small as possible.

We argue that the three-set assumption respects privacy realistically. Consider tightened airport security check after 9/11. Travelers who are subject to much more thorough body search can be regarded as giving up more privacy than before. However, many accept this as a price paid for a safer flight. The three-set assumption treats privacy as a form of utility and efficience as another, and allows them to be traded as desired by agent designer.

Furthermore, consider what would happen if human agent designers, instead of agents, are trying to construct efficient agent interfaces. For a complex domain, it is unlikely for each designer to classify its subdomain into private and public variables, and the resultant agent interfaces will be automatically both valid and efficient. More likely, they would start with initial interfaces and incrementally modify them, which effectively discloses some initially private variables to other agent designers. The three-set assumption enables this incremental process to be mirrored by agents.

We are unaware of other work on improving agent interfaces for multiagent graphical models. The most related are the information bottleneck (IB) approach [6] and its extension [1]. IB constructs a set T of variables that are stochastic functions of one set Y of variables and provide information on another set X. In general, T *approximates* information in X. Our enhanced interface conveys *exactly* all relevant information from one agent to another.

3. OVERVIEW OF MSBNS

An MSBN M is a collection of Bayesian subnets, one from each agent, representing probabilistic dependence of a *domain* divided into multiple *subdomains*. Agents cooperate to reason about the state of the domain [7]. To ensure distributed, exact inference, subnets satisfy conditions described below:

Let $G_i = (N_i, E_i)$ $(i = 0, 1)$ be two graphs. G_0 and G_1 are *graph-consistent* if subgraphs of G_0 and G_1 spanned by $N_0 \cap N_1$ are identical. Given graph-consistent graphs $G_i = (N_i, E_i)$ $(i = 0, 1)$, the graph $G = (N_0 \cup N_1, E_0 \cup E_1)$ is the *union* of G_0 and G_1, denoted by $G = G_0 \sqcup G_1$. Given a graph $G = (N, E)$, a division of N into N_0 and N_1 such that $N_0 \cup N_1 = N$ and $N_0 \cap N_1 \neq \emptyset$, and subgraphs G_i of G spanned by N_i $(i = 0, 1)$, G is *sectioned* into G_0 and G_1. Sectioning is used to relate graphical models at individual agents in a cooperative multiagent system.

DEFINITION 1. *Let $G = (N, E)$ be a connected graph sectioned into subgraphs $\{G_i = (N_i, E_i)\}$. Let the subgraphs be organized into an undirected tree Ψ where each node is uniquely labeled by a G_i and each link between G_k and G_m is labeled by the non-empty* `interface` *$N_k \cap N_m$ such that for each i and j, $N_i \cap N_j$ is contained in each subgraph on the path between G_i and G_j in Ψ. Then Ψ is a* `hypertree` *over G. Each G_i is a* `hypernode` *and each interface is a* `hyperlink`*. A pair of hypernodes connected by a hyperlink is said to be* `adjacent`*.*

Each hyperlink is an agent *interface*. Agents communicate by exchanging beliefs over their interfaces. An interface must be a *d-sepset*:

DEFINITION 2. *Let G be a directed graph such that a hypertree over G exists. A node x contained in more than one subgraph with its parents $\pi(x)$ in G is a* `d-sepnode` *if there exists at least one subgraph that contains $\pi(x)$. An interface I is a* `d-sepset` *if every $x \in I$ is a d-sepnode.*

The overall structure of an MSBN is a hypertree MSDAG:

DEFINITION 3. *A* `hypertree MSDAG` *$\mathcal{G} = \bigsqcup_i G_i$, where each G_i is a DAG, is a connected DAG such that (1) there exists a hypertree Ψ over $\mathcal{G}$, and (2) each hyperlink in Ψ is a d-sepset.*

Graphically, a hyperlink separates the hypertree MSDAG into two subtrees. Semantically, this corresponds to conditional independence given the d-sepset. An MSBN is defined as follows with an example shown in Figure 1.

DEFINITION 4. *An MSBN M is a triplet $M = (\mathcal{N}, \mathcal{G}, \mathcal{P})$. $\mathcal{N} = \bigcup_i N_i$ is the* `domain` *where each N_i is a set of variables. $\mathcal{G} = \bigsqcup_i G_i$ (a hypertree MSDAG) is the* `structure` *where nodes of each DAG G_i are labeled by elements of N_i. Let x be a variable and $\pi(x)$ be all the parents of x in $\mathcal{G}$. For each x, exactly one of its occurrences (in a G_i containing $\{x\} \cup \pi(x)$) is assigned $P(x|\pi(x))$, and each occurrence in other DAGs is assigned a constant table. $\mathcal{P} = \prod_i P_i(N_i)$ is the* `jpd`*, where each $P_i(N_i)$ is the product of probability tables associated with nodes in G_i. Each triplet $S_i = (N_i, G_i, P_i)$ is called a* `subnet` *of M. Two subnets S_i and S_j are said to be* `adjacent` *if G_i and G_j are adjacent on the hypertree MSDAG.*

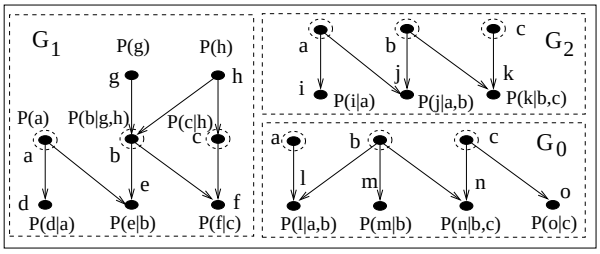

Figure 1: A trivial MSBN where each d-sepnode is shown with a dashed circle. The hypertree has the structure $G_1 - G_0 - G_2$ and each d-sepset is $\{a, b, c\}$.

To compute intra-agent messages effectively, each agent compiles its subnet into a junction tree (JT) [2], where variables are grouped into *clusters* with intersection of adjacent clusters referred to as *separators*. To integrate computation of intra-agent messages with computation of inter-agent messages seemlessly, the compilation is performed cooperatively. A key step is *cooperative triangulation* [7], during which each agent performs *constrained triangulation* through node elimination in partial order: A set N of nodes is eliminated according to a partial order (N_1, N_2) where $N = N_1 \cup N_2$, if nodes in N_1 are eliminated before nodes in N_2 are eliminated. We also refer to the triangulation as *constrained by* N_2, or *unconstrained* if $N_2 = \emptyset$.

For efficient computation of inter-agent messages, agents compile each d-sepset into a JT, called a *linkage tree*. See Figure 2 for linkage tree L_1 between T_0 and T_1. Each cluster in L_1 is called a *linkage*. Linkage $\{b, c\}$ is an message channel between cluster $\{b, c, f\}$ in T_1 and cluster $\{b, c, n\}$ in T_0. Its state space size (SSS) is 16 if the dimension (number of possible values) of variables a, b and c is 4, and that of L_1 is 32 which determines the efficience of inter-agent messaging. In general, the sparser the linkage tree (with many small linkages), the more efficient it is. If L_1 were made of a single linkage $\{a, b, c\}$, its SSS would be 64.

4. WHY NOT CENTRALIZE COMPILATION

An alternative to enhancing interfaces in MSBN is to build a centralized domain model, compile it into a JT, and separate the JT into subtrees one for each agent. Although it provides the most efficient run-time representation, it suffers from two major drawbacks compared to the approach we take.

First of all, the alternative requires that all domain variables and their dependence relations to be disclosed to the centralized model builder. There will be no agent privacy at all. In contrast, our approach does not disclose any private variables and dependence relations among them. It only discloses a subset of preferably private variables and does so in a cautious manner.

Secondly, even if the agent privacy were not a concern at all, the alternative will disrupt natural subdomain division among agents.

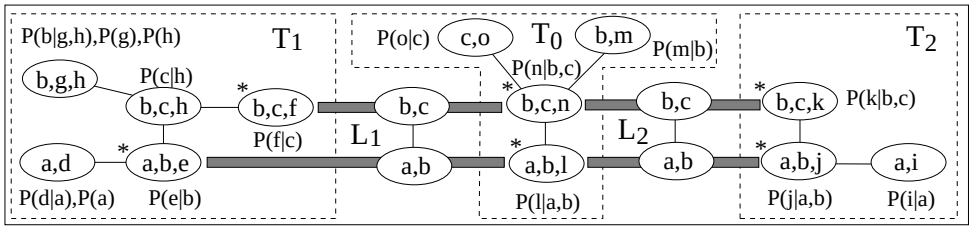

Figure 2: JTs and linkage trees obtained from Figure 1.

We illustrate this problem with a trivial MSBN shown in Figure 3. In (1), a trivial centralized domain model is shown as a BN. Sup-

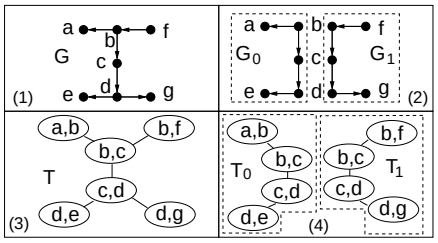

Figure 3: Illustration of natural subdomain disruption.

pose that it is naturally divided into two overlapping subdomains as shown in (2), where variables b, c and d form the interface. The BN in (1) is compiled into JT in (3). If this JT is to be separated into two, there are five possible ways, each separating the JT into two subtrees along one of the five separators (e.g., the separator between clusters $\{b, c\}$ and $\{b, f\}$ is $\{b\}$). None of them corresponds to the natural subdomains $\{a, b, c, d, e\}$ and $\{b, c, d, f, g\}$. The agents thus constructed lose their semantic coherence (the need for such coherence is also touched upon in [3]). On the other hand, according to the MSBN framework, the subdomain models in (2) will each be compiled into a JT in (4), which preserves the natural division while allowing efficient inference.

5. ANALYSIS

Inference in MSBNs is efficient mostly because agent interfaces, the d-sepsets, are represented as linkage trees, which enables potential factorization. Intuitively, this means that d-sepnodes are dispersed among a number of clusters in the local JT. Hence, the more scattered the d-sepnodes among clusters, the more efficient the inference. In the following, we analyze how adding more d-sepnodes can achieve such effect. Proposition 1 shows under what condition adding a node to d-sepset can disperse d-sepnodes into different clusters.

PROPOSITION 1. *Let S be the subnet of an agent, T be its local JT from S, and x and y be d-sepnodes contained in a cluster C in T. If a unique path exists between x and y in S, all other nodes on the path are non-d-sepnodes, and one of them, v, is head-to-tail or tail-to-tail, then adding v to d-sepset can disperse x and y into different clusters, unless it is prevented by other agents.*

Proof: Since the path contains at least v and it is head-to-tail or tail-to-tail, x and y will not be connected during moralization. Once v is added to the d-sepset, during constrained triangulation by the local agent, x can be eliminated before y and v, or y can be eliminated before x and v (neither is possible if v is not added to the d-sepset). In either case, x and y will not be connected by any fill-in. Hence, unless a moral link or a fill-in between x and y is added by another agent, x and y cannot be in the same cluster in the new local JT. □

The only way the condition in Proposition 1 can be violated is where the unique path between x and y consists of a single head-to-head node v. If any arc on the path is reversed or any additional nodes exist on the path, the condition in Proposition 1 will be true. Because a moral link will connect x and y, no matter what the rest of the d-sepset is, x and y must be contained in the same cluster. This means that Proposition 1 captures *all* possible cases where a non-d-sepnode can be successfully added to d-sepset to disperse x and y.

The following corollary generalizes Proposition 1 to the case where multiple paths exist between x and y in the local subnet.

COROLLARY 1. *Let S be the subnet of an agent, T be its local JT from S, and x and y be d-sepnodes contained in a cluster C in T. For each path between x and y in S, if all other nodes on the path are non-d-sepnodes, and one of them, v, is head-to-tail or tail-to-tail, then adding such v from each path to d-sepset can disperse x and y into different clusters, unless it is prevented by other agents.*

When d-sepnodes are dispersed into different clusters, they are effectively dispersed into different linkages in the linkage tree. On one hand, this reduces sizes of corresponding linkages. As individual linkages become smaller, the state space of the linkage tree is reduced and hence the improved efficience. On the other hand, according to Corollary 1, dispersing d-sepnodes requires enlarging the d-sepset. The new d-sepnodes increase the state space in each linkage they participate. To achieve the net effect of reduction in linkage tree state space, new d-sepnodes must be chosen carefully.

In general, when addition of a single non-d-sepnode disperses multiple pairs of d-sepnodes, the negative effect of the addition is smaller than its positive effect and the linkage tree state space is decreased.

The above analysis has emphasized the topological aspect of the issue. However, since it is the total state space of the linkage tree that directly affects inference efficience, not cardinalities of linkages, another important factor is the dimensions of variables involved. When a linkage of three variables each of dimension 3 is dispersed, by adding a binary variable v to d-sepset, into three linkages each made of v and another variable (see Figure 5 (d) later for an example), SSS is reduced from 3*3*3 = 27 to 3*2*3=18. However, if v has a dimension of 4, SSS is increased to 3*4*3 = 36.

In general, when a new d-sepnode v disperses existing d-sepnodes whose dimensions are higher than that of v, the linkage tree SSS is decreased.

6. SEARCH FOR ENHANCEMENT

To improve interface efficience, we add non-d-sepnodes to a d-sepset to make the linkage tree sparser and reduce its SSS. We refer to a non-empty set of non-d-sepnodes in a subdomain as an *enhancement*, whose effectiveness depends also on enhancements from other agents. Hence, the optimal set of enhancements (two

per d-sepset), which reduces the sum of all linkage tree state space sizes to the maximal extent, generally can only be obtained by exhaustive multiagent search. If each agent has $O(k)$ (where k is very large as shown below) alternative enhancements for each of its d-sepsets, then the search space of n agents has a complexity of $O(k^{2n})$. In the following, we consider several approximations with reduced complexity.

1. Each pair of adjacent agents performs cooperative search over the space of all pairs of enhancements (one from each agent), and then adds the pairwise top enhancement to their d-sepset.
2. Each agent searches for local top enhancements (there may be ties). Cooperative search is then performed by all agents over the space of all combinations of local top choices.
3. Each agent searches for local top enhancements. Then each pair of adjacent agents searches for pairwise top enhancements over the space of all pairs of local top choices.

The first approximation restricts cooperative search to pairwise. The computation has a complexity of $O(n\ k^2)$. The second approximation first reduces the number of alternative enhancements at each agent per each d-sepset from k to a few, say, k'. Then global cooperative search is performed with $O(k'^{2}\ ^{n})$ complexity. The third approximation has the lowest complexity of $O(n\ (k + k'^2))$. In this work, we study the effectiveness of this approximation and will investigate the other approximations in future research.

The top level algorithm below is run by the MAS coordinator to activate cooperative interface enhancement.

ALGORITHM 1 (COENHANCEINTERFACE).
choose an agent A_* arbitrarily;
call A_* to run EnhanceInterface with null parameters;

The following recursive algorithm is run by each agent. Without losing generality, we denote the agent executing the algorithm as A_0. The execution is activated by a caller, denoted as A_c, which is either an adjacent agent of A_0 or the MAS coordinator. If A_0 has additional adjacent agents, they are denoted $A_1, ..., A_m$. The subdomains of $A_c, A_0, ..., A_m$ are $N_c, N_0, ..., N_m$, respectively, their subnets are $G_c, G_0, ..., G_m$, the interface between A_0 and A_c (if an agent) is denoted D_c, and the interfaces between A_0 and $A_1, ..., A_m$ are denoted $D_1, ..., D_m$. The caller A_c passes two parameters into A_0: $NewD_c$ - a set of new d-sepnodes and $Arcs_c$ - a set of arcs (each either connecting elements in $NewD_c$ or connecting an element of $NewD_c$ with an existing d-sepnode). In return, A_0 will send parameters $NewD_c^{\rightarrow}$ and $Arcs_c^{\rightarrow}$ to A_c, where the arrow denotes output by A_0.

ALGORITHM 2 (ENHANCEINTERFACE). *When A_0 is called by A_c with parameters $NewD_c$ and $Arcs_c$, it does the following:*

compile G_0 into JT T_0^* by unconstrained triangulation;
for $i = 1, ..., m$ and $i = c$ if A_c is an agent, do
  compile G_0 into JT T_i through triangulation constrained by $(N_0 \setminus D_i, D_i)$;
  perform $UpdateDsepset(G_0, D_i, T_i, T_0^*)$ and denote return value by $NewD_i^{\rightarrow}$;
  denote arcs in G_0 relevant to $NewD_i^{\rightarrow}$ as $Arcs_i^{\rightarrow}$;
for $i = 1, ..., m$, do
  call A_i to EnhanceInterface with $NewD_i^{\rightarrow}$ and $Arcs_i^{\rightarrow}$;
  receive $NewD_i$ and $Arcs_i$ from A_i;
for $i = 1, ..., m$ and $i = c$ if caller is an agent, do
  enhance D_i with $NewD_i$ and $NewD_i^{\rightarrow}$ if both are non-empty;
  update G_0 with $NewD_i$ and $Arcs_i$;
if A_c is an agent, send $NewD_c^{\rightarrow}$ and $Arcs_c^{\rightarrow}$ to A_c;

EnhanceInterface consists of three *for* loops. In the first *for* loop, local subnet is compiled into a JT by constrained triangulation relative to each d-sepset. Using this JT and that obtained from unconstrained triangulation, the local top d-sepset enhancement is obtained by UpdateDsepset (see below for more on this step). Through the second *for* loop, the enhancement operation is propagated along the hypertree organization of the MAS, until it reaches agents located at the leaves of the hypertree. The results of local search by UpdateDsepset will then be propagated back towards A_*, through the last statement of the algorithm. In the third *for* loop, the agent enhances the d-sepsets and its local subnet.

The return value $NewD_i^{\rightarrow}$ from local search UpdateDsepset can contain an unique top enhancement. It can also contain a set of top enhancements (that tie). In that case, the search strategy 3 dictates a pairwise cooperative search, which can be performed by modifying the above algorithm as follows:

It may appear that the task to decide which pair of local top enhancements are pairwisely best requires cooperation of both agents. We show below that a simpler operation suffices.

We consider agent A_0 and its caller agent A_c. At the end of the first *for* loop of EnhanceInterface, A_0 has received $NewD_c$ and computed $NewD_c^{\rightarrow}$. For each enhancement in $NewD_c$ and each in $NewD_c^{\rightarrow}$, A_0 can perform constrained triangulation using the corresponding enhanced d-sepset. A linkage tree will then be derived. According to [7] [1], this linkage tree is equivalent to what would be derived by A_c. Hence, the best pair of enhancements can be computed by A_0 only, with the following statements added at the end of the first *for* loop:

search for best pair of enhancements with A_c based on $NewD_c$ and $NewD_c^{\rightarrow}$, breaking ties arbitrarily;
update $NewD_c$ and $NewD_c^{\rightarrow}$ accordingly by deleting other enhancements;

To inform A_c of the result, the last statement of the algorithm needs to be modified into the following:

if A_c is an agent, send $NewD_c^{\rightarrow}$ and $Arcs_c^{\rightarrow}$ to A_c as well as the pairwisely best enhancement in $NewD_c$;

7. LOCAL HEURISTIC SEARCH

For an agent to search for the locally best enhancement to a d-sepset, the alternatives must be identified. This can be done by examining the local subnet or the local JT. Since linkage tree is generated from local JT and preserves conditional independence encoded in the JT (Proposition 7.6 [7]), we identify enhancements based on the local JT.

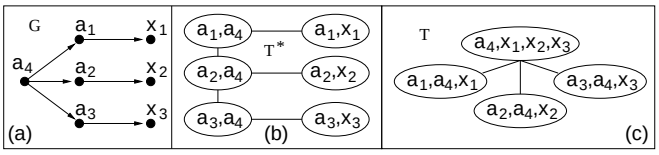

Figure 4: (a) Subnet G. (b) The JT T^* from G by unconstrained triangulation. (c) The JT T from triangulation constrained by $\{x_1, x_2, x_3\}$.

Consider the trivial subnet in Figure 4 (a). Given the d-sepset $\{x_1, x_2, x_3\}$, the local JT in (c) can be constructed. From the local JT, the linkage tree can be derived that has a single linkage $\{x_1, x_2, x_3\}$.

[1] Section 7.6.2 on two-agent cooperative triangulation and Section 8.3 on equivalence of linkage trees derived by adjacent agents.

To identify d-sepset enhancements, we consider JT T^* in (b) obtained by unconstrained triangulation. It preserves all conditional independence relations in (a) while T in (c) does not. Hence, T^* provides hints as to what conditional independence relations of (a) that has been removed in (c) can be utilized to improve the efficience of the d-sepset and the resultant linkage tree.

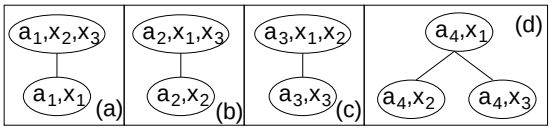

Figure 5: (a) The linkage tree obtained by adding a_1 to the d-sepset. (b) Obtained by adding a_2. (c) Obtained by adding a_3. (d) Obtained by adding a_4.

For example, $\{a_1\}$ is a separator in T^* between clusters $\{a_1, a_4\}$ and $\{a_1, x_1\}$, and it separates the cluster that contains the d-sepnode x_1 from clusters that contain the rest of the d-sepset. This suggests that $\{a_1\}$ is an alternative enhancement. After adding it to the d-sepset, the new linkage tree is shown in Figure 5 (a), where x_1 is indeed dispersed into a different linkage from the rest of d-sepset.

Following the same idea, $\{a_2\}$, $\{a_3\}$, $\{a_4\}$ are each an alternative enhancement. The corresponding linkage trees are shown in Figure 5 (b), (c) and (d), respectively. We define alternative enhancement formally below.

DEFINITION 5. *Let G be a subnet over N, D be its d-sepset with an adjacent subnet, and T^* be a JT of G obtained from unconstrained triangulation. An* `alternative enhancement` *E of D is the union of a set (possibly empty) of separators of T^* such that $E \cap D = \emptyset$.*

Given T^* with q clusters, in general, it has $O(2^q)$ enhancements, where q is bounded by the number of subdomain variables. We explore two techniques to improve computational efficience: leaf cluster removal and topological dominance. Below, we present the local search algorithm and then analyze two techniques. All d-sepnodes and non-d-sepnodes are relative to the d-sepset D.

ALGORITHM 3 (UPDATEDSEPSET).

Input: a subnet G over N and its d-sepset D with an adjacent subnet; a JT T from G by constrained triangulation with partial order $(N \setminus D, D)$; a JT T^* obtained from G by unconstrained triangulation;

perform the following recursively until no cluster can be deleted,
  for each leaf cluster Q of T^*,
    if Q contains no d-sepnodes, delete Q from T^*;
    else if Q is a leaf cluster in T with the same separator as in T^*,
      delete Q from T^*;
if T contains no separator with preferably private nodes only,*
  return $\emptyset$;

CanNewD = empty;
for each separator W of T with preferably private nodes only, do*
  add $\{W\}$ to CanNewD as an 1-separator member;
  copy T to T';*
  delete each occurrence of W in T' to split it into subtrees;
  if each subtree has a single cluster with d-sepnodes,
    label W as final;

k=1, more=true;
while more == true, do
  more = false;
  for each k-separator member M of CanNewD, do
    copy T to T';*
    for each separator R in M, do
      delete each occurrence of R in T' to split it into subtrees;
    if each subtree has a single cluster with d-sepnodes,
      label M as final;
    else
      for each 1-separator member $\{W\}$ of CanNewD, non-final,
          $W \notin M$, and $M \cup \{W\} \notin CanNewD$, do
        if there exists a subtree where W is a separator on the path
            between 2 clusters with d-sepnodes, do
          add $M \cup \{W\}$ to CanNewD as a k+1-separator member;
          more = true;
  k++;

for each member M of CanNewD, do
  perform constrained triangulation with M added to d-sepset;
  compute SSS α of the resultant linkage tree;
find member M^* of CanNewD with the smallest α value α^*;
β = SSS of the linkage tree derived from T;
if $\beta - \alpha^*$ is large than a threshold, return M^*;
else return $\emptyset$;

UpdateDsepset consists of four segments (separated by blink lines). The first removes leaf clusters in T^*. Proposition 2 below shows that these clusters are irrelevant and hence their removal reduces the space of alternative enhancements. The analysis is based on h-separation [7] in JTs:

DEFINITION 6. *Let H be a JT over N, and X, Y, Z be disjoint subsets of N such that no $x \in X$ and $y \in Y$ are contained in the same cluster in H. For $x \in X$ contained in cluster Q_x and $y \in Y$ contained in cluster Q_y, x and y are h-separated by Z if there exists a separator $S \subseteq Z$ on the path between Q_x and Q_y. X and Y are h-separated by Z if for every $x \in X$ and $y \in Y$, x and y are h-separated by Z.*

For instance, in Figure 4 (2), $\{x_1\}$ is h-separated from $\{x_2, x_3\}$ by $\{a_1\}$, written as $< x_1|a_1|x_2, x_3 >_{T^*}$ or simply $< x_1|a_1|x_2, x_3 >$. We are interested in h-separation relations $< X|Z|Y >$ relative to a given d-sepset D, where $X \subset D$, $Y \subset D$ and $Z \cap D = \emptyset$. We refer to such a relation as a *h-separation relative to D*.

PROPOSITION 2. *Let N be the domain of T^* and E be an alternative enhancement containing separators in T^*. After recursive deletion (relative to d-sepset D) of leaf clusters as specified in UpdateDsepset, let the resultant JT be T' whose domain is $N' \subset N$ and $E' = E \cap N' \subset E$. Let H denote the set of h-separations relative to D implied by E and H' be that implied by E'. Then $H = H'$.*

Proof: Intuitively, E and E' are the same except that E contains additional separators in T^* that are deleted by UpdateDsepset. We show that leaf cluster deletion by UpdateDsepset does not remove h-separations implied by E.

Let Q be a leaf cluster in T^* with separator V. We denote $Q \setminus V$ by C. The only h-separations relative to D that Q represents are in the form of $< C^-|V|U^- >$, where C^- is any subset of C and U^- is any subset of $N \setminus Q$.

The h-separations relative to D implied by E are in the form $< X|Z|Y >$ where $X \subset D$, $Y \subset D$, and $Z \cap D = \emptyset$. If Q contains no d-sepnodes, then C^- contains no d-sepnodes. Hence, removal of Q cannot remove any h-separations implied by E.

Next, consider the case where Q contains d-sepnodes. If Q is a leaf cluster in T (as defined in UpdateDsepset) and its separator in T is also V, then the h-separations represented by Q are also true in T. This means that these relations are not implied by E. Hence, removal of Q cannot remove any h-separations implied by E.

Since no h-relations in H is removed by leaf cluster deletion in UpdateDsepset, we obtain $H = H'$. □

Proposition 2 implies that leaf cluster deletion by UpdateDsepset does not introduce approximation to local search while improving its efficience. Proposition 3 below establishes that the early termination of UpdateDsepset is a correct action.

PROPOSITION 3. *If UpdateDsepset returns $\emptyset$ at the end of first segment, then the d-sepset D cannot be improved.*

Proof: When $T*$ contains no separator with preferably private nodes only, no legal separator Z can be found such that $< X|Z|Y >$ holds, where $X \subset D$, $Y \subset D$, and $Z \cap D = \emptyset$. □

8. TOPOLOGICAL DOMINANCE

The second and third segments of UpdateDsepset apply the technique of topological dominance or t-dominance to further trim the local search space. The concept of dominance has been used in game-theoretic research, e.g., [5]. We apply here from a topological perspective. In Figure 5 (d), each original d-sepnode has been isolated in a separate linkage. This suggests that adding more nodes to d-sepset may enlarge the linkage tree SSS. In fact, adding to $\{a_4\}$ any variable of a dimension no less than that of a_4 will do poor than $\{a_4\}$. We say that any such superset is *t-dominated* by $\{a_4\}$.

On the other hand, the enhancement $\{a_1\}$ does not t-dominate every proper superset. For instance, in the linkage tree produced from $\{a_1\}$ (Figure 5 (a)), x_2 and x_3 are contained in the same linkage. In the linkage tree produced from the superset $\{a_1, a_2\}$ (Figure 6 (a)), x_2 and x_3 are dispersed into different linkages. Hence, enhancement $\{a_1, a_2\}$ is not t-dominated by $\{a_1\}$.

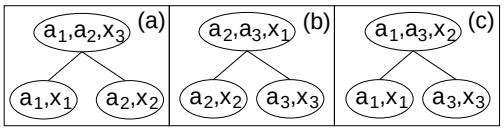

Figure 6: (a) The linkage tree obtained by adding $\{a_1, a_2\}$ to the d-sepset. (b) Obtained by adding $\{a_2, a_3\}$. (c) Obtained by adding $\{a_1, a_3\}$.

If an enhancement is not t-dominated by any proper subset, then it is called a *non-t-dominated* enhancement. For instance, $\{a_1, a_2\}$ is an non-t-dominated enhancement. If an non-t-dominated enhancement t-dominates every proper superset, it is called a *final* enhancement. Enhancement $\{a_4\}$ is final, but $\{a_1\}$ is not final.

Figure 6 shows linkage trees from three alternative enhancements each of which is obtained by including two separators in Figure 4 (b). All of them are non-t-dominated and final.

DEFINITION 7. *Let E be an alternative enhancement of a d-sepset D and H be the set of h-separations relative to D implied by E. Let $E' \supset E$ be another enhancement and H' the corresponding h-separations. E' is* $t - \texttt{dominated}$ *by E, if for each h-separation $< X|Z'|Y >$ in H', there exists $< X|Z|Y >$ in H, such that $Z' \supseteq Z$. If there exists no $E' \subset E$ such that E' t-dominates E, then E is* $\texttt{non} - \texttt{t} - \texttt{dominated}$. *If for all $E' \supset E$, E' is t-dominated by E, then E is* `final`.

Given the four separators in Figure 4 (b), there are a total of 15 alternative enhancements. Linkage trees from seven are shown in Figs. 5 and 6. The remaining eight are t-dominated.

As assumed, each agent classifies subdomain variables into private, public, and preferably private. For instance, the agent could classify a_4 as private, but a_1, a_2, a_3 as preferably private. This classification trims the set of non-t-dominated enhancements. In particular, only enhancements corresponding to Figure 5 (a), (b), (c), and Figure 6 (a), (b), (c) are now valid. Proposition 4 below shows under what condition, ignoring t-dominated enhancements causes no loss of accuracy to local search. We omit proofs for the remaining formal results due to space.

PROPOSITION 4. *Let AE be the set of all alternative enhancements of a d-sepset D for a given subnet. Let ND be the set of non-t-dominated elements of AE. Let TOP_{AE} be the set of elements of AE whose linkage tree state space sizes are minimal among elements of AE, and TOP_{ND} be the corresponding set relative to ND. If dimensions of non-d-sepnodes are identical, then $TOP_{AE} = TOP_{ND}$.*

The second and third segments of UpdateDsepset compute non-t-dominant enhancements. According to Proposition 4, local search over these enhancements is only accurate when preferably private variables have identical dimensions. When this condition does not hold, local search restricted by t-dominance becomes a heristics and introduces approximation.

The second segment identifies 1-separator non-t-dominated enhancements. The third segment identifies non-t-dominated enhancements made of multiple separators. Note that the concept of final enhancement is utilized to skip t-dominated enhancements and improve efficience. The following proposition shows that *final* enhancements are correctly identified. It can be proven by a direct application of Def. 7.

PROPOSITION 5. *Let E be an enhancement and Ψ be the set of subtrees resultant from deletion of each separator of E in T'. If each subtree in Ψ has a single cluster with d-sepnodes, then E t-dominates every enhancement $E' \supset E$.*

The following theorem establishes the significance of final enhancements and functionality of the second and third segments.

THEOREM 1. *At the completion of the third segment of UpdateDsepset, $CanNewD$ contains all and only non-t-dominated enhancements relative to d-sepset D.*

After local search space has been reduced to non-dominated enhancements, can it be trimmed without introducing further approximation? The following example answers the question negatively.

For variables in Figure 4 (a), denote dimensions of $a_1, \cdots, a_4$ as $m_1, \cdots, m_4$, respectively, and those for $x_1, \cdots, x_3$ as $n_1, \cdots, n_3$, respectively. Denote by k_1 the SSS of linkage tree from constrainted triangulation with d-sepset $\{x_1, x_2, x_3\}$ (Figure 4 (c)). Denote the SSS of linkage trees shown in Figure 5 as k_2, k_3, k_4, k_5, respectively, and those in Figure 6 as k_6, k_7, k_8, respectively. Then $k_1, \cdots, k_8$ can be computed as follows:

$$k1 = n_1 * n_2 * n_3,$$
$$k2 = m_1 * (n_2 * n_3 + n_1), \quad k3 = m_2 * (n_1 * n_3 + n_2),$$
$$k4 = m_3 * (n_1 * n_2 + n_3), \quad k5 = m_4 * (n_1 + n_2 + n_3),$$
$$k6 = m_1 * m_2 * n_3 + m_1 * n_1 + m_2 * n_2,$$
$$k7 = m_2 * m_3 * n_1 + m_2 * n_2 + m_3 * n_3,$$
$$k8 = m_1 * m_3 * n_2 + m_1 * n_1 + m_3 * n_3$$

Table 1: State space sizes $k_1, \cdots, k_8$ given variable dimensions. Upper half: variable dimensions. Lower half: state space sizes.

n_1	2	3	3	3	5	5	7	7
n_2	2	3	3	3	5	6	6	4
n_3	2	3	3	3	5	5	5	5
m_1	2	2	3	3	2	2	4	3
m_2	2	3	2	3	3	3	2	4
m_3	2	3	3	2	3	3	3	2
m_4	2	3	3	3	3	4	5	5
k_1	8	27	27	27	75	150	210	140
k_2	12	24	36	36	60	70	148	81
k_3	12	36	24	36	90	93	82	156
k_4	12	36	36	24	90	105	141	66
k_5	12	27	27	27	45	64	90	80
k_6	16	33	33	45	55	58	80	97
k_7	16	45	33	33	75	78	69	82
k_8	16	33	45	33	55	61	115	55

Table 1 shows values for $k_1, \cdots, k_8$ given dimensions $n_1, \cdots, n_3$, $m_1, \cdots, m_4$. The minimal linkage tree SSS for each row occurs at a different column. For instance, for the first row (with all variables binary), the optimal size is 8 and is located at the first column in the right half. For the second row, the optimal size 24 is located at the second column, and so on.

This example demonstrates that any non-t-dominated enhancement may be the best choice, given right variable dimensions. In order not to cause further approximation, all non-t-dominated enhancements must be evaluated. This is done in the fourth segment. For simplicity, we phrased return value as a single enhancement, although it can be multiple enhancements that tie or top the list.

9. SUBNET CONNECTEDNESS

When an agent A passes a set of new d-sepnodes to an adjacent agent A', it is possible that some new d-sepnodes are disconnected in the updated subnet of A'. These new d-sepnodes are dependent of the rest of the subdomain of A' (since they are connected to other d-sepnodes in the subdomain of A). Hence, their disconnectedness in the updated subnet of A' creates misconception of independence. They violate convention of graphical models where connection implies dependence and disconnection implies independence.

To avoid the misconception, for each new d-sepnode v, we need to ensure that, in the updated subnet of A', it is connected to at least one existing d-sepnode. When v is not already connected to existing d-sepnodes, arcs must be added to achieve the connection. The arcs added will make the new subnet denser, but should not make it unnecessarily so, because any increase in the density of the subnet will translate into an increase in the size of state space of the resultant linkage tree. Based on these criteria, we identify the following subtasks:

First, agent A needs to recognize when some new d-sepnodes are disconnected to existing d-sepnodes. A new d-sepnode v is connected to existing d-sepnodes if (1) v is directly connected to an existing d-sepnode, or (2) v is indirectly connected an existing d-sepnode through a path consisting entirely of new d-sepnodes. This subtask can be accomplished with the following algorithm:

ALGORITHM 4 (MARKCONNECTED).

mark each existing d-sepnode;
perform the following recursively,
  for each marked node, do
    if it has any adjacent new d-sepnode v, mark v;

The following proposition shows that any new d-sepnode left unmarked by MarkConnected is disconnected from the existing d-sepset. Its proof is trivial.

PROPOSITION 6. *After MarkConnected is performed, if there exist unmarked new d-sepnodes, then each such node is disconnected from the existing d-sepnodes.*

Second, once a disconnected new d-sepnode v is identified, agent A needs to propose arc(s) to be added, that is, which other d-sepnodes should v connect to and direction of arcs. We show below that inadequate arcs added may create either directed cycle or significantly increase the size of state space of the local JT.

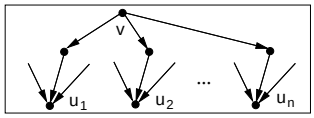

Figure 7: A subnet whose d-sepset with an adjacent subnet is $\{u_1, u_2, ..., u_n\}$.

In Figure 7, the existing d-sepset is $\{u_1, u_2, ..., u_n\}$. Enhancing the d-sepset with node v will significantly reduce the size of state space of the linkage tree. However, if v is added to the subdomain of the adjacent agent, it is disconnected. To make it connected to the existing d-sepset, it can be connected to a node u_i. If the arc (u_i, v) is added, it forms a directed cycle. On the other hand, if the arc (v, u_i) is added, the node u_i has one more parent. In the local JT, there is at least one cluster that contains u_i and all its parents. At least the state space of this cluster is enlarged by a factor of the dimension of v due to adding (v, u_i).

We propose a method for arc addition using the updated linkage tree in A. The following algorithm pairs a disconnected new d-sepnode with a connected d-sepnode (either existing or new).

ALGORITHM 5 (PAIRDISCONNECTED).

Input: existing d-sepset D, enhanced d-sepset D^+, subset X of D^+ marked by MarkConnected, and $Y = D^+ \setminus X$;

get linkage tree L with triangulation constrained by D^+;
find a cluster C such that $C \cap Y \neq \emptyset$ and $C \cap X \neq \emptyset$;
pick $v \in C$ such that $v \in Y$ and $u \in C$ such that $u \in X$;
return pair (v, u);

We show that as long as $Y \neq \emptyset$, there always exists a cluster C as described in PairDisconnected, and hence the pair (v, u) can always be found.

PROPOSITION 7. *Let D be the existing d-sepset of a subnet with an adjacent subnet, D^+ be the enhanced d-sepset, X be the subset of D^+ marked by MarkConnected, and $Y = D^+ \setminus X \neq \emptyset$. Then, PairDisconnected will succeed and return (v, u).*

For each pair of d-sepnodes (v, u) identified, agent A notifies agent A'. In response, A' adds new d-sepnode v to its subdomain and adds a new private binary variable c as the common child of v and u. This method has several desirable properties:

First, clearly the new node v in A' is now connected in the updated subdomain of A'. Second, since c is a private node of A', there is no arc to be added in A relative to v. Hence, the state space of its local JT will not be compromised. Third, since c has only two adjacent nodes in A', it will cause the formation of a cluster

$\{c, v, u\}$ in the local JT of A'. Since the cluster has only three variables, it increases the state space of the local JT only slightly.

Disconnected new d-sepnodes may be divided into several groups where nodes in each group is connected to each other. In such case, A needs to run MarkConnected and PairDisconnected once for each group.

10. PROPERTIES OF ENHANCEMENT

We analyze key properties of CoEnhanceInterface. First, after CoEnhanceInterface, each agent interface is a d-sepset.

PROPOSITION 8. *Let E be an enhancement of d-sepset D from agent A relative to an adjacent agent A'. Then $D \cup E$ is a d-sepset.*

Second, CoEnhanceInterface preserves the hypertree condition.

PROPOSITION 9. *Let a d-sepset D between two adjacent subnets of an MSBN M be enhanced to D^+. Then hypertree condition holds in updated structure of M.*

Propositions 8 and 9 guarantee that the outcome of enhancement is a valid MSBN. Finally, all dependence relations in the original MSBN are preserved after agent interface enhancement.

PROPOSITION 10. *Let a d-sepset D between two adjacent subnets of an MSBN M be enhanced to D^+. If the structure of M is an I-map over N, then the updated structure of M is still an I-map over N.*

From Proposition 10, it follows that the enhanced MSBN preserves exact inference.

11. EXPERIMENT

To evaluate the effectiveness of the algorithms, we simulated 10 MSBNs, each with 5 subnets. Each subnet has between 50 to 75 nodes and each variable has a dimension up to 4. Each d-sepset has 8 variables.

For improvement of local search efficience, results of UpdateDsepset in 14 subnets are shown below. The total number of enhancements for each subnet ranges from $2^{24} > 1.6 \times 10^7$ to $2^{51} > 2 \times 10^{15}$. Due to leaf cluster removal and topological dominance, the number of non-t-dominated enhancements per subnet is between 31 and 2495.

Subnet	n_0	n_1	n_2	n_3	n_4	n_5	n_6
$\lvert CanNewD \rvert$	71	355	239	1063	791	35	363
# enhancement	2^{24}	2^{51}	2^{24}	2^{41}	2^{24}	2^{24}	2^{44}
Subnet	n_7	n_8	n_9	n_10	n_11	n_12	n_13
$\lvert CanNewD \rvert$	725	31	35	77	31	119	2495
# enhancement	2^{24}	2^{33}	2^{24}	2^{24}	2^{43}	2^{26}	2^{35}

For overall efficience improvement, results of CoEnhanceInterface with pairwise search are shown below. For each MSBN, SSS for each linkage tree is counted and sum over the four linkage trees is shown. All randomly selected d-sepsets have the worst complexity. Enhancement reduces the sum to between 44% and 94%. As the price, the largest number of preferably private variables disclosed to other agents occurred in an agent with 3 adjacent agents and a subdomain of 75 variables. It disclosed a total of 12 variables (an average of 4 per d-sepset).

MSBN	m_0	m_1	m_2	m_3	m_4
Before enhancement	82944	82944	82944	82944	82944
After enhancement	34286	12398	4562	7220	7020
MSBN	m_5	m_6	m_7	m_8	m_9
Before enhancement	82944	82944	82944	82944	82944
After enhancement	7720	46098	14540	25860	6894

In addition, we simulated a digital system of 216 devices. To monitor it, we built a MSBN model of 5 agents whose subdomains are sized at 91, 202, 72, 149 and 91 variables, respectively. The initial four agent interfaces have a total linkage tree SSS sum of 11264 and it is reduced to 728 (6.5%) through enhancement.

12. CONCLUSIONS

Graphical models such as MSBNs provide a framework for exact and autonomous probabilistic reasoning for multiagent systems. However, construction of such models that are both valid and efficient is involved. This contribution allows MAS designers to start with a model that is not necessarily efficient and let agents to improve its efficiency automatically. This approach relieves designers from the burden of model efficiency and makes the MSBN-based MAS more accessible. Through formal analysis and experiments, we have shown that the proposed agent interface enhancement explores only a small portion of the local search space and joint search space, while improving the model efficiency significantly.

ABSTRACT

Participatory simulations are conducted to improve our knowledge of human behaviors, to help in solving conflicts, to shape interaction protocols between humans and to teach some aspects of collective management.

Agent-based participatory simulations differ from other kinds of participatory simulations including role playing games and experimental economics simulations. The control architecture of the agents, in these simulations, is more or less integrally replaced by a human player and the interactions between players are limited by the communication protocols designed for the agents, usually the exchange of electronic messages logged for further analysis. Such systems can be considered as ideal multi-agent systems featuring cognitive and intelligent agents. Previous work demonstrated that running this kind of simulations helps to design and improve multi-agent simulations.

In this paper, we present a series of agent-based participatory experiments studying negotiation in an abstract case of common resource pool management. The roles were designed in such a way that conflicts should emerge during the negotiations. Observing the behavior of human players, we noticed the apparition of power relations between players. We observed that this power in negotiations was unrelated to any a priori dependence between agents or between roles but was instead drawn from strategies and, more surprisingly, this power was built on an emerging ontology.

1. INTRODUCTION

The increasing use of computer-aided participatory simulations is related to an increasing coupling of participatory experiments with agent technologies.

One tradition of participatory simulations consists in combining role playing games with multi-agent systems [4, 5] within what was called the MAS/RPG methodology. Mainly concerned with common resource pool management, researchers from this tradition primarily use participation to better understand human behaviors. This methodology can be interpreted as a kind of participatory design, with an iterative process alternating role playing games and multi-agent simulations, aiming at building systems closer to the actual social phenomena.

Experimental economics, the oldest tradition of participatory simulations, now includes hybrid experiments with agents taking part in the simulation in order to validate and improve models or train participants [18]. The growing use of software agents as human peers fostered methodological studies such as the work of economists Jens Grossklags and Carsten Schmidt on the actual impact of revealing the presence of software agents [13].

From a multi-agent point of view, we define agent-based participatory simulations as simulations where human players take the control of agents. Unlike role playing games or experimental economics, these simulations are built with a multi-agent simulation design methodology. The model is agent-based and the interactions between the entities of these simulations are limited to agent-like interactions. Replacing the control architecture by human players builds up an idealistic multi-agent system with cognitive and intelligent agents. Previous work, based on a coalition formation problem, showed that the strategies elaborated by human players can overtake the distributed solving capabilities of the original multi-agent system [16].

The rationale of SimCommod agent-based participatory experiments was to study possible power relations in negotiations between ideal cognitive agents. The notion of power studied here is limited to negotiations and is based on Dahl's definition [10] : getting an agent to do something that it wouldn't do otherwise. It is of course not what happens when an agent sends a message to or calls a method of another agent.

Such power relations, among other aspects of negotiations, are extremely difficult to model and implement in multi-agent systems. Fifteen years ago, Cristiano Castelfranchi pinpointed the lack of social power in various models of

multi-agent systems [9]. Building on Castelfranchi's work, power in multi-agent systems has been historically associated with a dependence relation. Nevertheless, the tradition of participatory experiments shows that power is not limited to dependence.

This paper is organized as follows. We will first present the background of SimCommod participatory experiments including the notions of power and negotiations in both multi-agent systems and participatory simulations. We will then describe the experiments and how the model and the experimental protocol were tailored to analyze the ways to express power relations as agent interactions. Finally, we will present the results, with the strategies used to influence other players including the emergence of an ontology and we will compare them with power relations in participatory simulations not based on an agent methodology.

2. BACKGROUND

While any interaction between agents can be considered a negotiation, power attracts surprisingly very little interest in the agent community. Participatory simulations, by contrast, almost always feature roles with a priori power relations.

2.1 Negotiation and power in multi-agent systems

Negotiation can be defined as a discussion aimed at reaching an agreement. It can be translated in agents terminology as interactions between agents aimed at a cooperative behavior, ranging from concluding contracts to sharing beliefs. A working group at IWMAS98 [19] tried to characterize negotiation between agents and concluded that negotiation is an extremely broad term that covers most agent interactions. Indeed, our agents usually interact specifically to cooperate or share information.

Historically, negotiation between agents followed fixed protocols and agents that negotiated were designed at the same time. The protocol can be as simple as voting, which is considered a negotiation in the agent literature. With the standardization of agent communication languages, research can now focus on negotiation in open environments with autonomous agents of different origin and design. The very first difficulty when agents engineered by different programmers for different tasks need to negotiate is to allow them to perform an ontology alignment, i.e. to agree on what they negotiate about [22].

While they do provide a framework for collective behaviors, these negotiation protocols have very little in common with real-world situations of conflict. Unlike people, agents are designed to cooperate. Negotiation protocols that lack the notion of power are obviously inadequate to describe real-world conflicts.

Cristiano Castelfranchi introduced the notion of power in multi-agent systems by drawing a social power theory [9]. An implementation of this theory was proposed, relying on dependence relations between agents and on the ability to reason about others [21]. Dependence relation theory was later improved to address the case of dependences between more than two agents and to be more robust to possible changes in the strategies of other agents [7].

However, in participatory simulations, some of the power relations within the negotiations are not dependence relations.

Type	Expected outcome	Participants	Examples
Research	Design, improve and validate models	Stakeholders	SHADOC, SimCafé, PAT
Education	Teach the articulation between individual and collective behaviors	Students	Virus, ButorStar
Action	Favor negotiation between stakeholders	Stakeholders (exchanged roles)	Sylvopast

Figure 1: Typology of participatory simulations

2.2 Negotiation and power in participatory simulations

Participatory simulations can be sorted into three different kinds based on their expected outcomes (Fig. 1). Research participatory simulations aim at designing, improving and validating models of social behaviors. Education participatory simulations focus on training students and teaching them the articulation between individual and collective behaviors. Action participatory simulations try to favor negotiation between stakeholders by exchanging their roles.

In Sylvopast [11], an example of action simulation, participants are foresters or shepherds. As defined by their role, shepherds cannot perform forest management. They need to find incentives to convince the foresters to adapt the forest to their sheep. Officially, the foresters are independent and can ignore the requests of the shepherds. Actually, if the shepherds are eliminated after going bankrupt, the computer model will set fire to the forest. While there have been occurrences of this scenario during some experiments, stakeholders playing Sylvopast often know each other and share an history of common work in the forest. In spite of tensions between the two groups, they often succeed to cooperate.

ButorStar [17] is a typical example of an education participatory simulation as it was specifically designed for teaching purposes. Roles represent different stakeholders of the reedbeds: hunters, fishermen, breeders, reed harvesters and environmentalists. These roles are designed with conflicting interests and particularly, the economic interest of the other players is conflicting with the environmentalists who try to preserve the great bittern, an endangered species living in the reedbeds and after which the game is named (*Butor Etoilé*). In this role playing game, players have to cooperate to choose an irrigation level that affects everyone's outcome. The game master enters the final decision in the computer and, when no agreement emerged, the actual irrigation is the worst possible case for everyone.

In these examples, negotiation is a key element of the experiments. The models even punish negotiators who have failed to reach an agreement. The negotiation phase takes place in natural language, without the help of any computer. Many factors influence the outcome of the negotiation and are not logged or related to the game. We have no scientific means to analyze the power relation between players during such games. In fact, role playing game designers often intro-

duce a priori power relation between the roles they define. Interestingly, they notice the number of players with a given role affects the outcomes of the negotiation. For example, in ButorStar, two environmentalists rather than one will better succeed in preserving the great bittern because they are more convincing.

On the contrary, most experiments in economics, which are of the research type, do not channel negotiations through natural language. Instead, interactions and negotiations are based on abstract symbols for two reasons. First, the price, which is what is most often negotiated, is decided by using what economists call institutions, i.e. the mode of interactions between agents. Institutions usually consist in some auction protocol. Second, experimental economists use abstract symbols instead of representation of emotional concepts such as endangered species and players are anonymous to avoid conflicts with a previous relation [12, 8]. Economist James Andreoni argued that players behave differently depending on how things are called [1].

3. THE SIMCOMMOD EXPERIMENTS

The SimCommod experiments are agent-based participatory simulations that used the Simulación framework [15]. They inherit the conflicting situation of the e-ComMod model and they also borrow methodological aspects from experimental economics. The experiments took place in june 2005 in the Laboratoire d'Informatique de Paris VI and in september 2005 in the National Institute of Informatics, Tokyo.

3.1 Agent-based participatory simulations

Agent-based participatory simulations are multi-agent simulations where human players act as the control architecture of agents. In experiments based on the Simulación framework, each agent is a network entity. Each player sits at a computer and interacts with other players through the computer only (Fig. 2).

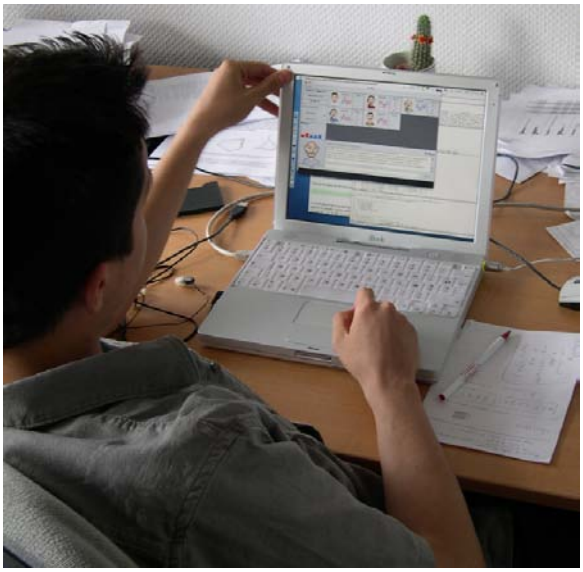

Figure 2: A player in an agent-based participatory simulation

The design of agent-based participatory simulations follows standard multi-agent simulations design methodologies. In particular, the process is iterative and consists in transforming the domain model into an operation model. While the operational model of multi-agent simulations is the actual code, in agent-based participatory simulations it is threefold: the experiment protocol, what players can do (agent effectors) and what information they have access to (agent sensors). When testing interaction patterns, the most important step in this design process is to break the exchanges into smaller primitives so that players can have unexpected behaviors and are not forced to comply to the original domain model [14].

Interactions are limited to messages exchanged between agents and are therefore easily recorded with one or more log agents on the network. The logs are then used for further analysis of the interaction patterns. Moreover, the environment which is the subject of the negotiation is yet another network entity. In the SimCommod experiments, the environment was simulated by a multi-agent model in Cormas [6]. Cormas could also simulate some agents such as the government.

3.2 The e-ComMod model

The e-ComMod model has been designed to epitomize the companion modeling approach [3]. It derives from classical models of participatory simulations belonging to the common resource pool management modeling tradition.

The environment is simulated by a cellular automata implemented in Cormas. It is represented by a grid of 16 cells. A resource is distributed on the cells. The amount of resource on each cell is a discrete property with four different levels, from none to plenty, represented by shades of green (Fig. 3).

Agents in the model belong to three different classes: the harvesters, the environmentalists (also called the conservationists) and the government (the policy maker). The harvesters are the agents really acting on the environment. The government can only prevent them from acting on some cells and the environmentalist has strictly no direct influence on the environment.

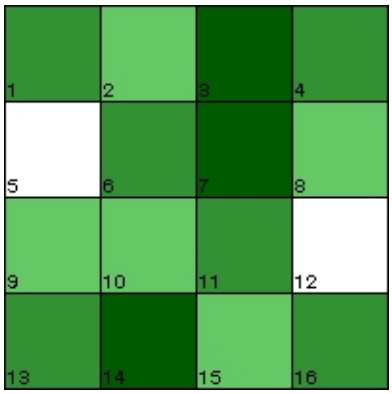

Figure 3: Environment: a grid with shades of green

The experiment is divided in turns. Each turn is divided in 4 phases: harvest, proposition, negotiation and validation.

- During the first phase, the harvesters can work on a maximum of three cells. The yield of a cell depends on the amount of resource and on the number of harvesters. The resource available on the cell is distributed to the harvesters.
- During the proposition phase, the harvesters and the environmentalists put positive and negative tokens on the map. The positive tokens represent the cells that they want to harvest next turn and the negative tokens the cells that they want to protect from being harvested. The harvesters have three tokens each, which they can cast as positive or negative tokens, and the environmentalists have ten tokens each.
- During the negotiation phase, the propositions are revealed synchronously to all players (Fig. 4). They can submit a new distribution of their tokens with an optional comment in natural language. The sum of the propositions may or may not converge during this phase.
- During the validation phase, the government decides to ban three cells. These three cells will not be available for harvesting during next turn. The decision can be taken from the sum of the tokens or the government can take actions to favor the emergence of a negotiation by penalizing the players who could not reach a consensus. The interface for the player who assumes the role of the government does not impose any strategy. The way the environmentalist and the harvesters affect this role's behavior is entirely up to the player. Besides, the user interface displays the discussion during the negotiation but the government cannot interfere with the negotiation process. It can only comment its decision.

The harvester's goal is to harvest as much resource as possible. There is competition among harvesters. Their best strategy is to harvest on cells with the maximum amount of resource and no other harvesters, since the resource is distributed among harvesters on a given cell.

Oppositely, the environmentalist's goal is to preserve the resource. The environmentalist does not act except by putting tokens on the map to influence the decision of the government. e-ComMod is similar to ButorStar in this respect where what some players could do was only to influence decisions of others. In the Sylvopast model, on the contrary, the shepherds can give money to the foresters and sheep actually clean the forest and decrease the risk of fire.

The actual evolution of the cellular automata is not revealed to the players, since they have to discover the dynamics of the game by themselves. The evolution rules of the level of resource on a cell do not depend on any other cell. In other words, the representation of the environment as a grid is strictly unrelated to the actual dynamics of the environment. The rules are the following:

- if more than one harvester is present, the level is decreased by the number of harvesters
- if one harvester is present, the level does not change.
- if no harvester is present for one turn, the level is incremented.

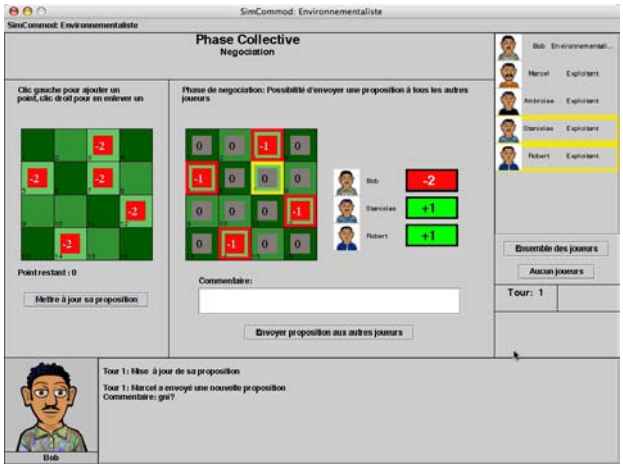

Figure 4: The user interface during negotiation

- if no harvester was present for the last two turns, the level does not change.
- if no harvester was present for more than two turns, the level is decremented.

These rules reflect actual common resource pool management situations where resource should not be over-harvested (more than one harvester) but a regular harvest maintains the resource.

3.3 Experiments to analyze power relations

A participatory experiment is typically conducted in three phases: a presentation of the model, the experiment and a debriefing session. The experiment conducted in the Laboratoire d'Informatique de Paris VI consisted in a single run. The model was calibrated during this first experiment. With five harvesters and one environmentalist, in addition to the competition between harvesters, the model featured a conflict situation: the environmentalist's goal is to preserve the resource and the pressure from the harvesters will make the amount of the resource decrease.

The experiments conducted at the National Institute of Informatics consisted of three runs. The first two sessions were performed in parallel and the government was played by an agent in Cormas. The players were told that the government would sanction the lack of agreement while in fact it played randomly. No complete agreement emerged, yet a player insisted that he found out that the government was acting randomly. During the third experiment, the government was controlled by a human player who penalized harvesters for their lack of agreement.

In order to study power relations between agents, the experiments had to be disconnected from the players' history. The participants knew each other, but the game was entirely anonymous. Players were represented by an avatar that was randomly chosen by the organizers (Fig. 4). While the simulation took place in an open space, players did not look into their neighbor's cubicle and seemingly did not try to find out who was controlling a particular avatar. Besides, when two experiments were conducted in parallel, players could not determine if their neighbor took part in the same

game. Anonymity seems to have been effective, even if negotiations were done in natural language: a player mistakingly thought that one of the avatar was driven by a particular fellow student while it wasn't.

An additional aspect of the methodology of experimental economics was introduced. Except for the name of the roles, the model used abstract symbols rather than emotional concepts such as an endangered species. The resource was only ever called "a resource" during the presentation of the model.

4. RESULTS

The analysis of the results is based on the logs of all exchanges during the experiment as well as interviews during the debriefing sessions. The most surprising aspect of the experiment is the emergence of a new ontology and its role in the power relations. This contrasts with previous participatory experiments grounded in real-world situations.

4.1 Ontologies and power relations

Although all participants had the same information about the game, during the first two runs conducted in parallel at the NII, one of the two environmentalists obviously negociated better than the other. When asked about their strategy, both mentioned that they tried to preserve some specific areas that needed to be preserved. Their choice seemed to consist in preserving the lighter green squares.

The less efficient environmentalist explained that he tried to convince the harvesters to work on the cells that would provide them with the highest revenue while preserving the selected cells. In other words, it consisted in a rationale negotiation approach, trying to obtain a reasonable agreement that served everyone's interest. The player who chose to always follow the environmentalist's advice is the one who collected the highest amount of resource. Others mentioned they simply ignored his messages.

The more efficient environmentalist's strategy was instead to tell players not to harvest the specific cells she wanted to preserve:

> I tried to protect this area by telling people "that's a very important area, go away", some people believed it very easily but some people opposed it.

The resource was better preserved with this strategy. According to these debriefing interviews, forbiding some cells proved to be more efficient than prescribing. Besides, this example seems to contradict common sense. Finding the agreement that satisfies one's constraints while maximizing other players' interest seems less effective than just trying to achieve one's goal and letting other players decide by themselves. This would contradict the social power theory as it would not be necessary to figure out the best interest of the other players.

In fact, the logs reveal that the main difference between the two environmentalists is not about forbiding and prescribing or advising. The more efficient environmentalist introduced notions such as endangered forest and trees, even if they were not present in the original presentation of the model that carefully used only abstract symbols. Furthermore, during the third experiment, the same environmentalist succeeded in prescribing as harvesters concentrated on some cells, allowing others to regenerate:

> In the final turn, it was in a way good that many harvesters concentrate on one white cell and I saw many white cells empty, in the end it worked well.

The success of this new strategy, based on prescription like the strategy of the environmentalist during the first run, is again related to the introduction of concrete notions. The environmentalist told harvesters that they could find gold in these cells. She was conscious that harvesting white cells was their less efficient behavior and somewhat surprised that this argument worked so well. Reluctantly, some players admitted they believed her during the debriefing session and the logs show that some white cells were harvested indeed, decreasing the global pressure on the resource.

4.2 Comparison with participatory experiments

Participatory simulations based on real common resource pool management problems introduce an a priori ontology. They also use abstract symbols. In Sylvopast, for example, the vegetation type is represented by primary colors. The cells with forest are blue, with shrubs red and with grass yellow. This code allows combination with composed colors. Michel Etienne notes that after one round, players argue about "more yellow" or "more blue" instead of "more grass" or "more forest".

Such a use of abstract symbols is not contradictory with the results of the SimCommod experiments. Players in role playing games need an a priori ontology to negotiate but their discussion can be based on symbolic information. In fact, in newer flavors of Sylvopast, some new roles have their own ontology that they can use to influence other players. In particular, the objective of the newly introduced environmentalist is to preserve an endangered species of turtle living in the forest. The very idea of an endangered species of turtles is absent from the ontologies used in negotiations between foresters and shepherds.

The environmentalists in the SimCommod experiments may have used an ontology to convince and influence the players but nevertheless used the abstract symbols to clearly explain what they wanted. For example, the environmentalist during the third run at the NII told players to go on "white cells" because there was gold there. The action is expressed in the common ontology based on abstract symbols.

On the other hand, experiments in economics that do not allow the emergence of an ontology and that only include emotionless abstract concepts could more difficultly feature power relations. We previously ran an agent-based participatory set of experiments based on a cooperative version of the El Farol bar problem [2]. The concepts were all abstract, participants played anonymously. Lacking the possibility to communicate in natural language and therefore to create an ontology, they could not negotiate and did not exhibit any power relation. During the debriefing sessions, some participants insisted that they needed to be able to tag other players as liars or cooperative in order to negotiate.

5. CONCLUSION

In multi-agent systems, power is the corollary of autonomy and pro-activity. Cooperation between agents that do not have a slave behavior implies that agents must influence each

other, especially when interests diverge. Likewise, in agent-based participatory simulations with built-in situations of conflict, human players who control the agents necessarily introduce power relations.

The power relations in multi-agent systems have been previously studied as dependence relations. From a first look at the SimCommod experiments where there was no direct dependence between agents, we could infer that prescribing is less effective than forbiding as a way to influence others. We could also infer that it is not necessarily a good strategy to try to find an agreement maximizing the interests of the other agents. The real lesson from SimCommod experiments is probably that some actions such as introducing new ontologies can be a surprisingly effective way to influence other participants. Consequently, in the multi-agent negotiation protocols that take the ontology alignment into account, the ontologies should not be merged beforehand but during the negotiation.

More generally, this paper also advocates the use of agent-based participatory simulations to test and validate features of interaction protocols. In the forthcoming months, we plan to run additional agent-based participatory experiments based on a similar model to test overhearing and over-sensing protocols against direct interactions [20].

Acknowledgments

The experiments would not have taken place without the work of Christophe Le Page and Patrick Taillandier. The former originally developed the e-ComMod model in Cormas and the latter adapted it to the Simulación framework. We would like to thank participants from the Laboratoire d'Informatique de Paris VI. We would also like to thank every member of Honiden-Lab at the National Institute of Informatics as well as Haruko Ishikawa for their participation in the simulations and for the extremely valuable feedback they gave us.

ABSTRACT

Team decision making under stress involving multiple contexts is an extremely challenging issue faced by various real world application domains. This research is targeted at coupling cognitive agent technology and human-centered teamwork to address the informational challenges associated with Command and Control (C2) teams in contemporary military operations. Two sets of experiments, each with various settings of context switching frequencies and tasking complexities, were conducted. To ensure that the human subjects were familiar with the C2 context, they were selected from US Army ROTC (Reserve Officer Training Corps) students. Experiments on C2 teams that involve human subjects only were conducted first. We observed the decision making behavior of human subjects and incorporated expert behaviors into R-CAST—an agent architecture built upon a naturalistic decision making model that captures how domain experts make decisions based on experiences and situational similarity recognition. We then conducted another set of experiments with R-CAST agents as teammates and decision aids for human subjects. The results show that RPD-enabled agents can significantly improve the tasking capacity of C2 teams in multi-context decision making under stress. It also suggests that higher demand situations require more competent teammates.

1. INTRODUCTION

Team decision making involving multiple contexts is an extremely challenging issue faced by various real world application domains. Command and Control (C2) in complex urban terrain is one of such domains, where C2 teams have to frequently confront the so called three-block challenge [5]—conducting humanitarian, peacemaking, and combat missions in close proximity (i.e., involving three contexts that overlap in time). Multi-context team decision making is challenging because it requires effective team collaborations in rapidly gathering dynamic information from multiple sources (collateral space), in proactively sharing relevant information for establishing global situation awareness, in managing and reasoning across multiple decision spaces for different contexts (areas of interest), and in choosing optimal corridors for movement.

In the Multi-Agent Systems field (MAS), there has been an increasing interest in empowering agents with naturalistic decision making models to better support *human-agent collaboration* in making decisions under time stress [4, 12, 13, 14, 16]. One of such models is Klein's Recognition-Primed Decision framework (RPD) [8]. The RPD model claims that in complex situations human experts usually make decisions based on the recognition of similarities between the current decision situation and previous decision experiences [9]. Cognitive studies have shown that over 95% of human decisions conform to the RPD model in various time-stressed situations [9]. Norling, Sonenberg, and Ronnquist [12] have examined the integration of RPD model into BDI agent framework. Fan, Sun, McNeese, and Yen [4] have implemented an RPD-enabled cognitive agent architecture (R-CAST) and evaluated the performance gains when human decision makers were assisted by R-CAST agents, operating under stress in a real-time simulation environment.

However, multi-context decision making, especially from the human-centered teamwork perspective, has attracted little attention from the MAS field. Norling et al.'s work [12] only explored ways of using reinforcement learning to en-

hance situational recognition. While Fan et al.'s attempt [4] centered on human-agent collaboration in the decision making process, they only investigated the impact of an adaptive decision making mechanism, with the issue of multi-context decision making left open. Although RPD-enabled agents were employed to start to address the issue of multiple contexts [5], we still need experimental studies for fully understanding the nature of multi-context decision making, which is critical to further developing agent technologies for enhancing the performance of human-centered teamwork.

In this paper, we investigate how and to what extent R-CAST agents, as teammates and decision aids, might help in human decision making under stress and multiple contexts. This research is conducted within the C2 domain and is targeted at coupling cognitive agent technology and human-centered teamwork to address the informational challenges associated with multi-context team decision makings. The remainder of this paper is organized as follows. Background on human-centered teamwork and the R-CAST agent architecture are given in Section 2. The problem domain, simulation environment, and scenario designs are described in Section 3. Experiments on human-only C2 teams and human-agent C2 teams are presented in detail in Section 4 and Section 5, respectively. Section 6 presents conclusions.

2. BACKGROUND

2.1 Human-centered teamwork

Multi-agent teamwork [3] is concerned with joint commitments and joint responsibility. In particular, human-centered teamwork, where human and software agents interact as peers, is about establishing situation awareness collaboratively, developing shared mental models as situation evolves, adapting to mixed-initiative activities, etc. It is claimed that agents, if they could collaborate with human peers effectively, can allow humans to pay attention to more important activities [1], and make better decisions using information at a greater accuracy and finer granularity[11].

Bradshaw et al. developed KAoS, a collection of agent services in the form of adjustable policies, which allow the renegotiation of roles and tasks among humans and agents when new opportunities arise or when breakdowns occur [1]. MokSAF is a computer-based simulation system developed to evaluate how humans can interact and obtain assistance from agents within a team environment [11].

Our research reported here differs from the above efforts in that we attempt to deepen the understanding of human-centered teamwork by examining multi-context decision making in time-stressed situations. In particular, we try to uncover the potential impacts of RPD-enabled (or experience-guided) cognitive agents, when acting as human's teammates and decision aids, on the performance of C2 teams.

2.2 The R-CAST Agent Architecture

The R-CAST agent architecture [4] is built on top of the concept of shared mental models [2], the theory of proactive information delivery [6], and Klein's Recognition-Primed Decision (RPD) Model [8]. The R-CAST agent architecture has implemented a "collaborative-RPD" decision process, which supports close human-agent collaborations in relevant information sharing, decision progress monitoring, and expectancy-based decision adaptation.

The major components of R-CAST are shown in Figure 1, where the "RPD-based Decision Making" module uses domain knowledge, past experiences, and the current situation awareness to produce a new or adapt an existing decision. The fulfillment of a decision can involve inter-agent and intra-agent activities, which are coordinated by the "Teamwork manager" and "Taskwork manager", respectively. Any unexpected conditions resulting either from situational changes or from action failures will trigger another round of decision making. Also, any behavior (plan) adaptations that have been tested as workable will be used to adapt the relevant experiences.

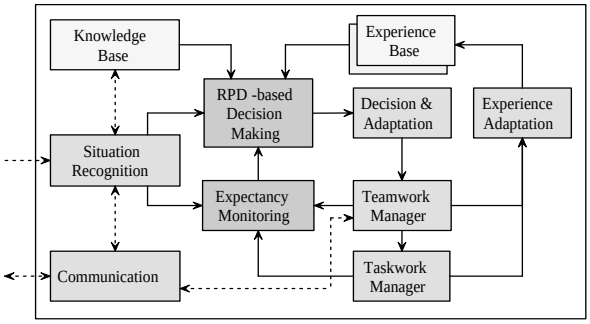

Figure 1: Major components of R-CAST.

R-CAST is a configurable architecture. Many of the components can be replaced (e.g., use JESS as the knowledge base) to serve the purposes of various studies. If the default R-CAST configuration is kept, using R-CAST to develop a multi-agent system involves two major steps: (1) elicit domain knowledge and implement a domain adapter for the problem to be studied, and (2) elicit and represent domain expertise about decision making in terms of experiences (cf. Section 5.1.1 for an example and refer to [4] for detail).

Two important features that are relevant to this study are the "expectancy-based adaptive decision making" and "situation-guided switching of decision spaces."

First, R-CAST agents adapt their decisions by detecting and responding to situations that are anomalies to the original expectancy (i.e., what is observed/informed conflicts with what was expected). Anomalous situations can happen frequently in a dynamic environment. For example, suppose under the current situation it is expected that two crowds, G_1 and G_2, should be active in two isolated regions. Anomaly occurs if G_1 and G_2 start to move closer and closer.

Experiences in an experience base are organized hierarchically: experiences at a higher level are refined by those at a lower level (with more relevant cues and expectancies considered). The RPD-based decision making is a process of finding an experience that worked in a previous situation that is closest to the current situation according to certain similarity metrics. This is an iterative and adaptive process in R-CAST. Start with the most abstract experience in the current decision space, as more and more situational information becomes available, agent's recognition of the past experience closest to the current situation becomes more and more concrete (at the lowest possible level of the hierarchy). During the process, the agent simultaneously monitors the expectancies associated with the recognized experience. The recognition is enforced as new events are emerging as expected. It is challenged when some expectancy becomes

false as the situation evolves; in such a case, the agent has to backtrack along the experience hierarchy to seek a better recognition. In the study reported here, this feature is used such that an R-CAST agent (S2) can determine what information the other teammates (S3/S4 agents) need, and then proactively provide the information.

Second, R-CAST allows the specification of multiple experience bases, and the management of multiple decision spaces at run time. The nature of a situation determines what the current working-context is, and situational changes can cause the switch of one context to another. Consequently, an agent working in one decision space can switch into another decision space, and return to a previous space when the current context switched back. This feature allows us to implement agents that can dynamically switch between humanitarian, peacemaking, and combat contexts.

3. SETTING STAGES FOR EXPERIMENTS

In this section we describe the problem domain, scenario design, and the simulation engine used in the experiments.

3.1 Problem Domain

The problem domain involves C2 teams reacting to potential threats that emerge unexpectedly in a metropolis. It imposes challenging information demands associated with the command and control of urban operations, including humanitarian, peacekeeping, and combat operations.

In the environment, of special interest are main supply routes (MSRs) and three kinds of key buildings (religious buildings, schools, and hospitals). A C2 team consists of S2 (intelligence cell), S3 (operations cell), and S4 (logistics cell); they, as a team, need to work collaboratively to handle incoming threats. Their roles have been simplified and defined as follows: S2 is responsible for processing incoming reports, called Spot reports, collecting relevant information from other sources, and alerting S3 and/or S4 of threats appropriately. S3 needs to process alerts from S2 and decide on the courses of action (COA) to handle threats, given varying timing constraints and limited resources. Two types of friendly units are under S3's charge: squad units and EOD (Explosive Ordnance Disposal) teams. S4 needs to process alerts from S2 and minimize damages to MSRs.

Potential threats come from three types of targets: Crowds, Insurgents, and IEDs (Improvised Explosive Device). A *crowd* represents a group of people that may contain key friends or foes. A crowd can be of medium (M) or large (L) size, and the group size of a crowd can change over time. A crowd can move around and it may get merged with another crowd. Table 1 shows under various situations the credit value (the points a C2 team can get if a target is handled successfully) of a crowd, the resources required to handle a crowd, and what action should be taken on a crowd, where 'U' refers to "squad unit", and the value of a crowd has additional 10 points when the crowd is near an MSR. For example, the second entry says that to disperse a medium size crowd with a foe needs two squad units, and 40 points can be credited if the crowd is dispersed successfully.

Another type of movable targets is *insurgents*, each is associated with a threat level that can be L(low), M(medium), or H(high). As shown in Table 1, how many squad units are required to capture an insurgent depends on its threat level. *IEDs* are motionless targets. An IED, if exploded, can cause damage to the nearby buildings and MSRs. One squad unit and one EOD team (E) are required to remove an IED. If successful, 60 points can be credited if the IED is close to buildings only or MSRs only, 80 points if it is close to both.

Table 1: Requirements on handling targets

Targets			*Value*	*Res. req.*	*Action*
Crowd	M	w/o foe	20	1U	monitor
	M	w/ foe	40 (+10)*	2U	disperse
	L	w/o foe	40 (+10)*	2U	disperse
	L	w/ foe	50 (+10)*	3U	disperse
Insurgent (3 threat levels: L, M, H)			50+50n	(n+1)U	capture
			n=1,2,3 for L,M,H		
IED			60 (80)*	1U + 1E	remove

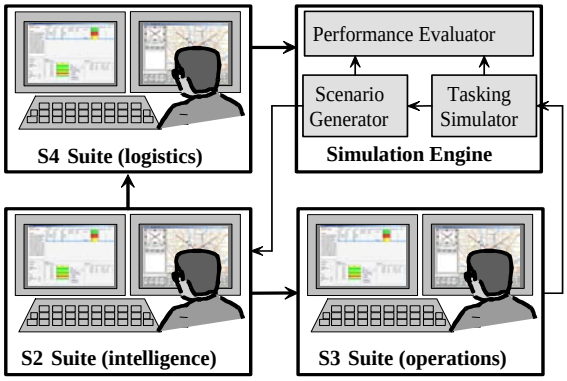

Figure 2: Environment settings of the experiments.

3.2 Simulation Engine

Figure 2 depicts the general settings of the experimental deployment, where each C2 cell (S2, S3, S4) has equipment with a map display and a human user interface (HUI). Human operators can monitor the current situation through the map displays, and interact with other peers through their HUIs.

The development of situations is controlled by the Simulation Engine module. Spot reports about situational changes are dynamically generated and fed to the S2 suite following certain controllable patterns (e.g., every n seconds; interleaving reports of different target types in fixed order or randomly). The S2 suite recognizes potential threats and decides whether and when to alert the S3 and S4 suites. Thus, although each suite has a map display, the S3 and S4 suites may only have partial views of the current situation.

The Simulation Engine module has three components: scenario generator, tasking simulator, and performance evaluator. At every cycle, the *scenario generator* creates a Spot report for each active target based on the script of its dynamics. Here is an example script of a crowd:

```
(  (crowd C121 40.04 -82.96 0.8 10)
   (report_key A12 friend 7) (successor C112)
   (m 40.04 -84.995 1.0) (m 42.05 -82.975 0.5)
   (s 27 20) (s 39 90))
```

This defines a crowd named C121, that appears at location (40.04, -82.96) 10 seconds after the system starts, and can move at full speed of 0.8 u/s. A friend named A12 shows up 7 seconds later. The crowd moves to (40.04, -84.995) at

Table 2: Scenario settings

Active targets	*Macro context switching frequency*		
(3 types in total)	*L: 15 sec.*	*M: 10 sec.*	*H: 5 sec.*
TC = 2 (× 3)	Scenario 1	Scenario 4	Scenario 7
TC = 3 (× 3)	Scenario 2	Scenario 5	Scenario 8
TC = 4 (× 3)	Scenario 3	Scenario 6	Scenario 9

its full speed, then moves to (42.05, -82.975) at 0.5 times of its full speed. The crowd size changes to 27 after 20 seconds and to 39 after 90 seconds. The disappearance of this crowd will trigger another target named C112 to show up.

Whether a generated Spot report is sent to S2 suite depends on the communication pattern set before each run, which is flexible, so that it allows, for example, the setting where reports about crowds being sent every other cycle.

The *tasking simulator* manages the tasks issued by the S3 suite by monitoring the engagement (e.g., taskload) of each squad/EOD unit, tracking the progress of each ongoing task, and reporting to scenario generator about any situational changes effected by the completion of a task.

The *performance evaluator* records the number of targets successfully handled; whether the S3 suite paid attention to the nearby buildings when issuing tasks; how many times all the resources are engaged after issuing a task; how many times S3 canceled a task that was no longer correct relative to the current situation; how many times resources were wasted on non-threatening targets (i.e., small crowds, IEDs far away from key buildings or MSRs); and how many times resources were re-allocated to another target that could offer a better chance to succeed.

3.3 Scenario Design

To study multi-context decision making, we first clarify what "context-switching" means in the problem domain. Humanitarian context refers to activities related to IEDs; peacekeeping context refers to activities related to crowds; and combat context refers to activities related to insurgents. It is a *macro* context-switching when Spot reports from two consecutive cycles are about different types of targets.

When the S2 (or S3) suite gets Spot reports (or alerts) about multiple targets simultaneously, even though they are of the same type, human operators have to switch their attention back and forth to handle the targets. We refer to this as *micro* context-switching. Because task difficulty correlates with time demands [17], varying the number of active targets (i.e., controlling *micro* context-switching) changes how much time a human operator can take on each target, thus varying task complexity.

We thus designed 9 scenarios as listed in Table 2, each with a different combination of context-switching frequencies and task complexities. For example, Scenario 5 switches context every 10 seconds, and has 3 active targets for each type (9 active targets in total). The scenarios also differ in settings of initial locations (targets, MSRs, key buildings, IEDs), itineraries and velocities of movable targets, sizing of crowds, threat levels of insurgents, targets' appearance time, etc. These are specified as scripts to the Scenario Engine.

Each target has a lifespan, which depends on whether a movable target moves to the end of its pre-specified itinerary, whether it comes to the expiration time of a motionless target, or whether the target has been successfully handled by the S3 suite, whichever comes first.

Other settings common to the 9 scenarios include: (a) each scenario lasts 10 minutes; (b) under the control of the S3 suite are 10 friendly units (1 EOD team and 9 squad units); they all move at the same speeds; (c) crowds with size between 10 and 35 are of M size, crowds with more than 35 people are of L size; (d) the Scenario Engine is set such that Spot reports of different target types are sent interleavingly in a random pattern.

4. EXPERIMENTS ON HUMAN C2 TEAMS

The aim of the experiments on Human C2 teams is twofold. First, we want to gain a better understanding of how cognitive limitations affect C2 team performance and how to minimize such impact. Second, we need to gather experiences for RPD-agents to use in experiments on human-agent C2 teams. We thus chose US Army ROTC (Reserve Officer Training Corps) students as the human subjects. At the current stage, we only used a dummy agent simulating the S4 suite, focusing mainly on S2 and S3 suites.

4.1 Team Organization

4.1.1 S2 Human

The left screenshot in Figure 3 is the S2 human user interface, the design of which was largely influenced by the domain experts we consulted. Displayed on the left are incoming Spot reports and the details. The upper-left area shows the current *macro* context. In the experiments, S2 human subjects were asked to do communication actions by following the current macro context as far as they could.

Shown in the list on the upper-right pane are fused information about targets, which are categorized into target type, name, status, crowd size, persons associated with crowds, nearby buildings, and whether S3/S4 suites have been alerted once. Except for a target's location information, which will be sent automatically to S3/S4 suites once they are aware of the target, S2 human has to update S3/S4 suites' knowledge about the situational changes in a timely manner. S2 humans can perform four kinds of communication actions. After selecting an active target from the target list, an S2 human can (a) press the button "MIDB Query" (MIDB stands for Military Integrated DataBase). Depending on the type of the selected target, from MIDB S2 humans can gather threat level information for an insurgent, recognize whether a key person is a friend or foe, and update information about buildings nearby an active target; (b) press the button "Alert to S3" to refresh S3 suite's view of the selected target; (c) press the button "Alert to S4" to alert S4 when the selected target is moving close to a MSR; and (c) press the button "Cancel Alert to S4", if the selected target is moving away from MSRs. The bottom portion of the interface shows S2's communication behaviors.

4.1.2 S3 Human

Figure 4 shows a screenshot of the S3 user interface used in *human-agent* C2 experiments. The interface used in human-only experiments is the same except that (1) there is no cue for resource requirements (i.e., the "Expected Units" column is blank), and (2) there is no color coding for target priorities (cf. Section 5.1.2 for improvements and the reasons).

Shown on the left are context indicator (S3's context switching depends on S2's situated decision making on information

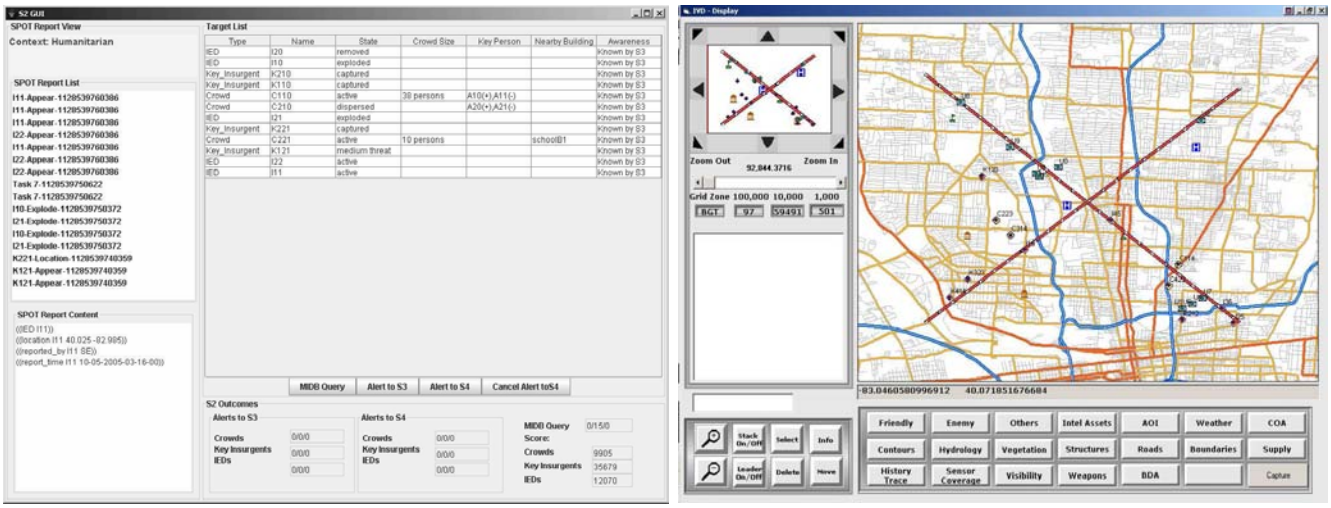

Figure 3: Left: S2 human user interface; Right: Map Display (one for S2, one for S3).

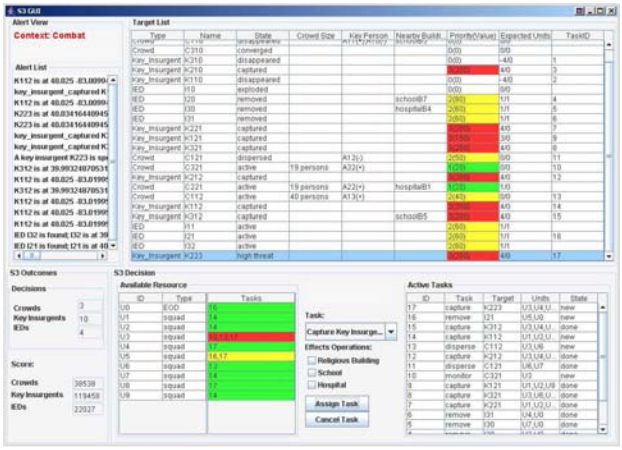

Figure 4: S3 human user interface.

sharing), a list of alerts from the S2 suite, and the S3 suite's current performance. The upper-right list shows target information, similar to S2 human interface. Allocatable resources and their taskloads, command area, and task list are displayed on the bottom-right. S3 subjects can issue 4 types of operations: monitor/disperse a crowd, capture an insurgent, and remove an IED. S3 subjects also need to pay special attention to the effects of their operations; here we simply require S3 subjects to check the type of buildings nearby the selected target, if applicable, when they issue a task. S3 subjects were asked to follow the target values and resource requirements listed in Table 1 when issuing tasks.

The S3 suite's main task is to decide which target to handle first, and how to allocate resources appropriately to multiple active targets, which is a constraint-satisfaction problem. In the multi-tasking environment, S3 subjects need to consider (a) resource constraints–balancing requirements (resource type, amount) among multiple targets; (b) utility constraints–maximizing the total values of targets successfully handled; (c) spacial constraints–others being equal, considered first resources closest to a target; and (d) timing constraints–earlier tasking has a better chance to succeed, due to the uncertain nature of a target's lifespan.

4.2 Result Analysis

We recruited 10 C2 teams (20 human subjects): 8 teams composed of ROTC students, and 2 teams composed of ROTC officers. Each team was tested using the 9 scenarios described in Table 2. The average performance in terms of the total value of targets handled successfully is plotted using a dotted line in Fig. 5(a). It clearly indicates that there is a tasking capacity (limit); the human teams approached the limit roughly in the medium context-switching settings.

This conforms to cognitive studies [17, 10] in general, because both S2 and S3 subjects are limited by their cognitive capacities. While monitoring the situation development from the Map Display, at the same time S2 subjects need to process Spot reports under time stress, to recognize/ gather missing information, and to constantly make decisions on *when* to share information with *whom* about *what*. Similarly, S3 subjects, while being limited by resources and multi-tasking capacity, need to constantly monitor the status of active targets, to decide *when* and *how* to handle *which* target (prioritization, resource (re-)allocation), and to judge whether to cancel an ongoing task if situation changes.

In addition to gaining expert experiences that can be applied to the human-agent studies, critical issues were also revealed from the experiments. For instance, in low-stressed situations some S2 subjects tended to frequently query MIDB much more than necessary, while in high-stressed situations, some S2 subjects simply ignored the spacial information from the Map Display when they should. It was also observed that some S2 subjects had difficulties in switching to the new context, tending to process targets belonging to the last context until completion. Similarly, in high-stressed situations, having no time to check the Map Display, some S3 subjects tended to allocate resources in bundles (e.g., U1-U4), rather than those closest to the target.

Such human "errors" rest on their fundamental cognitive capacities. The performance cannot be improved by simply providing a better human user interface without employing

appropriate technologies to appropriately support or match human cognitive capacities and capabilities.

5. HUMAN-AGENT C2 TEAMS

In this set of experiments, we (1) used an R-CAST agent (S2 agent) to play the role of S2 suite, and (2) used another R-CAST (S3 agent) to act as S3 human operators' decision aid. The purpose is to investigate whether and to what extent cognitive agents, being empowered with expert experiences, could help in improving C2 teams' performance.

5.1 Team Organization

5.1.1 S2 Agent

An S2 agent, playing the role of the S2, acted as the S3's teammate. The S2 agent uses a knowledge base to track the current world state (including targets, S3/S4's information needs, status of their information awareness). Whenever receiving a Spot report, the S2 agent will update the current state of the target under concern, query relevant information from the MIDB, then check whether the target's state has changed significantly (i.e., the change can affect the S3/S4's decisions and decision adaptations). If so, send alerts to whoever affected.

Most importantly, expertise about the S2's operations has to be encoded as experiences in the form acceptable to R-CAST agents. Since the problem domain involves three contexts, the S2 agent also needs to maintain three experience bases. The following is an example experience format used by an R-CAST agent:

```
(Experience      e26
    (Cue         (Close_enough ?crowd1 ?crowd2))
    (Expectancy  (Move_closer ?crowd1 ?crowd2))
    (Anomaly     (Move_away ?crowd1 ?crowd2))
    (Goal        (peacekeeping yes))
    (Action      (Alert_converged_threat)))
```

It says that experience "e26" applies to the cases where two crowds are coming close enough, and it is expected that they are moving closer; if this is the case, the action "Alert_converged _threat" is triggered; if it turned out that the crowds moved away, the action would be terminated.

5.1.2 S3 Agent and S3 Human

For the S3 suite, an S3 agent acted as the S3 human's decision aid. To offer highly acceptable aids for decisions and decision adaptations, we incorporated a recommendation model into the S3 agent based on the observations during and confirmations after the experiments on human-only C2 teams. Such an approach of employing heuristics from human experts to further help them is significant in practice.

The recommendation model has four components. First, the S3 agent can recommend *target priorities* to the S3 human. Based on the advice collected from the S3 subjects in the human-only C2 experiments, the S3 agent was implemented such that it can use colors to show target priorities: red for targets with a high priority, yellow for targets with a medium priority, and green for targets with a low priority. However, there may exist multiple targets with a high priority at the same time. Also, due to the uncertainty of targets' lifespans and the current locations of targets and friendly units, the best target selection may not be the one with the highest priority. Thus, which target to handle first still depends on the S3 human's decision, which can largely impact how the situation evolves and the team performance in the long run. Second, the S3 agent can remind the S3 human about the current resource requirements of each active target (i.e., how many more units are needed). Third, the S3 agent can automate the selection of operation types and the "effects of operation". This releases the S3 human's attention for other activities.

Lastly, based on the following heuristic model, the S3 agent can recommend resources to the currently selected target to support S3 human's *resource allocation behavior*.

We use $1, 2, \cdots, n$ to denote resource types; R_i^o to denote the set of resources of type i; R_i to denote the set of *free* resources of type i; and R_i' to denote the set of *re-assignable* resources of type i. *Re-assignable* resources are those that have already engaged in a task but can be preempted by another task. The current domain has 2 resource types: squads and EOD.

Each target places a resource requirement (cf. Table 1). The resource requirement of target t is denoted by $\overline{r_t} = (r_1(t), r_2(t), \cdots, r_n(t))$, where $r_i(t)$ is the number of needs on resources of type i. For example, $\overline{r_{c121}} = (2, 0)$.

Given a target t, if $r_i(t) > |R_i|$, we need to find re-assignable resources engaged in the on-going tasks. The on-going tasks can be ordered ascendingly by *priorities* up to tasks with priorities no more than the task being considered. Let $target(T)$ be the target of task T, $R(T)$ be the set of resources engaged in T. The priority of a task T with respect to a target t, is determined by its $TValue$:

$$TValue(t,T) = \frac{TargetValue(t)}{\sum_{r_i \in \overline{r_t}} w_i \cdot r_i} \times \frac{TargetRemainTime(t)}{max\{distance(t,\gamma) | \gamma \in R(T)\}}$$

where w_i is the weight of resources of type i, representing the cost of using a resource with type i, and the second factor on the right represents the chance of success when using resources engaged in T to handle target t. Here, $TargetRemainTime(t)$ represents the *estimated* value of how long t will remain before being removed from the simulation.

Resources engaged in task T will be considered re-assignable for t if $TValue(t,T) > \delta * TValue(target(T), T)$,
where a relatively good value for the adjustable variable δ can be obtained by running pre-experiments.

Let $(T_1, T_2, \cdots, T_k)$ be a list of tasks determined in the above way relative to target t, and $(y_i^{T_1}, y_i^{T_2}, \cdots, y_i^{T_k})$ be a list, where $y_i^{T_j}$ is the set of resources of type i from task T_j. Then, resources of type i re-assignable for t is $R_i'(t) =$

$$\begin{cases} y_i^{T_1} & (r_i(t) - |R_i|) \leq |y_i^{T_1}| \\ \bigcup_{j:1..m} y_i^{T_j} & |\bigcup_{j:1..m-1} y_i^{T_j}| < (r_i(t) - |R_i|) \leq |\bigcup_{j:1..m} y_i^{T_j}| \end{cases}$$

Next, given the set $R_i(t)$ of resources of type i available for target t, resources closest to the target t ought to be selected first. Let $D = (D_1, D_2, \cdots, D_x)$, where $\{D_i : (1 \leq i \leq x)\}$ is the partition of $R_i(t)$ by the distance of resources to target t, and D_i in D are ordered by distance ascendingly. That is, resources in D_i have the same distance to t and they are closer to t than those in D_{i+1}. Then, $closest(R_i(t), x) =$

$$\begin{cases} select(D_1, x) & x \leq |D_1| \\ select(\bigcup_{j:1..m} D_j, x) & |\bigcup_{j:1..m-1} D_j| < x \leq |\bigcup_{j:1..m} D_j| \end{cases}$$

which returns x number of resources closest to t, where $select(A, z)$ returns any one of A's subset of size z. Here, it

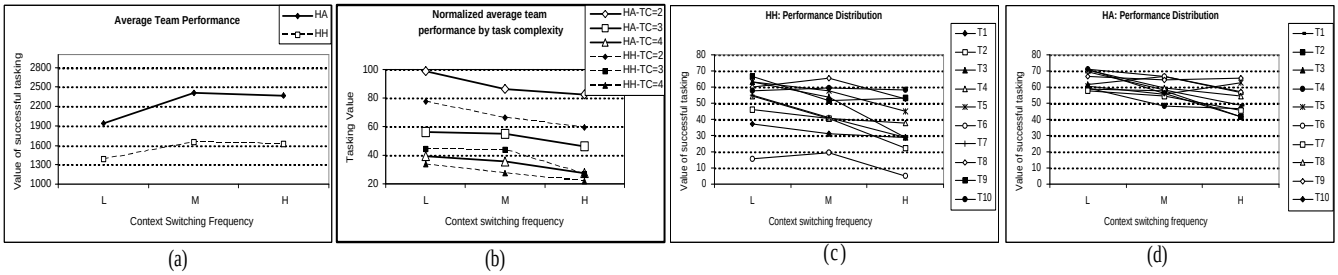

Figure 5: (a) Average performance (in net value); (b) Normalized performance by task complexity, (c) Performance distribution of human C2 teams, (d) Performance distribution of human-agent C2 teams.

doesn't matter whether to consider resources in $\bigcup_{j:1..m-1} D_j$ first, because at least one will come from D_m, which dominates the time it takes for the resources to reach t's location (we assume all the resources move at the same speed).

Now, given a target t and its resource requirement $\overline{r_t} = (r_1(t), r_2(t), \cdots, r_n(t))$, S3 agent follows the criteria below to allocate resources for target t. For each resource type i, (1) if $r_i(t) \leq |R_i|$, return $closest(R_i, r_i(t))$; (2) if $|R_i| < r_i(t) \leq |R_i \cup R'_i(t)|$, return $R_i \cup closest(R'_i(t), r_i(t) - |R_i|)$.

Actually, in cases where $r_i(t) > |R_i \cup R'_i(t)|$, two tasks can be issued separately to meet the resource requirement of t: one task employs resources in $R_i \cup R'_i(t)$, then issue another task later when more resources become available. However, this might mess things up and human subjects may easily forget to return to finish those partially committed operations. We thus left this open: human subjects could choose to split tasks if they could manage their attention.

In experiments, S3 humans could, if they want, override the above four kinds of recommendations from the S3 agent.

5.2 Result Analysis

We recruited ROTC students to form 10 human-agent C2 teams, and each team was tested using the same 9 scenarios. The average performance in terms of total value of targets handled successfully is plotted in Figure 5(a). It suggests that the C2 teams, even assisted by cognitive agents, still have a tasking capacity (limit). However, it also clearly indicates that, compared with human-only C2 teams, the tasking capacity of human-agent C2 teams have been significantly improved (all results discussed were 'significant' at the $p < .05$ level). This suggests that cognitive agents can play a critical role in alleviating the impact of human's cognitive capacity on the performance of decision makings involving multiple contexts.

5.3 Performance Comparisons & Discussion

In order to gain a better understanding of the performance difference, we plotted the *normalized performance* categorized by task complexities (amount of concurrent tasks, cf. Table 2) in Figure 5(b). It shows that the performance of both human C2 teams (dotted lines with filled markers) and human-agent C2 teams (lines with hollow markers) were affected considerably by task complexity. In addition, human-agent C2 teams performed much better when the performance at the same level of task complexity is compared.

Going deeper, we plotted the performance of individual teams in Figure 5(c)-(d). It shows that human-agent C2 teams' performances are relatively stable, while human C2 teams differed enormously. This may demonstrate that cognitive agents could augment human cognitive capacity and improve the overall C2 performance. Additionally, in both cases, the performance deviation became larger as context switching frequency increased. This may suggest that more stressed situations require more competent C2 operators.

Table 3: Decision making behaviors in detail

	Tasks	*FullUses*	*Reassigns*	*W. use*	*W. att.*
HA	32.52	3.84	11.65	0.207	0.336
HH	23.73	3.07	4.97	0.443	0.556

W. use: incorrect resource use; W. att.: incorrect attention

The experiment logs also allowed us to further identify what had contributed to the performance difference. Table 3 gives some descriptive statistics.

With the help of R-CAST agents, S3 subjects could issue more tasks (32.52 vs. 23.73), could use the limited resources more effectively (the number of times where all the resources were engaged: 3.84 vs. 3.07), and were apt to reallocate resources (11.65 vs. 4.97). Such improvement can be attributed to the balance of workload between the humans and agents such that the limits of human cognitive capacity were accommodated. In particular, the impact of S2 subjects' cognitive capacity was eliminated (S2 agent took the role); the impact of S3 subjects' multi-tasking capacity and mental efforts in resource allocation was alleviated.

With respect to the metric of "closer-resource-used-first", S3 subjects in human C2 teams (HH teams) made more incorrect judgments than S3 subjects in human-agent teams (HA teams): 0.443 vs. 0.207. S3 agent's recommendation could be wrong because its world model can be outdated: it only gets updated information periodically from the Simulation Engine. Also, S3 subjects missed most of the attention requirements on the selection of "Effects of Operations", while it was a big change when S3 agent helped S3 subjects: 0.556 vs. 0.336. Again, S3 agents might judge the situation incorrectly due to its outdated world state. Using agents, other kinds of human errors (e.g., wasting resources on non-threatening targets, issuing wrong operations to targets) were significantly diminished or avoided under high-stressed situations.

The results are encouraging. Although the sample space is restricted, the selected human subjects can be taken as representatives of domain experts—they have been trained to do similar operations. It may be argued that ROTC students typically are near the bottom of the expertise hier-

archy. Referring to the subjects as experts might be problematic, because the working memory load for a task differs greatly for experts vs. non-experts. However, as far as this particular experiment is concerned, ROTC students can be taken as domain experts. This was confirmed by our experiment which showed that the performance of the 2 ROTC officer teams were not the best among the 10 teams.

6. CONCLUSION

Multi-context real-time decision making is an extremely challenging problem faced by various real-world application domains. We have started to address this challenge associated with C2 teams operating in complex urban terrain, using the R-CAST cognitive agent architecture as human operators' teammates and decision aids. This paper, focused on the coupling of cognitive agent technology and human-centered teamwork, reported our experimental studies about the impact of RPD-enabled agents on C2 teams' performance in multi-context decision making under stress.

The experiments represent an important step forward in uncovering the nature of real-world problems, because the environment simulated the real domain and the human subjects were recruited from Army ROTC students. The results demonstrated that C2 team performance, while still limited by the human cognitive capacity, could be largely improved when they were assisted by cognitive agents capable of proactive information gathering/sharing and experience-based decision making.

Intelligence analysts need tools and techniques to help protect themselves from avoidable errors [15, 7]. Our experiments demonstrated that RPD-enabled agents can serve as one such tool to achieve reduced cognitive load, enhanced situation awareness, and positive human-agent collaboration. However, in real-world applications where information availability and credibility is concerned, it is expected that C2 teams with both the S2 and the S3 assisted by an R-CAST agent could outperform either of the two team structures considered in this paper, because S2 human's ability to reason about imperfect information can be fully exploited. This is worthwhile to consider in future studies.

ABSTRACT

This paper describes a camera-based observation system for football games that is used for the automatic analysis of football games and reasoning about multi-agent activity. The observation system runs on video streams produced by cameras set up for TV broadcasting. The observation system achieves reliability and accuracy through various mechanisms for adaptation, probabilistic estimation, and exploiting domain constraints. It represents motions compactly and segments them into classified ball actions.

1. INTRODUCTION

In order to realize computer systems that can interpret and analyze cooperative and competitive activity in multi agent systems, we need to realize powerful observation systems for agent behavior. One domain that is intensively studied and has proven to be a very interesting and challenging domain in the multi-agent community is football — in particular in the context of the RoboCup competitions.

In this paper, we investigate the observation of real football games based on video streams provided by a set of TV cameras. This computational problem is interesting because it can be solved with an ordinary setup for broadcasting football games without further additions. Based on the camera image streams the software system computes a representation of the game that enables it to answer questions such as: What are the characteristic offensive plays of the two teams? What are the strengths/weaknesses of a particular team/player? What roles do the players have? Do their capabilities match their roles? Do they achieve their tasks? How does a team create scoring opportunities? What are each players' skills? What is the tactical formation of a team?

Here we consider the problem of generating an action model suitable for answering such questions. The knowledge representation mechanisms needed for inferring such answers and the application of these techniques to the analysis of football games are investigated in a companion paper [3].

Building up a game representation for analyzing multi-agent activity requires a software system to exhibit the following capabilities,

- The reliable and accurate estimation of the positions of the players and the ball.
- The compact representation of motions and their segmentation into actions

The realization of these capabilities is also very difficult for various reasons. The positions, direction, and zooming factor of the camera are not known and must therefore, be estimated from the image stream. Processing the image streams is made difficult by the change in lighting conditions. These conditions change substantially when taking a camera sweep from one part of the field to another one or from one moment to the next when clouds are passing. Other complications include the inaccuracy in depth estimations caused by the low height of the camera positions and the fact that TV cameras are typically placed only on one side of the field resulting in players at the other side being very small in the image. There are also frequent occlusions of players by other ones.

The contributions of this paper are twofold. First, we describe the design, implementation, and empirical analysis of a camera-based observation system for football games. Second, we demonstrate how abstract representations of the game actions can be inferred that enable automatic game analysis systems to represent and reason about the actions in multi agent systems in sophisticated ways. These techniques are described in a companion paper [3].

In the remainder of the paper we proceed as follows. The next section presents an overview of the observation and interpretation mechanisms of the system. Section 3 details the components and methods used for the visual perception of the players and the ball. Section 4 then describes the probabilistic estimation methods that

enable the system to keep track of players on the field and estimate their postions more accurately. The interpretation of position data in terms of actions is detailed in section 4. We conclude with a discussion of related work and our conclusions.

2. SYSTEM OVERVIEW

Before we dive into the technicalities of the vision-based game analysis system let us first describe the sensing apparatus of the system and the overall software architecture.

2.1 Physical Setup

The physical setup of the system consists of a set of cameras used to broadcast football games on television. The cameras are pointed and zoomed by a camera man and provide complete image streams. The game observation system passively receives the camera stream without having control over it, and without receiving information about the pan and tilt angles of the camera nor its zoom parameters.

The cameras do only partly cover the playing field and not all players are visible all the time. In addition the cameras usually focus on the surroundings of the ball that is information about other parts of the field are only available at a substantially lower resolution. Another complication is the lack of height of the camera positions. Because the cameras are fixed in a maximal height of about 18 meters the depth resolution of a pixel imaging the opposite side of the field is about 1,5 meters. The sizes of players are only about 35 pixels where the course grained resolution of pixels blurrs the colors. Therefore the appearance of players close to the camera differs substantially from those of distant players. Finally, drastical and abrupt changes of lighting conditions complicate the reliable interpretation of color information.

2.2 Software Architecture

The software architecture of the game analysis system is depicted in figure 1. The system is decomposed into two main components: the model acquisition and the reasoning and model mining component.

The model acquisition component consists of the *visual perception module*, the *blob tracker*, and the *motion and action interpreter*. The *visual perception module* receives multiple streams of camera images and computes for each image the blobs that correspond to players, the referee, and the ball. A blob description contains an $\langle x, y \rangle$ coordinate on the field, a class label that specifies the team the player belongs to or whether it is a referee, and the covariance as a measure of the expected inaccuracy of the estimated position.

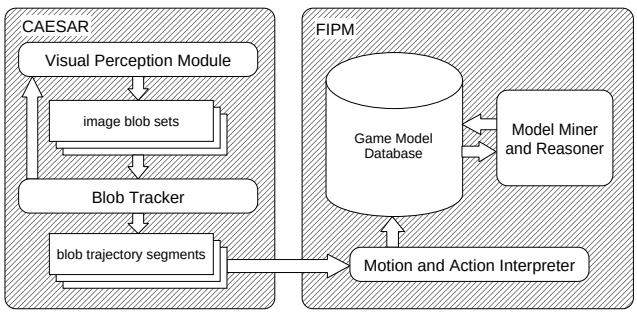

Figure 1: Software architecture of the FIPM analysis system.

The *blob tracker* integrates the observations generated by the *visual perception module* and produces trajectories of the observed object motions and associates these trajectories with the respective players. Using temporal redundancy and coherence the *blob tracker* estimates the player motions much more reliably and accurately. Additional computational tasks that the blob tracker performs are the association of player track identities with blobs and the completion of partly unobserved object tracks through probabilistic guessing.

The final component of the model acquisition component is the *motion and action interpreter*. The interpreter stores the motion data very compactly as a concise motion model and structures the continuous motions into application specific ball actions such as passes, dribblings, and shots. The interpreted motions and ball actions are then stored into the game model database that is used by the *reasoner and model miner* for game analysis purposes.

The *reasoner and model miner* learns situation specific models of the skills and action selection criteria of the football players using the game model database as the relevant set of experiences. It then uses the models in order to predict, analyze, and diagnose the teams' playing behavior.

The FIPM system is implemented as a distributed system running on multiple computers. In the current version the visual perception module for each camera is running on its own computer, so is the tracking, and the motion interpretation module. The modules communicate via Corba.

3. VISUAL PERCEPTION

As we have sketched before the computational task of visual perception is to estimate the 3D position of each player, the referees, and the ball in the camera view. A camera image and the recognized objects and their positions are shown in figure 6. Since the estimated positions are inaccurate the expected accuracy is computed and returned with the estimates.

Figure 2: Output of the visual perception. The players and the ball in the camera view are detected. The players are labelled with respect to the team they belong to. For each player, the referee, and the ball the $\langle x, y \rangle$ position is estimated.

The visual perception of the players and the ball based on a stream of camera images entails a number of difficult computational problems. The first problem is the camera position that gives the system a very flat viewing angle, which causes high inaccuracies in depth estimates. For example, if a player is at the opposite side of the field one pixel in the image corresponds to more than 1,50m depth. Also, if the camera does not zoom in on a player who

stays at the other side of the field the size of the player in the image is about 35 pixels. This reduction in size also results in a considerable change of the visual appearance of players causing the color models of football dresses to exhibit much higher entropies. There is also frequent occlusion especially caused by one player covering another one. Luckily the space occluded by players is quite small because of the distance and position of the camera. Another issue is the rapid change of lighting conditions either due to change of cloudiness or due to the sharp shadow caused by the stadium roof in intense sun shine.

There are, on the other hand, also a number of assumptions that we can make in order to simplify the computational task of visual perception drastically [7]. The first assumption is the *ground plane assumption*. We can assume that all objects that interest us are standing on the field and have roughly the same size. Another important assumption is the *distinctive color* assumption: we assume that objects and their classes can be recognized by their colors. The football field is green and the lines white and the two teams are required to wear dresses that are visually easy to distinguish. We further know the static environment: the form of the field lines and all but a few parameters such as the length and the width of the field. Also since the frame rate is about 25 frames per second and the motions of the observing cameras and the players are not too fast, there is a high temporal coherence between subsequent camera images.

The visual perception of football games is decomposed into three closely interrelated subproblems: (1) the identification of the relevant color regions, (2) the estimation of the pan- and tilt angle of the camera and the zooming parameter, and (3) the identification and positioning of the players and the ball that are in the camera view. In the remainder of this section we will describe our approaches to the solution of these computational problems.

3.1 Color Segmentation

Since football is a spectator sport the playing field, the lines, and the dresses of the players are designed to be visually distinctive. From the visual features that allow for these distinctions color is the most informative one: the field is green, the lines are white, and the players of the teams are required to dress so as to achieve the highest possible contrast.

Figure 3: Computing the regions that are colored football field green.

Thus our first step in processing the camera images is to apply color classification and segmentation to the images. Given a previously learned set of color classes including ones for *field green*, ones for the dresses of the teams, and others, the visual perception module finds the regions of interest by first mapping the image pixels into the respective color class and then grouping the pixels that belong to the same color class into regions using morphological operations for noise elimination. Figure 3 shows the mapping of an image into the color class field green. The white pixels belong to this class the black ones not.

In order to find meaningful regions or blobs, in particular those that correspond to the objects of interest, the visual perception module applies morphological operations to the images resulting from color classifications.This step eliminates noise and makes regions more homogeneous.

In addition, we can characterize the objects of interest through properties of the image blobs they generate. In particular, using the assumptions that players are in upright positions and having contact with the field plane (at least, if we consider image sequences of particular length) we obtain very accurate estimates of the blob sizes based on the $\langle x, y \rangle$-coordinates of blobs in the image. Furthermore, the objects of interest, the players and the ball, have to satisfy certain compactness (ratio between area and perimeter). We can apply these assumptions to filter the data, and to more reliably extract the relevant objects.

Having color regions and color blobs as building blocks we can define complex regions of interest to which we might apply certain image processing operations. For example, in order to look for field lines in a focussed way we consider the image region that is field green, in the area where we expect the field but disregard those regions that are occluded by a player or the referee. This region can be expressed by: *(¬ green ∩ field region) - Team1Regions - Team2Regions - RefereeRegion*.

Robustness of Color Classification. Lighting conditions change when the camera sweeps from one side to the other, when the clouds change, when it begins to rain, etc. For these reasons reliable color segmentation cannot be achieved by learning color classes in advance and then hold them fix during the game. Rather they have to be adapted on the fly, in particular the color class *field green*. Thus we adapt the color class *field green* in an expectation maximization manner. In one step we use the estimates of the camera parameters to identify those regions that must be *field green* given the field model and the camera parameters. The relevant region is: *FieldRegion - Team1Regions - Team2Regions - RefereeRegion - neighborhoods of fieldlines ...* processed by some morphological operators to eliminate holes in the regions. We then take the pixels in these regions to estimate the color class *field green*. This color model is then used for the estimation of the camera parameters. In praxis, the class model can be estimated at a much lower rate than the camera parameters.

3.2 Estimation of Camera Parameters

In order to estimate the 3D position of the players and the ball, we need estimates of the camera parameters, that is its position, the direction it is pointed to, and the zoom parameter. Given the camera parameters and an assumption about the plane in which pixels lie the 3D coordinates of each pixel can be determined. In this section we will investigate the estimation of the camera parameters for a given image sequence.

We will do so by first describing our model of football fields. Then we look at the three-step iterative estimation process, detailed in section 3.2.2.

3.2.1 The Model of the Football Field

The purpose of the field model is the estimation of the exact position of the camera, of the direction it is pointed to, and the zoom of the camera. Based on these camera parameters and the knowledge

of the exact position and orientation of the field plane the visual perception module can accurately determine the $\langle x, y \rangle$ positions of the players on the field (see section 3.3).

The model of the football field is a set of 3D curves where each curve can either be a line or an edge. Edges are curves that separate two neighboring surfaces. Lines are combinations of two parallel curves where the area between the curves is visually distinct from the areas left and right of the line. The field lines are perfect examples of this line notion.

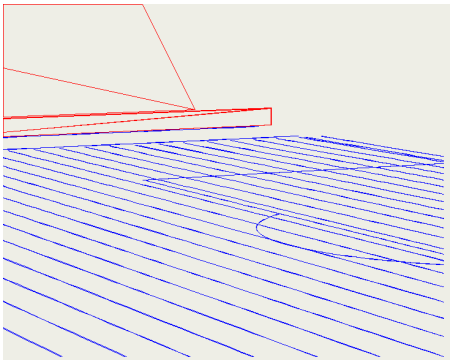

Figure 4: Field model used for estimating the camera parameters. Curve segments are depicted in blue and triangles in red.

The FIPM system uses the field model depicted in figure 4. The model contains the lines on the field. In addition, it contains the boards surrounding the football field and the stands. Both the boards and the stands are modeled as triangles with given position and orientation in space. Using these triangles the visual perception system can accurately determine the 3D position of each pixel that lies in the projection of such a triangle onto the image.

The boards and the stands are included in the field model because for many camera views the field lines alone do not suffice to unambiguously estimate the camera parameters. Using the boards and stands submodels the visual perception module can on the fly determine visual landmarks on the boards and in the stands and use them for estimating the camera parameters even if no field lines are in the camera view.

3.2.2 Estimation Process

We formulate the estimation of the camera parameters as an iterative optimization problem. The opimization process performs in each iteration three steps. In the first step the model is projected onto the image using the predicted parameter values. In the second step the optimizer searches for the image points that correspond to given model points. In the third step, the predicted parameter settings are modified such that we obtain the best match between the model and the image data. The search window for finding the best match is determined based on the expected innaccuracy of the predicted parameters. These three steps are depicted in figure 5.

Since the frame rate of the camera is about 25Hz (50 Hz interlaced) the change from one image to the following one is typically very small, the exceptions being camera sweeps following very long and hard passes. We will return to this issue later in section 3.2.3. So in the typical case, where the changes are small the predictions are also very accurate allowing for the use of small search windows.

The search methods for correspondences are specific to the different types of curves which allows for the realization of a high performance hybrid correspondence search. This means that we have curve segment specific "curve line" detectors. For example, the lines on the field are detected by looking for edges in the *field green* region, the edges resulting from lawn mowing look for points along the search perpendicular such that brightness variation left and right of the point becomes mininmal, that is the points to the left have a very similar brightness and so do the pints on the right. Other mechanisms for finding correspondences are taken for the edges between the field and the surrounding boards.

Given the correspondences we perform an optimization of the camera parameters such that the distance between corresponding points becomes minimal. This is done by a Newton iteration step. The system also estimates the covariance of the parameter values which captures the expected accuracy of the estimation outcome. The camera parameter values resulting from this optimization step is returned as the estimate of the parameters.

3.2.3 Increasing Robustness

In order to estimate the camera parameters reliably and accurately even if the field lines in the camera view do not suffice for an unambiguous estimation we generate visually distinctive landmarks on the fly and track them over sequences of camera images.

For this purpose, we first generate regions of interest by projecting the triangles of the field model onto the image. These are the regions where we can determine the 3D coordinates of the surface that generated the pixel. To these regions of interest we apply the feature detection and tracking method of Shi and Tomasi [14].

Even with these extensions the estimation of the camera parameters will sometimes fail, in particular when the camera man makes fast sweeps. To deal with failures in parameter estimation we run a monitoring process in parallel with the estimation process. This monitoring process signals a failure whenever the quality of the match between the predicted parameters and the parameters that result in the best local fit fall below a specified threshold. In this case a reinitialization of the camera parameters is triggered.

3.2.4 Empirical Results

At the current state of implementation the system can keep track of the camera orientation and the zoom parameter for up to 2,5 minutes, depending on the speed of camera motion and zooming and the visible components in the camera view. As far as we can tell the cases where the system looses track are caused by our model of the field beeing too inaccurate. In general, the length and the width of the field can vary substantially from stadium to stadium. An accurate and reliable estimate of these parameters from an image is not possible because if the camera view covers enough of the field then the field lines of the opposite side are blurred too much. Thus, so far we work with field models that are locally consistent with respect to the assumed camera position but not globally accurate. We currently, work on mechanisms that are less sensitive to the lack of globally accurate field models.

When successfully tracking the camera position the average accuracy of the field model being back projected onto the image is typically within a pixel occasionally 3-4 pixels. The system can automatically recover from lost tracks if the estimate is still within the convergence area of the model fitting procedure. For the remaining situations we currently develop a monitoring mechansm that detects lost tracks and reinitializes the system as soon as the camera view allows for an unambiguous match of the field lines.

At the moment processing an image can still take up to more than a second. We expect that by applying faster methods, and exploiting more prior information, we can reduce the processing time and bring the system close to frame rate.

3.3 Blob Recognition and Localization

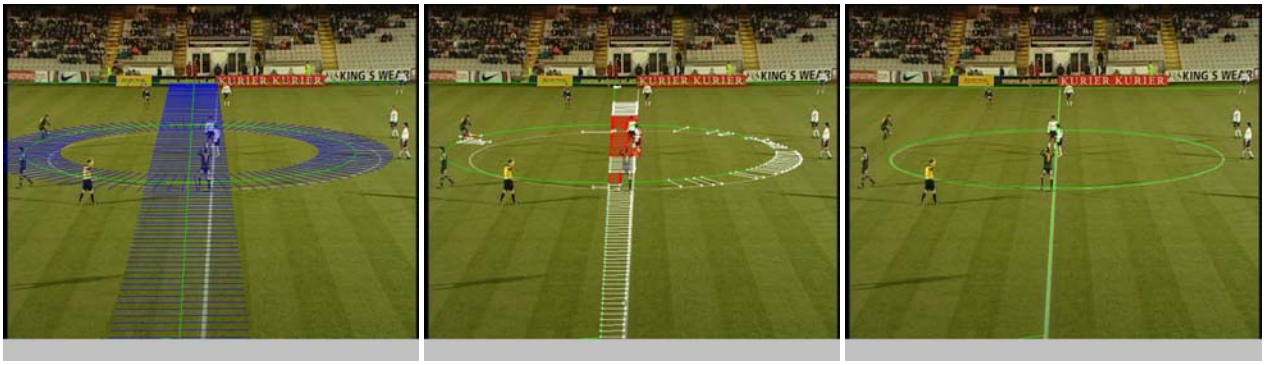

Figure 5: Estimating the camera parameters by taking the current parameters, projecting the field model using the current parameters onto the image (left), finding the correspondences between model points and the imagepoints (middle), and adjusting the camera parameters to achieve minimal errors (right).

The visual perception module gets all blobs in the field green region as its input. These are obtained through the regional expression: InRegion(field) $\cap$ $\neg$FieldGreen $\cap$ $min \leq Compactness \leq max \cap min \leq Size(blob, distance) \leq max$

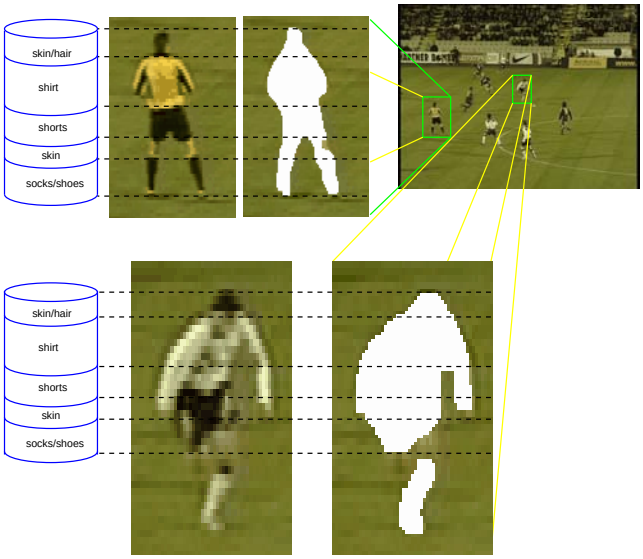

Figure 6: Player blobs segmentation. The player blob detection algorithm finds compact regions that are not field-green. The segmentation of players close to the camera is fairly accurate, but the situation is harder for the distant players because of the course grainedness, which causes some of their pixels to look field-green. Then they are segmented into two regions.

The next step is the blob classification. Blobs are classified into: the ball, the players of the one and the players of the other team and the referees. All other blobs on the field are ignored. The classification of the blobs into the different categories is straight forward. We first apply size constraints to the blobs and then identify the dress colors of the players. These color models are learned and updated during the game. The biggest complication are the partly occluded players that result in bigger blobs with possibly not identifiable color classes. These complications are resolved using the information provided by the object tracking system (see next section).

Another module monitors the blob sizes in the camera image. If the blob size is big enough, the blob identifier attempts to read the player number — if possible. If the player number is recognized the information is passed to the object tracker as evidence about the players' identity.

Given a blob that is inferred to be a player or ball the FIPM system estimates the $\langle x, y \rangle$ of the corresponding object on the field. To do so, we estimate the 3D position of the center of gravity of a player which can be much more reliably and accurately estimated than the position where the player stands on the field. The gain in accuracy and reliability has been empirically studied in several experiments.

Surprisingly, the player blob detection and localization was substantially less robust and accurate than we initially expected. This is explained by a number of reasons including the motions of the legs and the typical colors of skin and player dresses varying substantially. In particular as the players in the image are smaller and more distant a pixel in the image covers a much larger area in the world. Therefore many of the pixels depicting the player have a high fraction of field green and therefor cannot be segmented easily from the background.

To deal with these issues we have then implemented blob recognition using predictions made on the basis of previous observations (see next section). In this method the perception module receives hypotheses about players from the state estimation system and then validates and rejects these hypotheses based on the image. This way we can concentrate the player recognition mechanisms on selected regions of interest and use much more informative expectations about the blob size and the color distribution within the blob. Using this prior knowledge the accuracy and reliability of player recognition is increased substantially while at the same time reducing the computational cost for the player recognition.

4. PLAYER TRACKING

The detection of players and their classification based on single images is unreliable. Players might violate size restrictions when bending down or when colors get blurred due to fast camera motion. Sometimes players are hallucinated due to specular reflections in the field that make regions appear to be not field green.

4.1 Multi-Object Tracking

To reliably estimate the positions and motions of the players we apply probabilistic multi object tracking algorithms to keep track of player positions.

We use an extension of Reid's Multiple Hypothesis Tracking (MHT) algorithm [11, 4] that has been further developed by Schmitt and his colleagues [12, 13]. Using probabilistic motion and camera models the MHT maintains probabilistic estimates of the players positions and update these estimates with each new observation. The computational structure of the algorithm is shown in Fig. 7. An iteration begins with the set of hypotheses of player states $H^k = \{h_1^k, \ldots, h_m^k\}$ from the previous iteration k. Each h_i^k is a random variable ranging over the possible positions of a player on the field and represents a different assignment of measurements to players, which was performed in the past. The algorithm maintains a Kalman filter for each hypothesis.

```
algorithm MULTIPLEHYPOTHESISTRACKING()
 1  let Ĥ^k = {ĥ_1^k, ..., ĥ_{m_k}^k}  % pred.hypos.
 2    Z(k) = {z_1(k), ..., z_{n_k}(k)}   % ob.feat.
 3    H^k = {h_1^k, ..., h_{o_k}^k}  % new hypos.
 4    X^{k-N}  % world state at time k-N.
 5  do for k ← 1 to ∞
 6    do Z(k) ← INTERPRETSENSORDATA();
 7       Ĥ^k ← APPLYMOTIONMODEL(H^{k-1}, M);
 8       for i ← 1 to n_k
 9       do for j ← 1 to m_k
10             do h_ij^k ← ASSOCIATE(ĥ_j^k, z_i(k));
11                COMPUTE(P(h_ij^k|Z(k)))
12       for j ← 1 to n_k
13       do H^k ← H^k ∪ {GENERNEWHYP(z_j(k))};
14       PRUNEHYPOTHESIS(H^k);
15       X^{k-N} ← {x_1^{k-N}, ..., x_{o_{k-N}}^{k-N}}
```

Figure 7: The multiple hypothesis tracking algorithm.

With the arrival of new sensor data (6), $Z(k+1) = \{z_1(k+1), \ldots, z_{n_{k+1}}(k+1)\}$, the motion model (7) is applied to each hypothesis and intermediate hypotheses $\hat{h}_i^{k+1}$ are predicted. Assignments of measurements to players (10) are accomplished on the basis of a statistical distance measurement, such as the Mahalanobis distance. Each subsequent child hypothesis represents one possible interpretation of the set of observed players and, together with its parent hypothesis, represents one possible interpretation of all past observations. With every iteration of the MHT probabilities (11) describing the validity of an hypothesis are calculated. Furthermore for every observed player a new hypothesis with associated probability is created (13).

Obviously, the heart of the MHT algorithm is the computation of the likelihood of the different hypothesis-observation associations, $P(h_{ij}^{k+1}|Z(k))$, in line 12 of the algorithm in Algorithm 7. Let Z^k be the sequence of all measurements up to time k. A new hypothesis of a player at time k is made up of the current set of assignments (also called an event), $\theta(k)$, and a previous state of this hypothesis, h_j^{k-1}, based on observed features up to time step $k-1$ inclusively. We can transform the probability of a player's hypothesis $P(h_i^t|Z^k)$ using Bayes' rule and the Markov assumption in an expression that can be obtained more easily:

$$P(h_i^k|Z^k) = P(\theta(k), h_j^{k-1}|Z(k), Z^{k-1}) \quad (1)$$

$$= P(\theta(k), h_j^{k-1}|Z(k), H^k) \quad (2)$$

$$= \alpha * P(Z(k)|\theta(k), h_j^{k-1}, Z^{k-1}) \quad (3)$$
$$P(\theta(k)|h_j^{k-1}, Z^{k-1}) P(h_j^{k-1}|Z^{k-1})$$

According to Bar-Shalom and Fordham [1], this equation can be transformed into an expression over a set of parameters, and they allow us to fine tune the calculation of probabilities to exploit the domain constraints. These parameters include ones for prior probability mass functions of the number of spurious measurements and of new detection of players, probabilities of detection and termination of a track originating from a particular hypothesis, model the declination of an unobserved hypothesis probability over time, and total numbers of spurious measurements and new detections of players. The exact form of the transformed data association probability and a more thorough explanation of its terms and parameters can be found in the papers by Cox and Hingorani [4] and Schmitt et al. [13].

In our tracking system we dynamically modify these parameters for each track and measurement according to the relevant situation. For example, it is highly unlikely that a player disappears while being well observed by the camera and in the middle of the field. The likely explanation is that the player is being obstructed by another one and the detection module is having problems detecting him/her. In this case, we set the parameters accordingly to favour the continuation of the track without measurements, hoping to detect the player in the next images. See section 4.2 for further discussion of the used constraints.

4.2 Exploiting domain constraints

The nature of our tracking task allows us to make assumptions that do not hold in the general case of multi object tracking. Under these assumptions we are able to substantially increase the robustness, accuracy, as well as reduce the required computational resources by specializing the estimation and inference techniques to the characteristics of the application. We will list some of these assumption that result in substantial improvements of the algorithm below.

The first and obvious way of increasing the performance of the MHT is to set the parameter of the formula in situation specific ways. For example, players cannot magically appear or disappear in the middle of the camera frame. This constraint is implemented by adjusting the average time of new track appearance and track termination. New tracks are to be primarily created at the boarders of the camera frame. The same holds for the termination of tracks. Making these assumptions enables the system to substantially prune the hypotheses tree and therefore allows for more thorough analysis of the individual hypotheses. This is done by maintaining hypotheses trees of greater depth.

Another improvement is the handling of occlusions of one player by another one. This could be handled by increasing the time that a track survives without being supported by additional observation. A more controlled way of "remembering" occluded players is to generate virtual observations from hypotheses that the system knows to be occluded. A similar mechanism was used by Fox and his colleagues [6] to avoid collisions with known obstacles that were invisible for the robot sensors.

Another twist of the tracking problem is that we can assume that the players all move in the same 3D plane. Under these conditions a player is closer to the camera if and only if his position in the image is lower than that of the other one. This qualitative relationship holds independently of the inaccuracy of our estimate of the camera position and can be exploited to reject many data associations that are impossible with respect to this constraint.

These and other modifications to the MHT algorithm allow for reliable and accurate player tracking in situations where the more general version of the algorithm is doomed to fail [7].

At the moment our algorithm generates maximally extended trajectories for which the system is sure that they are generated by the

same player. The player identity itself is specified manually.

In particular the semi-automatic inference of the player identity will be a focus of our future research. The tracking system will use prior distributions of player positions, knowledge about the player roles, occasionally read player numbers, the identity of players that are known in order to estimate a probability distribution over the identity of a given but unknown player.

5. MOTION AND ACTION RECOGNITION

Motion and action recognition abstracts away from the details of the estimated position data and the track segments generated by the Multi Hypothesis tracking algorithm. The raw data are transformed into compact motion models and then classified into ball actions [2]. These computational tasks are detailed in this section.

5.1 Motion Interpretation

The motion interpreter computes motion models for the players and the ball *o* that are sequences of motion segments $m = m_1, m_2, ..., m_n$. The trajectory of an object is represented as a piecewise defined function *f* that maps time indices into the respective *x* and *y* coordinates of the object. The function f is defined for all t with $t_1 \leq t_2$ and $f(t)$ returns the position of o at t. The individual tuples m_i have the form $\langle o, t_1, t_2, p_1, p_2, f : \mathbb{T} \rightarrow \mathbb{P} \rangle$ where o denotes the object (ball or player number), t_1, t_2 the starting and end time point of the motion segment, and p_1, p_2 the respective start- and end position.

The motion model also contains the set of all ball contacts, ball out of bounds, and referee whistles (game interruptions and continuations) as instantaneous events. These events are asserted manually. Ball contact events are those where the ball is accelerated due to the action of a player. Ball out of bounds events occur if the ball leaves the football field.

As the motion model we have chosen piecewise linear models. This model is very efficient to compute and the motion tuples are very compact. The linear modeling of motions also simplifies the computation of distances, intersections, and other derived information. The accuracy can, as in the other models be adjusted through the segmentation thresholds.

The motion interpreter maps the position data into a sequence of motion tuples, where each motion tuple describes a uniform motion segment. The interpreter works iteratively. If it has a partial segment m_i it represents this partial segment as a motion function. It then uses this motion function to predict the next position p_j. If the difference between the predicted and the observed next position is smaller than a threshold ϵ_1 then m_i is extended to cover p_j and the motion function is updated accordingly. Otherwise m_i is asserted to the motion model as a complete motion segment and a new motion segment m_{i+1} is started.

Instantaneous motion events are currently recognized mainly manually. Referee whistles are explicitly asserted. Out of bounds events are detected by intersecting the linear motion segments with the field lines. Finally, the ball contacts are asserted by hand.

5.2 The Episode Model

The motion model is further abstracted into the episode model.

In the episode model we consider the episodes of ball movement to be primary. This is natural because people watching football and summarize plays in football games primarily as a sequence of ball actions. Actions away from the ball are included only if they become relevant for the ball actions later.

We distinguish three different classes of ball actions: keeping control over the ball, passing, and shooting. If ball actions had very high success rates we could recognize them using simple rules. A *ball possession* is a sequence of ball contacts of the same player. A *pass* is a ball contact of one player followed by a ball contact of another player (hopefully a team mate). A *shot* is a ball contact of a player followed by an out of bounds event, where the out of bounds event occurs in or close to the goal.

Unfortunately, the high technical difficulty of playing football makes such simple classification rules very inaccurate. Control over the ball, in particular with opponents around, is very difficult and therefore actions do not only have nondeterministic effects but often fail completely: the player looses possession of the ball. It is often impossible to distinguish whether a lost ball is caused by a bad pass, shot, or dribbling. In our approach we deal with these ambiguities with probabilistic reasoning techniques.

We consider an *episode* e to be a triple $\langle \langle m_i, ..., m_j \rangle, se, fe \rangle$ where $m_i, ..., m_j$ is a sequence of motion segments, se is the starting and *fe* the finishing event. To be an episode the triple must satisfy the following requirements: (1) m_i is started by ball contact se of player p. (2) m_j is ended by *fe*, which is of the type ball contact, referee whistle, or out of bounds. (3) All events e that occur are ball contacts of player p. (4) $m_i, ..., m_j$ is the maximum sequence of segments that satisfies (1) to (3).

For the recognition of episodes we use a small finite automaton that starts a motion segment sequence if it receives a motion segment starting with a ball contact of player p. The automaton stays in its intermediate state as long as the motion events are ball contacts of player p. It terminates for all other motion events. All accepted motion sequences are episode candidates.

The episode model differentiates between passes, shots, and extended ball possessions of a single player. The main problem is the classification of football actions that have failed. To deal with ambiguities in the classification of failed actions we apply classification rules that assign classes to episodes with a subjective probability. To get a principled way of stating such rules we apply decision tree learning . Given a set of classified examples a decision tree learning algorithm learns a set of classification rules with the objective of making the rules as general and accurate as possible. Decision tree learning algorithms also estimate the expected accuracy of the classification rules.

When we apply decision tree learning to the acquisition of classification rules for football actions two problems must be solved. First, we need a suitable feature language for representing episodes such that their representation correlates well with their classification. Second, we must provide the examples that we need for learning. The main problem here is that we need to know the intentions of the players to provide examples of ball actions and their classification. For the feature language we have used the following features: the duration, the number of ball contacts within the episodes, whether ball possession changed from one player to another one, from one team to the other one, the dominant motion direction, and the average velocity of the ball.

We obtained the best results by classifying at the toplevel into the action classes pass, dribbling, and shot and adding one additional class "lost ball" that comprises the episodes where ball possession goes from a player to the other team, from a player to the out, and episodes interrupted by referee whistles. In this approach, we have the advantage that we can specify all toplevel classes crisply. The top-level classification rules are complete and classify uniquely. That implies that every episode candidate is classified as an instance of exactly one top-level class. The biggest assumption is that the classification assumes that if a football action was successful the player has intended it. We believe that by making this assumption the resulting accuracy is higher than it would be when learning the classes from examples. We will reevaluate this assumption when

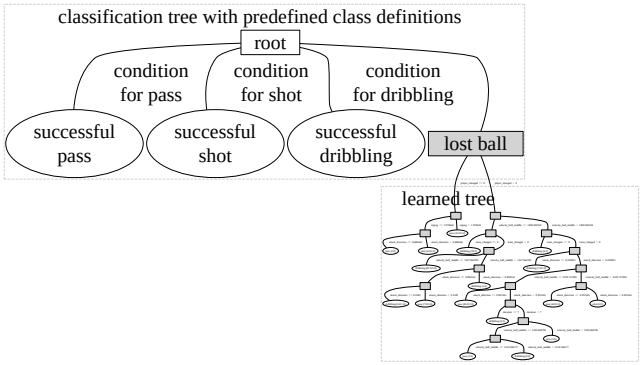

Figure 8: Classification tree. To classify the ball actions into different action classes we use a classification tree consisting of defined conditional leafs for successful actions and a learned decision subtree for lost balls.

we have comprehensive data from real games.

In this approach we apply decision tree learning only to the class of lost ball possession. A sample classification rule that we obtained is: A failed pass is an episode in which the ball is played to the front but not in the accurate direction of the opponent goal, the ball velocity is smaller than that of shots, and the ball possession changes from one team to the other.

6. RELATED WORK

A number of observation systems for football games and sport games have been developed, most of them in the sport sciences and some of them even commercially. Those systems are typically characterized by their requirements for extensive manual data entry by operators. Intille and Bobick [9, 8] have developed a seminal visual observation system for American Football and this is the closest approach to ours. Their system include mechanisms for action, formation, and play recognition. Differences are caused by the different natures of the game. American football is structured into modular, preplanned plays with failed actions (interceptions and turnovers) being exceptions, players having very specific roles in plays, and the ball being held most of the time. In the real football these characteristics are not met and complicate the visual observation drastically. Another difference is our emphasis on accurate estimation of player positions which is the key for the recognition of game situations such as scoring opportunities, players being under pressure, passing opportunities, etc.

The research work in computer vision that is applicable to game observation is too big to be discussed in detail. Perhaps most relevant is the work of Malik's and Forsyth's vision group. In particular ideas of their work on recognizing actions at a distance [5] and the learning and application of appearance models for tracking human action [10] have been incorporated into our system.

7. CONCLUSIONS

This paper has described the nuts and bolts of observing multi agent systems for analyzing agent behavior. We have considered a particular application domain: the visual observation of football games. Football, in particular in the disguise of RoboCup has become a challenging testbed for agent technology.

The observation and interpretation system described in this paper is a part of a larger system. The analysis of Football games based on position data is discussed by Beetz, Kirchlechner and Lames [3]. Kinds of action models that are proposed in this paper are also used for making autonomous robots "action-aware" [15].

We plan to showcase the vision-based game observation system for games of the Football World Championship 2006 in Germany.[1]

ABSTRACT

In this paper, we propose an agent-based model of human decision making: CODAGE (Cognitive Decision AGEnt). Classical Decision Theories have been widely used in multi-agent systems, but imply a too rational behavior when faced with real-world human data. Moreover, classical model usually exceeds human capabilities. Therefore, we derived our decision model from several cognitive psychological theories (e.g. Simon's decision theory, Montgomery's search of dominance structure, etc.) to take human bounded rationality into account. While most of existing cognitive agents use the BDI framework, we propose a new kind of architecture. In the CODAGE model, the decision maker is modeled by an entire multi-agent system, where each agent is in charge a particular sub-process of the whole decision. The architecture is intended to be as generic as possible. It could be viewed as an agent-based decision framework, in which different decision heuristics and biases could be implemented. We illustrate this approach with a simulation of a small experimental financial market, for which our model was able to replicate some human decision behaviors.

1. INTRODUCTION

Multi-agent systems (MAS) have been already used to model human decision making processes (e.g [19, 17]), and many successful applications have been derived from these works in various fields (e.g. economics [14], electronic commerce [7]). MAS seem appealing for human decision making because they capture the two levels of decision processes: the *individual level* (i.e. agent level), where each decision process could be modeled, from the reactive to the more cognitive one ; and the *collective level* (i.e. system level), where one has to model interactions among agents, communication between them, coordination, etc. For instance, in the field of Computational Economics, most works used rather reactive (zero-intelligence or zero-intelligence plus) agents and large-scale interactions in order to exhibit interesting market properties [14]. Other works would use more cognitive agents, mostly based on the BDI (Belief Desire Intentions) architecture [17].

When reactive (or zero-intelligence) agents are used, the emphasis is made on *emergence*: from a simple individual computation process, a global collective behavior emerges. This is consistent with the Artificial Life principles, stating that most of the complex phenomenon we observe in our world should be built from the bottom-up. This approach offers a variety of behaviors and phenomena at the macroscopic level. For instance, in the case of Financial Market Simulations, with few equations, reactive models could lead to equilibrium, oscillations, non equilibrium states, bubbles, that is to many phenomena observed in the real world at the macroscopic level. However, when one needs to explain these phenomena at the agent-miscroscopic level, the reactive approach suffers from its limitations to model the information processes the human agent may have used in the real world. In order to understand and explain complex social human functions (real markets, organization dynamics, coalition formation), more complex (i.e. more cognitive) models of human mind and actions are needed [4].

In the case of decision making, where can this more complex (more cognitive) theory be found ? In the last years, Classical Decision Theory and Game Theory have been used to design multi-agent systems. This includes classical (e.g. utility-based) theory models, extension of utilities, and Markovian Decision Processes (see [19] for a review), and yields several interesting applications. However, most of them are not compatible with the limitations of human capabilities, as stated by Simon with his concept of bounded rationality. Decision and Game Theories usually imply op-

timization processes, while agents are to explore a quasi-infinite (or exponential-growth) search space. And even if one relaxes this request of optimality, cognitive psychology has shown that humans violate most of the principles underlying Decision Theory Models. These works in psychology have been initiated by the seminal theories of Kahneman and Tversky, where the focus is made on the *heuristics* a decision maker used and the *biases* he/she had during a decision process [10]. Many recent models of decision making are based on these psychological facts, and focus on information processing [13].

This is the path we want to take. To do so, we follow a methodology based on what we called earlier *psychomimetism* [11]: (i) we need a cognitive model of decision based on psychological facts that have shown to be consistent with experimental observations, and (ii) we need to implement this cognitive model within an artificial system as faithfully as possible, so that the behavior of the artificial system gives some insights on the real-human cognitive process.

The remainder of this paper is organized as follows. In the next section, we present the cognitive model used in CODAGE, and then we give its implementation as a MAS architecture in section 3. To illustrate how CODAGE works, we present some results from an experimental financial market simulation in section 4. Finally, we conclude this paper with a discussion on our results, limitations and future work.

2. COGNITIVE MODEL

2.1 Simon's Descriptive Approach

There are three basic types of models: descriptive model, prescriptive and normative. Descriptive models tell us what people do or have done, prescriptive models suggest what people should and can do, and normative models tell us what people should ideally do (in theory). A typical example of normative theory is the Classical Decision Theory we mentioned above. In this paper we focus on *descriptive* theory, that is we try to model real-world human decision making. Broadly speaking, decision making could be defined as the cognitive process of selecting a course of action from among multiple alternatives. However, it should not be reduced to a simple selection of prototyped behavior or a case-based reasoning process, that is to a "déjà vu" kind of strategy. Decision Making is a *construction process*: the decision is built based on complex information processing mechanisms, and deals with various forms of knowledge representations (e.g. features, criteria, rules, etc.). Moreover, this process implies a commitment to the selected action.

To clarify what a decision making process is, we adopt the framework introduced by Simon in 1960 [22], as depicted in Figure 1. The decision process includes three steps. *Intelligence* means here the understanding of the decision situation, that it to identify what the decision is about (the need for a decision), the problem we have to solve and the context. Once this environment has been searched, the *design* phase begins, where a deep analysis of the problem domain and context leads to the identification of all possible options and alternatives. The final *choice* phase is the selection of the most appropriate course of action from the set of possible alternatives produced by the design phase.

The Choice phase may include an optimization process (choosing the best alternative) or not. According to the Satisficing model proposed by Simon[21], the decision maker will chose the alternative that exceeds a particular criterion. Not surprisingly, the Satisficing model is fully consistent with Simon's idea of human Bounded Rationality[20]: humans have limited cognitive capacities, they usually are not able to optimize in most situations. A descriptive model of decision-making should take these limitations into account.

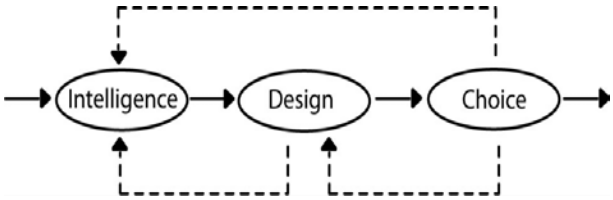

Figure 1: Decision Making as a three-step process (from Simon, 1960)

Finally, one should note that the decision process depicted in Figure 1 is not linear, as it includes feedback loops at each phase. For instance, the alternatives construction at the design phase might need further intelligence. Moreover, each phase incorporate a decision-making process itself, making Simon's decision model a quite complex system. From this framework, many models have been proposed (e.g. see [6, 13] for some reviews). Let us now present our decision model we implemented in CODAGE, which brings a synthesis of several cognitive theories.

2.2 Our decision model

The decision model implemented in CODAGE starts from the three phases of Simon's descriptive theory we described above:

Intelligence: due to limited perception abilities and thanks to its experience[1], the decision maker has the ability to quickly select the important informations. For instance, he/she might be more attentive to an information concerning himself or inducing some emotional reaction. The perception of the decision environment is based on a highly *selective attentional process*. The importance of attentional process in our model partly derives from the framing effects, as first observed by Kahneman and Tversky, where the formulation of a problem drastically influenced decision strategy [23]. This is because subjects focus primarily on a limited number of aspects (e.g. gain or loss in Kahneman and Tversky's experiments) and give the highest importance at these aspects to design alternatives and choose one of them. The concept of *salience* of information implements this principle (Cf. section 3.1.2). Moreover, we incorporate an *anchoring* mechanism, where some information is not continuously encoded : there is a set of relevant discrete value around which the decision maker anchors his/her judgment. This is consistent with the anchoring and adjustment heuristic observed in psychology of decision making [10].

Design: due to its bounded rationality, the decision maker cannot represent the whole world, he/she cannot produce all consequences and all possible actions. However, he/she needs an ability to anticipate short-term events, that is not

[1]As in many modeling works on decision making, we assume our decision maker to be what psychologist called an *experienced* subject. This subject is familiar with the decision task and has developed particular skills to solve similar problems. An experienced subject is not necessarily an expert, but never a novice.

only design a set of alternatives, but also produce some consequences of these alternatives. This will be implemented in CODAGE with a partial *tree of alternatives* where only some branches will be computed and explored (Cf. section 3.1.3).

Choice: in order to chose a satisficing alternative without requiring an optimization process, we adopt a heuristic proposed by Montgomery, the Search for Dominance Structure (SDS) [16]. Broadly speaking, the dominance structure is made of selected attributes that represent the good arguments by which one alternative dominates the others. The decision maker processes the information (the set of attributes) in order to find a dominant alternative. If one is found, it is chosen. Otherwise, he/she will look at a different set of attributes and alternatives. We present in section 3.2 our agent-based implementation of SDS.

Finally we slightly depart from the information flow in Simon's phase model. Instead of a sequential process combined with feedback loops between each phase, we view the three phases as a fully *concurrent and parallel* process. As soon as some information is perceived, the building of the alternatives tree starts and will be updated continuously as new information are coming. In parallel, dominance structures are built and as soon as one satisfying decision is found, the whole process is stopped to make the final decision. Hence this concurrency mechanism enables to take bounded capacities into account, by preventing the decision maker from exploring useless alternatives.

To sum up, our decision model incorporates the Simon's phase model augmented by five mechanisms:

- selective attention (salience) ;
- anchoring ;
- partial tree of alternatives ;
- search for dominance ;
- concurrency.

3. THE CODAGE MACRO-AGENT

In this section, we propose an agent architecture to implement our cognitive decision model. Broadly speaking, the CODAGE agent is a *macro-agent* managed by a cognitive multi-agent architecture. Let us first give some intuitions that support this idea. In section 2.2, we described our decision model with five mechanisms we incorporate into Simon's model. These mechanisms could be viewed as modules of decision subprocesses. As suggested by the concurrency mechanism, we do not believe in a sequential organization of theses modules. On the contrary, we claim that most of decision subprocesses are autonomous entities that interact at different phases of the decision process. Let us take the example of anchoring. In trading, round values (e.g. 50) are easier to be memorized and might be favored as decision thresholds. This number anchoring effect will not only bias the perception process, but also the alternative choice and probably the dominance search (round numbers will be favored to be the attributes of the dominance structure). Given our concurrency mechanism, we adopt the "Minsky's Society of Mind" point of view [15] and propose to model all these subprocess modules as autonomous agents in interactions.

The MAS comprises a set of specialized agents, we call *micro-agents* in order to distinguish them from the CODAGE macro-agent they belong to, and a tree of alternatives implemented as a blackboard system to facilitate information sharing, as depicted in Figure 3 below.

3.1 Knowledge representation

3.1.1 Facts

In CODAGE, we represent facts with a set of attributes, values, and predicates. For instance in a trading game, `$capital[capital_euros]=2501.2` means that the attribute "capital" has a value of 2501.2 and this numerical value is typed as "capital_euros";
`buy_proposition(alice,3,14.5)` encodes the fact that Alice proposed to buy 3 stocks at 14.5 euros each. We add two important mechanisms to encode the information processing prescribed by our cognitive model : salience and tree of alternatives.

3.1.2 Salience

The *salience*[2] of a fact represents its importance within the selective attention process. Each micro-agent ma of global agent pool $\mathcal{P}$ can vote to set the salience of a knowledge K within an alternative C (context, i.e. a possible state of the world). We denotes $v_{ma,K,C} \in [0,1]$ the resulting value of such a vote. If the value is strictly positive, K is added to C with the corresponding salience value $v_{ma,K,C}$ if K is new to C ; if K is already instantiated in C, then its value is simply updated in the equation 1 that gives the final value $S_{K,C}$ of the salience of a given knowledge K within the context of an alternative C as the mean of the micro-agents ' votes:

$$S_{K,C} = \frac{\sum_{ma \in \mathcal{P}} v_{ma,K,C}}{card(\mathcal{P})} \quad (1)$$

Neurobiology supposes that a salient fact is processed more quickly than an non-salient one [8]. In our model, knowledge-source agents will focus their attention on salient facts. This is implemented with two kinds of delays: an *event propagation delay* $d_{K,C}$, which causes agents to be warned later for non-salient facts, and a *reaction delay* $d_{R,C}$ for each rule R activable in a knowledge-source agent.

The propagation delay is 0 if the salience is 1, and rises to a maximum level (γ) if the salience is 0. We use the following function:

$$d_{K,C} = -\gamma . \left(\frac{S_{K,C} - 1}{S_{K,C} + 1} \right) \quad (2)$$

Figure 2 shows how this delay evolves in function with salience.

Let $A_{R,C}$ be the activation of a rule R in alternative context C. It equals the mean of premise 's saliences:

$$A_{R,C} = \frac{\sum_{\pi \in Premises(R)} s_{\pi,C}}{card(Premises(R))} \quad (3)$$

The agent reaction delay is inspired by the ACT-R theory [1, p.1043]:

$$d_{R,C} = I + Fe^{-A_{R,C}} \quad (4)$$

where $I = 597ms$ and $F = 890ms$.

Finally, the total information propagation delay of knowledge K in context C is given by:

$$td_{K,C} = d_{K,C} + d_{R,C} = -\gamma . \left(\frac{S_{K,C} - 1}{S_{K,C} + 1} \right) + I + Fe^{-A_{R,C}} \quad (5)$$

[2]Several psychological studies support the concept of salience. Due to lack of space, we suggest this review of salience effects [9]

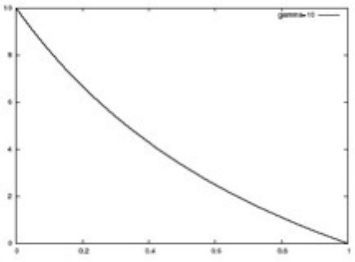

Figure 2: Propagation delay as a function of salience ($\gamma = 10$)

Our mechanism of propagation delay has two major benefits:

- the system is more robust to information permutation: even if a low-salient information is added prior to a high-salient one, the latter will be considered first.
- it enables the partial exploration of the tree of alternatives, since the micro-agents will act based upon the most salient facts. Alternatives based on low-salient facts will not lead to further consequences exploration.

3.1.3 Tree of Alternatives (TA)

In CODAGE, the knowledge that the decision-maker has about the world is encoded into a decision tree[3], as the one depicted in Figure 4.

Each node is an alternative that represents a possible state of the world (past, current or future). TA is a decision tree, as in decision theory, but it will be only partially built and explored to be consistent with bounded rationality. TA works at a symbolic level: each alternative represents an instantiation context in which each micro-agent may add a fact and/or an action into the tree: this is a way to share information between micro-agents. Each fact in the tree has a salience that measure its degree of importance.

Arcs between alternatives nodes represent *transitions* in time, that what produce the transition from one alternative (parent) to another one (child). We implemented two types of transitions that triggers the change to a new state of world:

- *action* transition: a possible action, performed by the macro-agent (myself)
- *fact* transition: the probability that some attribute will have a certain value (e.g. the final stock value will be 56.2 Euros at the closing of the market) or that an other agent perform some action (e.g. bob has sold 5 stocks to alice at 14.6 Euros).

TA could be viewed as a *blackboard* system. As one knows, the opportunistic control of knowledge sources (the micro-agents in our case), that is running the right agent on the right data at the right time, is a tricky issue in blackboards [5]. In our model, there is no fixed agenda to select one agent at a time: each agent is autonomous, and is able to modify data on the decision tree whenever it needs to. From a computer implementation point of view, it is a full multi-threading process. To preserve data coherence and integrity inside the tree, we implemented a mechanism to *solve eventual contradictions*. Any agent can signal a contradiction inside a given context C. In this case, the blackboard removes the two contradictory facts from C, creates two children of C (C_1 and C_2) and instantiates the two incompatible facts in two separated contexts. This method preserves the existence of the two solutions while avoiding the contradictions.

[3]We do not assume that a human decision-maker actually has such a decision tree inside his/her head. This is just a convenient modeling tool to tackle alternatives management in our model.

3.2 Agents

Each agent encodes a subprocess of the decision system, like an heuristic, an inference mechanism, perception, etc.

The *perception agent* (abbreviated as **PER** in the remaining part of this paper) imports informations from environment: e.g. buy and sell orders, accepted transactions and so. This knowledge is introduced at the root of the TA as symbols, predicates and variables. Initial salience values are set, depending on decision maker's habits and experience (what he/she is used to consider as important information)[4].

The *egocentric agent* (**EGO**) helps the macro-agent to selectively enhance the salience on every facts and actions he/she is involved in (e.g. the orders he gave, the proposals he made).

The *world rules agent* (**WRU**) contains the knowledge about the world rules. It encodes the main rules and constraints within the environment like the possible actions (e.g. in our simulated game, a trader can emit buy or sell order, or cancel a previous order), the forbidden actions (e.g. to buy with a null capital), and some anticipated consequences of actions (e.g. if an order is accepted, capital and bids count are updated according to a particular formula).

The *expertise agent* (**EXP**) contains a set of domain-specific heuristics and strategies the decision maker may use to perform his/her actions. In our example of a trading game, these strategies will increase the salience of critical attributes like total capital, gain and loss. They will give the relevant hypothesis to explore, like buying or selling a share. They also value the different facts (e.g. in term of expected outcomes).

The *anchoring agent* (**ANC**) gives the set of anchoring values, that will be used as reference points. In a predicate where some attribute value is unknown, the anchoring agent enumerates all possible values, and will propose to anchor to an already perceived value or to a given reference-point value, e.g. a value linked to the personal situation of the decision maker, or a constant specific to the problem domain (a national interest rate for instance).

The *uncertainty agent* (**UNC**) encodes the uncertainty of informations in the TA. It (i) sets probability p_K for a fact K to occur, and (ii) sets the probability $Pr(C)$) of alternative context C to occur in the real world.

The *decision agent* (**DEC**) monitors the decision tree and implements the search for dominance. When an alternative is added into the tree, it evaluates it. If this is a *satisficing solution*, the tree building process is stopped, and the action that created this branch is selected. If the alternative is too low (the aggregated utility of this alternative is lower than an elimination threshold), it is ignored. In other cases, the alternative is considered to be studied later, and added to

[4]In real-world applications, we could ask some experienced subjects to give their rankings importance for a set of domain facts, and derive the initial salience from this. However, when we will design a learning mechanism for the salience, the importance of these initial values will be much lowered (Cf. section 5.2 in the discussion)

an internal list. When this list is full, the alternative having the highest aggregated utility is selected. We compute the utility of an alternative A as follows :

$$AU(A) = f(\sum_{C \in Child(A)} Pr(C).u(C)) \quad (6)$$

where $Child(A)$ is a the set of immediate children of A in the tree. $Pr(C)$ the probability given by UNC agent (see above) and f is an utility normalization function, a numerical function valued in $[0, 1]$. For instance, we could adopt CARA (Constant Absolute Risk Aversion) function for risk-averse subjects $f(x) = -(1/\rho).e^{-\rho.x}$, where $\rho \in [0, 1]$ is a risking factor.

The utility $u(C)$ of an alternative C is given using a classical multi-attribute utility model, where we use the salience to weight each fact :

$$u(C) = \sum_{K \in C} p_K.S_{K,C}.v(K) \quad (7)$$

where K is a knowledge fact in C, p_K his probability, and $v(K)$ its associated value (e.g. expected outcome) as given by EXP agent. It is worth noticing this influence of salience (computed by the other agents) into the decision process : the most salient knowledge will have the highest weight in the utility function.

3.3 Decision process overview

We summarize the decision process in CODAGE with the flow charts depicted in Figure 3.

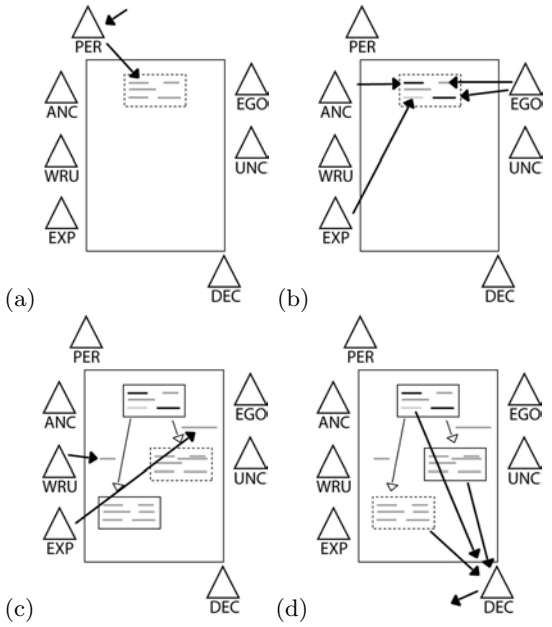

Figure 3: CODAGE decision process overview

Intelligence (a) The perception agent represents the current world in the root of the tree TA. (b) As soon as information appears, the EGO agent look for personal concerns and increases the corresponding saliences. Expertise agent may also update salience based on new information and its heuristics, while ANC agent increase the saliences of anchored values.

Design (c) Based on the most salient facts, agents use the TA to simulate actions, and to anticipate events and other decision maker's actions in a short or medium term. New alternatives are added to the TA, from EXP, WRU and DEC among others.

Decision (d) In parallel with (b) and (c), the decision agent assesses alternatives (utility computation), apply dominance search that leads either to the choice of an action or a selection of alternatives to be further explored.

4. SIMULATION RESULTS

4.1 Simulating an experimental market

This architecture has been instantiated in the economy field. We did not reuse the classical benchmarks used by the *Agent-based Computationnal Economics* community, like the well-known Santa-Fe Artificial Stock Market (SF-ASM), since we want to focus on cognitive aspects of decision-making within a simulated market, while SF-ASM focus on conditions of equilibrium and market behaviors using reactive agents.

We have selected an experimental financial market conducted by Biais, Hilton, Mazurier and Pouget [2]. This experimental market is aimed to study the effects of cognitive biases on the decision of traders placed on a market under asymmetric information. On this market, traders can publish at any time buy or sell orders (fixing the count and the limit price), accept an offer or cancel a previous order. There is a single risky asset, which pays a liquidating dividend at the end of the game which can be A, B or C with equal probability (in the experiment, 50, 240 and 490). Before trading starts the players receive heterogeneous private signals. For instance, if the final dividend is B, half the participants are privately informed it is not A, while the others know it is not C. There exists no communication between participants.

Hilton et al. suggest than the participants try to analyze the actions of the others to find the final asset price. Traders are reasoning in a high-uncertainty context, making them more influenced by **cognitive biases**. The authors study two biases : *overconfidence* and *self-monitoring*. Overconfidence makes the decision-maker to overestimate the representativity of his current informations. Traders suffering of self-monitoring are more attentive to the image they present to others, making them more manipulative.

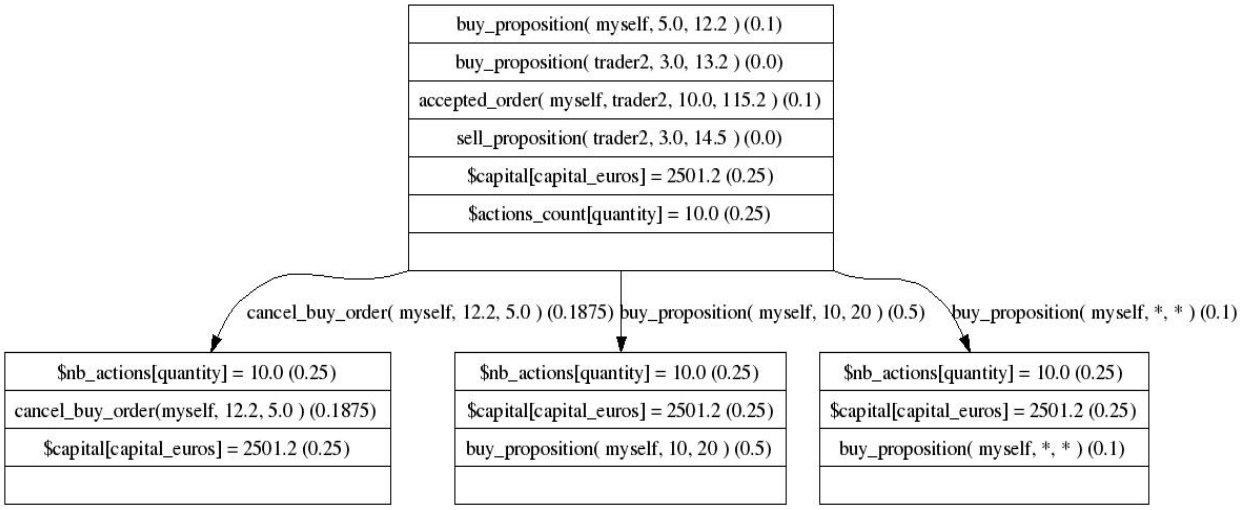

Figure 4: A Tree of Alternatives

We implement the **overconfidence bias** in CODAGE. To do so, we decrease the importance of initial probabilities (to favor current informations). Giving p_i the initial probability, $nb\_observations_K$ the number of times K is observed by the macro-agent, and $total_nb\_observations$ the total number of observations, the probability of a fact K is given by :

$$p_K = \frac{\beta.p_i + nb\_observations_K}{\beta + total_nb\_observations} \quad (8)$$

The modification of the β parameter of UNC agent modifies the sensitivity of personal experience. The self-monitoring bias seemed to be too general to be implemented yet.

The other experimental settings are as follows. We use the decision equations (7)-(8) described in section 3.2, with f set to a simple mean function, and $v(K)$ set to fixed randomly chosen values (no prior knowledge). Finally, we use here two instantiations of ANC agent : one for quantity values anchoring, and the second for prices anchoring. Each ANC agent only favor a set of discrete value (e.g. price value or quantity value), according to a salience anchoring curves like the one depicted in Figure 5. In this Figure, the quantity values are discretized using a step equals to 5, other values will a null salience value :

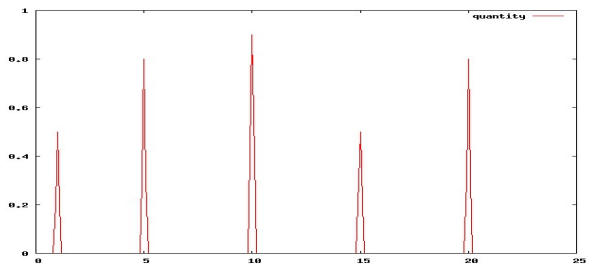

Figure 5: salience anchoring curve for quantity

4.2 Example of simulation

To see how CODAGE implements the experience described above, let us examine a tree generated by our program depicted in Figure 4 above. The process that generated this tree is the following:

- the *perception agent* added facts in the root alternative. At this time, no fact is salient, it is the raw perception.
- when a fact is added, an event "NewNonSalientFactEvent" is sent to all agents. Agents dealing with salience vote for facts : EGO agent votes for all facts concerning this trader, the ANC agents vote for salience according to their own salience curve, and the EXP agent highlights facts useful for trading (salience is displayed between brackets on the figure).
- each time a salience is modified, an event "NewSalientFactEvent" is sent with a latency, computed using Equation 5 . Each agent can react. Here, the WRU agent has proposed to cancel a previous offer or to emit a new buy order.
- when an agent proposes a new action, the TA copies salient facts (over an given recopy threshold) in the new alternative.
- WRU has added an incomplete predicate $buy\_proposition(myself, *, *)$, which contains two undefined variables : count and price. The ANC agents propose first the most salient values, here 10 unities and 20.0.
- at each alternative modification, the DEC agent evaluates - if possible - the alternative, and selects it if it is a satisficing one.

4.3 Overview of market simulation

An overview of the market simulation is displayed in Figure 6, which shows offers (plain) and demand (dotted) curves, and the trades (squares). During a primarily period, the agents put orders that are too riskless for being accepted (low offers, high demands). Then the EXP agent modifies salience of facts leading to a compromise (we supposed it was one of the trader's general heuristics). Traders will trade on this basis. Since traders use values generated by ANC agents, only anchored values will be used in the market.

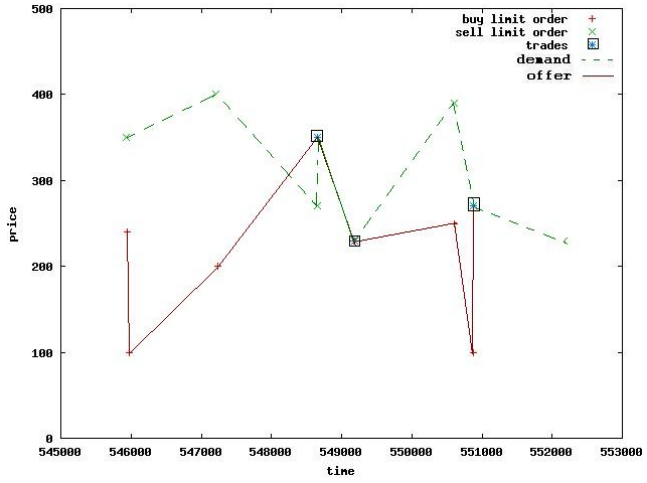

Figure 6: Biais et al. 's market simulation (extract)

5. DISCUSSION

In this paper, we propose the CODAGE approach to model human decision-making, where the decision-maker is modeled with a multi-agent system. Following psychomimetism, we designed a cognitive decision model based on psychological theories. We implemented this model with a specific multi-agent system architecture, made of a set of specialized cognitive agents that share information using a tree of alternatives TA. We gave some simulation results, and have shown how a cognitive bias could be implemented into the system. Now that we have fully described our approach, it is easier to compare to related works. Due to lack of space, we limit this comparison to the most used cognitive architecture in MAS : BDI.

5.1 CODAGE and BDI

Belief-Desire-Intention (BDI) agents have been very popular to implement cognitive processes, including decision making [18, 17]. Based on the philosophical concepts of intentions, plans and practical reason as developed by Bratman [3], it involves two important processes: deliberation where the agent commits to a particular plan, and means-end reasoning where the agent builds the possible options (plans). The agent *intends* to do what will achieve its *desires* (goals) given its *beliefs* about the world. An intention means an action the agent commits to. The question arises whether a BDI architecture could implement our cognitive decision model, and to what extent the CODAGE agent differs from the BDI framework. BDI and CODAGE do have things in common. First, they both try to account for bounded rationality: they incorporate partial exploration of states (alternatives in CODAGE, plans in BDI). Second, they both implement Simon's three stages decision model: in BDI, intelligence includes beliefs building and beliefs revision, design includes means-end reasoner to generate options and filtering, and choice includes deliberation.

However, they differ from several points. At first, it should be noted that BDI theory intends to capture rational behavior as a combination of deliberative planning and alternatives selection. It is strongly goal-oriented, and is aimed to produce plans, i.e. organizing a sequence of actions through time. In CODAGE, we adopt a broader - more abstract view of decision-making, where actions could be selective (e.g. buying a particular stock at a given price) or more complex (e.g. executing a plan). We focus on how possible actions (alternatives) are built, explored, biased and interact with other subprocess like perception and choice. We propose a descriptive theory on how a decision-maker may process information to do so. Second, CODAGE includes several mechanisms derived from psychological theories of decision-making (selective information, anchoring, search for dominance, miscalibration bias) which is not the case in original BDI architecture[5]. Last but not least, as we mentioned above, BDI is a sequential process. In CODAGE, we believe that most of the subprocesses involved in decision-making are independent and concurrent, they influence each-other at several phases within the Simon's model and therefore should be implemented as autonomous agents in interaction within a MAS. At this early stage of our work, we are aware that this strong concurrency assumption needs further validation (we discuss the validation issue in 5.2 below).

To sum up, BDI and CODAGE do not tackle the same issues, and are not exactly concerned with the same kind of cognition process: CODAGE focuses on alternatives and decision-making while BDI focuses on plans and reasoning. Therefore, when the emphasis is made on planning, nothing prevent from using a CODAGE agent to select a plan within a BDI architecture. Similarly, one could add a BDI agent within the MAS architecture in CODAGE in order to implement some practical reasoning and planning process within a complex decision making. Again, this is yet a theoretical view, and further work is to be done in that direction to study the mutual benefits of BDI and CODAGE.

5.2 Limitations and future work

At first, we need a more complete experimental validation of our model. In section 4, we presented some experimental results of the Biais et al 's experimental market that are encouraging as the global results look like the one observed in the experiment. CODAGE is a "white box" which produces a decision process to explain human data in a human-readable form. However, we lack many informations and expertise about this experiment, since we did not have access to it. As many symbolic systems aimed to model mental behavior, we need many informations (heuristics, anchors, initial probabilities, game rules...) to be inserted into the agents. We are now looking for an experimental market to set up, with an associated methodology to define how the necessary knowledge will be obtained. Concerning the validation process, we could use external experts (e.g. economists, traders) to assess to model and/or we could put real decision makers "into the loop", that is we have real decision makers that play against our artificial macro-agents.

Second, concerning the current model itself, one shall note that we introduced saliences only for facts and not for alternatives. But, when the tree of alternatives is enough developed, too many branches might be explored simultaneously. This could affects the stability of the system, and is not "cognitive-like" as it violates bounded rationality. There-

[5]Recently, Norling proposed to incorporate some elements of Folk Psychology into BDI, by adding an ability to learn to recognize situations and select appropriate plan based upon this [17]. This is done by adding a metal-level plan with a Q-learning reinforcement algorithm to select plans. However, the rest of BDI architecture remains unchanged

fore, we need to implement the salience notion at alternative level, allowing only one alternative to be salient at the same time. We need to determine the rules to manage this salience of an alternative, that is to define what makes an alternative salient.

Third, we need to incorporate *learning* into the system, so the CODAGE agent becomes more adaptive. In order to overcome the influence of prior knowledge, and to enhance the reliability of the decision system, we plan to introduce reinforcement learning, where the critical parameters will be affected by the results of actions. The first step would be to have salience values learned. To do so, we could use the reinforcement learning of the RALF neural network, a cognitive architecture designed to set the parameter values in order to get a positive reward as much a possible (RALF does not optimize reward, but find a satisficing solution) [12].

Finally, the CODAGE architecture is intended to be as much generic as possible. It could be viewed as an agent-based decision framework where different decision heuristics and biases could be implemented. We should move further into that direction, and try to incorporate new types of agent (e.g. emotional), new kinds of biases and heuristics.

Acknowledgments

We woud like to thank Nicolas Sabouret for helpful discussions and comments on early versions of our model.

ABSTRACT

Modeling dynamical systems composed of aggregations of primitive proteins is critical to the field of astrobiological science, which studies early evolutionary structures dealing with the origins of life. Current theories on the emergence of early life focus either on RNA-world models [2, 3] or protein world models [4, 5]. Traditional modeling based on either model are generally either too slow to converge or too simplified to provide good tools for exploring the trade-offs in the early stages of the emergence of life. This paper focuses on protein-world models and discusses how to model protein aggregations through a utility based multi-agent system. We define agents to control specific properties of a given set of proteins. These properties determine the dynamics of the system, such as the ability for proteins to join or split apart, while additional properties determine the aggregation's fitness as a viable primitive cell. We show that over a wide range of starting conditions, there are mechanisms that allow protein aggregations to achieve high values of overall fitness. In addition through the use of agent-specific utilities that remain aligned with the overall global utility, we are able to reach these conclusions with 50 times fewer learning steps.

1. INTRODUCTION

In this paper we show how multi-agent systems can make an important contribution to the field of astrobiology - the study of primitive ecosystems that occurred early in Earth's history and may be present of other planets. We focus on the subfield of "non-genomic evolution," involving the evolution of protein ecologies that do not contain nucleic acids (DNA and RNA) which form the basis of modern evolution. Protein ecologies are important since simple proteins are easier to make through natural processes than nucleic acids and it is thought that life on Earth might have started with these ecologies. The significant feature of protein ecologies is that unlike nucleic acids, proteins cannot directly replicate themselves. As a result, non-genomic evolution is concerned with the global behavior of the entire protein ecology and its ability as a whole to form new protein ecologies. It is therefore a good domain to use multi-agent systems to model the interactions between proteins and the emergence of specific protein ecologies.

The study of non-genomic evolution seeks to find the initial conditions and mechanisms that must be present to form self-sustaining protein ecologies [6]. Unfortunately with current knowledge it is impossible to directly simulate the evolution of a protein ecology. Direct evolution of low-level chemical processes has limited promise, because of the computational difficulties in creating a simulation that would encompass a full planetary ecology. In principle, feasible simulations can be obtained by modeling the higher level dynamics of protein interactions that map a protein's chemical structure (amino-acid sequences) to probability distributions over possible functions. However, because at present few of these mappings are known, a meaningful simulation at this level is not possible. As a consequence non-genomic evolution is currently analyzed using "plausible" models for the dynamics of the protein ecology [4, 5]. These simplified dynamical models are then run and are evaluated based on a global utility function. This global utility abstractly measures the value of the resulting protein ecology. Unfortunately creating a model that leads to a good final ecology is laborious and extremely time comsuming.

This paper shows how learning agents can be used to improve this modeling process by having agents automatically learn parameters of protein ecology models that lead to high global fitness, allowing more complex and meaningful models than the ones currently used in the astrobiological community. In this approach agents choose properties of individual proteins that affect the dynamics of the system (such as a protein's ability to split other proteins) as well as

protein properties that are important in producing a viable ecology, such as the ability of an ecology to produce lipids needed for a cell membrane. In a continuous process, agents choose protein properties while the distribution and number of proteins is being updated through the dynamics of the ecology. Using reinforcement learning, the agents attempt to make choices that lead to high global fitness, determined by a given utility function evaluating the ecology's viability. In our experiments the mapping between the proteins' properties and the ecology's global utility is more complex, indirect and realistic than in the models previously used in the astrobiological community. As a consequence ecologies that are able to achieve high fitness provide a better example of mechanisms that can lead to self-sustaining protein ecologies.

Section 2 describes the underlying principles and previous work associated with non-genomic evolution. Section 3 mathematically describes the model used in this paper simulating the dynamics and evaluating ecologies of proteins. Section 4 shows how learning agents are used to optimize the properties of the proteins so that the entire system achieves high global fitness. Section 5.1 presents results from simulations of the system showing that ecologies with high global fitness can be found quickly. Section 6 then discusses the significance of these results to the field of astrobioligy, and provides future directions in which multi-agent systems can be used to benefit this study.

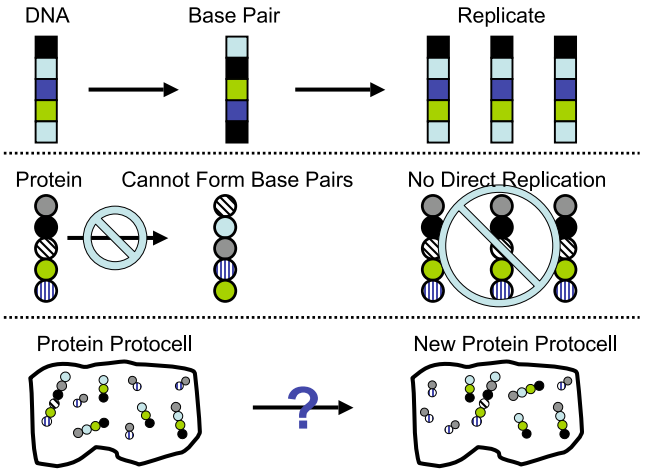

Figure 1: Replication of Proteins. DNA and RNA can form base pairs and directly replicate their sequences. Proteins cannot form base pairs and therefore cannot directly replicate themselves. However as a system, a group of proteins forming a protocell may be able to replicate by creating other protocells with approximately the same characteristics.

2. BACKGROUND AND PREVIOUS WORK

All current life is based on organisms replicating through information coded in their DNA (Deoxyribonucleic acid) or RNA (Ribonucleic acid). DNA and RNA are composed of sequences of nucleic acids, which can form base-pairs allowing replication of the sequence. Due to their ability to replicate, models of the origins of life based on DNA or RNA are the most popular models [3]. However, DNA and/or RNA based models have many difficulties [6]. Current organisms require a complex interaction between DNA and RNA to survive. Even hypothetical organisms based only on RNA ("RNA worlds") require complicated interactions between different types of RNA [2, 3]. In addition, the nucleic acid sequences which form DNA and RNA are difficult to make under the pre-biotic conditions that existed early in Earth's history.

Therefore, there is a growing interest in non-genomic evolution - the study of organisms that do not use nucleic acids. Instead of using nucleic acids, these organisms use only proteins. The non-genomic evolutionary model of primitive organisms has the advantage that the proteins are made of sequences of amino-acids, which have been shown to be made under conditions similar to those that existed in Earth's early history. However, since amino-acids cannot form base-pairs, unlike nucleic acids, proteins cannot be directly replicated (Figure 1). Therefore the field of non-genomic evolution focuses on global properties of protein ecologies to see if protocells (precursors to cells which have some properties of cells such as having a membrane, but do not have all cell functions or cell components) formed from these ecologies can produce new protocells [2, 6]. Understanding the combined behavior of the ecology is paramount in order to ascertain the potential place of nongenetic evolution in the history of life on Earth.

While recent laboratory and computation progress has been made in understanding self-replicating protein ecologies, we are still far from being able to precisely model the evolution of a protocell based on its constituent proteins [4, 5, 7, 8, 11]. As a result current models are greatly simplified, using high-level assumption about the dynamics of the system [6]. One of the few models for non-genomic evolution is described in New and Pohorille [6] and is based on the relationship between the length of the protein and its efficiency - the percentage of time it succeeds in performing operations on other proteins. In this model, proteins perform two operations: hydrolysis and ligation. Hydrolysis is the process of decomposing a protein, whereas ligation is the process of building a new protein by joining two proteins. In this model the efficiency of ligation and hydrolysis are based on Gaussians, with longer proteins generally being more efficient. The fitness evaluation of the protocell in this model is based on protein length with longer proteins being evaluated higher than proteins with shorter length. The computational experiments performed with this model show that protocells become more fit with time. However, in this model the fitness evaluation is only concerned with the efficiency of two functions while numerous other properties are required for a viable protocell, such as a protein's ability to produce cell-membrane building lipids.

In this paper we will expand on these results and develop a more complex model of non-genomic evolution with the help of a multi-agent system. This setup differs from previous ones in that efficiencies that the proteins attain at certain tasks is determined by the actions of learning agents, allowing many more degrees of freedom in the dynamics of the evolution. In addition the proteins have more functions besides their ability to break and build other proteins. Finally the global utility used in evaluating the fitness of the protocell takes into account the distribution of all the protein functions in the protocell.

3. THE PROTOCELL MODEL

The model of the primitive protocell used in this paper is based on different protein types performing different tasks within the protocell and contributing differently to the fitness of the protocell. In this model a protocell has a set of proteins of various types. The two most important types of proteins are combiner and breaker proteins. Combiner proteins take two other proteins and combine them into a single protein (ligation). Breaker proteins take a single other protein and break them into two separate proteins (hydrolysis). Other protein types have important functions such as lipid production for cell walls, energy production and energy transport. However in our model, these other proteins do not actively contribute to the dynamics of the system and are only important in evaluating the final viability of the protocell as defined by the system's global utility.

3.1 Global Utility

For a protocell to survive and thrive, it needs different types of proteins performing different tasks. Certain types of proteins are needed for building cell membranes, while others are needed for tasks such as energy production, energy transportation and chemical exchange. If a cell has a poor distribution of proteins, such as having no proteins for building cell membranes, it will be unlikely to survive and should receive a poor utility. Our model makes an abstraction over the different types of possible proteins, ignoring their low-level functions. We only assume that there are optimal numbers of each type of protein and we use an exponential decay to assign utility to off-optimal distributions.

To formally define the global utility of a protocell, let there be k possible types of proteins and let y_i be the desired amount of proteins of type i in the system, while x_i represents the current amount of proteins of type i present in the system. We choose the functional form $x_i e^{-\frac{x_i}{y_i}}$, which takes its optimal value of 1 when $x_i = y_i$, to describe how close we are to the desired number of proteins performing function k. The intuition behind this choice is that there is an optimal amount of a particular protein needed in the protocell. If there is less than that amount, the protocell would not function properly, and if there is more than that amount, the protein uses more resources than needed to perform its task.

The global utility for the protocell is simply the sum of these functions:

$$G(x, y) = \sum_{i=1}^{k} x_i e^{-\frac{x_i}{y_i}} , \quad (1)$$

where x is the vector of the current amounts of each protein type and y is the vector of desired amounts of each protein type.

3.2 Protocell Dynamics

The dynamics of the protocell are determined by hydrolysis and ligation. During ligation, a "combiner protein" joins two proteins into a single protein. During hydrolysis, on the other hand, a protein is broken into two proteins. There are two crucial issues in both operations. First, the combiner or breaker protein has to choose the proteins on which it will act. Second the protein(s) resulting from the operation need(s) to inherit certain properties of their predecessors. These issues will be modeled through concepts of *specialization* and *clustering* respectively.

Based on current theory of non-genomic evolution, it is unlikely that combiner proteins in early protocells were specialized, i.e. they would combine two other proteins together regardless of what type they were [6]. However, it is likely that breaker proteins were somewhat specialized: There were some types of proteins which a particular breaker protein would not break. While the actual specialization dynamics are complex, we will model this specialization by assigning each breaker protein a single type of protein which it will never break. All other proteins will be broken by that protein.

When new proteins are created as a result of combining or breaking operations, they will be assigned types based on the proteins they came from. This assignment will be modeled through the principle of "protein type clusters." In this model we assume that proteins of the same type tend to congregate near each other, forming clusters. In our model each protein belongs to exactly one cluster, though multiple clusters may have proteins of similar types (Figure 2). When a new protein is created as a result of a breaking operation it will tend to go to a cluster of the same type as its parent (though not necessarily the same cluster). When a new protein is created based on combing two proteins, it will go to a cluster chosen based on the properties of the parent clusters. Details of these assignments are given in Section 4.

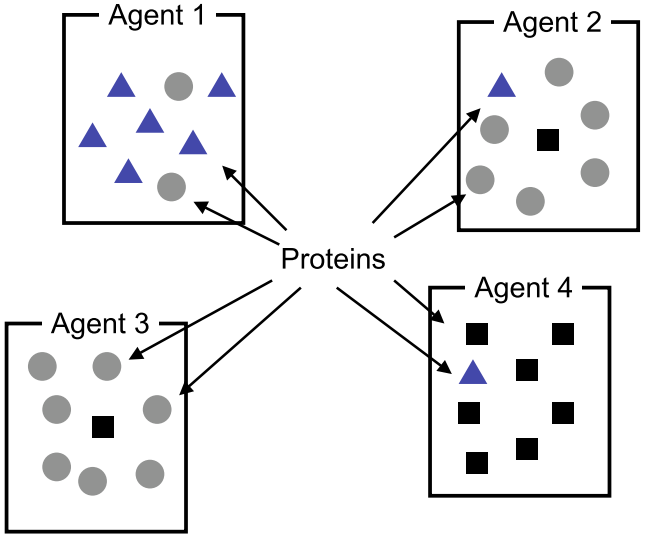

Figure 2: Type Agents. Each type agent determines the protein types in its cluster. Each agent makes decisions about the type of protein in its cluster independently, so proteins in the same cluster can have different types.

4. AGENT FRAMEWORK FOR PROTEIN MODEL

In this paper, agents play an important role in determining the specialization of the breaker proteins and determining the properties of the clusters. Specifically, each cluster will be assigned a "type" agent, whose actions determine the type of each protein in its cluster. Also each specialization

of a breaker protein will be determined by the actions of a "breaker-specialization" agents. This section describes the details of the learning process and the actions taken by the agents.

4.1 Type Agents

The types of the proteins in a cluster are determined by an agent assigned to that cluster. In our model an agent takes a discrete action ranging from 1 to k, where k is the number of possible types. Every time an agent takes an action, its action determines the type of a single protein in its cluster chosen at random. Over time, an agent takes many actions, defining the types of more and more proteins within the cluster. The goal of the agent is to choose types that ultimately lead to a protocell of high global utility. To accomplish this task, our agents learn through a simple reinforcement learning.

The system is modeled using a series of discrete time steps, where each agent takes an action after each time step. At the beginning of a time step each type agent takes an action determining the type of single protein in its cluster. This action is determined by an ϵ-greedy reinforcement learner with a learning table of size k, the number of protein types. Each entry in the table represents the agents expected utility when choosing the action associated with that entry. With probability $1-\epsilon$ an agent takes an action associated with the highest table entry. With probability ϵ it takes a random action. Note that with the ϵ-greedy learner, we would expect a cluster to have proteins of several different types. Most of the time the agent would set proteins to the type associated with highest expected utility, though sometimes it will choose random types with frequency depending on ϵ.

If an agent sets the protein type to something other than a combiner protein or a breaker protein, then nothing happens in the system until the next time step. However, if an agent chooses a protein to be a combiner or a breaker protein, the corresponding combining or breaking operations then take place. If the protein is a combiner, then two other proteins are chosen at random and combined together to form a new protein. If the protein is a breaker protein, then another protein is chosen at random for possible breaking. Whether this protein is actually broken depends on the specialization of the breaker protein, discussed next.

4.2 Breaker-Specialization Agents

Each protocell has several breaker-specialization agents associated with the proteins. A breaker-specialization agent will typically be associated with several proteins, but a protein will only be associated with one breaker-specialization agent. The actions of its breaker-specialization agent determine the specialization of any breaker proteins that are associated with it. At each time step, the breaker-specialization agent takes one of k actions chosen with an ϵ-greedy reinforcement learner. This action then defines the specialization of a breaker protein chosen randomly. This specialization determines the type of protein the breaker protein cannot break: If the protein it operates on during its breaking operation is of the same type as its specialization, then the operation does nothing.

4.3 Cluster Assignment of New Proteins

After a combining or breaking operation, the cluster that the new protein belongs to is determined by the clusters of the original proteins involved in the operation. In our model we want the child protein(s) that result from these operations to end up in cluster(s) that are "similar" to the cluster(s) the parent protein(s) came from. While there are many ways to define the similarity between clusters, our model will use the learning tables for the agents assigned to each cluster to define similarity (Figure 3). For a breaking operation, a protein p in cluster c is broken into two new proteins. To find the cluster c_{new} for one of the new proteins p_{new}, we first compute a vector, v as follows:

$$v = Q_c + e \ , \tag{2}$$

where Q_c is the learning table of the type agent associated with cluster c, and e is Gaussian noise. The cluster for the new protein, c_{new} is then chosen as the cluster associated with the agent that has the closest learning table to v, based on the Manhattan Norm (1-norm):

$$c_{new} = argmin_c \delta(Q_c, v) \ , \tag{3}$$

where $\delta(\cdot)$ is the Manhattan Norm.

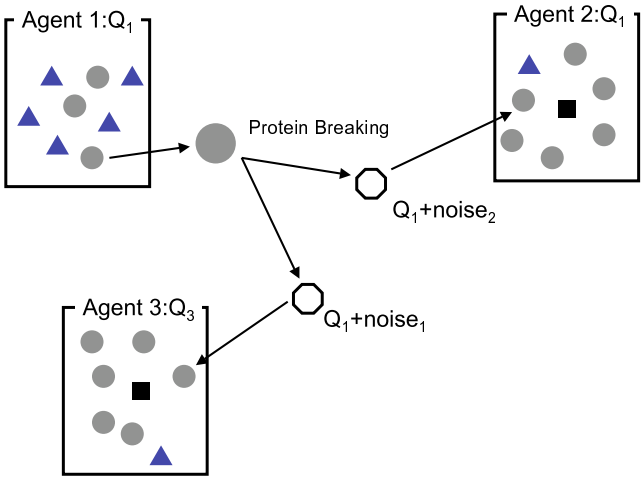

Figure 3: Breaking Proteins Apart. When a protein is broken apart, two child proteins are created. The types of each of the child proteins depend on the learning table of the agent for the cluster the original protein came from. For each child protein a new table is made by adding noise to this learning table. Each child protein is assigned to the the cluster whose agent has the learning table is closest to the proteins table.

For a combining operation a protein p_1 in cluster c_1 is combined with protein p_2 in cluster c_2 to form a single new protein, p_{new}. As with the breaking operation, to find the cluster c_{new} for the new protein we first compute a vector, v. However this time v is a function of two learning tables since p_{new} is created from two proteins. To handle this we combine the learning tables using the element-wise max operator $m(x, y)$, which assigns to each component of m_i the maximum of x_i or y_i: $m_i = \max(x_i, y_i)$. The vector v can then be computed as:

$$v = m(Q_{c_1}, Q_{c_2}) + e \ , \tag{4}$$

where Q_{c_1} and Q_{c_2} are the learning tables of the type agents associated with clusters c_1 and c_2, and e is Gaussian noise.

As before the cluster for the new protein, c_{new} is then chosen as the cluster associated with the agent that has the closest learning table to v, based on the Manhattan Norm (1-norm):

$$c_{new} = argmin_c \delta(Q_c, v) \ , \quad (5)$$

where $\delta(\cdot)$ is the Manhattan Norm. The process for determining the breaker-specialization agent associated with a new protein is parallel, with the learning tables of the breaker-specialization agents being used.

4.4 Agent Utilities

The goal of the agents is to maximize the global utility $G(x, y)$ as defined in Equation 1. However when there are many agents, it is difficult to maximize this utility. This difficulty arises from the fact that a single agent will only have a small impact on the value of G. If an agent takes an action and G increases, that agent does not know if the increases were due to its action or the actions of the other agents. When agents do not have significant influence over their utility as compared to the influence of all the other agents, it usually takes a very long time for them to learn to take actions that maximize it.

To alleviate this problem, this paper has each agent maximize a "difference utility" instead of the global utility. A difference utility is specific to an agents i, and can be computed as follows:

$$D_i(z) = G(z) - G(z_{-i}) \ , \quad (6)$$

where z is a vector of all the actions taken by all the agents and z_{-i} is a vector of all the actions except for the action taken by agent i. The second term of the difference equation is a counterfactual version of the global utility that can be seen as the value of the system without agent i. Therefore the difference utility can be seen as the agent's net contribution to the system. By subtracting this counterfactual second term from first term, the difference equation removes much of the noise caused by the actions of the other agents. The difference utility has been shown to greatly speed up reinforcement learning in many domains, including internet traffic routing, multi-robotic control and satellite communication [9, 10, 1].

The specific form of the difference utility for our global utility, $G(x, y)$, defined in this paper is:

$$D_i(x, y) = G(x, y) - G(x_{-i}, y) \ , \quad (7)$$

where x_{-i} represents the counts of the protein types for a protocell, had agent i had not taken any action. The exact form of x_{-i} depends on the type of action made, especially if the agent made a protein a combiner or a breaker. For all actions let j be the type of protein chosen by the agent. For combiner actions let a and b be the types of proteins that were combined and let c be the type of protein produced. For breaker actions let a be the type of protein broken and let b and c be the types of proteins produced. Then the value of x_{-i} is as follows:

1. $x - e_j$ for non-combiner or breaker proteins ,
2. $x - e_j + e_a + e_b - e_c$ for combiner proteins ,
3. $x - e_j + e_a - e_b - e_c$ for breaker proteins ,

where e_j is a vector where element j has a value of 1 and the other elements are 0. Essentially for combiner and breaker proteins, the proteins created are removed from the counts and the proteins consumed are returned.

5. RESULTS

To test the ability of our agent-based system to produce effective models, we ran a number of experiments where agents had to create models that led to protocells with high utility starting with different protein distributions. In this task as agents had to create a model with the proper distribution of combiner and breaker proteins, and had to ensure that the breaker proteins had the proper selectivity profile. In addition agents had to ensure that the functions of all the proteins were in the proper distribution.

In all the experiments there were thirty agents. In each experiment there were five different types of proteins that were desired in the final outcome besides combiner and breaker proteins (e.g., proteins for energy collection, energy transport, membrane building, and nucleus building). The experiment tested different starting conditions, different desirable combinations of these proteins by selecting an optimal number of each these five proteins, y_1, y_2, y_3, y_4, y_5, along with a corresponding optimal total $y = y_1 + y_2 + y_3 + y_4 + y_5$, and changing optimal conditions.

- The first experiment tested the ability of the agents to create a model that reached a good final equilibrium, starting from y proteins. The intent of this experiment was to determine whether the desired combination of proteins can be reached by rearranging the proteins present at the start.
- The second experiment tested this ability starting from 2 proteins. The intent of this experiment was to determine how few proteins are needed for the process to start, and whether a protocell can develop starting from just two proteins and generate the necessary proteins to perform all the required tasks.
- The third experiment tested this ability starting with $3y$ proteins. The intent of this experiment was to test whether the protocell can cut through clutter and eliminate unnecessary proteins.
- The fourth experiment tested the ability of the protocell to adapt to a sudden change in environment where the optimal number of each type of protein is changed halfway through the simulation. The intent of this experiment was to see the robustness of the protocell to sudden changes in its environment.

5.1 Protocell Evolution from y Proteins

In the first experiment the protocell started with 30 proteins. The optimal number of proteins was 31 (1+2+4+8+16), with $y_1 = 1, y_2 = 2, y_3 = 4, y_4 = 8$, and $y_5 = 16$. Since the starting and optimal number of proteins was almost the same, this problem was relatively simple and the only task of the agents was to create a model that forms the proper distribution and maintains it. However, despite the simplicity of the task, Figure 4 shows that agents directly maximizing the global utility could not produce an adequate model. In fact the initial actions of the agents produced a model that was worse than the starting one, and after 5000 learning trials they still did not manage to reach their initial starting performance. This result is not surprising since many choice

of model parameters can be very destructive, such as creating too many breaker proteins. Since it was very difficult for the agents to learn from the global utility, they had difficulty avoiding these destructive choices. In contrast, agents using the difference utility were able to produce adequate models for this task. By changing the distribution they were able to create a model that achieved a utility of 3.7, up from the initial utility of 2.8. The agents using the difference utility were more effective than the agents using the global utility because the difference utility was much more learnable. The significance of this model to non-genomic evolution, however is minimal. It shows that the proper distribution can be maintained, intuitively meaning that there should be few combiner and breaker proteins.

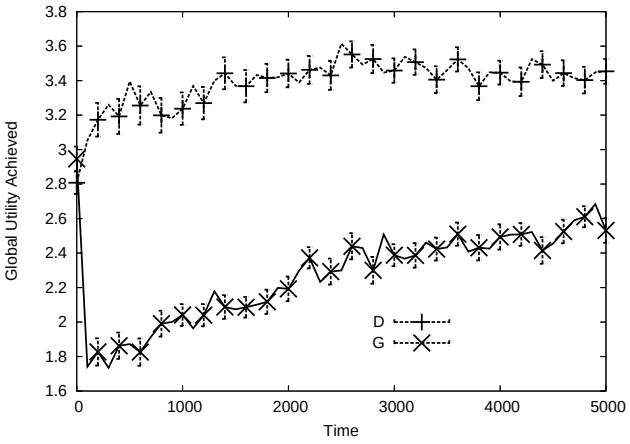

Figure 4: Performance for protocell starting with near optimal number of proteins. Agents using difference utility form adequate model by changing protein distributions to fit targets. Global utility cannot reach original (random) performance.

5.2 Protocell Evolution from 2 Proteins

In the second experiment, the protocell started with 2 proteins. The optimal number of proteins was 31, with $y_1 = 1, y_2 = 2, y_3 = 4, y_4 = 8$, and $y_5 = 16$. This presented a much more difficult setting than the previous one, since starting with 2 proteins, the agents had to create a model that increases the number of proteins by a factor of 15, while providing that the proteins are in the proper distribution. This requires an initial increase in the distribution of breaker proteins to create enough total proteins and a shift in the distribution, as well, to maintain the proper protein levels. Figure 5 shows that agents using the difference utility are able to create a model that leads to highly fit protocells. In this experiment, the performance of the protocell goes from 0.8 to 3.5, a significantly larger increase than in the previous experiment. This larger increase is expected since the initial protocell with two proteins is in a much worse state than the one starting with 30. This experiment shows that a model exists where a protocell with a small number of proteins can grow to one with a large number of proteins and form the proper protein distribution. This has significant insight into the required initial conditions for the formation of protocells. This result demonstrates that with the proper conditions a protein ecology can be formed starting from only 2 proteins.

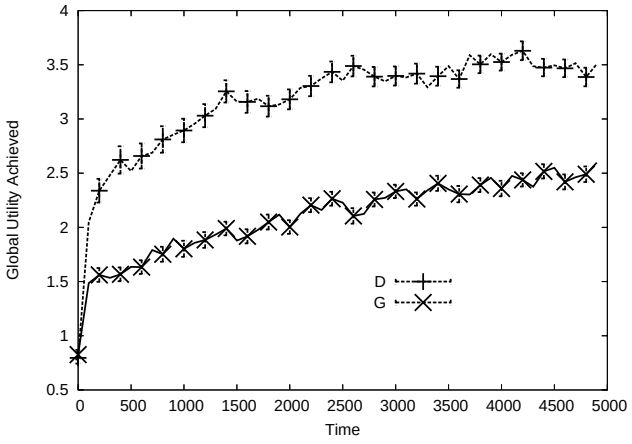

Figure 5: Performance for protocell starting with 2 proteins. Agents using difference utility are able to form model where combiner and breaker proteins are formed, and lead protocell to an equilibrium where there are enough proteins, and the proteins are in the correct distribution.

5.3 Protocell Evolution from 3y Proteins

In the third experiment the protocell started with 95 proteins. The optimal number of proteins was again 31, with $y_1 = 1, y_2 = 2, y_3 = 4, y_4 = 8$, and $y_5 = 16$. This experiment requires an initial increase in the distribution of combiner proteins so that proteins in the initial high population are combined together to form a smaller population. As before results show that agents using the difference utility are able to create a model that leads to highly fit protocells. In this experiment the performance of the protocell quickly shoots from 2.2 to 3.6, but then goes down slightly. This slight reduction in utility is due to the model producing too many combiner proteins that causes the system to overshoot its protein reduction. Figure 6 shows that when there are too many proteins in a protocell, a mechanism can be created to reduce the number and create a proper protein distribution.

5.4 Protocell Evolution in Dynamic Environments

In the final experiment, the protocell started with 35 proteins with an optimal number of proteins of 31. The optimal number of proteins was thirty one, with $y_1 = 1, y_2 = 2, y_3 = 4, y_4 = 8, y_5 = 16$, but at 5000 episodes is changed to $y_1 = 16, y_2 = 8, y_3 = 4, y_4 = 2$, and $y_5 = 1$. This experiment requires the agents to adapt to new model requirements after they have already developed an existing model. The results shown in Figure 7 show that the agents are able to quickly adapt to this change in model requirements.

6. DISCUSSION AND CONCLUSION

In this paper we explore multi-agent models to simulate potential ways in which early non-genomic cells can evolve to perform the tasks required for survival. Through the use of learning agents, we create an abstract dynamical model

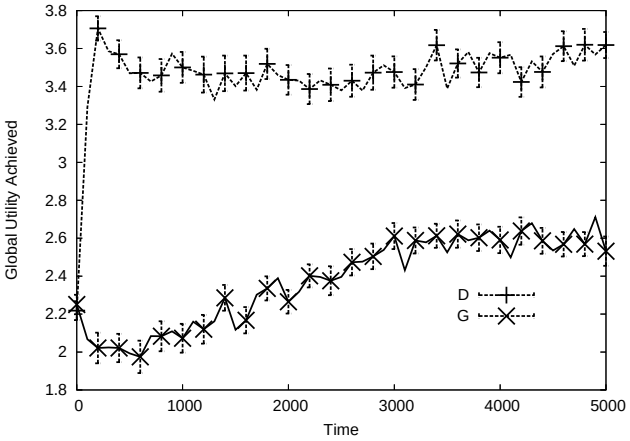

Figure 6: Performance for protocell starting with three times too many proteins. Agents using difference utility are able to form model where combiner and breaker proteins are formed that lead protocell to an equilibrium where there are enough proteins, and the proteins are in the correct distribution.

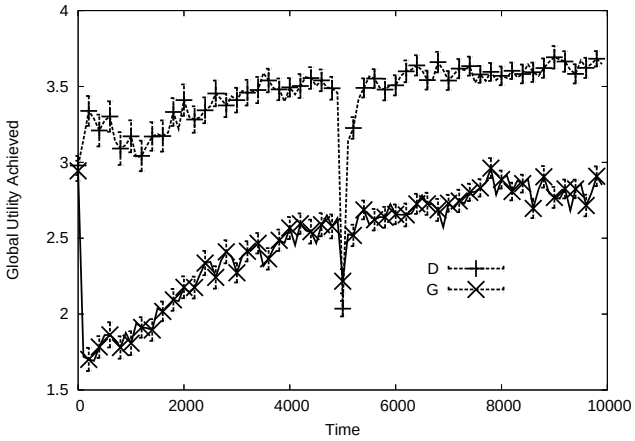

Figure 7: Model Formation for Changing Distribution. When requirements for the distribution of proteins changes at time step five thousand, agents are able to form a model that adjust to change.

for a primitive protocell of considerably greater complexity than previous models. In particular our models include proteins that had many different properties and had more complex dynamics for protein combining and breaking. In addition, while the fitness utility used in other models directly reflects the dynamics of the system, such as efficiency, our fitness utility is only indirectly influenced by the dynamics. Therefore our fitness utility is more realistic and provides many more degrees of freedom for the system to evolve. With our framework, we show that models exists that can produce highly fit protocells from a wide variety of starting conditions.

While our use of multi-agent systems allow us to create models of non-genomic evolution that are more complex than previous models, they are still highly abstract. One issue with the model is that only combiner and breaker proteins affect the dynamics of the system. We are currently working with astrobiologists to help add other dynamics into the framework. Another issue is that the optimal protein distributions used in our global utility of the protocell are somewhat arbitrary. However our framework allows other distributions to be plugged in, and we are also working with astrobiologists to come up with more realistic values.

Even though many details need to be added to our models to increase their biological plausibility, the multi-agent framework provides the power and flexibility to do so and naturally matches the distributed properties of protein-only ecologies. In general more complex evaluation of protocells can simply be implemented through the agent utilities. In addition more complexity can be introduced by adding different types of agents or changing the agents action space. Due to their flexibility we believe that multi-agent systems will become an important tool the study of astrobiology.

ABSTRACT
This paper proposes to use cognitive multi-agent based simulation to facilitate human team formation decision processes. The models of organizational actors are acquired by a data-gathering monitoring system that stores all the interactions that take place in the selected cooperative task. In this knowledge acquisition process, only a relatively small number of team compositions are monitored. The extracted models are used in the agent-based simulation of all the possible team compositions. Simulated team compositions are evaluated and only a small set of the most promising ones is submitted to the human decision maker. An emergence model overrides the multi-agent based simulation in localized situations for which the involved set of agents should not be trusted. The model of the simulation agents is a motivated case-based reasoning system, in which the regular functioning of the CBR is biased to fulfil the agent's motives. The motivation model includes individual motivation and social influence.

General Terms
Algorithms, Experimentation, Theory.

Keywords
Multi-agent simulation, agent motivational model, brainstorms.

1. INTRODUCTION
This paper addresses the KnowledgeAndCulture.org project. The main objective of the project is to use multi-agent simulation of teams of organizational human actors to assist the decision process involved in selecting the best human team for a specific cooperative task. The chosen cooperative task to be studied is the brainstorm, which frames a broad set of specific cooperative processes in a large range of problems and domains.

In some resourceful advanced organizations team formation involves highly specialized psychologists that manually create cognitive maps of all the available people [9]. This approach is a long and very expensive process. In order to improve this extremely resource consuming decision process we propose to use multi-agent based simulation.

The project has reached the first year of its duration therefore no simulation results have yet been produced. However, several other intermediate concrete results have been achieved. This paper presents some of those achieved results and contributions.

1.1 General Approach
Our approach (see Figure 1) is divided in two main stages: organizational knowledge acquisition stage; and simulation and evaluation stage.

In the first stage, a reduced set of human teams is observed while performing the cooperative task (brainstorms, in our case study). The interactions among the human team members are extracted through a computational system and stored into a repository of interaction cases. Only a few team compositions are monitored.

The stored interactions combined with a motivation model used to determine the agents courses of action based on their motives, allows us to create an artificial cognitive agent for each available organizational actor.

In the second stage, different teams of agents are simulated and evaluated according to defined evaluation criteria. Since there are agent teams that have not been observed, we've decided to use models of emergent social behaviour as a way of generating plausible emergent interactions among the agents that represent people that have not been observed working together.

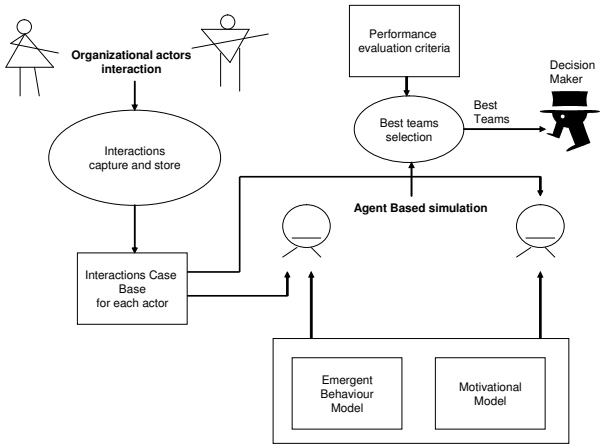

Figure 1. Cooperative work simulation model

The result of the simulation process is the set of a few best teams, which are then considered by the human decision makers. This approach will help focus the human decision process on more promising choices.

1.2 Contributions

The main contributions of the project stem from its decision to use multi-agent based simulation for real concrete organizational problems instead of relying upon toy problems. The requirement to use multi-agent simulation of real organizational problems places constraints on the design of the simulation process and on the computational and conceptual tools to be used. The satisfaction of such constraints continuously produces results for similar future simulation processes.

The first and maybe the most innovative contribution of the project is the designed simulation process. The proposed design has not produced simulation results yet. However the new proposed ideas contribute to and can be essayed in other simulation processes. The proposed simulation design makes two contributions regarding the multi-agent based simulation mainstream: the use of knowledge extracted from actual simulated organizational actors monitored during real interactions in the simulated task, and the integration of cognitive simulation agents with a model of emergent behaviour. In traditional multi-agent based simulation, the agents of the simulation are endowed with pre-defined mental models that are assumed to capture each simulated human actor. In the proposed simulation process design, such kind of pre-defined models are integrated with knowledge extracted from actual organizational actors. Besides, when the behaviour of the simulation agents is not believed to accurately mimic the simulated actors, the model of emergent behaviour takes control over the agents.

The second contribution of the project is the rigorous formalization of brainstorms, which is the cooperative task considered in the project. The formalism models all possible brainstorm interactions between participants.

The third contribution is the definition and implementation of a computational system that supports brainstorm interactions based on the mentioned brainstorm formalization [8], avoiding the complexity of natural language processing. This system monitors the interactions and stores them in a case base for each actor.

The fourth contribution is the definition and partial implementation of a motivated case based reasoning system (CBR). The motivated CBR system integrates a model of motivated behaviour defined in the project with traditional case based reasoning techniques. The flat CBR system (CBR without motivation) has been defined and implemented. Several contributions regarding the use of CBR in large real-life problems have been made. The model of motivated behaviour has been defined and implemented.

The fifth main contribution is the design of two sets of evaluation criteria, domain dependent and domain independent, to be used during the simulation of the cooperative task for ranking the teams according to their performance in the task.

In section 2, we describe the brainstorm formalization. In section 3, we present the model of the simulation agents. Section 4 presents the evaluation criteria used to rank simulated teams. Section 5 presents the chosen simulation scenario. Section 6 provides an overview of related work. Finally, section 7, presents our work's conclusions and plans for future developments.

2. BRAINSTORM FORMAL MODEL

Brainstorms are cooperative tasks in which a set of participants proposes a problem to be solved for which they try to find a satisfactory solution. There are two aspects to be considered regarding brainstorms: the process consisting of proposing a problem and the components of its solution, and the decision process used by the set of participants to accept the proposals being made.

The decision process depends on the structure of the particular group of participants. There are autocratic decision processes, democratic decision processes and hybrid decision processes. The steps of the decision process are not considered in this paper. Final decisions regarding the several alternatives being proposed and discussed during the brainstorm are modelled as if they were the responsibility of a particular virtual actor hereafter referred to as the *Brainstorm Decision Maker*. This option does not commit to a particular decision process. The decisions are made according to the group decision structure but they are represented as if the virtual *Brainstorm Decision Maker* made them.

This section describes the brainstorm processes involved in the proposal of the problem to be solved, the proposal and discussion of the several components of the problem solution. This process will be called hereafter as the *Brainstorm Problem Solving Process*. The formalization of the *Brainstorm Problem Solving Process* encompasses two issues: the formalization of the general problem solving process, and the representation of the individual proposals made by the participants.

2.1 General problem solving process

Traditionally, Artificial Intelligence and Operations Research view problem-solving processes as search problems in the problem space or in the solution space. These search problems are formally represented as graphs in which nodes represent states, and hedges represent actions causing state transformations.

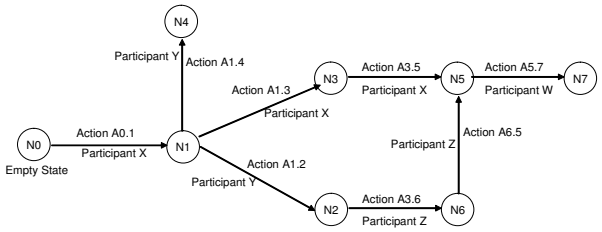

Figure 2. Brainstorm search graph

We propose to represent the general problem solving process used in brainstorms as an acyclic directed graph. In general, nodes represent partial solutions to the proposed problem; and arcs represent actions performed by brainstorm participants that transform the partial solution to which they were applied into a new partial solution.

In Figure 2, the arc from node *N1* to node *N2* is the action *A1.2* performed by participant *Y* in the state contained in node *N1*, which originates the new state contained in node *N2*.

Brainstorm actions always add new elements to brainstorm partial solutions therefore it is impossible to have closed loops in a brainstorm graph. Although it is possible to remove elements from a given partial solution, the removed element is not erased; instead, it is marked as removed. This way, it is possible to capture all the proposals being put forth by all participants during the brainstorm. The result of this policy is that the brainstorm problem solving process is represented by an acyclic graph. Brainstorm graphs are branching structures because it is possible that two or more different actions are performed by possibly different participants in the same partial solution. Different actions performed in the same partial solution give rise to different alternative approaches to solve the same problem.

Brainstorm graphs are not trees because, as shown in Figure 2, it is possible that two alternative courses of action meet in the same brainstorm state (node *N5*, in this case).

By convention, the initial node in a brainstorm graph is the empty state. Usually, the first step in a brainstorm is the definition of the problem to be solved. Problems are introduced in the brainstorm by the addition of a goal to the brainstorm. Among other possibilities, goals may be satisfied by plans of action, by systems design, and by strategy / policy definition, depending on the goal's nature. These elements that directly or indirectly contribute to achieve a brainstorm goal (actions, propositions, objects) are called solution elements. Besides goals and solution elements, brainstorm states may include documents, arguments, different kinds of compositions of those elements, and individual and collective approvals and rejections of proposed elements. As previously explained, collective approvals or rejections are achieved through group decision processes whose model will not be addressed in this paper.

There are brainstorm actions to add and remove (mark as removed) goals, to decompose a goal in sub goals, to add and remove solution elements of any kind (e.g., relationships, classes and objects), to relate existing brainstorm elements (e.g., "this element contributes to this goal", or "from those two elements, it is possible to derive this new element"), to add and remove documentation about any brainstorm element, to add and remove arguments against or in favour of any brainstorm element, to individually and collectively accept or reject any solution element.

2.2 Brainstorm state description

Nodes in the brainstorm graph represent brainstorm states. The formalism used to represent brainstorm states is a propositional version of a SNePS like language [13], which is a specific semantic network representation language. Currently, we use the SNePS graphical notation for being seen by people and an equivalent textual notation to be processed by agents. We are considering using only the graphical notation in future versions of the system if an automated reasoning mechanism can be created that takes advantage of the properties of the graphical notation to improve efficiency.

The brainstorm state representations are used in agent-based simulations. The simulation agents have to mimic the behaviour of the actual organizational human actors therefore they don't need to understand the detailed contents of brainstorm states' propositions. They only need to learn when and how to use the same propositions. Hence propositions are always represented as propositional symbols. However using only propositional symbols is not enough for automated processing therefore the formalism uses classes (i.e., attribute-value descriptions) to better describe propositions.

Since human participants must understand the detailed contents of propositions, the brainstorm state representation language allows adding free text annotations to propositional symbols. Such annotations are often natural language and / or predicate logic based versions of the propositional symbols. Besides being necessary to improve human readability, textual annotations may be used in future applications of the brainstorm representation for instance for the automated generation of meeting minutes or for more demanding automated reasoning systems.

The graphical notation of the brainstorm state representation is a graph in which nodes represent atomic and compound concepts, and arcs represent structural relations between nodes. There are two kinds of nodes: atomic and molecular nodes. Molecular nodes are nodes with arcs to other nodes and represent compound concepts. Atomic nodes do not have arcs to other nodes.

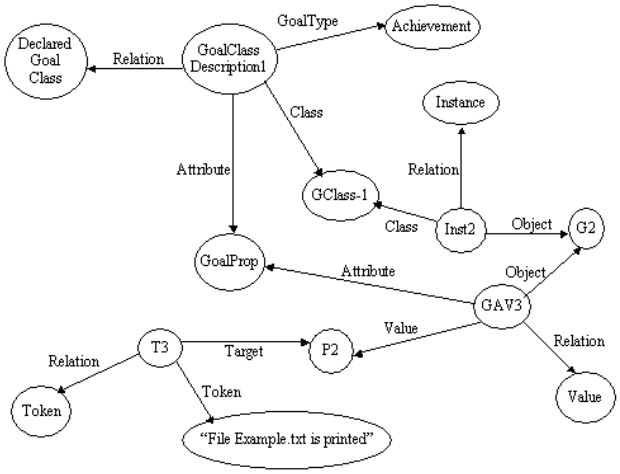

Figure 3. Brainstorm state: Goal definition

In the brainstorm state shown in Figure 3, the molecular node *GoalClassDescription1* describes the goal class *GClass-1* of type *Achievement* with an attribute named *GoalProp* (goal proposition); the molecular node *Inst2* represents the fact that the goal *G2* is an instance of *GClass-1*; molecular node *GAV3* represents the fact that the value of the attribute *GoalProp* of goal *G2* is the proposition *P2*; and finally, *T3* attaches the annotation *"File Example.txt is printed"* to proposition *P2*. All other nodes in Figure 3 are atomic nodes representing atomic concepts. In summary, the brainstorm state of Figure 3 represents the problem to be solved, namely to achieve a state of the world in which *P2* is true (i.e., the file *Example.txt* is printed).

In the brainstorm state of Figure 4, molecular node *Contr23* states that the action of printing file *Example.txt* in printer *LPT1* (molecular node *Act5*) contributes to achieve goal *G2*, which as explained earlier (see Figure 3) is the goal of having the file printed. This statement can now be accepted or rejected by individual participants or collectively by group, according to its decision structure. Acceptance or rejection of this statement would be represented by a propositional molecular node taking another proposition as an argument (*Contr23*). That is, the acceptance / rejection of this proposal would be a proposition taking another proposition as an argument. Since first order logic cannot represent such kinds of knowledge, we have decided to use the SNePS representation language.

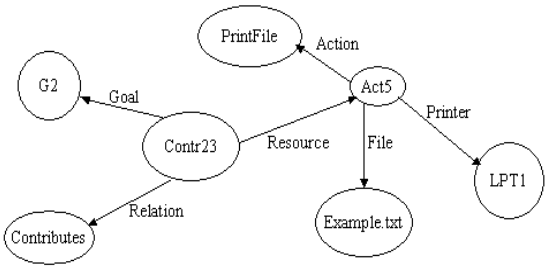

Figure 4. Brainstorm state: solution element

The graph of Figure 4 is textually represented by the following expression:

```
Contr23 # Contributes(resource : Act5 #
PrintFile(printer : LPT1, file : Example.txt),
goal : G2)
```

In the textual representation, the nodes representing relationships (*Contr23*) and actions (*Act5*) are attached to the expressions representing those relationships and action.

2.3 Brainstorm assistance tool (BAT)

The presented formal model allowed us to define and implement a computational system supporting distributed brainstorms with a user interface (BAT – Brainstorm Assistance Tool) [8]. Using the BAT tool, organizational actors participating in the distributed brainstorm only have to choose menu options. Those options are general brainstorm actions like: "propose a discussion problem", "argue", "propose a (partial) solution for a chosen problem", remove previously proposed solutions, and approve and reject previously proposed solutions.

The computational system supporting distributed brainstorms has a distributed peer to peer architecture through which each peer can be used by a brainstorm participant to interact with the others.

This system, besides supporting distributed brainstorms, records the interactions of each participant in a case base. The generated case bases are used in the simulation stage, in which artificial agents representing the real organizational actors interact with each other using the BAT system.

For brainstorms related with particular domains it is possible to create plug-ins capable of converting domain specific actions into domain independent actions used by the computational system (e.g. cell phone selection plug-in).

3. BRAINSTORM SIMULATION AGENT MODEL

The agent model (see Figure 5) comprises two sub models: domain specific knowledge used to control the agent's actions; and the motivational model used to select the agent current motives, to compute their strengths, and to influence the operation of the domain specific action control knowledge. Despite being developed for the brainstorm specific application, the agent model is absolutely independent of the domain.

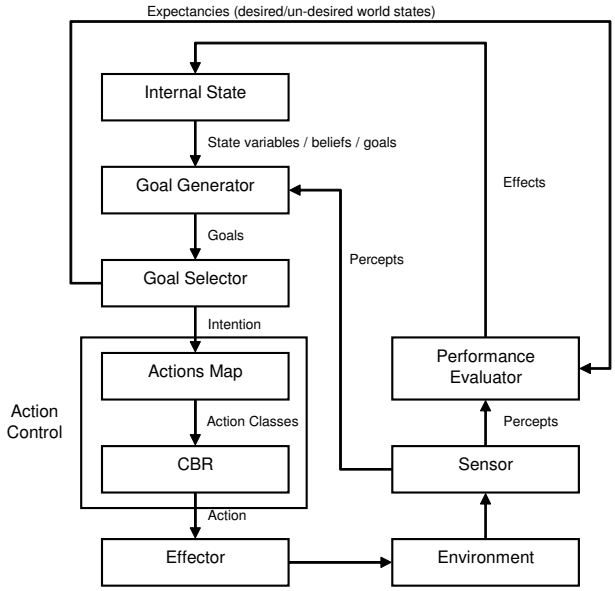

Figure 5. Brainstorm agent model

The domain action control knowledge of the agents of the simulation consists of the case bases extracted and stored during the organizational knowledge acquisition stage. A case based reasoner is used to solve the new problems faced by the agent during the simulated brainstorm. The CBR is influenced by the agent motivation, as determined by the agent motivational model.

According to the proposed motivational model, the agent motivation depends on the agent mental state (e.g., beliefs) and percepts, as suggested by Sloman [14], and also on a set of nuclear internal state variables (e.g., fatigue) [1][3].

We have adopted a BDI (Belief-Desire-Intention) [2][4] approach for representing the agent mental states, mainly for compatibility with a strong agent research community.

The agent acts to maintain the values of its state variables within satisfactory limits. The distance between the current value and the optimal value of a state variable influences the level of motivation to act (e.g. the motivation to sleep depends positively on the fatigue level). We assume that, in brainstorms, the agent's motives (i.e. states that led the agent to act) have two main natures: an individual nature, and a social nature. For this specific activity (brainstorms), we have identified the nuclear state variables in Table 1:

Table 1. Brainstorm agent state variables

Name	Type	Description
Intellectual performance	Individual	Perceived level of mental task performance (interventions quality)
Activity level	individual	Level of brainstorm activity (interventions quantity)
Fatigue	individual	Level of psychological fatigue
Empathy with agent X	social	Level of empathy with agent X
Trust in agent X	social	Level of trust on agent X interventions

The agent model implements three main processes: goal generation and selection, action control, and performance evaluation. The process repeats itself indefinitely while the agent is alive. First, one or more goals are generated with corresponding strengths. In the second step, the agent selects the strongest goal that it believes to be achievable. The selected goal and its strength become the agent current intention. The action control mechanism is guided by the generated intention, leading the agent to act. The performance evaluation process assesses the extent to which the agent's motives have been achieved by the enacted behaviour, and updates the agent mental state and state variables accordingly. These processes are described in detail in the next sub-sections.

3.1 Goal generation and selection

The goal generation and selection process described in this section is mainly inspired by the ideas put forth by Sloman [15].

At the goal generation stage, internal states (state variables, beliefs and goals) and external states (percepts) are evaluated, and goals are generated if certain conditions hold.

Goals consist of a proposition representing a desired state of affairs, a numeric value representing its importance, a numeric value representing its urgency, and a numeric value called strength, representing a heuristic combination of the urgency and importance of the goal.

```
goal(accepted_proposal(proposal),0.4,0.6,0.5)
```

The goal strength is calculated by the following formula:

$$strength = importance \times icf + urgency \times (1 - icf),$$

with $0 \leq strength \leq 1$; $0 \leq importance \leq 1$; $0 \leq urgency \leq 1$; $0 \leq icf \leq 1$.

The *icf* value represents the importance contribution factor for strength.

Goal generation is implemented through a rule-based system (see Figure 6) whose rules are supplied by the agent designer. The rules structure comprises: the generation conditions (beliefs, goals and percepts); a list of alternative mental state and percept conditions (msc/2) used to influence the goal importance; a list of fuzzy rules used to compute the goal importance by evaluating the state variable values; a list of alternative mental state and percept conditions (msc/2) used to influence the goal urgency; a list of fuzzy rules used to influence the goal urgency by evaluating the state variable values; and the goal information structure, which comprises: the goal proposition, the goal failure conditions, the list of goal achievement effects, and the list of goal failure effects.

```
goal_generation_rule(
    (
        percept(brainstorm_problem(Problem)),
        belief(competent_towards(Problem))
    ),
    [   msc(bel(importance(Problem,high)),0.5),
        msc(bel(importance(Problem,medium)),0.25)
    ],
    [   fuzzy_rule_1,
        fuzzy_rule_2
    ],
    [   msc(bel(brainstorm_available_time(0)),0.5)
    ],
    [   fuzzy_rule_3
    ],
    goal(
        accepted_proposal(Proposal, Problem),
        (
            rejected_proposal(Proposal, Problem)
        ),
        [  increase(intellectual_performance)
        ],
        [  decrease(intellectual_performance),
           remove(belief(competent_towards(Problem
           )))
        ]
    )
)
```

Figure 6 – Goal generation rule example

Goal importance and urgency are determined by a set of mental state conditions, and a set of fuzzy rules whose conditions refer to the agent state variables, for example:

- If activity_level is low and intellectual_performance is high then importance is high;
- If fatigue is high then urgency is high;

Only goals whose strength would exceed a certain threshold (i.e. generation threshold) are generated. This prevents the agent from having irrelevant goals.

The agent continuously evaluates its goals in order to generate intentions. At each moment the agent intention is its strongest goal. The importance and urgency of the generated intention is the same as those of the corresponding goal. Intentions are states of affairs that the agent is committed to achieve.

```
intention(accepted_proposal(proposal),0.4,0.6,0.5)
```

The importance and urgency of goals and intentions are not static. They may change as the result of new evaluations of the goal generation rules. Goals may be removed when their strength decreases beneath the generation threshold. Intentions may be removed and their associated action control processes abandoned when their strength decreases beneath the generation threshold. When an intention is replaced by other, the action control process serving that intention is suspended, possibly being resumed afterwards if the originating goal becomes again the strongest.

The described interruption mechanism is inspired on the ideas put forth by Simon [14].

In order to achieve intended states, the agent uses its action control component, described in the next section.

3.2 Action Control

The first step of this process, implemented by the Action Map component (see Figure 5), is to identify the action classes that are likely to contribute to the achievement of the current intention.

The second step is the selection of the action to be performed. This action selection process is provided by the motivated CBR. Traditional CBR systems [5][11] select the case whose problem is the most similar to the current state of affairs. In the motivated CBR model, there are two criteria for case selection: the similarity of the stored case with the current state of affairs, and the extent to which the action class of the action prescribed by the case (i.e., the case solution) may contribute to the achievement of the agent intention, as determined by the first step. Often the solution prescribed in the most similar case is not adequate to the current problem therefore it must be adapted to fit the current problem.

Intention importance and urgency are used to determine the amount of effort to be employed for seeking the case to be used for the current problem, for the comparison between the current problem and each case that is retrieved from the case base, and for the adaptation to the current problem of the solution prescribed by the selected case. In the presence of an important intention, it is reasonable to expect that the agent performs an exhaustive search process, performs a systematic comparison process, and spends the best of its efforts to adapt the prescribed solution to the current problem. However if the urgency of the intention demands a quick response, it is reasonable that the agent assigns less effort to systematic and thorough processes.

These processes may influence state variables. For instance, exhaustive search processes can increase fatigue; and the discovery of a suitable case can increase the perceived level of intellectual performance.

The intention strength influences the way some actions are expressed in the agent world [1]. For example if the agent has the intention "injured(Creature)" and the CBR chooses the action "attach(Creature)", it is expectable that the intention strength influences positively the motor strength used in the attach as well as the number of strikes. The influence of intention strength on the intensity of a given behaviour depends on the type of action to be performed therefore the agent designer must supply the strength influence model for each type of action.

For this specific application (brainstorms) we have chosen the CBR approach because it is suitable to generate new behaviours from the record of past cases. Besides, it is easy to capture specific interactions between organizational actors, in specific brainstorm instances as cases in which the case problem corresponds to the brainstorm state and the case solution corresponds to the action performed by the organizational actor in the specified state. For other types of applications, the agent designer has the possibility of extending the motivational model with the most suitable action control component (e. g. a planning algorithm or a rule based system).

3.3 Performance evaluation

The performance evaluator (see Figure 6) checks the extent to which the current/observed state of affairs satisfies the agent current goals. When a goal proposition is observed in the agent world, the agent performance is positively evaluated and the achievement effects specified in the goal generation rule are computed. When the goal failure conditions are observed in the agent world the performance is negatively evaluated and the failure effects are computed. The effects can be to increase or decrease the value of state variables, and the creation and deletion of beliefs. The magnitude of the effects in the state variables depends on the evaluated goal strength, and on the effort already spent by the agent trying to achieve the goal. The effort is calculated dividing the total time used by the action control processes serving this goal by the total time that the goal persisted. The effort is maximum when all the available time was used trying to achieve the goal, and minimum when no time was used.

3.4 Domain dependent components

Sensors and effectors are domain dependent components supporting the agent connection with its environment. The sensor role is to obtain the world sensorial information (percepts) and to deliver that information to the model components that require it. The effector converts the action descriptions (which include the originating intention strength) in effective actions in the agent environment.

3.5 Process description

In the presented model the goal generation and selection, the action control, and the performance evaluation processes run asynchronously. This option ensures that the agent is capable of identifying sudden internal and environmental changes and readjusting its course of action accordingly, at any time. Namely, it is capable of interrupting or suspending its current motives and attending new high priority motives.

4. SIMULATION AND EVALUATION

During the simulation stage, different teams of agents simulate the cooperative behaviour of the represented organizational actors with the purpose of selecting the best teams. Each team performance is then evaluated according to two sets of criteria: quality of the solution generated as the result of the brainstorm (domain dependent), and quality of the brainstorm problem solving process (domain independent). This section addresses these two steps.

4.1 Multi-agent simulation

The simulation process is carried out by a multi-agent platform populated with cognitive agents, each one representing a different organizational actor. The simulation agents interact within a brainstorm process according to the underlying models of the organizational actors they represent. The main idea is for them to fully interact with each other in the same way as the organizational actors would.

This simulation system is built on top of the agent platform JADE [18], which was built based on the FIPA specifications [19]. The simulation agents were built using component-based software developed within our research lab: XSP [20].

The simulation agents incorporate a brainstorm engine component built for the BAT system. This engine comprises the interaction capabilities needed for each agent to communicate with the remaining agents in the brainstorm.

The remaining capabilities of the simulation agents were developed as separated components that were assembled together with the brainstorm engine. These include the motivational and the domain action control (CBR) components. The emergence behaviour component will be developed as an external sub-system that, under certain circumstances, can influence all agents' activity.

4.2 Simulated Team Evaluation

The evaluation of each agent team brainstorm problem solving process involves the following domain independent criteria:

- Brainstorms taking less time are better;
- Shorter brainstorms (with less states) are better;
- Brainstorms revealing more cooperation among participants are better;
- Brainstorms revealing low levels of indecision and divergence are better.

The first two criteria are simply evaluated and therefore do not need any further explanation.

It is clearly undesirable that a single person proposes most of the solution elements in a cooperative context. Since state transitions are labelled with the identifications of the participants, it is possible to assess if actual cooperation is taking place.

The degree of indecision can be determined considering the number of times that a given solution element is introduced and subsequently removed. And the degree of divergence by evaluating the number of ramifications and reunifications in the brainstorm graph.

5. SIMULATION SCENARIO

We have defined and implemented a demonstration scenario in which to evaluate our proposals. The brainstorm task for the demonstration scenario was that of designing a cell phone specification (set of characteristics) for a specified customer profile. This task is an instance of brainstorm problems in which the solution is incrementally and cooperatively generated through a constellation of components. The same kind of decision process can be applied for instance in house design.

With this purpose, we have identified a set of critical cell phone characteristics, a set of customer's critical characteristics (defining customer's profiles), and also the type of arguments that are likely to be used in the mentioned decision process. The cell phone critical characteristics are those that are more likely to support the customer choice, for example: talk time and video capability. The customer profile is the set of observable user characteristics that can give clues about the customer expectations regarding a cell phone (e.g., the user occupation and the user age). The arguments are used to support or contest solution elements (mobile phone characteristics), based on the customer profile characteristics. For example, a brainstorm participant may argue that, for a customer with eighteen years old, it is necessary that the cell phone has a photo camera. In this case, the argument type is "necessary".

We have implemented a plug-in for the Brainstorm Assistance Tool (BAT) that provides a domain dependent graphical user interface for the described cell phone design task.

Besides the domain independent evaluation criteria (see Section 4.2), the agent team evaluation process is based on the user feedback regarding the cell phone design decision achieved through the brainstorm.

6. RELATED WORK

Agent based simulation is being used in a large variety of problems of different scientific areas, namely it has been used in modelling social processes with the purpose of structuring and exploring theoretical hypothesis. In the mainstream multi-agent based simulation approach, the knowledge used by the agents of the simulation is endowed to the agent by the agent designer [16] [17]. In our approach, the domain knowledge used by the agent is previously extracted from the actual human organizational actor being simulated. This knowledge extraction process is done through a computational system that monitors the actual human actors performing cooperative tasks of the same class of those used in the simulation.

To conveniently simulate the expected behaviour of organizational actors, it was essential to adopt a cognitive approach, namely an agent that has explicit and symbolic representation about itself, about the other agents and its environment, and reasoning capabilities. For those representations, the BDI architecture [2][4] has been chosen since it is a successful and respected theory of human behaviour.

BDI architectures do not formalize the way goals are generated, and they also do not formalize the way goals are selected to become intentions. Some authors [10] have implemented a motivational architecture that works like an extension to the BDI principles, bridging the previously mentioned gaps.

According to Savage [12], motivation is a process where the individual decides what is important to its continued existence and determines the means of achieving the relevant goals. This process is responsible for determining the deliberative human behaviour in all activities, including brainstorm activities.

Simon [14] and Sloman [15] have presented complex and fairly complete conceptual models of motivation, but none are described with the necessary detail for being expressed computationally. Our approach is inspired in the ideas put forth by these two authors but providing the necessary detail for implementation.

Avila-Garcia and Canãmero [1] and Breazeal [3] have presented computational motivation models. These models are far from implementing the properties identified by Simon and Sloman as optimal. No attention is paid to the influence of mental states (beliefs, goals and intentions) in the behaviour choice.

Motivation, besides influencing action control, also influences cognitive processes. This influence is determined by epistemic motivators [6], [7]. This kind of motivators influences the idea formulation, planning and any other kind of reasoning, including CBR. In our motivated CBR approach the amount of effort to be used in the various CBR processes (search, comparison and

adaptation), is determined by the importance and urgency of the motivation (intention) being handled, and the selection of the case to be used depends on the extent to which the prescribed action contributes to satisfy the agent motivation.

7. CONCLUSIONS AND FUTURE DEVELOPMENTS

This paper describes a decision making framework regarding human team formation in which a combination of cognitive multi-agent based simulation and an emergence model is used to simulate and evaluate the performance of all possible team compositions in order to identify a small set of the most promising ones.

In the described framework, the domain specific action control knowledge of each available organizational actor is acquired through a computational system designed to support his or her interaction with the other organizational actors in a selected collaborative task. The acquired models are used by cognitive agents in the simulation stage. This process considerably reduces the human decision-making workload.

The project selected the brainstorm as the test bed collaborative task, created a general model of domain independent brainstorms, implemented the computer system that supports distributed brainstorms, defined the models of the agents of the simulation, implemented the CBR system used for the agents model, and defined the initial set of domain independent criteria used in the performance evaluation of each simulated team composition.

An important contribution of this project is the proposed agent model. This model is an extension of BDI models, since its motivational model bridges two important gaps in that class of models: goal generation, and goal selection (i.e., intention formation).

Recently we have realised that the chosen brainstorm state representation for realistic examples becomes impracticably huge. So we will move towards a sentence based representation. Case comparison is also very resource consuming. Nevertheless, we expect the model of motivation will judiciously constrain the amount of computation assigned to each of the agent's tasks.

The project next steps are to implement the sentence based representation for the brainstorm states, to design and implement the emergence model, and to run the simulation process.

ABSTRACT
Social insects perform complex tasks without top-down-style control, by sensing and depositing chemical markers called "pheromone". We have examined applications of this pheromone paradigm towards realizing intelligent transportation systems (ITS). Many of the current traffic management approaches require central processing with the usual risks of overload, bottlenecks and delay. Our work points towards a more decentralized approach that may overcome those risks. We use new category of the ITS infrastructure called the probe-car system. The probe-car system is an emerging data collection method, in which a number of vehicles are used as moving sensors to detect actual traffic situations. In this paper, a car is regarded as a social insect that deposits multi-semantics of (digital) pheromone on the basis of sensed traffic information. We have developed a basic model for predicting traffic congestion in the immediate future using pheromone. In the course of our experimentation, we have identified the need to properly tune the model to achieve acceptable performance. Therefore, we refined the model for practical use. We evaluate our method using real-world traffic data and results indicate applicability to prediction. Furthermore, we describe the practical implications of this method in the real world.

1. INTRODUCTION
Many social insect species such as ants, bees, and wasps coordinate the activities of individuals in the colony without direct communication or complex reasoning. Instead, they deposit and sense chemical markers called "pheromone" in a shared physical environment (pheromone potential field) that participates actively in the system's dynamics. We will examine applications of this pheromone paradigm towards realizing intelligent transportation systems (ITS).

ITS have spread widely recently. Beyond car navigation systems and traffic information systems [22], various types of sensors and communication devices are being introduced for various kinds of applications. Solving traffic congestion is a serious problem among such applications.

One of the key technologies for solving this problem is traffic prediction. There are traffic information systems which are now operational in many countries. Drivers can easily grasp the current surrounding traffic situations through traffic information systems. However, the problem of traffic information system is that traffic information may be delayed due to communication between the road and data center or due to processing time at the data center. This leads to a driver often receiving traffic congestion data that are different from the actual traffic situation.

Another problem in solving traffic congestion is that current traffic data will become useless after a while on a given route. Traffic prediction techniques can solve this problem by predicting appropriate data for each stage of traffic data on the route. Traffic prediction techniques are widely studied in many institutions [4] and have already been introduced in commercial car navigation systems [23]. Some of such techniques deal with long-term predictions, such as predictions spanning 1 hour to 1 day based on statistical analysis of past data. However, long-term predictions cannot be applied to driving in a small area and cannot predict the innately sharp fluctuation of traffic. Short-term prediction is suitable for driving in a small area and for improving prediction accuracy.

Short-term prediction methods have also been studied [24, 26].However, most of the studies use statistical data of the past. As such, it does not work sufficiently with sharp or irregular fluctuations in traffic.

We propose a short-term traffic prediction method using the pheromone model, which has a relatively simple mechanism that

does not require statistical data. In our method, a car is regarded as an agent or an ant. Each car would deposit some pheromone into a virtual space with its amount based on their sensing of traffic situations.

To implement our idea as an actual service, we use new categories of the ITS infrastructure called the probe-car system (it is also called the floating car system) [19]. The probe-car system is an emerging data collection method, in which a number of vehicles are used as moving sensors to detect actual traffic situations. Our new method realizes traffic prediction by employing a pheromone mechanism and the probe-car information system without resorting to the use of a traffic control center.

We experimented with the pheromone prediction method the basis of real-world traffic data to evaluate its performance. The results indicate its applicability to the prediction of traffic congestion in the immediate future. Furthermore, we describe the relationship between model type and prediction accuracy.

2. PHEROMONE

2.1 Basic Mechanisms

The term “pheromone” (Greek for ``carrier of excitement'') was named by P. Karlson and M. Luscher in the 1950s [11]. Pheromone is defined as a communication chemical that possesses certain meanings that are mutually understood by individuals of the same species. Pheromones have various kinds of functions (flavors). For example, ants use trail pheromone (attractive sign) to guide other ants to food, and bees use alert pheromone (repulsive sign) to inform of disturbance to other bees.

The trail pheromone mechanism has already been applied to certain areas to efficiently solve problems such as the traveling salesman problem [6]. The mechanism works as follows: Ants find food and transport it to their nest, depositing trails of pheromone on their return path. The pheromone diffuses into the surrounding environment and its intensity weakens over time. However, the density of pheromone left on the path where ants have passed most frequently increases. Eventually, pheromone on the shortest path to the food becomes most dense (see Figure 1).

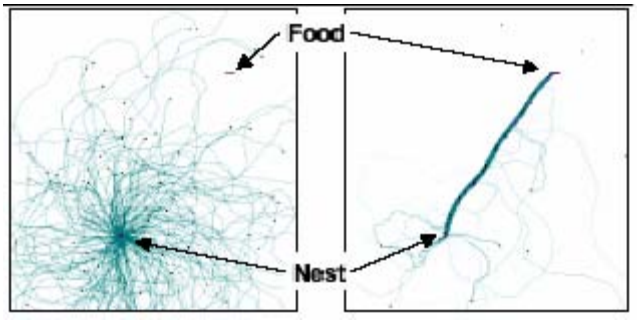

Figure 1: Action pattern of ants which used trail pheromone [20].

On the other hand, bees use alarm pheromone. A leading bee would inform of any danger using alarm pheromone and other bees that follow would avoid the alarm pheromone. This simple mechanism has also been applied to some technologies [16].

2.2 Characteristics

Pheromone is a simple chemical media for delivering information. Although each individual ant or bee possesses just a simple and local behavior rule, they are capable of enabling complex functions. This is largely related with the characteristics of “evaporation”' and “propagation” [5]. “Evaporation” represents old information disappearing as time passes due to the volatile nature of pheromone. This enables other ants to receive the most recent information. “Propagation” represents the characteristic of pheromone spreading out towards the surrounding environment. This allows other ants in different places to receive this information.

3. MODEL FOR TRAFFIC

In this paper, we discuss the use of this dynamism to predict traffic. The model used here will regard cars as ants or bees and will deposit pheromone on the pheromone potential field. Cars equipped with some kind of sensors would deposit multiple pheromone on the basis of sensed traffic information. Other cars that follow their route would avoid traffic congestion by checking the intensity of pheromone.

3.1 Digital Pheromone

We propose a traffic prediction method based on digital pheromone [21]. Digital pheromone is modeled on the pheromone fields that many social insects use to coordinate their behavior. A formal model of the essential components of these fields has been developed and applied to a variety of problems. Digital pheromone is defined as having the following characteristics:

1. Pheromone is information deposited on a certain place by agents when an event occurs (Information aggregation)
2. Deposits of a certain flavor are added to the current amount of that flavor of pheromone located at that place. Total amount represents the information potential of each location (Information fusion)
3. Pheromone evaporates over time thus decreasing its value (Truth maintenance)
4. Pheromone propagates towards the surrounding environment (Information diffusion and dissemination)
5. Each agent is affected by pheromone.(Decision making)

Following the above this definition of digital pheromone, we define traffic prediction pheromone as follows.

1'. Pheromone is information deposited by cars on the basis of the surrounding traffic situation.

2'. Deposits of a certain flavor (certain sensing traffic data) are added to the current amount of that flavor of pheromone located on the road. Total amount represents the traffic situation at each location.

3'. Pheromone evaporates over time. This corresponds to traffic moving towards another location over time.

4'. Pheromone is propagated towards nearby roads. This corresponds to traffic movement along the flow.

5'. Each driver is then affected by the traffic prediction based on pheromone.

3.2 Pheromone Vocabulary

Several "flavors" of pheromone are used to improve system performance. For example, in this study [17], multiple flavors of pheromone such as target, nest and threat pheromone are used to find the optimal path to a target.

We have explored several basic mechanisms essential to the engineering deployment of pheromone mechanisms. In our traffic scenario, there also exist various kinds of factors that affect near-future traffic. We will present three kinds of traffic pheromones and explore the performance of the system for various combinations of these three pheromones. The three pheromone flavors are as follows:

3.2.1 Basic Traffic Pheromone

This is a pheromone of repulsion which informs other cars about the possibility of an increase in traffic congestion. Each car, equipped with a speed sensor and a communication device, deposits basic traffic pheromone according to congestion rate. Generally, speed is used to represent congestion rate, so a car agent will deposit some amount of pheromone depending on its speed.

Let the external deposit of basic traffic pheromone of pheromone flavor *traffic* at time t and location p be $d(\Phi_{traffic},t,p)$. $v_i(t,p)$ is the speed corresponding car ID i and $C(t,p)$ is the set of car IDs within the interval $(t-1, t]$ at location p. Location p represents a road link or some span of a road between intersections. This function is represented as follows.

$$d(\Phi_{traffic}, t, p) = \frac{1}{|C(t,p)|} \sum_{i \in C(t,p)} \frac{1}{v_i(t,p)} \quad (1)$$

Equation (1) implies the following:

- The deposit increases with decreasing speed (Figure 2 (a)).
- The deposit decreases with increasing speed (Figure 2 (b)).

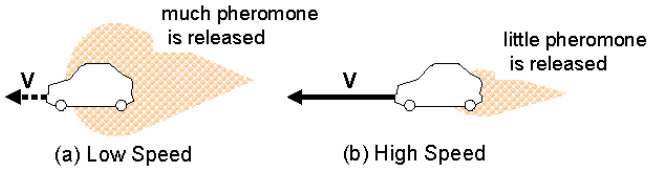

Figure 2: Image of car agents depositing basic traffic pheromone

3.2.2 Braking Pheromone

This is also a pheromone of repulsion which informs other cars about the possibility of an increase in traffic congestion. Each car, equipped with a brake sensor, deposits this repulsive pheromone. Generally, stepping on brakes causes traffic congestion; thus, a car agent will deposit some amount of pheromone depending on the number of times its brakes are applied.

Let the external deposit of braking pheromone of pheromone flavor *braking* at time t and location p be $d(\Phi_{braking},t,p)$. $braking_i(t,p)$ is the number of times stepping on the brakes is performed corresponding to car ID i and $C(t,p)$ is the set of Car IDs within the interval $(t-1, t]$ at location p.

$$d(\Phi_{brake}, t, p) = \frac{1}{|C(t,p)|} \sum_{i \in C(t,p)} braking_i(t,p) \quad (2)$$

3.2.3 Distance Pheromone

Different from above two pheromones, this is the pheromone of attraction which informs other cars about the possibility of a decrease in traffic congestion.

A car equipped with a millimeter-wave radar deposits this pheromone. Generally, the distance between cars increases with decreasing congestion level. Thus, a car agent will deposit some amount of pheromone depending on its distance between cars.

Let the external deposit of distance-between-cars pheromone of pheromone flavor *distance* at time t and location p be $d(\Phi_{distance},t,p)$. $dis_i(t,p)$ is the intercar distance corresponding to car ID i and $C(t,p)$ is the set of Car IDs within the interval $(t-1, t]$ at location p. $T_{distance}$ represents the threshold below which $dis_i(t,p)$ is set to zero.

$$d(\Phi_{distance}, t, p) = \frac{1}{|C(t,p)|} \sum_{i \in C(t,p)} dis_i(t,p) \quad (dis_i(t,p) > T_{distance}) \quad (3)$$

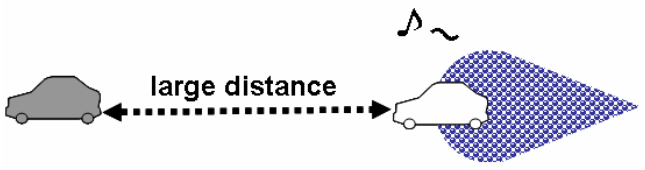

Figure 3: Image of car agents depositing distance pheromone

3.3 Transition Function

Each place maintains a scalar variable corresponding to each pheromone flavor. Our model is based on the pheromone transition model proposed by Brueckner [2]. Brueckner's model is a kind of coupled map lattice (CML) [12] or continuous cellular automaton. It performs the basic functions of aggregation (as mentioned above), evaporation and propagation.

Evaporation: Aggregated pheromone decreases over time due to evaporation. Let the amount of pheromone of pheromone flavor f at place p and time t be $s(\Phi_f,t,p)$. The predicted amount of a single pheromone flavor $s(\Phi_f,t+1,p)$ is represented as follows.

$$s(\Phi_f, t+1, p) = E_f * |(1 - G_f) * (s(\Phi_f, t, p) + d(\Phi_f, t, p)) + g(\Phi_f, t, p)| \quad (4)$$

E_f reflects evaporation of pheromone, the 1-G_f factor calculates the amount remaining after propagation to its neighbors, $d(\Phi_f,t,p)$ represents the total deposits made since that last update cycle, and $g(\Phi_f,t,p)$ represents the total pheromone propagated in from all the neighbors of p.

Propagation: Another fundamental equation describes the propagation received from neighboring places. The transition function of the propagated amount $g(\Phi_f,t,p)$ is shown as follows.

$$g(\Phi_f, t, p) = \sum_{p' \in N(p)} \frac{G_f}{|N(p')|} (s(\Phi_f, t-1, p') + d(\Phi_f, t-1, p')) \quad (5)$$

N(p') represents the upper stream neighbors of location *p* that affect the next status of location *p*. G_f is the propagation rate, which is a function of the pheromone value of the upper stream in our model.

3.4 Combination of Multiple Pheromones

In a previous section (section 3.2), we explained three kinds of pheromone and classified two types of signal (A sign to make a traffic congestion increase and a sign to make a traffic congestion decrease). In this section, we describe how to combine different flavors of pheromone. This mechanism is based on how each pheromone affects predicted link travel time. We propose a combination method of three patterns in addition to a basic model.

First, we describe only uni-flavor pheromone, that is, basic traffic pheromone. When using it, we derive Equation (6). Predicted link travel time is a scaled pheromone amount based on a scaling parameter and the length of each link. Let *Prt(t,p)* be the predicted link travel time, *S* be the global scaling parameter and *l(p)* be the length (*m*) in a link *p*.

$$\Pr t(t, p) = s(\Phi\ traffic\ , t, p) \times S \times l(t, p) \quad (6)$$

Second, we use two flavor pheromones, that is, traffic pheromone (repulsive pheromone) and distance pheromone (attractive pheromone). We derive Equation (7). Distance pheromone makes a traffic congestion decrease, so predicted travel time is given as follows.

$$\Pr t(t, p) = (s(\Phi traffic, t, p) - s(\Phi distance, t, p)) \times S \times l(t, p) \quad (7)$$

Third, we use another set of two pheromones, that is, basic traffic pheromone (repulsive pheromone) and braking pheromone (repulsive pheromone). We derive Equation (8). Braking pheromone makes a traffic congestion increase further, so predicted travel time is given as follows.

$$\Pr t(t, p) = (s(\Phi traffic, t, p) + s(\Phi braking, t, p)) \times S \times l(t, p) \quad (8)$$

Finally, we use the all above three pheromones, that is, basic traffic pheromone (repulsive pheromone), distance pheromone (attractive pheromone), and braking pheromone (repulsive pheromone). We derive Equation (9).

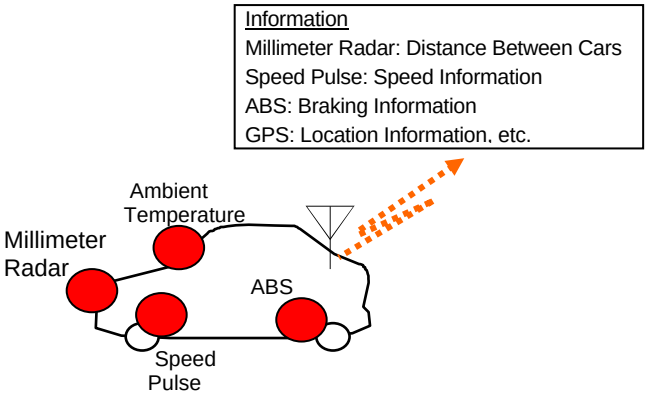
$$\Pr t(p) = (s(\Phi_{traffic}, p) - s(\Phi_{distance}, p) + s(\Phi_{braking}, p)) \times S \times l(t, p) \quad (9)$$

Here, we only used a linear combination of pheromones, and the combination ratio of each semantic of pheromone was tuned by sensitivity analysis.

4. PRACTICAL IMPLICATION

In this section, we discuss the above-described pheromone model as it might be implemented in actual services. To develop the pheromone system, we must first consider its system architecture. An implementation of a pheromone system has two components: the agents (which deposit and react to the field maintained by the environment), and the environment (which maintains the pheromone field and performs aggregation, evaporation, and propagation). Our implementations use an ITS infrastructure which currently exists.

The internet-based ITS project in Japan is moving ahead through public and private sector cooperation to create new categories of ITS services. One of the key technologies is the probe-car system (Figure 4). The probe-car information system utilizes vehicles as mobile sensors for collecting traffic data, which are stored and processed to produce new information useful for providing various public services, among other applications. It can collect data over a much larger area at a much higher precision data, than conventional fixed detectors. Many experiments are carried out using of "taxi-type" or "bus-type" probe-cars in many countries [7, 19]. Moreover, a commercial probe-car service mounted on common vehicles through a cellular network has started in Japan [8]. We use these probe-cars as agents (which deposit pheromone and calculate travel time by reacting to pheromone).



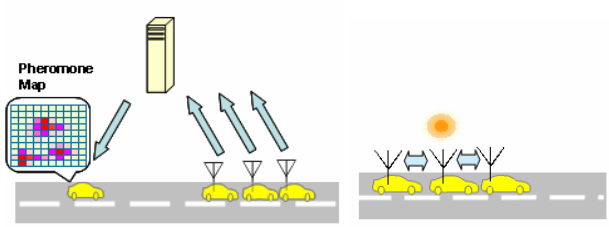


Figure 4: Probe-car system

On the other hand, there are two ways of implementing the environment. One method is to realize a virtual pheromone map on the car navigation system. Each car receives surrounding probe information from the probe-car information server, then maps it and calculates pheromone on the digital map in the car navigation system (Figure 5 (a)). The other method is to realize a virtual pheromone environment using intervehicle communication technology. Some researchers have proposed a virtual information server on an inter-vehicle communication system [18], such that these technologies would make a complete distributed system which is called a "center-less probe car system" (Figure 5 (b)). This will bring about effectiveness in pheromone calculation because no communication between the probe-server and cars in required.

(a) Server-type Probe-car System **(b) Center-less Probe-car System**

Figure 5: Realization of Pheromone System

5. EVALUATION

We conducted a simulation of our model using actual traffic benchmark data. Then we evaluated how accurate our model predicts traffic on the basis of error indices. This section describes the data used in the simulation and simulator specification.

5.1 Data

The data we chose has high time granularity and a relatively sharp fluctuation in traffic. The real data used in the simulation is the "Kichijoji-Mitaka benchmark dataset" provided by i-Transport Lab. Co., Ltd. This dataset consists of road link information, complete trail data of approximately 12000 cars in an area between Kichijoji and Mitaka stations on a certain day (see Figure 6) [9]. These data were collected by human observers at about 100 observation points in the area. Each trail data includes license plate data and time data to the minute, representing the time at which a car passed an observation points.

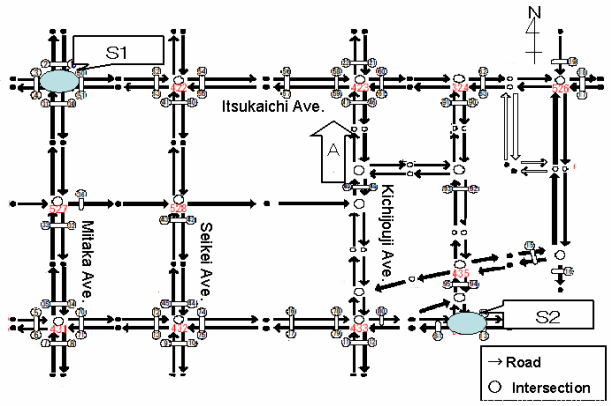

Figure 6: Map of the area where actual survey data were observed

5.2 Simulator

We use Pramics which is a widely used commercial microscopic traffic simulation platform [15] to evaluate the pheromone model and some other baseline model. It calculates the error rate of these models. It also has visualization features to read actual traffic and predicted traffic through animation (See Figure 7).

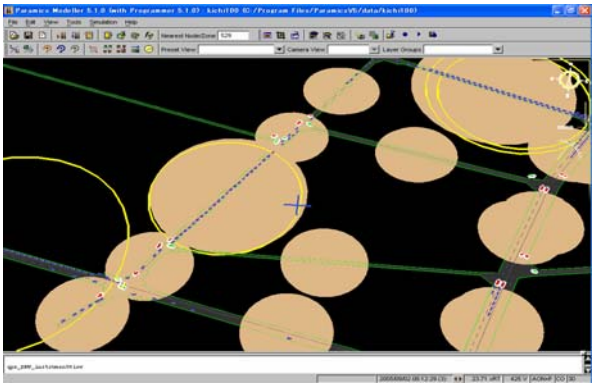

Figure 7: Screenshot of Simulator. (Shaded circles denote pheromone on each road link)

5.3 Assumptions for Simulation

The average link travel time is around 1 minute since the average link length on the map is around 1 km and the speed of the fastest car is around 60 km/h. Therefore, it would take 1 minute for a car to reach the next link after a prediction has been provided from a preceding car. Thus, in the simulation, the transition time step is set to 1 minute and the pheromone model predicts the situation 1 minute into the future (See Figure.8)

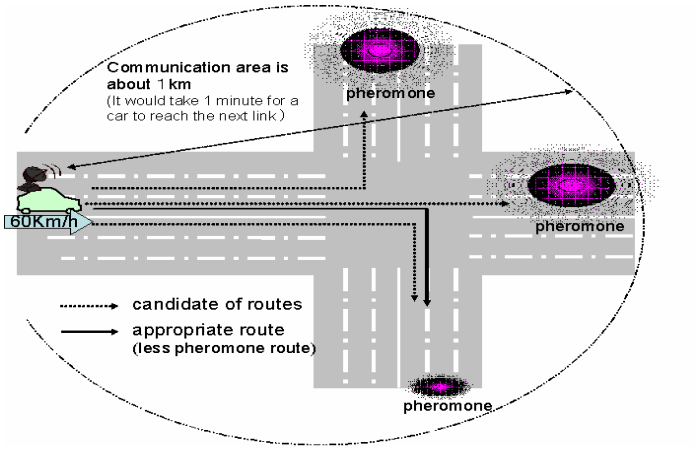

Figure 8: A Communication range of a car and relation of prediction time.

6. EXPERIMENTAL RESULTS

Evaluation has been performed from the standpoint of (i) the prediction accuracy of the basic model, (ii) the relationship between model type (uni-semantics of pheromone or multi-semantics of pheromone) and prediction accuracy, and (iii) the relationship between model parameters and accuracy.

6.1 Prediction Accuracy of Basic Model

Prediction accuracy is calculated as error rates between the predicted link travel time sequence and the actual link travel time sequence. The error rate indices we used are correlation coefficients. The prediction results are compared with two types of baseline predictions. One is a prediction based on a simple moving average time. The other is a prediction based on a persistent prediction model which assumes that the current situation will persist for some duration of time. The traffic information by current traffic control center can be received within 5 minutes or more after sensing; thus, we can assume that the persistent prediction model corresponds with the data of traffic information system.

Figure 9 shows fluctuations of actual traffic and traffic predictions in about 1 hour between 8:00 and 9:00 at a certain link. Actual traffic is the average link travel time of all cars that passed the link at the time the actual data was collected. Predicted link travel times of three types of prediction method are also drawn in the same graph. The correlation coefficient is shown in Table 1. These results show that our method outperforms baseline predictions. We can say that baseline predictions become worse when traffic fluctuations become very sharp.

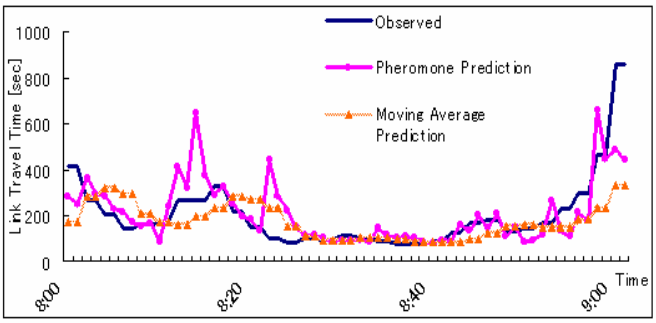

Figure 9: Prediction examples of each prediction methods in a certain link

Table 1. Accuracy of pheromone and other prediction schemes in a certain link

	Pheromone	Persistent	Moving Average
Correlation Coefficient	0.67	0.55	0.57

Additionally, the overall result of all links on the map, presented in Table 2, shows that pheromone prediction has higher accuracy than the other methods.

Table 2. Average accuracy of pheromone and other prediction schemes

	Pheromone	Persistent	Moving Average
Correlation Coefficient	0.36	0.34	0.30

6.2 Prediction Accuracy of Multiple Semantics of Pheromone

Next, we study the effect of different configurations of the pheromone model described in sections 3.2 and 3.4 (uni-semantics of pheromone or multi-semantics of pheromone).

The overall prediction accuracies of uni-semantic pheromone and multi-semantic pheromone are shown in Table 3. We confirmed the correlation coefficient of multi-semantic pheromone is significantly greater than that of the traffic pheromone.

Table3. Overall accuracy of uni-semantic and multi-semantic pheromone models

	Uni-semantics of Pheromone (only Traffic Pheromone)	Traffic + Braking	Traffic + Distance	Traffic + Braking + Distance
Corre-lation	0.36	0.44	0.38	0.45

The result implies that combining of some pheromones can be used to refine the prediction accuracy. Here, we only used a linear combination of pheromones that have different semantics. However, this scheme might contain nonlinear or logical combinations of semantics. Furthermore, more factors (such as ambient weather, traffic rules, and various events) might affect the prediction accuracy.

6.3 Parameter Modeling

In a previous work, the parameter of this pheromone model was tuned by learning algorithms such as GA [13, 14]. However, such a method is not so feasible for practical use because much learning data (empirical factor) and calculation costs are necessary.

In our experiment, we analyzed the relationship between the optimal parameters and real-world traffic data, and studied the effective parameters modeling schema to simplify determination of optimal parameters. In this section, we introduce a few example of the parameter modeling that got the most influential result in experimental results. The two examples of experimental results are as follows:

Modeling Example 1

First, we take the following assumption regarding the evaporation parameter and evaluated the relationship.

When the velocity of cars in a certain place is fast, evaporation occurs frequently (evaporate much pheromone). The model function is as follows.

$$E_f = 1 - \frac{v(t,p)}{v_{\max}(t,p)} \qquad (10)$$

Equation (10) implies the following.

- The evaporation decreases with decreasing speed at the given place (much congestion information remains behind).
- The evaporation increases with increasing speed at the given place (much congestion information disappears).

Modeling Example 2

Second, we take the following assumption regarding the propagation parameter and evaluated the relationship.

When the velocity of cars in a neighboring place is fast, propagation occurs frequently (propagate much pheromone). The model function is as follows.

$$G_f = 1 - \frac{v(t,p')}{v_{\max}(t,p')} \qquad (11)$$

Equation (11) implies the following.

- The propagation decreases with decreasing speed at the neighboring place (much congestion information remains behind).
- The evaporation increases with increasing speed at the neighboring place (much congestion information disappears).

Results of the parameter modeling of the evaporation parameter and the propagation parameter are shown in Table 4. We confirmed that modeling of pheromone parameters based on real-world traffic data can be used to refine the prediction accuracy.

We tried much variation of parameter modeling; however, they cannot be discussed here for lack of space.

Table 4. Impact of Parameter Modeling

	Basic Model	Example 1 After Modeling	Example 2 After Modeling
Correlation Coefficient	0.36	0.42	0.49

7. RELATED WORK

An application of the pheromone mechanism has been studied in the so-called swarm intelligence research field. On the other hand, traffic congestion prediction has various kinds of solutions such as the statistical method and simulation-based method. Such related works are discussed in the following sections.

7.1 Application of Pheromone Mechanism

There are various studies concerning applications of the pheromone mechanism. This study regards cars as mobile agents that deposit pheromone, which is similar to the approaches used in actual agents for sensors or planes.

One example of an application is an unmanned plane in a war zone [16, 20]. The unmanned plane would launch mobile agents which would deposit alarm pheromone when they encounter enemy missile sites. The plane would analyze the pheromone potential field and then determine a route to its destination.

Another example of an application is a mobile sensor network [10]. Studies in this field of application are concerned with methods to improve the efficiency of the overall monitoring task by making mobile sensors deposit alarm pheromone to indicate that it has observed a certain area so that other mobile sensors can avoid observing the same place again.

These researches use alarm (negative) pheromone while most of the researches regarding swarm intelligence use trail (positive) pheromone. These researches also deal with the flexible nature of pheromone appropriately. However, note that previous research studies involve evaluations using virtual data and not actual data. Our study has performed evaluations using real traffic data to confirm the applicability to a practical traffic system.

7.2 Traffic Congestion Prediction

There are two types of short-term traffic congestion prediction methods in the field of traffic engineering research. One is based on statistics of past traffic fluctuation patterns. The other is based on traffic simulation.

Statistical prediction is performed by matching current traffic patterns (time series data) to typical traffic patterns in the past. The most applicable pattern among the past traffic patterns is used for future-pattern prediction. The time span may vary from minutes to days depending on the application.

The matching process for short-term prediction uses algorithms such as those based on neural networks [24] or Bayesian networks [26]. The cost incurred for processing is significant since large amounts of past traffic history data are used. Furthermore, prediction of irregular traffic patterns cannot be achieved using only this pattern-matching-based method.

On the other hand, traffic simulation is used for short-term traffic prediction [1]. The simulation based model describes the mutual interference of cars that consists of running car dynamics, various road types, traffic flow model, and driver model. Thus, the simulation tends to be complicated and time consuming. Distributive methods of simulation such as cellular automata (CA) are also introduced into this traffic prediction scheme [3]. While prediction using CA has proved to be effective when information regarding incoming stream volume is available, it does not seem to be effective when the information is partially not available, such as in the case of normal road data.

Naturally, since these predictions are carried out based on information from a traffic information center, data will have low granularity (only three levels: "normal," "congested," and "stacked").

The traffic prediction method using pheromone which we have introduced does not require past traffic data and much processing cost, and it works with a relatively simple mechanism.

8. CONCLUSION

In this paper, we proposed a traffic prediction method that employs a pheromone mechanism and described the practical implication of this method. Cars are regarded as agents that deposit pheromone at virtual places. The pheromone would then evaporate and propagate on the basis of a modified version of the state transition model of digital pheromone. A car would be able to predict traffic on the road ahead from the information provided by preceding cars. On the basis of the results of the experiments that used real traffic data, we confirmed the applicability of our method to short-term traffic prediction.

Moreover, we introduced multiple semantics of pheromone as well as parameter modeling of the evaporation and propagation parameters. We confirmed that both approaches can refine the prediction accuracy of the method. However, we only used a linear combination of multiple pheromones; thus, we have to examine nonlinear or logical combinations of semantics because the semantics can be affected by factors such as traffic rule, some buildings, various events on road side, and weather. The contribution of such factors to traffic might be optimized by GA.

Furthermore, we have to validate the global optimization of this traffic system through a multi-agent traffic simulation. Because previous research efforts have revealed that individually optimizing performance with only traffic congestion information by traffic control center is difficult [25], thus, we believe that swarm-based decentralized traffic system is best approach that may achieve the global optimization.

ABSTRACT

When multiagent simulations are used for consensus building among stakeholders, it is important not only that the domain experts can deeply understand stakeholders' actual behavior but also that the stakeholders can feel the simulation result as their solution. To this end, we propose a modeling methodology which combines several techniques with the participatory method which takes stakeholders into the modeling process using role playing games (RPG).

There are two types of model required to simulate a social system as a multiagent system: agents (internal models) and interactions. Hence, we considered a modeling method according to each character. In modeling an agent (e.g. decision making) which is implicit in human, the identification of the model greatly depends on the modeler's ability. Therefore we propose a modeling method wherein classification learning creates an alternative model from RPG log data for validating the domain experts' hypothesis. On the other hand, in modeling interactions (e.g. negotiation) which are emerged outside of human, it is rather important to show and capture continuously appeared interactions. Therefore we propose a modeling method with participatory simulation where a stakeholder participates as an avatar and agents act as the other stakeholders in order to deeply understand the stakeholders' interactions. Our methodology was effective to give the domain experts a deeper understanding through a real case study of agricultural economics in the northeast of Thailand [17].

multiagent simulation, participatory simulation, machine learning, agent interaction, modeling methodology

1. INTRODUCTION

Multiagent simulation has been used to analyze and design social systems (traffic [1], disaster management [6][11], market [14] etc.). The general modeling process is that a model created by the domain knowledge is adjusted to output the same kind of results as the real data. However, when using multiagent simulations for consensus building among stakeholders, it is important not only that the domain experts can deeply understand stakeholders' actual behavior but also that the stakeholders can feel the simulation result as their solution. In this paper, we aim to provide a modeling methodology to satisfy these points.

The participatory method by social scientists is suitable for this purpose [3][4]. The key idea is that stakeholders can understand the simulation result as their solution because they share the modeling process with the domain experts and can believe that the model reflects their actual behavior. A role playing game (RPG) where stakeholders play on a board representing their environment is used to share the modeling process and to well understand their actual thinking and behavior. "Participation" is the key aspect of our modeling methodology.

To simulate a social system as a multiagent system, two types of model are required: agents (internal models) and interactions. For example, in an economic system in agriculture described in this paper, decision making models and negotiation models of farmers and seed suppliers are required. Hence, we have to consider a modeling method according to each character.

In modeling an agent (e.g. decision making) which is implicit in human, the identification of the model greatly depends on the modeler's ability. Therefore, a method for model validation is very important. On the other hand, in modeling interactions (e.g. negotiation) which are emerged outside of human, it is rather important to show and capture continuously appeared interactions. RPG using a board in the participatory method is not enough to express such dynamic process as interactions, and it is important to give a method for this purpose.

In this study, to give solutions of each issue above, the following technological methods are applied in the notion of the participatory method.

Modeling agents with classification learning

A hypothesis of domain experts is validated by a model which classification learning creates from RPG log data. The merits are 1) classification learning creates an objective model without influence of the modeler's ability because the creation is based on the algorithm, and 2) classification learning is more robust than human in performance even when the number of elements to be compared is large. What is important here is to consider a method that classification learning creates a model which logically explains the stakeholders' behavior even if the data available is sparse (it is difficult to gather enough data for classification learning because of the cost of RPG).

Modeling interactions with participatory simulation

In participatory simulations, stakeholders participate as avatars and agents act as the other stakeholders. The merits of using this kind of simulation are 1) it is easy to express and record every interaction on a computer, and 2) domain experts can concentrate on a specific stakeholder because agents act as the other stakeholders. What is important here is to create an environment that supports the domain expert in designing agent-avatar interaction so as to elucidate the behavior of the stakeholder.

Our modeling methodology was actually evaluated in an actual case study of agricultural economics in the northeast of Thailand in co-project of IRRI[1] and CIRAD[2] [17].

The following section will first explain the related works. Section 3 will explain the agricultural economics used in our evaluation. Sections 4 and 5 will explain the modeling method of agents with classification learning and interactions with participatory simulations, respectively, using our example.

2. RELATED WORKS

Two studies have used machine learning with participatory simulation for modeling. 1) One applied machine learning to the logs of participatory simulations for developing diverse agent models in a virtual training system [12]. 2) The other allowed agents to learn effective negotiation strategies for the participatory simulations of a virtual market [9]. In these two studies, participatory simulation is not used to share the experience of domain experts and stakeholders. Moreover, machine learning is not used for validating a hypothesis of domain experts.

We know of two studies which use participatory simulation. 1) One developed a web forum of agents and stakeholders for holding a continuous RPG free from the constraints of time and place [4]. 2) The other used participatory simulations in which only humans participated as avatars so as to eliminate a drawback with the RPG approach in which roles of participants are fixed and emergence of new roles cannot be handled [5]. In the first study, participatory simulation is intended to create a place for continuous meeting of stakeholders and this differs from our use of participatory simulation: to exploit interaction models of stakeholders. The second also mentions design processes of participatory simulation, but they are not for constructing an environment where agents and avatar participate.

3. AGRICULTURAL ECONOMICS OF NORTHEASTERN THAILAND

In this research, we applied our proposed processes to the agricultural economics of northeastern Thailand in a collaborative research project with IRRI and CIRAD [17].

The background is as follows. In the northeast of Thailand, the Thai government distributes a few different rice varieties. The problem is that the organization of this distribution is not always efficient: farmers do not always get the seeds they want while the seeds of some varieties are produced in excess. Also, it seems desirable that this distribution should not reduce the use of local varieties. The problem is how to develop a system that can both deliver good quality seeds and also conserve rice biodiversity. Researchers have been studying two subjects: 1) understand farmers' needs concerning rice varieties and the selection model of rice varieties and 2) to identify the problems of the current delivery system of rice seed by acquiring a farmer's selection model of seed suppliers and a flow model of rice seeds among the seed suppliers and farmers.

To realize this economic system in multiagent simulation, we need to have a) decision making model of farmers for rice varieties, b) decision making model of farmers for seed suppliers, c) negotiation model of suppliers for rice seeds and d) negotiation model of farmers for rice seeds. In this study, we will apply our modeling process of decision making and negotiation to b) and c), respectively.

4. MODELING AGENTS WITH CLASSIFICATION LEARNING

In this section, we will discuss the issues and the solutions in using classification learning to model agents (internal models) and explain the processes involved with an example: decision making of farmers for seed suppliers. The decision making model is represented in a decision tree and we selected the well-known decision tree learning algorithm "C4.5" for classification learning [13].

4.1 Issues

The characteristics as a classification learning problem are as follows:

1. The number of features tends to be large because the experts take into account all elements that they think might be related to the classification. However, the more features that are included, the more data sets tend to be needed to assure reasonable learning performance [10]. Unfortunately, it is difficult to gather enough data because the cost of RPG is high (an RPG session usually engages 12-15 players for 2 days).

2. Noise data can affect the learning result because the amount of data may be insufficient.

3. The classification knowledge gained through learning should logically explain the real behavior of stakeholders and satisfy the experts.

4.2 Approaches

In our approach for these issues, expert knowledge is effectively used for obtaining a model even from insufficient amount of data sets. Here, the unneeded features are winnowed in two ways:

Feature Selection Method

The wrapper approach[3] [10] is used for eliciting a model with higher classification accuracy for unknown data; that is, a model with more generality. This method identifies a feature subset that maximizes the prediction accuracy as determined by cross validation[4], by eliminating irrelevant features from the initial feature set through hill-climbing search. In this method, however, when the quantity of data sets is insufficient, there is a possibility that some features needed for adequately reproducing reality will be eliminated due to noise data. Therefore, in our approach, the features contained in the hypothesis (in a decision tree) are regarded as being candidates to adequately explain reality and retained in the process (e.g. five features in figure 2 are not eliminated in this process). These features are always contained in the feature subset, but the learning algorithm selects a part of features from the subset, so the important features are not always contained in the learning result. This means that the wrapper approach can winnow the features to prevent the learning from selecting irrelevant features which do not ensure generality.

Visualization Method

In order to obtain a result which logically explains the stakeholders' behavior, the learning model is refined by eliminating irrelevant features contained in it and applying the classification learning again. Such conditions are selected by the domain expert. Here, It is important to consider an evaluation method that gives domain experts intuitive understanding of the model and excludes their bias to the model. To this end, the environment and participants of the RPG are reproduced on a computer using a graphical interface and computer agents. The expert is shown the results made by the agents who have the learning model and the RPG log data itself (the expert is not told which is from the RPG log data). Then he puts comments to each result. After this, the model itself is directly shown to the expert. He selects irrelevant features, comparing his comments to the visualized result with the model.

There are three merits on this method. First, a visualized method helps the expert to find apparently strange results and eliminate irrelevant features. Second, the learning result can be neutrality evaluated, while the expert tends to criticize the learning result when the model is shown from the beginning because he is obsessed with his hypothesis. Third, he can scrutinize the learning result because a model is re-evaluated based on his comments to the visualized result. The reason why RPG log data is also shown to the expert is to convince him of validity of the learning result (he can accept a part of the learning result when the output of it resembles the one from the RPG log even if it does not support his hypothesis.).

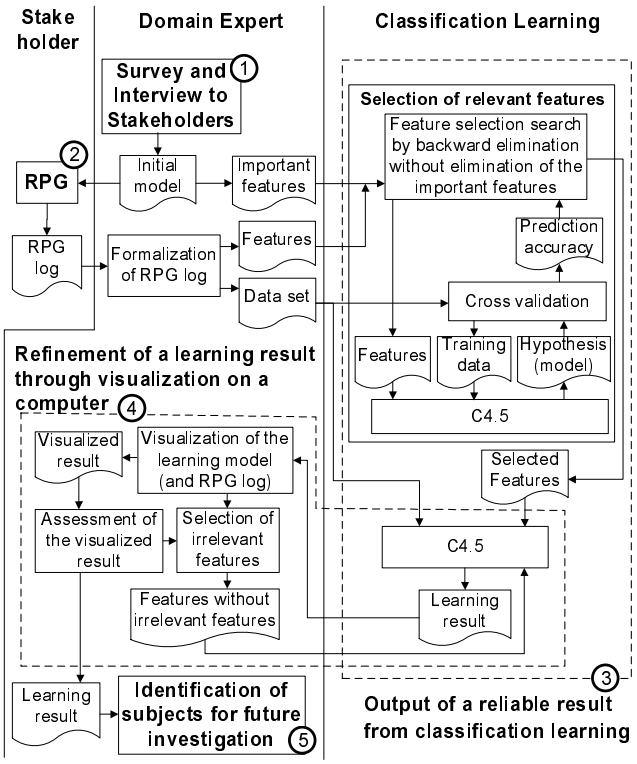

Figure 1: Modeling process for agents with classification learning

4.3 Modeling Process: a Real Example

We constructed five steps in which the approaches above are combined (Figure 1 shows the detail of this process); 1) Survey and Interview to Stakeholders, 2) RPG, 3) Output of a reliable result from classification learning, 4) Improving the result by expert knowledge and classification learning, 5) Identification of subjects for further investigation. This process will be explained with the results gained by applying it to a real example (see [15] for the detail explanation of the decision making model).

STEP1: Survey and Interview to Stakeholders

Domain experts create an initial model (decision tree) from relevant literature and interviews with stakeholders. Important features are extracted from the initial model. In our example, five features were extracted for the feature selection method (Figure 2).

[3]A method using a searching algorithm that identifies a feature subset which gives the best performance of a model outputted from an inductive learning. In many cases, cross validation is used to estimate the performance and hill-climbing is used to search a feature subset with the best estimated performance. In hill-climbing, there are two searching direction: one is backward elimination which begins at the full set of features and eliminates one feature which makes the estimated performance the best. Another is forward selection which begins at the empty set of features and adds one features which makes the estimated performance the best.

[4]Data sets are divided into n groups without overlapping. A machine learning program is applied to the n-1 groups and the result is tested by one unused group. The classification accuracy of the test data is used as criterion for the performance estimation. Switching the group used for the test data, this process is repeated n times. We assigned n to 10 which is the frequency generally used.

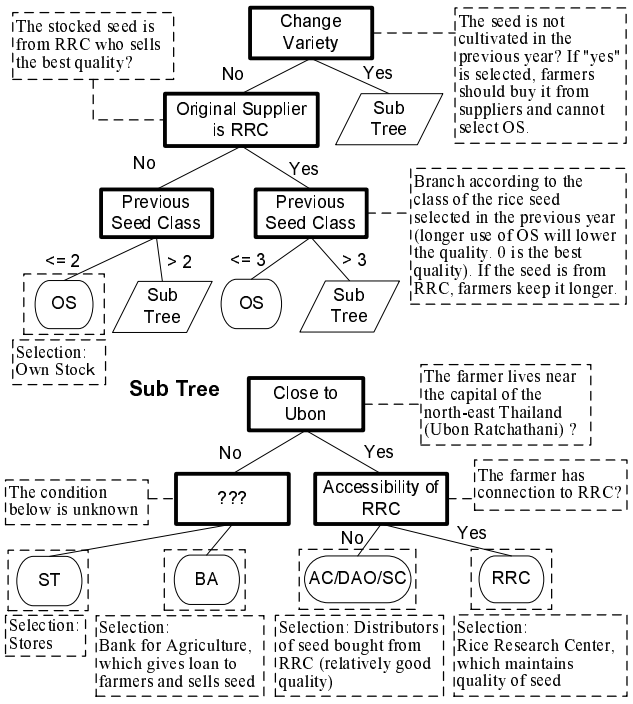

Figure 2: The initial decision tree model about farmers' selection of a rice supplier: The rectangles surrounded by bold lines are features. Five kinds of feature except "???" are the important one.

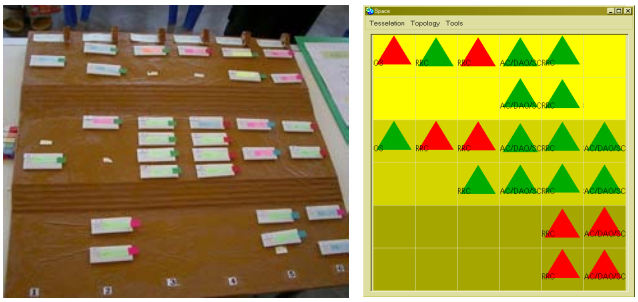
STEP2: RPG

RPG sessions using a board that represents the stakeholders' environment are organized. Log data for each stakeholder is recorded.

In our example, two RPG sessions were held. A board representing farm land was created (Figure 3 (a)). Totally, we got log data of 25 stakeholders.



STEP3: Output of a reliable result from classification learning

Learning data is created by transforming the RPG log data into a format that the learning algorithm can understand. Next, irrelevant features are eliminated by the feature selection method (mentioned in section 4.2). In this process, important features identified in STEP1 are not eliminated. Finally, the machine learning outputs a model from the feature subset and the data set.

In our example, after formatting the log data, we had 16 features and 80 data sets. Next, the feature selection method was applied. Here, five of the features identified in STEP1 were not eliminated. Finally, the feature selection method eliminated 3 features and we got the first result from the remaining 13 features.

STEP4: Refinement of the learning result through visualization on a computer

The environment and participants are reproduced on a computer using a graphical interface and computer agents. In this evaluation, the experts are shown two types of results: results from the learning model and RPG data. After this,

(a) RPG board [17] (b) Visualized Interface

Figure 3: Interfaces for modeling: These are examples used in a case study of rice production in the northeast of Thailand. Both show upper, middle, and lower lands.

the model is directly shown to the experts. When there are irrelevant classification conditions in the model, the expert eliminates that feature which consists of the conditions and C4.5 will be applied with the resulting feature subset. This process is repeated until the expert is satisfied with the learning result.

We implemented the first learning model in CORMAS [2] (Figure 3 (b)) and evaluated the model by showing the results to the expert. At each step (equivalent to one year), the expert carefully observed the results and commented on the decision making of each agent.

After this, the first learning result was evaluated by directly showing the decision tree to the expert and an irrelevant condition was pointed by the expert (one feature was selected here and was eliminated from the feature set). The expert understood the reasons for the phenomena seen in the visualization. Classification learning was applied again with the reduced set of features. After applying the same processes in STEP4, the expert thought the learning result (Figure4) is logical to explain the decision making of the stakeholders in RPG and was satisfied with it, then we went to the next step.

STEP5: Identification of subjects for further investigation

By comparing the experts' hypothesis (Figure 2) with the learning result, the experts investigated their hypothesis and find subjects for investigating in the future. These will be discussed among the domain experts or investigated by repeating the process from STEP1.

In our example, the expert found that some parts supported his hypothesis: a) A condition "Close to Ubon = yes" leads a branch by "Accessibility of RRC", b) The bigger value of "Previous Seed Class" leads not *OS* but *RRC* or *AC/DAO/SC*. Meanwhile, other parts did not support it and the following subjects were identified: a) The value of "Previous Seed Class" (2 or 3 in the hypothesis while 0 in the result), b) The importance of two features which contains in the hypothesis but do not contain in the result ("Change Variety" and "Original Seed Supplier is RRC"). c) The possibility of the other important features (there should exist several features for the decision of *OS* except "Close to Ubon = No").

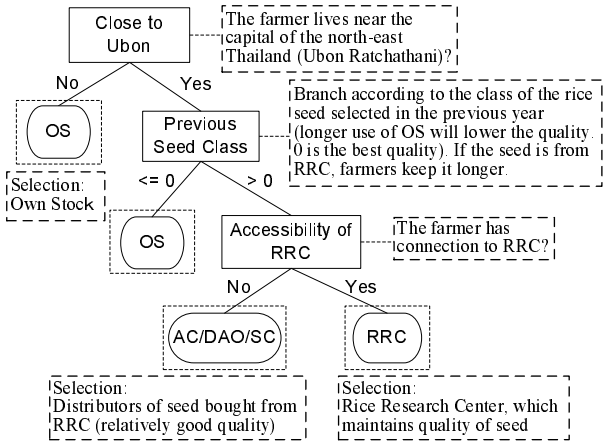


Figure 4: The final learning result

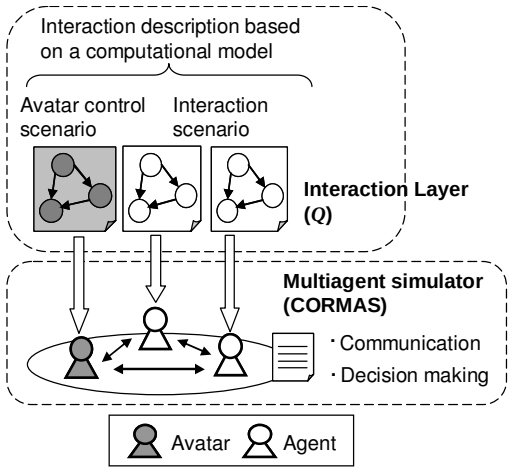

Figure 5: Agent Control from Interaction Layer

4.4 Evaluation

We can explain the effectiveness of our approach in the following way: first, the feature selection method reduced the cost of the expert refining the learning model. In our example, when the expert eliminates features without the feature selection method, it is necessary for the expert to iterate the refinement process three times, but when using the feature selection method, just one round of refinement was enough, because the feature selection method eliminated three features. In our approach, considering the preparation costs of the visualization method, it was desirable for the expert to reduce the refinement process. Moreover, we confirmed the effectiveness of our proposed method in which the features the expert thinks important are not eliminated in the feature selection method process. In our experiments, important features like these were often eliminated when this method was not used, and the experts could not explain the results as a decision making model of the stakeholders.

Second, we consider that using visualization to evaluate the learning model was useful for gaining a better understanding of the characteristics of the model and for facilitating the collaboration with the expert. The expert was able to make various comments about the decision making of agents who used the learning model because the interface had the same characteristics as the RPG. This is effective because it leads to more comments than when the learning model was shown directly to the expert, an approach that was tried in the early stage of our research.

5. MODELING INTERACTIONS WITH PARTICIPATORY SIMULATION

In this section, we will discuss the issues and the solutions in using participatory simulation to model interactions and explain the processes involved with an example: negotiation of seed suppliers. The negotiation model is represented in a state automaton and we implemented our participatory simulation in CORMAS/Q [16].

5.1 Issues and Approaches

Issues

For coaxing the actual behavior from stakeholders, it is important to design how the stakeholder controls an avatar and how agents interact with the avatar. Therefore, it is indispensable to give a development environment where domain experts are able to focus on designing interactions and the interaction design is directly used in system implementation. To this end, we developed a simulation system that uses the system architecture described in the next section.

Agent Control from Interaction Layer

We use a system architecture shown in Figure 5 where an interaction layer constructed outside of a simulation system controls the agents in the system[7][16]. This architecture makes it possible to use descriptions based on a computational model that makes it convenient to write interactions. Therefore, users can focus on interaction design.

As an actual simulation system based on this architecture, we combined the scenario description language Q [7] with the multiagent simulator CORMAS [2] which is often used in research based on the participatory method [3] (the system is called CORMAS/Q [16]). The computational model behind a Q scenario is an extended finite state automaton, which is commonly used for describing communication protocols. By using Q, users can directly create scenario descriptions from extended finite state automata. In Q scenarios, we can use sensing functions (cues) and action functions (actions). Scenarios are interpreted by Q interpreter, while cues and actions are executed by CORMAS. Cues/actions become the interface between domain experts and system developers, which enables collaboration in the design of interactions.

5.2 Interaction Description

For realizing participatory simulations where agents and avatars interact, it is necessary to assume the three kinds of interaction descriptions shown in Table 1. These descriptions are designed according to the modeling process shown in the next section. Interaction protocols are very important because they define the activity of avatars (stakeholders) in the simulation world. An interaction scenario regulates an agent's behavior about interactions (e.g. a negotiation

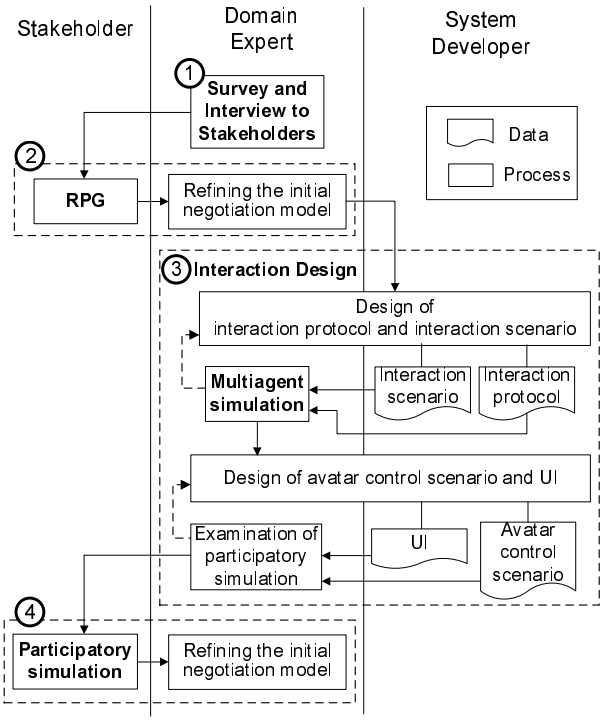

Figure 6: Modeling process for interactions with participatory simulation

model for agents who access the other agents and avatars). The avatar control scenario is an extended scenario of the interaction protocol. There are four elements in this scenario: 1) control of user interfaces (UI) (display etc.), 2) observation of input by a user through UI, 3) sensing from other agents, 4) action with other agents; this is triggered by input to the UI by a user.

Table 1: Interaction Descriptions

Classification	Definition of interaction description
Interaction protocol	Procedures which should be abided to negotiate with another agent or avatar
Interaction scenario (negotiation model)	Interaction procedures (e.g. access priority of trading or condition for completion of the deal) are described within the framework of the interaction protocol
Avatar control scenario	Control procedures of UI and an avatar along the interaction protocol

5.3 Modeling Process: a Real Example

The following four steps aim to refine an interaction model of a stakeholder and show a process to design three interaction descriptions shown in Table 1; 1) Survey and Interview to Stakeholders, 2) RPG, 3) Interaction Design, 4) Participatory Simulation (see Figure 6).

In this real example, we aimed to refine a negotiation model of *SC (Seed Center)* who is one of the important suppliers in northeastern Thailand. There are four types

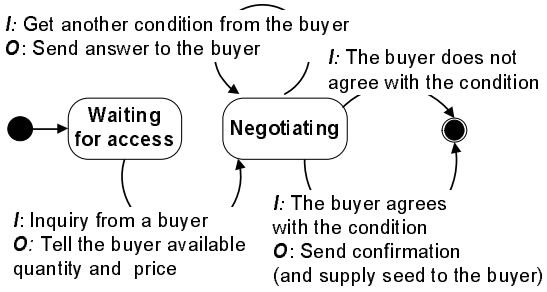

Figure 7: Example of interaction protocol (for sellers): Conditions are exchanged between the seller and the buyer in enough times to agree and the negotiation is settled if the buyer agrees/disagrees with the condition.

of supplier except SC and they are realized as agents in the participatory simulation (they are shown as A, B, C and D for descriptive purpose.).

STEP1: Survey and Interview to Stakeholders

Domain experts create an initial model from relevant literature and interviews to stakeholders. (In our example, the initial model was very abstract which just specified a contact list of each supplier).

STEP2: RPG

RPG based on STEP1 is held with stakeholders. In the process, RPG is very important because RPG is a good place for communication between domain experts and stakeholders unfamiliar with the research process and sometimes unfamiliar with computer systems. Through RPG, behavioral model and the reason behind the behavior are exposed. The initial model is improved by knowledge acquired through RPG.

The refined model of SC in our example is that rice seed is supplied according to a priority order (A, B, C and D)

STEP3: Interaction Design

An interaction protocol and interaction scenarios are described based on observation in RPG. What is important here is that several kinds of interaction scenarios are created for each agent to observe reaction of a stakeholder in participatory simulation. These descriptions are designed by a computational model of the interaction description through collaboration of a domain expert and a system developer. Finally, these descriptions are implemented in a computational language and tested through several runs of multiagent simulation. The processes of design and simulation are repeated until a domain expert is satisfied.

Next, UI and an avatar control scenario are designed by the domain expert and system developer for participatory simulation. In the avatar control scenario, the control procedures of UI are considered based on the interaction protocol. Next, UI and the avatar control scenario are implemented by the system developer and the participatory simulation system is tested by the domain expert. The processes above are repeated until the domain expert is satisfied.

In our example, through discussion between a domain expert and a system developer, an interaction protocol and

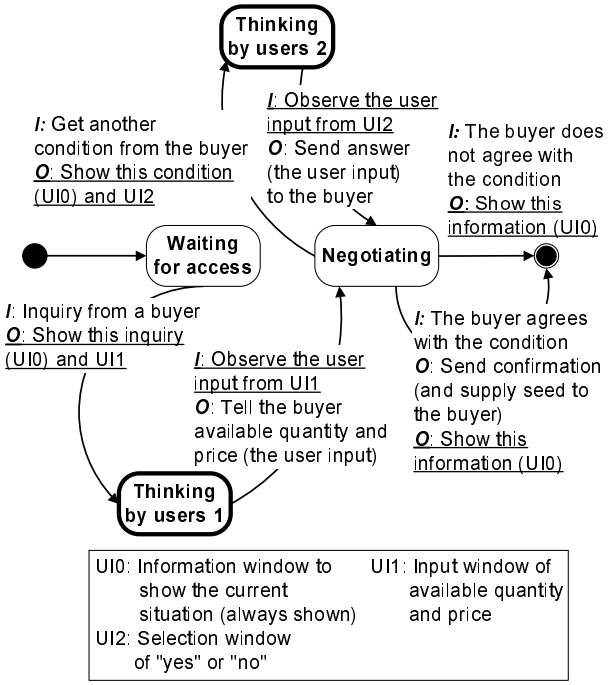

Figure 8: Example of avatar control scenario (for *Seed Center*): the interaction protocol shown in figure 7 is extended by putting controls concerning to UI (states surrounded by a bold line and conditions/actions with underlines)

interaction scenarios for each agent were designed by a state transition model which is a computational model of Q. The interaction protocol is shown in Figure 7. Three kinds of interaction scenarios are also prepared: a) access in a fixed order, b) access in a cheap price order and c) access in a short distance order. Next, the domain expert and system developer defined cues/actions of Q and the system developer implemented corresponding behavior of the cues/actions in CORMAS (this part of design process are described in [11]).

UI for our participatory simulation was not one big panel with all functions but small panels with only necessary functions at each scene, which are opened and closed according to the avatar control scenario. As in the interaction scenario, the avatar control scenario was designed by state transition diagram (Figure 8). Then, cues/actions are designed and corresponded to the control of UI or avatar behavior in CORMAS.

STEP4: Participatory Simulation

Participatory simulation with stakeholder is held. The domain expert refines the interaction scenario by analyzing the log data and knowledge acquired through conversation with the stakeholder.

In our example, the refining process of the model is as follows. The result after several times of participatory simulation was that supplier B was always selected first then the selection of A, C and D was not fixed. This was observed every time, though we changed the interaction scenario given to the agents in every run of simulation. After the domain expert recognizes this phenomenon, he tried one

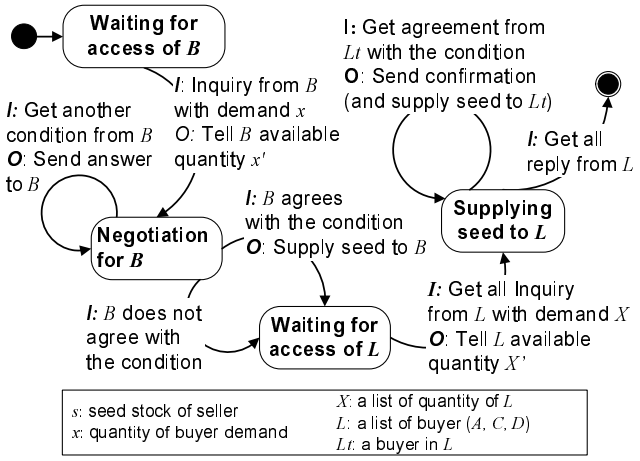

Figure 9: Refined negotiation model of *Seed Center (SC)* after Participatory Simulation: B is first chosen then A, C and D are equally distributed. If the stock remains, the other buyers will be supplied.

more around of simulation while he gave questions to the stakeholder. From the conversation with the stakeholder, the domain expert could refine the model as shown in Figure 9.

5.4 Discussion

We confirmed the merits to use participatory simulation. 1) The domain expert could focus on observing specific stakeholders (only SC in our example) because agents took roles instead of the stakeholders in RPG and a computer program automatically conducts the simulation. 2) The domain expert could give questions according to the progress of simulation. The stakeholder could monitor the simulation progress and see the impact of his own decision, which enabled him to give more concrete answer.

We consider that this participatory simulation operated as intended. This is because the system architecture could give the environment for the domain expert to focus on interaction descriptions and our proposed processes of designing three kinds of interaction descriptions were effective to reflect his knowledge acquired through surveys and RPG to the simulation world.

6. CONCLUSION

In this study, we proposed a novel methodology of modeling agents (decision making) and interactions (negotiation) in multiagent simulations for consensus building among stakeholders. This methodology combines several techniques with the participatory method, which takes stakeholders into the modeling process. We tackled the following two problems.

Modeling agents with classification learning

A modeling method wherein classification learning is applied to RPG log data was established for validation of domain experts' hypothesis (agent's internal model). The key ideas are 1) a feature selection method for enhancing reliability of the learning result by classification learning, and 2) visualization of the learning result on a computer to promote

understanding of domain experts in refining the learning result. The modeling process with these methods was applied to farmers' decision model of seed suppliers. As a result, the domain expert's hypothesis was validated and several subjects for further investigation were found.

Modeling interactions with participatory simulation

A modeling method with participatory simulation was established for deep understanding of stakeholders' interactions (e.g. negotiation). The key ideas are 1) a system architecture where interaction layer controls agents gives an environment for the domain expert to focus on interaction descriptions, and 2) three kinds of interaction descriptions (interaction protocol, interaction scenario, avatar control scenario) are defined and designed through the modeling process. Actually, a participatory simulation was developed on CORMAS/Q [16] and the domain expert could get deeper understanding of a negotiation model among seed suppliers.

Our modeling methodology has the following two important features for multiagent simulations to build consensus among stakeholders. First, RPG and participatory simulation give shared experience of modeling with domain experts, which is important for stakeholders to find their solutions in the simulation results. Second, the modeling method with classification learning and participatory simulation enables domain experts to deeply understand and model stakeholders' actual behavior in the system. Indeed, the impact was confirmed in the real case study of agricultural economics in the northeast of Thailand [17].

In this study, we could use a decision tree and a state automaton to represent decision making and negotiation, respectively. In the other cases, however, we might find or develop suitable models, the learning algorithms, systems providing the interaction description. This will be the future works, which also give new seeds of artificial intelligence and multiagent research. Another future work is use of new technologies for user participation. For example, *Augmented experiment* [8] can give an environment where stakeholders take part in the simulation world from their real work space, which enables domain experts to understand more actual behavior of stakeholders.

7. ACKNOWLEDGMENTS

This research was supported by the young researcher development program of the JSPS 21st century COE program "Informatics Research Center for Development of Knowledge Society Infrastructure". We would like to thank Dr. Guy Trébuil and Dr. Chirawwat Vejpas who gave valuable comments as a domain expert, and farmers and seed suppliers who joined our experiment in Ubon Ratchathani.

ABSTRACT
In this paper, we propose a new integration approach for simulation and behaviour in the learning context that is able to coherently manage the shared virtual environment for the simulation of autonomous virtual agents. Our low-level learning technique has proved fast, simple and robust. It is also able to automatically learn behavioural models for difficult tasks. Thus, we believe it will be more useful to the computer graphics community than a technique based on the classical Q-learning approach. The results are illustrated in two case studies that require effective coordination of behaviours.

Categories and Subject Descriptors

Algorithms, Human Factors, Performance.

Keywords
Computer animation, character animation, reinforcement learning, behavioural modelling, AI-based animation, machine learning.

1. INTRODUCTION
Autonomous Virtual Agents (AVAs) play an important role in computer graphics. Animating them is one of the fundamental challenges.

In this paper we are presenting research in the domain of behavioural animation using a low-level learning technique. This is accomplished with a behavioural model defining how an AVA reacts to stimuli from its environment.

Human-like behaviour is achieved through the use of a complex "cognitive map" and the application of a hierarchy of behavioural strategies [1]. The overall cognitive mapping process involves acquisition, coding, storage, recall and decoding of environmental information [2]. In fact, an individual "cognitive map" will often contain numerous inaccuracies or distortions [3]. Many of these anomalies result from the fact that humans use a predominantly visual perception system and are not capable of processing everything they see due to the tremendous amount of incoming information. Other errors result from the way the information is processed and stored within the "cognitive map" structure itself [4].

Previously, [5] have proposed new methodologies to carry out the mapping of all information coming from virtual sensors of vision, audition and touch as well as from the Virtual Environment (VE) in the form of a "cognitive map". The approach enables the partial re-mapping of cognitive and semantic information at a behavioural level. For example, when spatial attention is primed with tactile stimulation, the location of the attention spotlight is only partially remapped in visual coordinates. This framework will generate the multi-sensory information necessary for our *behavioural learning*.

In summary, this paper presents an original contribution with a novel approach allowing an AVA to independently learn a behavioural model.

This paper is organized as follows: Section 2 – State of the Art; Section 3 – Methodology; Section 4 - Integration; Section 5 – Experimental Results with two Case Studies; Section 6 – Discussion.

2. STATE OF THE ART
A great deal of research has been performed on the control of animated autonomous characters by [6], [7], [8] and [9]. The various techniques have produced impressive results, but they are limited. They have no learning ability and are therefore limited to explicit pre-specified behaviours.

On-line *behavioural learning* has begun to be explored in computer graphics [10] and [11]. A notable example is in [12], where a virtual dog can be interactively taught by the user to

exhibit a desired behaviour. This technique is based on *Reinforcement Learning* (RL) and it has been shown to work well in [13]. Also, since all these learning techniques are designed to be used on-line, they have, for the sake of interactive speed, a limited learning capacity.

In RL, the machine learning of an input-output mapping is performed through continued interaction with an environment in order to maximize a scalar index of performance. This performance index is called a fitness function. Some of the earliest research in computer graphics involving RL sought to make AVAs automatically learn how to walk, swim, or jump [14] and [15]. However, whilst interesting and useful, this type of learning does not provide AVAs with decision-making abilities. On-line *behavioural* (reactionary) *learning* in computer graphics is a new field of exploration.

The goal of RL is to automatically learn an optimal policy. Optimal implies that the policy always maps the current state to the best possible action according to the fitness function. Since it is impractical to store a large Q-factor table explicitly, it must be approximated. We have performed several experiments using *Q-learning* for AVA learning, where the only information available to an AVA was a fitness function. Previously, [13] have demonstrated the difficulty of this approach. Firstly, to obtain stable results, the Q-factor table must be approximated to a high degree of accuracy. Secondly, *Q-learning* is harder to perform if there are no terminal states. Also, as discussed in [16], *Q-learning* can be challenging to successfully use, especially since it requires the animator to visit every state-action many times.

The technique presented in this paper is built on the success of traditional behavioural modelling with the goal of alleviating two of its major weaknesses: performance and time-consuming construction. In our opinion, the difficulties associated with *Q-learning* make it an undesirable approach for our application. For this reason, we have developed an alternative technique for AVA low-level learning. The objective is to allow an AVA to explore its unknown VE and to build structures, in the form of cognitive models or maps, based on this exploration. Once its representation has been constructed, the AVA could then easily communicate its knowledge to, for example, other naive AVAs.

3. METHODOLOGY

In this section we introduce our low-level learning methodology. This means that an AVA can automatically learn a behavioural model. We have developed a new technique to perform AVA learning, using a tree search with *Inverse Reinforcement Learning* (IRL).

3.1 Planning-based Reinforcement Learning (RL) with Subagents

Given the shortcomings of *Q-learning* discussed above, we have developed an alternative approach to AVA low-level learning by computing discrete examples of a policy.

A planning-based RL technique will only learn a sub-optimal policy, the quality of which depends on the search depth limit used [17] and [18]. To ensure that on the whole an AVA's behaviour is optimal, we utilize the *Q-decomposition* approach proposed by [19], where only the sum of the subagent *Q-values* for a particular state determines the optimal action. This requires each subagent to indicate, from its perspective, a value for every action. Subagent *j* reports its action values $Q_j(s, a)$ for the current state *s* to the *arbitror*. Then, the *arbitror* chooses an action maximizing the sum of the *Q-values* (see Figure 1). In our proposed methodology we use *pseudo values* – instead of *Q-values* – for vision (Pv_{vision}), avoidance ($Pv_{avoidance}$) and navigation ($Pv_{navigation}$) to trade-off different features of virtual sensors.

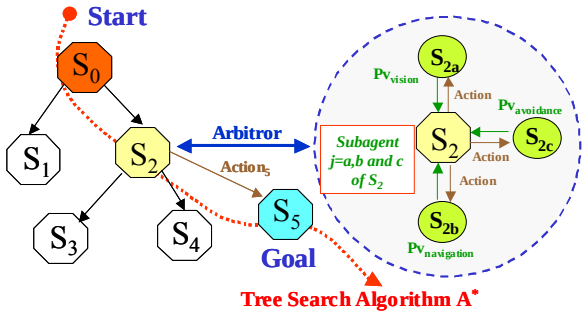

Figure 1: (left) Planning is performed with a tree search algorithm A* of all proposed actions throughout the time limit. (right) The *arbitror* chooses an action maximizing the sum of the *pseudo values* ($Action_5$).

3.2 Apprenticeship Learning via Inverse Reinforcement Learning (IRL)

It may be impossible to use straightforward RL since an AVA may only have an approximate idea of the reward function which, when optimised, should generate a "desirable" behaviour. We believe that the difficulty of manually specifying a reward function represents a barrier to the broader applicability of RL and the optimal control of the algorithms.

As the entire field of RL is founded on the supposition that the reward function, rather than the policy or the value function, constitutes the most succinct, robust and transferable definition of the task, it seems natural to consider an apprenticeship learning approach via IRL [20] to learn the reward function.

In the learning process, one source of information consists of observing the behaviour of other "expert" AVAs as in *imitation* and *apprenticeship learning*. In this context, it is commonly assumed that the purpose of observation is to learn a policy which is represented by the mapping of states to actions.

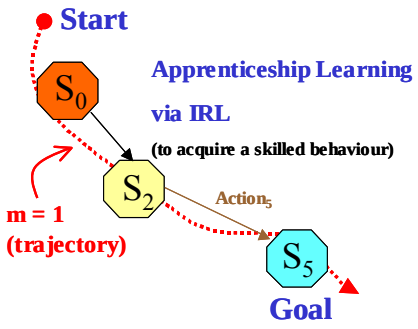

Figure 2: *Apprenticeship learning* via IRL is performed after *m* trajectories generated by the expert.

In our methodology, IRL is used in *apprenticeship learning* to acquire a skilled behaviour and to ascertain the optimisation of a reward function through a natural system. Yet, in using IRL, it is difficult to extract an observed reward function [21]. This is a fundamental challenge in theoretical biology, econometrics and other fields.

Using this method, an AVA can automatically learn a behavioural model. For the animator, this alleviates the workload of programming an explicit behavioural model (see Figure 2).

4. INTEGRATION

The integration of our low-level learning technique combined with different machine-learning techniques – but with several greatly improved – will be more useful to the computer graphics community than techniques based on a purely machine-learning approach (see Figure 3).

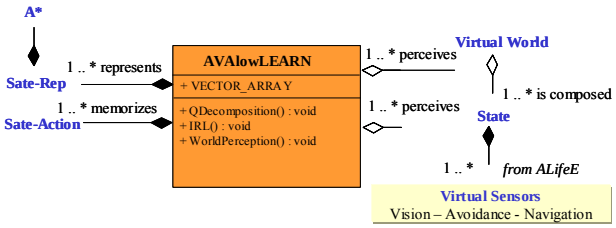

Figure 3: Comprehensive UML design of AVA low-level Learning (AVAlowLEARN). (left) State and action space. (right) Multi-sensory information necessary for our *behavioural learning*.

Firstly, we used a tree search algorithm A* [22] to observe the trajectories (state sequences) generated by the user (expert) and which take actions according to π_E (π_{expert}).

Secondly, we integrated the same *Q-decomposition* approach as [19], which uses all *pseudo value* function components (vision, avoidance and navigation) to choose the actions. *Q-decomposition* allows for multiple value functions, with each of these residing in a subagent, but it still requires each subagent to report its value estimates to an *arbitror* and to receive in turn the action chosen by the *arbitror*.

Thirdly, we took the *apprenticeship learning* via IRL with the projection algorithm proposed by [20] and adapted it to our behavioural animation.

A policy π is a mapping from states to probability distributions over actions. Given that the reward R is expressible as a linear combination of the features ϕ, the expectation values of the features for a given policy π completely determine the expected sum of discounted rewards for acting according to that policy (see Figure 4).

Given a MDP\R (denotes a Markov Decision Process without a reward function), a feature mapping ϕ and the expert's feature expectations μ_E, the problem is to find a policy whose performance is close to that of the expert's, on the unknown reward function $R^* = \omega^*.\phi$.

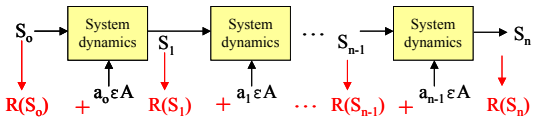

Figure 4: Reinforcement Learning (RL) description with a finite-state Markov Decision Process (MDP).

The *apprenticeship learning* projection algorithm proposed by [20] for finding a policy is as follows (pseudo-code):

1. Randomly we pick some policy $\pi^{(0)}$, $\mu^{(0)} = \mu(\pi^{(0)})$, and set i = 1.

   $\mu(\pi) = E[\sum_{t=0}^{\infty} \gamma^t . \phi(s_t) \mid \pi] \varepsilon \Re^k$

   ($\mu(\pi)$ is the expected discounted accumulated features value vector)

2. Set $\bar{\mu}^{(i-1)} =$

   $$\bar{\mu}^{(i-2)} + \frac{(\mu^{(i-1)} - \bar{\mu}^{(i-2)})^T (\mu_E - \bar{\mu}^{(i-2)})}{(\mu^{(i-1)} - \bar{\mu}^{(i-2)})^T (\mu^{(i-1)} - \bar{\mu}^{(i-2)})} (\mu^{(i-1)} - \bar{\mu}^{(i-2)})$$

   (This computes the orthogonal projection of μ_E onto the line through $\mu^{(i-2)}$ and $\mu^{(i-1)}$).

   Set $\omega^{(i)} = \mu_E - \bar{\mu}^{(i-1)}$

   Set $t^{(i)} = \left\| \mu_E - \bar{\mu}^{(i-1)} \right\|_2$

3. If $t^{(i)} \leq \varepsilon$, then terminate.
4. Using the RL algorithm, compute the optimal policy $\pi^{(i)}$ for the MDP using rewards $R = (\omega^{(i)})^T \phi$.
5. Estimate $\mu^{(i)} = \mu(\pi^{(i)})$.
6. Set i = i + 1, and go back to step 2.

Upon termination, the algorithm returns $\{\pi^{(i)}: i = 0 \ldots n\}$.

The performance of this algorithm only depends on (approximately) matching the feature expectations, not on recovering the true underlying reward function.

5. EXPERIMENTAL RESULTS WITH TWO CASE STUDIES

To test whether our low-level learning model was qualitatively able to learn the demonstrated AVA's behaviour, we created two environments requiring effective coordination of behaviours: a virtual apartment and a more complex situation with a car driving simulation inside a virtual city.

5.1 Case Study No. 1: an AVA learning to avoid obstacles and to navigate inside a virtual apartment

We chose to simulate an AVA in an apartment where he can "live" autonomously by perceiving his VE and generating a few behaviours at specific locations.

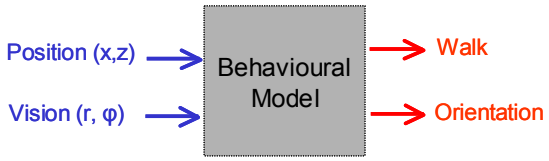
We can test our *behavioural model* applied to an AVA by implementing the model in C++ and Python [23] thanks to the Python module of the real time framework [24] for advanced virtual human simulations.

As depicted in Figure 5, an interface has been designed to monitor and change, if necessary, the evolution of the AVA's states and actions in real-time inside the virtual apartment. The path planning module [25] is applied for obstacle avoidance when the AVA walks to a specific location (see Figure 6). It is also utilized to the decisions the AVA makes. Its 3D viewer shows, in real-time, what the AVA decides to do at each moment and can play keyframes for the learned actions using the walk engine [26].

Figure 5: Top view of the virtual apartment.

Figure 6: (upper left corner) Top view of the virtual apartment with path planning after low-level learning process. The AVA is now inside the kitchen.

Figure 7 shows the inputs and outputs of the behavioural model for the navigation inside a virtual apartment. The input for Vision (r, φ) is the spherical coordinates of the AVA's head. Our Artificial Life Environment (ALifeE) [5] gives multi-sensory information to the AVA's sensors of vision, audition and touch (see Figure 3).



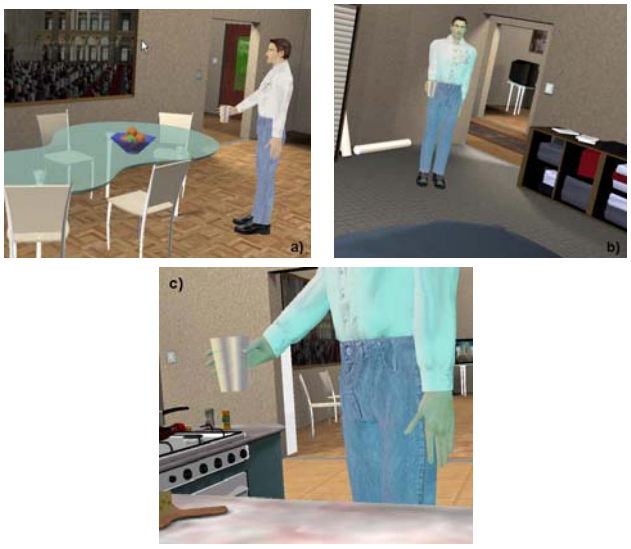


Figure 7: Behavioural model for the navigation inside a virtual apartment with inputs and outputs. The MDP has two different actions: walk and orientation.

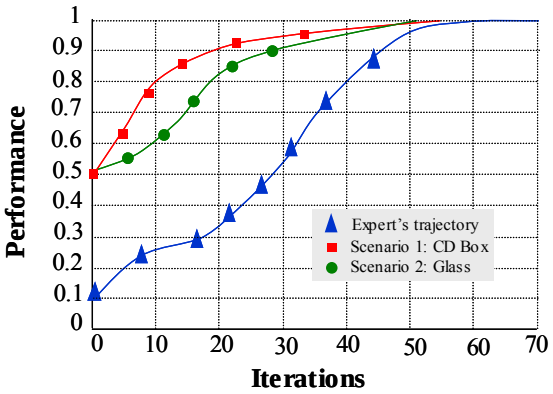
In the first scenario (see Figures 8 a), b) and c)), an AVA learns the behaviour of taking a *CD box* from the kitchen table. Then, the AVA walks around inside the different rooms whilst taking care to observe and avoid virtual objects and also navigates with a path planning between doors. Finally, the AVA puts the *CD box* on the desk in the office.

Figures 8 a), b) and c): Snapshots of the AVA learning (through seeing, avoiding and navigating) to take a *CD box* from the kitchen table and to put in on the office desk.



In the second scenario (see Figures 9 a), b) and c)), an AVA learns to take a *glass* from the living room table or from the bedroom shelf and to bring it to the kitchen.

Figures 9 a), b) and c): Snapshots of the AVA learning (through seeing, avoiding and navigating) to take a *glass* from the living room table and to bring it to the kitchen.

The two scenarios were reported in Table 1 to illustrate the performance of our low-level learning methodology. Using our methodology, only a few sample trajectories were needed to attain a performance mimicking that of the expert. Thus, by learning a compact representation of the reward function, our methodology outperformed.

Table 1. Plot of performances obtained with our low-level learning methodology. All animations were rendered in real time using OpenGL on a 3.0 GHz PC with an nVIDIA GeForce FX Go5350 video card.

5.2 Case Study No. 2: an AVA learning to drive a car inside a virtual city

We implemented our approach to learn the behavioural model applied to a car driving simulation inside a virtual city. An AVA is the driver and has dual control over the acceleration and the wheel of the car (see Figure 10). The controls are real-value (e.g., the action space is continuous) and the car can move to any location or take any orientation.

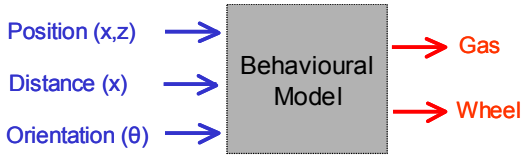


Figure 10: Behavioural model for the car driving simulation inside a virtual city with inputs and outputs. The MDP has two different actions: gas and wheel.

Figure 10 shows the inputs and outputs of the behavioural model for the car driving simulation inside a virtual city. The input for Distance (x) is the distance between the driver and the traffic signal.

The continuous action space was quantified to achieve real-time performance. The simulation ran at 15 [frames/s] and the expert's features were estimated from a single trajectory of 2'700 samples, corresponding to 3 minutes of driving time.

Our approach communicates the semantic information required for the "right way" behaviour of our low-level learning method in two ways:

- adding semantics to dynamic objects, and
- adding tools to sound, pedestrians and semantic objects (e.g., road signals).

Adding Semantics to Dynamic Objects

The appropriate description of tools for autonomous cars and pedestrians is available inside our simulation application. We use scripts to configure the VE application and to determine the behaviour of the autonomous cars in each different situation. The behaviour of the autonomous cars is controlled with Python scripts [23]. To simulate the life of a virtual city in a realistic manner, the VE also integrates some semantic notions about specific areas.

Adding Tools to Sound, Pedestrians and Semantic Objects

We have defined three types of plug-ins:

1. The plug-in for sound permits the definition of the properties of the sound environment in 3Ds max® (3D render software). To achieve a realistic illusion, it is important to generate a 3D spatialization in sound. The geometry of each object is transformed into a list of points outlining the sound obstacle. We define four types of sound primitives: environment, obstacle, listener and sound source. Inside the VE, we can have several sound sources with the following essential parameters: position, orientation (e.g., the direction of propagation) and ray configuration of the two cones of propagation. A sound source can be attenuated, absorbed or reflected depending on when the sound strikes an obstacle. The

obstacles are characterized by a two dimensional contour.

2. The plug-in for pedestrians covers a crowd composed of two types of people: those who walk in the virtual city with a precise goal and those who stroll.
3. The plug-in for semantic objects, inspired by the smart objects concept [27], gives significance to the road signals and traffic lights so that the sensory module of vision [5] can recognize them.

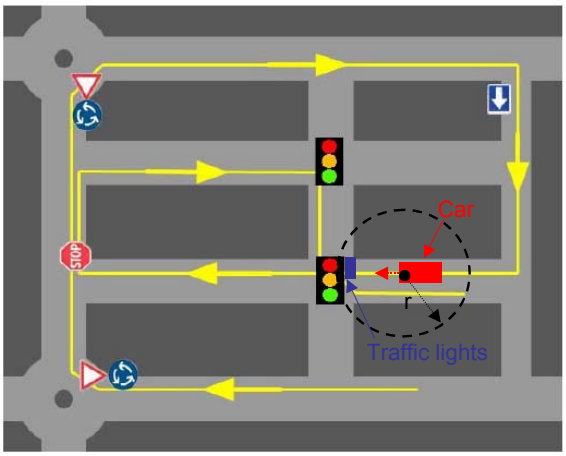

Figure 11: AVA learning to drive a car inside a virtual city with visual pseudo-perception.

Using our plug-ins along with 3Ds max®, designers have the information necessary to construct all types of VEs. We are now able to create the semantic information for our simulation but it will have a static character. However, we wish to obtain dynamic semantic information and we will use pseudo-perception (see Figure 11) or virtual perception [5] to achieve this goal.

In our car driving simulation, ϕ is the vector of the features indicating the different driving desiderata that need to be accounted for, such as a collision with another car, a pedestrian or a virtual object, or driving on the sidewalk, for example. The unknown vector ω^* specifies the relative weight of these various desiderata.

Blindly following the expert's trajectory would not work, because the pattern of traffic encountered is different each time.

We applied *apprenticeship learning* to try to learn behaviours to avoid pedestrians and to take traffic lights into account (e.g., stop at a red light, decelerate at an orange light and keep driving at a green light).

The final result was a good driving behaviour, since the driver could plan far enough ahead to manoeuvre the car adequately around the virtual city, avoiding pedestrians and reacting correctly to traffic lights (see Figures 12 a) and b)).

Figure 12 a): The car "sees" the traffic lights and the pedestrian inside a circular zone. The panel informs the driver that he/she must brake (B – in red at bottom right corner).

Figure 12 b): A pedestrian wishes to cross the road according to the rules defined.

We achieved our best results by performing the low-level learning method for 40 iterations and a policy was selected by inspection (see Table 2).

Table 2. Results obtained with our low-level learning methodology and one driving style (as estimated from 3 minutes of driver demonstration). All animations were rendered in real time using OpenGL on a 3.0 GHz PC with an nVIDIA GeForce FX Go5350 video card.

	Gas	Wheel
μ_e	0.060	0.290
$\mu(\pi)$	0.059	0.266
ω	0.107	0.059

Our method was qualitatively able to mimic the demonstrated driving style. Table 2 shows the feature expectations of the expert (driver) μ_e, the feature expectations learned $\mu(\pi)$ and the weights ω used to generate the policy.

Although our technique performed well in our two case studies, there is no guarantee that it will work for every imaginable AVA and simulated VE.

6. DISCUSSION

Our low-level learning technique has proved to be fast, simple and robust. It has also succeeded in automatically learning behavioural models for difficult tasks. Thus, we believe it will be more useful to the computer graphics community than a technique based on the classical *Q-learning* approach. Unlike explicit *Q-learning*, our technique is not guaranteed to find an optimal policy. But *Q-learning* is usually impractical because of a large Q-factor table

Our AVA low-level learning technique will only learn a sub-optimal policy, whose quality depends on the selected search depth limit. However, optimality is probably not necessary to achieve the appearance of intelligent behaviour in an AVA. Indeed, good behaviour usually looks just as, if not more, realistic than perfect behaviour

With our method, an AVA can automatically learn a behavioural model. For the animator, this relieves the workload of designing an explicit model. Moreover, it allows to model tasks for which it would be difficult or virtually impossible, to develop an explicit model.

Our work needs to be distinguished from that of [28]. In fact, when they performed off-line AVA learning, it could be difficult to design a fitness function that resulted exactly in the desired behavioural model. Our contribution in this paper is important because we present a solution for this previously unsolved problem and also we perform on-line AVA low-level learning.

In the robotics field, various methods like *teaching by imitation*, *imitation learning* or *learning by observation* are effective. However, since they are not automatic, they cannot be used for on-line adaptation. The technique presented by [29] for teaching a robot simple navigational behaviours is too limited for AVA behavioural learning. By comparison, our mimicking method is less general, but is fully automatic, learns quickly and can easily encapsulate very complex behaviours. One of its most original aspects is indeed to detect automatically novel behaviours.

However, there are some weaknesses in our approach. When performing AVA low-level learning, it can be difficult to find a policy that exactly corresponds to the desired behavioural model. Also, the reward function should be expressible as a linear combination of known features.

The methodology behind automatic learning behaviour is difficult but interesting. This could take interactive computer graphics, especially in the entertainment market, to a completely new level. It could also be interesting if an animator could interactively train an AVA for *behavioural learning*, rather than using a reward value.

The approach presented here is part of a more complex model that is the object of our research. The goal is to realize an Artificial Life environment for an AVA including different interfaces and sensorial modalities coupled with various evolving learning methodologies.

ABSTRACT
Aiming to represent individuals in a very realistic way, several works have attempted to introduce personality characteristics into artificial agents, usually based on theories of human personality. However, different theories require different structures in the agent architecture, reflecting on the way they influence agent behavior. This paper presents a flexible framework to generalize the influence of personality traits on the behavior of the agents. The framework provides an easy way to test and compare different personality models. In order to validate the framework, a simulation of working environment was developed and three personality theories (Big Five, Jung and Millon) were tested.

Categories and Subject Descriptors
I.2.11 [**Distributed Artificial Intelligence**]: Intelligent agents, Languages and structures, Multiagent systems. I.6 [**Simulation and Modeling**]: Applications.

General Terms
Design, Standardization.

Keywords
Agent architecture, Agent-based framework, Personality-based agents.

1. INTRODUCTION

The notion of autonomy is an essential concept for social systems. From the social point of view, autonomy is an important aspect to distinguish individuals within a society. This concept is largely used in the agent paradigm when modeling social systems [6].

When modeling human social systems, autonomy becomes intrinsically related to how the agents behave and what make them to behave differently for each other. In other words, it is necessary to identify what makes two individuals playing the same roles in a society (or in a group) and facing the same situations to behave differently.

Psychologists have tackled this issue for several decades through what they named *Personality* [2]. Personality represents the structured and dynamic set of characteristics of an individual, normally acquired from the environment and personal experiences [4]. The study of personality aims the understanding of the dimensions that allow individuals to be psychologically distinguished from another [13].

Therefore, for social systems, autonomy of an agent is also a result from its personality. In order to take the autonomy of agents into account when modeling human social systems in a low-level of abstraction, it is necessary to include the notion of individual personality. Several agent actions and characteristics, even the internal ones, may emerge from the encounter of the event perceived by the agent and its internal personality.

The use of the multi-agent paradigm for building social system simulations leads to a more natural way to represents an observed system, since its dynamics is expressed in terms of interactions between autonomous agents. However, most of the agent architecture used in multi-agent simulations considers the agent behavior based only on rational processes (e.g. BDI [5]). This does not provide tools for representing the chaotic nature of social systems. The use of personality in multi-agent applications for simulating social systems can lead to more chaotic (and realistic) results. This is one of the objectives of works dealing with synthetic actors with personality [8][12][10] and also in crowd simulations [7].

Another example of social scenario where the personality of the individuals has strong influence on the emergent behavior is in a working environment [14]. Individuals playing the same role in a working organization may have very different reaction (and consequently different performances in their tasks). This happens, among other reasons, because they have different personalities, affecting, as a consequence, the behaviors of these individuals.

There are several psychological theories and paradigms highlighting the concrete aspects of the influence of personality on the way in which we behave. However, none of them has reached a complete consensus among psychologists. Indeed, personality is subjective and subject to different interpretations. Specifically for working environment, in the Organizational

Psychology area, several models have already been proposed. Different companies may use different approaches for understanding their employees. A simulation application aiming to be generic enough to be able to represent different models will certainly face the intrinsic characteristics that is present in a model, but not in another one.

In order to solve this issue, it is necessary to conceive an agent architecture able to be adaptable to different models of human personality. Surrounding this architecture, a framework must be placed for providing enough flexibility to take into account several facets of the human personality. This paper describes the framework developed to smooth out the aforementioned problem. Flexibility is provided by description files and action scripts, separating the agent structure from its personality and behavior. Three models were implemented for testing purposes, based on the theories of Big Five [3], Jung [9] and Millon [11]. Also, a simulation application, named SimOrg – Simulation of Human Organizations, was adapted to this framework. This paper presents the framework structure and how personality-based behaviors are modeled in it.

Before presenting how different personality models can be handled in the proposed framework, it is necessary to analyze some characteristics usually found in different theory models. The Section 2 presents three theories already used in previous works related to agents. Models of those theories are also used for validating the framework. With those concepts in mind, it is possible to more easily understand the choices for the framework, which is presented in the following section (Section 3). In this section, it is pointed out how to generically represent personality in agents. The generic framework for personality-based agents is described in Section 4. In this section, it is also presented a tool to generate the scripts and description files for the framework. After, it is presented an application used to validate the framework. The application is a simulation tool for project management.

2. HUMAN PERSONALITY

Among the various paradigms (psychoanalytic, behaviorist, humanistic, biology and evolutionary, and personality traits), personality trait is the most widely accepted theory. This approach structures the human personality by a hierarchical model of traits. The behavior of an individual might be "interpreted" as a combination of the different levels of intensity of the different traits. The next sections present three different approaches for modeling personality traits. They will be used to validate the framework proposed in this paper.

2.1 The Big-Five Model

Among the several ways of organizing personality traits, the "Big-Five" dimensions (used by the Five-Factor Model [3]) have a large acceptation by psychologists, as well as computer scientists modeling personality into human-like artificial characters (virtual humans) (see, for instance [6]). It describes the human characteristics according to five main factors: extraversion, agreeableness, consciousness, openness to experience and neuroticism.

The combination of those five factors reflects the several aspects of human personality. For instance, an authoritarian person would be high on conscientiousness, but low on agreeableness and openness to experience [1] (example cited in [4]). Other combinations might be possible, resulting in a large variety of personality styles.

Although it is widely accepted, the Big-Five Model presents a constraint for us, who are modeling artificial behaviors (and not studying people). Whereas the Big-Five Model maps a behavior into its five factors, one cannot derive a behavior from the level of the factors. In other words, it is not possible to predict if someone is authoritarian only by the means of the level of his/her conscientiousness, agreeableness and openness to experience. Individuals with the same level of those factors might behave differently for the same situation. Indeed, a behavior is also a function of the personal experiences from the past and the personal ambitions for the future.

2.2 The Jung Model

Carl Gustav Jung has also proposed a theory that attempted to describe the differences of personality using categories of introversion and extroversion and also using cognitive and emotional functions. These aspects can be seen as the basic dimensions of the individual differences. According to Jung, these dimensions offer a basic typology needed to classify individuals [7].

In order to identify a psychological type, it is necessary to determine the fundamental attitudes of an individual. In other words, to define whether a person is preferentially guided through its internal world (introversion) or through its external reality (extroversion). Once it is defined, an individual can be classified according its dominant function, also known as *Main Function*, which describes the preferential behavior of the individuals. There are four possible psychological functions that can be chosen as dominant, which are the following: Thought, Felling, Sensation and Intuition.

Jung divided the four aforementioned functions into two classes, rational and irrational. The rational functions (thought and feeling) help to make judgments and decisions, and the irrational functions (sensation and intuition) supply information in which it can be based on those judgments. The fundamentals attitudes (introversion and extroversion) may be combined with the fours functions (thought, felling, sensation or intuition), which can lead to eight different combinations, constituting eight psychological types to represent the dominant function of an individual. In order to provide a more complete description of an individual, a classification of the least preferred behavior can also be defined. It uses the same function classification of the dominant function and it is called auxiliary function. It defines the function that an individual utilizes to cope with the direction least preferred situations.

According to Jung, all the aforementioned functions are present in every individual, in higher or smaller degree, but just one is predominant, which is defined in the *Main Function* [3]. The auxiliary function is identified as the function that someone uses to work with less favorite directions and it is usually the opposite of the main function. For example, if the main function is one of the rational functions (thought or feeling), the marginal function it will be one of the irrational functions (sensation or intuition) or vice-versa [3].

2.3 The Millon Model

The theoretical model of personality proposed by Millon takes into account the importance of biological factors such as genetics [11]. These factors are described in one specific matrix for each individual, which represents a fundamental role in the formation of personality [13]. This matrix is also composed of environmental perceptions and actions taken during conflict situations. During the development of an individual, personality has influence from biological and psychological factors, that interact in an endless spiral, in which each circle of this spiral is constructed over previous interactions, creating, in this way, new bases for the next interactions [14].

Millon proposed a measurement to express personality, which is based on the theoretical comprehension of the actions taken to reach the goals that an individual has in his/her life. Also, it takes into account the way to process information received from the environment. In this sense, it has been elaborated a tool to verify a dynamic configuration of interactions, representing three large areas: motivational aims, cognitive styles and inter-personal relations.

According to Millon, personality can be viewed as a result of twelve bipolar[1] attributes. The area Motivational aims includes three bipolarities, linking the ecological and evolutionist theories. It is based on the conceptual antecessors of theses two theories through three main formulations: the existence of organisms, its adaptation to the environment and the answers provided in this relation. Based on this theoretical model, Millon presented the following polarities: openness versus preservation, modification versus accommodation and individualism versus protection. In these groups of attributes, it can be observed the orientation of an individual in relation to the role of the environment as a motivation of the actions of an individual [14].

The cognitive styles can be found in the evolutionist perspective as well as in contribution of authors such as Jung and Myers. They are related to how individuals are oriented when interacting to the environment. Their main aim is to evaluate the way an individual can process information, along with three main models proposed by Jung (extroversion versus introversion, feeling versus thinking and sensation versus intuition). Based on this and in [15], the bipolarities can be defined as extroversion versus introversion, feeling versus thinking, reflection versus affectivity and systematization versus innovation.

Millon proposed to use the inter-personal component to evaluate the style of the relationship of an individual with the others. All bipolarities of this area are based on a bio-psychosocial theory of reinforcement learning as well as active and passive strategies. The bipolarities are: shyness versus communicability, doubt versus security, discrepancy versus conformity, control versus submission and satisfaction versus dissatisfaction.

3. REPRESENTING PERSONALITY INTO AGENTS

One of the issues of representing personality into agents is the transposition of the concepts coming from Psychology, in general difficult to generalize (each individual is unique), to the computational form, which functioning tries to systematize and, as a consequence, to generalize behavior. However, although personality is defined as "*an individual's characteristics pattern of though, emotion, and behavior*" [4], the main issue of representing human personality into agents is the use of the aforementioned theories on the inverse way in which there were conceived. Indeed, human-personality theories tries to generalize the behavior of an individual within a pattern group, but this does not necessarily means that knowing the group an individual bellow one can predict the individual behavior for every situation.

[1] *Bipolarity can be seen as a complementary measure between two concepts. For instance, if an individual has 30% of modification, it automatically has 70% of accommodation.*

In other words, from an observed behavior pattern, it is possible to categorize an individual (according to a theory), however it is hard to generalize a behavior from a categorized individual.

The models used by psychologists to acquire personality traits of an individual aim to "classify" the individual behavior pattern according to the different dimensions (for instance, the five-factor model deals with five characteristics). This classification is then a function of the observed behavior pattern (or from a pattern acquired from filling a questionnaire), mapping the behavior to a classification. However, the mapping function is not bi-directional for every situation. An individual classified as introverted does not necessarily acts introverted for all situations, but at least in those ones observed or asked in her/his questionnaire.

In order to simplify this issue, without losing generality, the function that maps personality to behavior patterns can have an error parameter for representing possible variations on the behavior pattern. The model proposed by Jung attempted to solve this issue through the Auxiliary Function, which represents the behavior pattern used when the Main Function is not trigged (Jung worked deeply on the subject of unconsciousness). In the same way, an agent architecture dealing with personality must handle unpredictable behaviors of the agents. The agent behavior is then a function (Eq. 1) of the situation it is facing (*s)*, its personality characteristics (*p*), and the level of error (*e*), which model the variation of the personality attributes in the agent behavior.

$$b = f(s, p, e) \qquad \textbf{Eq.1}$$

The way in which the personality is represented and how it is handled, providing a general framework for personality-based agent systems, is presented in the next section.

4. A GENERAL FRAMEWORK

As previously mentioned, autonomy is an attribute intrinsically related to social systems. In the context of agent paradigm, this is related to Multi-agent systems, where agents are organized in one or more groups. Agents also perform tasks and, eventually contribute to each other through coordination mechanisms. The proposed framework takes those characteristics into account, conceiving a way to structure the agents inside its multi-agent system as well as how they coordinate their actions. The source of inspiration for defining the framework was the way in which individuals work within of a human organization. Several pieces of code were also adapted from a previous framework developed by one the author of this paper; the framework MAVIS [17]. The MAVIS framework was developed for ecosystem simulations based on reactive agents. The simulation structure of the framework (simulation kernel, event treatment, etc.) was conserved, but the agent-side of the framework was remodeled for taking into account the agent architecture presented in the paper.

In a working environment, individuals are grouped and structured in a hierarchical way, composing the configuration of organization. Individuals may also be member of several groups. This approach is similar to organizational model AALAADIN [15] used by the MadKit platform [16]. Usually, in working environment, there is also a process guiding the actions of individuals. The process indicates which activities must be performed for the first place, which are the dependencies of each activity, and so on. This idea was also translated to the framework proposed in this paper.

Then, the framework takes into account three different aspects of a multi-agent system:

- **The organizational structure**: that defines the static component of the system. In this model, the hierarchical distribution of agents in groups and the roles they will play inside their groups are defined. The roles are useful for determining the actions an agent is responsible for;
- **The organizational process**: that defines the dynamic component of the system. It structures how the agents integrate their actions to achieve a common goal. The organizational process is organized in activities, where each activity is an set of actions; and;
- **The behavioral component**: that defines how the agents perform the tasks described in the organizational process. It is in this component that personality attributes plays an important role. Each action that an agent performs will suffer influence on its personality attributes.

In order to provide flexibility for these three aspects, the framework takes in charge three description files, each one for a different aspect. In this sense, the organizational structure, process and behavioral component can be customized according to the application without changing the framework code.

4.1 The agent architecture

Each agent in the framework represents an individual within a multi-agent organization. The interactions, rules, structures and interaction protocols that happen within the organization are dependent to the way the agents process information. Then, it is necessary to model the internal architecture of the agents in order to structure the framework. Moreover, the agent architecture must also take into account personality attributes when enabling, disabling or activating an agent action.

The architecture for the agent is shown in Figure 1. As it can be observed, the defined architecture contains not only modules commonly used in a common agent architecture, such as perception, planning, goal definition and action, but also it is composed of a base, defining the artificial psychological profile of the agent.

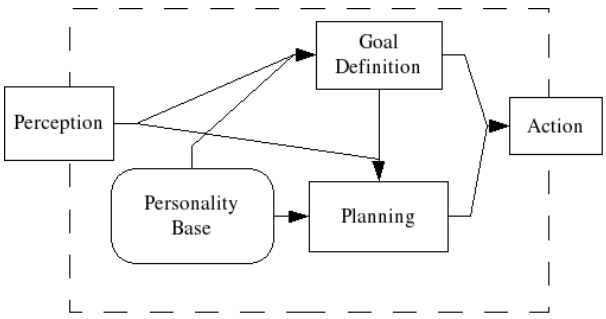

Figure 1 – The agent architecture.

As personality can be seen as the way in which an individual interacts with the environment, it is represented as an information base, or personality base. Depending on the personality model used by the framework in a specific application, the attributes used in that base might differ. For instance, for the model proposed by Millon, it is composed of the three aforementioned topics of the human personality (motivational aims, cognitive modes and inter-personal relations), each area having its respective bipolar attributes.

The personality base has strong influence in the definition of the goals of an agent (goal definition module) as well as in the choice of the actions to perform the chosen goal (planning module). In other words, when the module of Goal Definition is activated, it can request information from the personality base in order to define the agent goal.

In considering the personality base as a common knowledge base, this agent can be seen as a common BDI (Beliefs, desires and intentions), in which based on its beliefs, an agent can choose its goals as well as the needed actions to reach this goal. The use of personality will help to transform the modeling in a more natural one, in which the personality of an individual should and will be taken into account.

As it can be observed in Figure 1, there are some arrows indicating the influence of the personality base over the modules of Goal Definition and Planning. The arrows represent mapping functions from the personality to the respective modules. This mapping is provided by behavioral scripts, explained more in detail in next section.

In order to model the complex set of behaviors that an agent might perform within an organization, it is necessary a huge amount of rules associated to the agent. Depending on the role the agent plays inside the organization (or inside the groups of the organization), the agent must organize its activities (or tasks) according to a priority criterion. This priority order of the activities that an agent is responsible for is modeled by a horizontal layered architecture, similar to the reactive architecture defined by Brooks (Subsumption). This architecture was however extended to provide the following needs:

- **The ability to deal with two level of action abstraction:** The first level is composed of activities, which represents the tasks the agent are responsible for. For instance, an agent that is member of two groups might play different roles at the same time, having, as a consequence, to execute different activities. The second level is composed of actions. In fact, an activity is defined as a set of actions that might be performed in a specific sequence or not;
- **The ability to dynamically define priorities for activities:** In the agent architecture, the layers define the level of priority of an activity. However, this priority might be changed dynamically as a result of an action performed by the agent. Whenever the priority of an activity is changed, the respective set of actions assigned to the agent will also change.
- **The actions of the activity with the greater priority compete between themselves to be activated:** If an agent is executing an activity composed of several actions that one does not depends on the other, the independent action will compete between themselves to be activated, according to a probability degree. This degree is defined as a function that maps the attributes specified in the personality base and the corresponding action. This approach is suitable for representing the "personal" choice of the action, since there is no dependence of the competing actions.

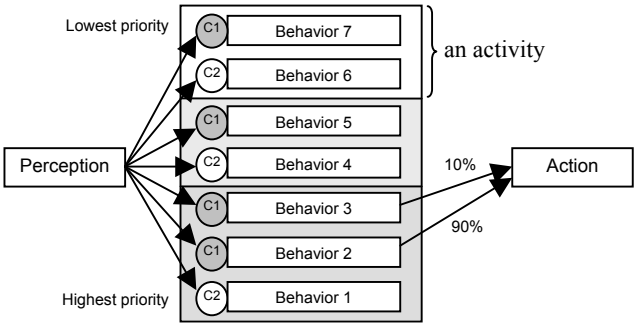

Figure 2 – Functional schema for the agent architecture.

The Figure 2 illustrates the functioning of the layered architecture. Each behavior rule, in order to be activated, needs that its antecessors (represented in the figure as C1, C2, etc.) be validated. Among the behavior rules of the activity with the highest priority (in the figure, represented by the Behaviors 1, 2 and 3), just one will be activated. Supposing that two of them have their corresponding conditions validated (C1), they will compete according to the "personal" interested of the agent. The system will then define the degree of probability for activating the behaviors (in the case illustrated by Figure 2, it is the behaviors 2 and 3) according to the personality attributes saved in the personality base, resulting in the most probable action the agent will take.

The way in which the agent architecture maps the personality to the actions is through a function, scripted when implementing a behavior action. The function itself is based on empirical feedback given by an expert (psychologist). There is no good or bad match between personality and actions, however it normally requires several simulation executions before the simulation model (the script function mapping personality and actions) be considered calibrated by an expert. The next subsection describes the simulation model more in detail.

4.2 Scripting Personality and Behavior

The personality model in the proposed architecture influences the agent behavior. Since, as previously mentioned, there are several ways to represent personality, it is necessary to adapt one of them in a specific application. In order to do this adaptation in easy way, we used a rapid prototyping strategy. We moved the behavior part that relates the actions execution and the personality models into a bean shell script. Therefore, in order to update the agent behavior, it is just necessary to alter the script file.

An action is a Java class that encapsulates an action script. The action accesses the script interpreter and, then, calls its methods separately. Each action method is related to a script method. The main methods that the script must implement in order to integrate with the framework are:

- **The evaluating method**: `validate()`: it is used for calculate the probability of the action to be executed, according to the personality parameters;
- **The quality method**: `getQuality()`: it calculates the amount of work the agent will do in that action. The higher the quality is, the better the action execution, and;
- **The execution method**: `execute()`: it performs the sequence of steps for an specific action.

Besides the methods, the script has the personality type data. The simulation uses that data to link the agent personality to the action ideal characteristics, influencing, in this way, the evaluation and quality methods. In other words, in order to have a better chance to execute an action, the agent must have a personality that is close to the ideal profile described in that action.

As presented in section 3 (Eq.1), the behavior of an agent also takes into account a level error, representing unpredicted behavior. This error is a randomly generated value in [-0.1;01] that is added to the personality attributes when the `validate()` and `getQuality()` methods are requested. Then, a level of error is introduced for simulating unpredicted behavior.

In order to facilitate the end-users of the framework, a tool for generating the scripts files was developed. As previously mentioned in the framework description, the framework deals with three different aspects of a multi-agent system. The tool attempts to facilitate the handling of theses aspects by generating three different files, all of them specified in XML format:

- The organization structure file.
- The work process file.
- Several files containing the personality and scripts.

The file containing the personality descriptors is written for each personality model. It consists on three main tags:

- The `script` tag containing pieces of bean shell script;
- The `personality_descriptors` tag describing the personality stereotypes for each model;
- And the `action_descriptors` tag describing the personality ideal profile to execute the action;

Figure 3 illustrates description of a personality following the Jung approach of personality. Bean shell pieces of code constitute the `script` tag in the XML file. These pieces of code compose the actions files. They have a method-like format to enable the action script generation. This kind of format is necessary to get the action to execute correctly for each model. Since the Jung, Big Five and Millon models have different approaches, it is not possible to use the same evaluation model for them.

```
<model theory="JUNG">
    <script>
        <method name="execute">
int p =
entity.getActivityPriority(activity.getName());
runningTime++;
aux = getQuality(entity);
...
        </method>
        <method name="quality">
personality = entity.getPersonality().getName();
a =  ideal{personality};
...
return new Double(apt);
        </method>
    </script>
    <personality_descriptors>
          <personality name="ES">
            ...
          </personality>
    </personality_descriptors>
    <action_descriptors>
          <action name="code" size="700">
              <property name="ES" value="0.7"/>
          </action>
    </action_descriptors>
</model>
```

Figure 3 –XML file illustrating the personality description.

The `personality_descriptors` tag consists of personality stereotypes. Each stereotype is a personality pre-defined description. They were conceived by a specialist to give a theoretical basis to the use of human personality in the simulation.

Finally, the `action_descriptors` is composed of personality descriptors. This part of the XML file links the action to the personality models. This part of the file contains information about the ideal personality profile to execute the action, this data are used to generate the script file as well.

An agent action is composed of a sequence of several steps. The agent might read its messages in the mailbox update its internal states and/or execute its behavior pattern. Part of agent cognitive mechanism stay in the behavior. The behavior evaluates the list of activities in which the agent is involved. When an activity is chosen (by its priority), the agent create a list of actions. In next step, the agent validates its list accessing the method "validate" of action. This method answer if the action can be executed (it is the condition explained in Figure 2). When more that one action is valid, the agent begins the decision process. On that moment the behavior access the `evaluate()` method of the action. This method determine the probability of the agent execute an action. Then, the personality descriptor of the agent is compared to the personality descriptors of the action. The comparison result is used for provide the degree of probability that the action will be executed by the agent. Finally, when an action is chosen, it starts the its execution. To execute an action the method `execute()` of action is called. During the action execution, it is necessary to access the method `quality()`. This method, as well as, method `evaluate()` compare personality descriptor, but for a different purpose. The method `quality()` use the information of personality to determine the agent performance when execute the action. The greater is the quality of action performed by an agent better is the result from that execution. An example of personality profile used in the framework is illustrated in Figure 4.

```

The XML files can be written manually or using the graphical tool showed in Figure 5. The graphical tool can read, edit and write the XML files used by the framework. It is a friendly user interface, that it abstracts the user of the XML complexity.

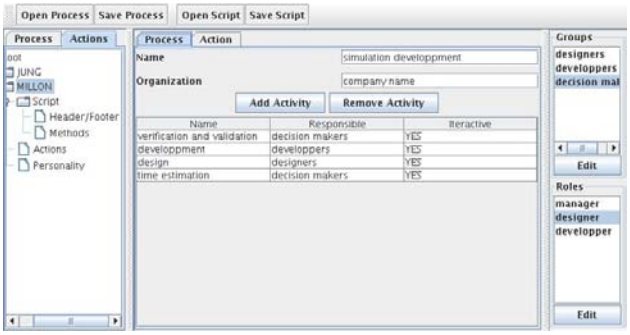

Figure 5 – Initial display of the XML generator tool.

5. APPLICATION TO WORKING ENVIRONMENT SIMULATIONS

The proposed framework was developed to solve the flexibility issue faced during the development of a simulation application, named SimOrg. This application aims to reproduce the organizational dynamics found in working environment and can be used for studying individual behavior within an organizational as well for education and training purposes.

As the original version of the SimOrg application does not give flexibility for representing personality-based agents on different models, a new version of the simulator was proposed in order to generalize the application. The adaptation of SimOrg to the framework provided the ability to accept a larger number of agent personality models such as the Millon, Jung and Big Five models.

5.1 The SimOrg Scenario

In order to analyze the influence of personality in the performance of the SimOrg agents, it has been defined a scenario for a working organization, where agents could not only interact and act according to their own personality, but also follow a working process (organizational rules). The scenario was based on the experience of the authors in developing software. In this sense, the fictitious organization is a software development company.

In the scenario, the chosen development process is an iterative one based on agile methodologies [18], which was simplified for testing purposes. Agile methodologies are ideal for testing the proposed architecture as individuals and their informal communication are very important for them. In other words, the success of a project is not only a matter of passing formal documents through staff., but also individual interactions that can represent a successful project.

The scenario was then represented as having formal, informal interactions and task actions, like *manager, design*, *estimate time*, *code*, *test code* and *validate design*. Those actions were organized into four activities, each one having an individual or group responsible for.

The communication acts follows a small subset of an ACL structure, composed of *performative*, *sender*, *receiver* and *contents*. Although this is enough for representing communication between agents, it was observed that human communication is not necessarily binary (to send or not to send a message). In order to model working human organizations, it is also necessary to represent how good (or bad) an individual performs an action, including communication acts, and the importance that an individual gives for those actions. For instance, suppose that a very introspective individual can not perform a task as desirable. Although there is reluctance in

asking for help, s/he will end up asking for a colleague help. The way in which s/he performs such an action (*quality*) and the need for doing that (*importance*) will certainly be influenced by his/her personality (very introspective). As a consequence, we have introduced in our ACL subset two other components: *quality* and *importance*, whose values are functions of the individual personality attributes (openness, introversion etc.). In this way, an agent is also able to react to a received message according to its quality and importance.

5.2 Scripting the scenario

The structure of the software company described in the scenario is composed of managers, designers and developers; these are meant as roles in the organization and on the simulation as well. The workers (agents) are allocated on groups that are semantically separated according to the roles of their agents. An agent performs one or many of those roles in the organization depending on the groups in which the agent is. In other words, for each group that the agent A belongs, a role is associated to A in the group. A group must always have roles agents that will play them. In this XML script, this is represented by the organization description file. The Figure 6 shows a piece of the XML file that describes the agents and its roles in a group.

```
<group name="X" type="developpers">
   <agent-role agent="C" role="manager"/>
   <agent-role agent="E" role="developper"/>
   <agent-role agent="F" role="developper"/>
</group>
```

Figure 6 – A piece of code representing a group and the roles and agents associated to it.

Once the static part of the organization is defined, the agents will have to perform some actions. The organization sets the actions that each role will execute, so the agent will perform all the actions associated to its roles like in real organizations. The set of possible roles is: Manager, Designer and Developer. And the set of actions is: Manager, Estimate Time, Design, Code, Validate and Verify.

The organization, in order to accomplish the software product manufacturing, must complete some activities in certain order. An activity is a part of the organization's process; it consists of an actions sequence, so when all the actions in one activities are done, the activity itself will be over. Activities can depend on other activities in a certain percentage, that is, suppose that the activity B depends on the activity B in 30%, then when 30% of A is done, B can begin. There are four activities in the organization process: time estimation, design, development and verification and validation. The design activity depends on time estimation, the development activity depends on 30% of the design and verification and validation activity depends on 30% of the development activity.

The actions were conceived in order to clearly distinguish the agent structure: its motivation, fatigue, roles; the agent personality and the action itself. For each action is defined in its script an ideal suitable personality to perform that action, the closer the agent personality is to that ideal, the more efficient the agent will be executing that action. Each agent has an attribute called motivation, this feature also defines the quality of the agent work on the action, if an agent has got a low motivation, this will affect negatively in the action performed by that agent. Another attribute is the fatigue; it influences the agent motivation, so indirectly influences the quality of the agent work.

All those settings for the organization and the process are made in the XML file. The user can share the scenario file that he has build in the application through the Web and then other users can construct their simulation scenario based on that one.

5.3 SimOrg Application

At this stage of the implementation, a stable version of the Simulator is ready and on use. Some tests have already been done in the current version and it is now being validated by possible users. Also, an interactive graphic interface has been built in order to fulfill the requirements of an interactive simulation, as the SimOrg simulation is. The main graphic elements of the simulator are the following: the different data visions of the fictitious organization and the actions that the users could use to interact with the simulations.

Figure 7 illustrates a screenshot of the initial screen of the simulation system. On the top left-hand part of the figure, shown by arrow 1, it is possible to have a vision of the organization, described in a tree-structure. It shows the structure of all groups hierarchically. In Figure 7, for instance, the simulated organization has three groups, decision makers, designers and developers.

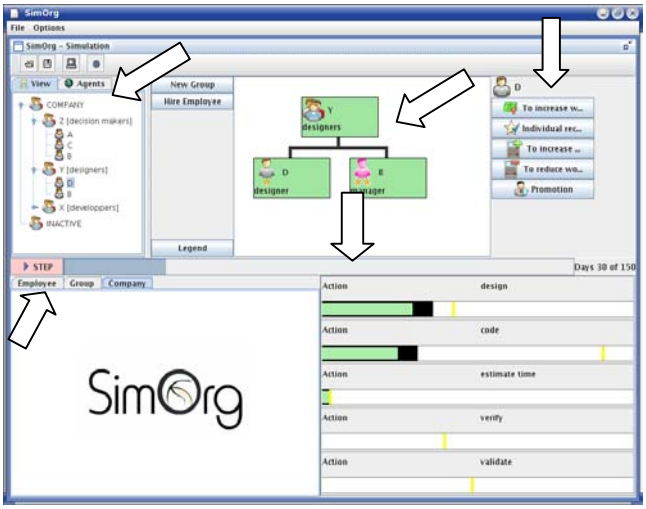

Figure 7 – Screenshot of the initial screen of the simulation.

On the top center part of the figure, shown by arrow 2, it is possible to see the organization chart, which describes the distribution of the agents into the groups. Also, it describes information about the state of the agents, such as the role of the agents in the group. The organizational chart can represent the whole company or parts of it. In Figure 7, for instance, it is shown the organizational chart of the designer group, which is composed of one designer (D) and a manager (E). In the organization chart and in the tree-structure, a user has the permission to change the structure of the organization, changing some agents to different groups and roles. Also, a user can perform user actions for the selected agent, pressing the left bottom of the mouse.

On the top right-hand part of the figure, shown by arrow 3, all the possible user actions are shown and, at any time during the simulation process, a user can choose to apply a user action. As already mentioned, the user actions can be done in order to improve the motivation level of an agent, aiming to increase the productivity of the organization.

On the bottom left-hand side, shown by arrow 4, there is a panel which contains information about agents, groups and the simulated organization. In this part, information about the agent history, such as: the roles that the agent performs within the group and activities of the groups, activities already performed by the agent, are described.

On the bottom right-hand side of Figure 2, shown by arrow 5, action graphics are described. These graphics represent the progress of all active actions of the system in relation to time. The main aim of these graphics is to show how early or late the agents are in the execution of the actions. The graphics show the estimated time of an action (yellow line) as well as the amount of time already used by the agents. In order to let the understanding of the graphic more intuitive, there is a variation of colors to represent the progress of the actions. The green color means that there is no delay of the action until the current iteration. On the other hand, the red color represents a delay in the progress of the action Also, the black part of an activity means the optimal execution time. In using the real and optimal execution time, it is possible to analyze how late an activity is.

In addition to that, as an activity can be performed by a group of agents, in analyzing the agent history (bottom left-hand side), it is possible to detect which agent is having the most negative contribution to the delay in the execution of the activity. Also, for each activity performed by the agents, it is possible to visualize a graphic in which the contribution of each agent in the execution of the activity is described. It is shown when pressing the left button of the mouse in the activity required.

6. CONCLUSION

This paper presented a flexible framework for representing agents in a multi-agent system taking into account personality attributes for deriving the agent behavior. The flexibility refers to the ability to represent human personality into agents by the means of different models. This framework is based on the concept of working environment and reflects the static and dynamic structures and processes usually found in working organizations. As proof of concept, an existing simulation application, SimOrg, was adapted to the framework, having now the ability to represent personality in several ways.

The gain of the flexibility provided by the framework in this specific application is the possibility to easily adapt SimOrg to different companies. Indeed, as there is no consensus among psychologists about human personality, the Human Resource Department of company might work in a differently from another one. The simulation training tool SimOrg must then reflect the concept used by the company.

The ability to quickly change behaviors and personality traits has also been important tool for psychologists, since they can now analyze some important behavioral aspects of groups by prototyping by themselves their own experiments. These analyses will help the psychologists to define which aspects will have influence, for instance, in the productivity of a group and, then, to define which solutions could be done in order to improve the productivity of a working organization.

ABSTRACT
A review of recent theories of emotion indicates close interconnections between emotion and social norms in human societies. We consider the possibility of implementing these mutual influences in a multi-agent system in order to establish dynamic and flexible control structures. According to some theories, emotion plays a key role in establishing and maintaining these structures by fostering the internalization of and compliance with social norms. Here we introduce a Petri Net based approach to modeling the emergence and maintenance of social norms in multi-agent systems.

1. INTRODUCTION
Controllability of multi-agent systems (MAS) is one of the main challenges for current Distributed Artificial Intelligence (DAI) research: the desire for systems' autonomy, flexibility, and proactivity may conflict with imperative issues of global system control [13]. Achieving system control without abandoning core strengths of DAI systems might be accomplished by using the social mechanisms providing coordination and control in human societies. Applying these mechanisms and their functions to artificial societies is the main goal of this paper.

One feasible solution to the problem just outlined is the implementation of a system of shared norms which is not coerced by the designer, but instead emerges from mutual interactions of agents [15]. To realize such an approach, it might be beneficial to adapt to the computational context the mechanisms of norm maintenance and compliance in human social systems. Proper theorizing and empirical evidence both indicate that emotion is essential in sustaining social norms and enforcing sanctions in cases of non-compliance [6, 7, 9]. This regulatory function of emotion in societal affairs was recently corroborated by empirical findings suggesting that emotions reinforce norm-compliant behavior and punishment of deviant behavior [4, 5].

In support of the plea to integrate theories of emotion into the computational study of social norms [16], we aim to show how emotion theories of different disciplines can jointly specify the interrelation between social norms and emotion. Furthermore, we argue that emotion may provide a basis for establishing solid control mechanisms within MAS by promoting norm-compliant behavior, provided that social norms are at all implemented in the system. First, we offer some initial theoretical foundations and second, we represent selected aspects in a Petri Net based model.

2. THEORETICAL APPROACHES
In this section we will briefly review some social science theories suggesting a crucial function of emotion in sustaining common behavioral norms. Basically, the theories claim that some emotions sustain social norms whereas others (e.g., contempt, disdain, disgust) are incentives to punish violators [6, 8]. "Self-conscious" emotions such as shame, embarrassment, and guilt are, inter alia, evoked by violating a social norm. They are negative payoffs and the desire to avoid them contributes to sustaining social norms within an actor, ancillary to any third party punishment. Thus, the anticipation of certain emotions promotes the internalization and, subsequently, the enforcement and maintenance of social norms.

In addressing the "foundational theoretical problem of the social sciences – the possibility of unconscious, unplanned emergent forms of cooperation, organization and intelligence among intentional, planning agents" [2, p.6], we have argued that the potential of social norms in explaining social structural dynamics cannot be investigated properly without considering the role of emotion [14]. Conte and Castelfranchi view a norm as a mental object, i.e. a hybrid configuration of beliefs and goals [3]. Endorsing this approach, the social, temporal, and spatial distribution of norms makes them instances of a macro system; at the same time, however, their definition as configurations of

beliefs and goals renders them an instance of the micro level and accordingly a primary subject matter of different kinds of reasoning processes. Previously, we have shown that emotion may be a loophole in this respect [14] and that Elster's [8] conceptualization thereof is well suited to serve as an amendment to existing positions.

Elster proposes a definition of certain qualities of social norms instead of the concept as such [8]. Accordingly, norms are "social" insofar as they are sustained through sanctions by a third party which is by definition unaffected by the norm transgression. Consequently, the presence (or representation) of other agents is necessary to enforce and maintain a social norm. Elster argues that imposing sanctions on the norm violator is driven by emotions such as contempt or disgust, whereas "sanction" may just mean a subtle expression of such an emotion, e.g. a gesture, a facial expression, denial of communication, etc. Even if the norm violator would not suffer any material loss, the effectiveness of sanctions is still ensured through the emotion of shame, which a norm violator will suffer when perceiving the sanction "as a vehicle for the emotions of contempt or disgust" [8, p.146]. Also, the mechanisms described by Elster have in part been validated empirically [9, 12, 5, 1].

Damasio provides evidence for the utility of social emotions in view of the internalization of social norms [4]. His somatic-marker hypothesis explains the role of social emotions in categorizing social situations experienced in individual socialization and ontogeny, in which social and personal experiences are to a particularly high extent emotional. Actors experience a wide range of (social) emotions (e.g., sympathy, pride, contempt, shame) which might be induced by punishment or reward. Gradually, experienced situations are categorized according to their intrinsic structure, components, and their significance in terms of prevailing goals and beliefs. Hence, the resulting conceptual categories are connected with the mechanisms responsible for emotion generation. The intrinsic structure of a social situation, options for action and probable future outcomes are more and more associated with corresponding emotions. The subsequent occurrence of a situation of the same category then more the less automatically induces the respective emotional state [4]. "This arrangement allows us to connect categories of social knowledge – whether acquired or refined through individual experience – with the innate, gene-given apparatus of social emotions" [4, p.147]. Moreover, it is demonstrated how cooperation – as an epitome of the norm of reciprocity – can be stimulated and in fact be reinforced by positive emotions [4, p.156].

In view of the interaction of emotion, norms, and normative behavior we can sum up that shame and contempt in particular serve as vehicles for maintaining norms by promoting normative behavior and avoidance of adverse consequences. Compliance with social norms therefore not necessarily arises as a consequence of anticipating a loss of material resources through sanctions. Rather, it is (also) the result of internalized strategies to prevent emotion-based sanctions (e.g., contempt, disdain, detestation or disgust in the punisher) that would entail negative emotions (e.g., shame, guilt, embarrassment) in the violator. Similarly, emotion-based rewards (by way of admiration, appreciation or approval expressed by observers of normative behavior) reliably cause positive emotions (e.g., contentment, satisfaction, pride) in the conforming actor. In consequence, the anticipation of positive emotions facilitates the internalization of social norms. In what follows, we give a sketch of possible formalization of these views and represent them with a Petri Net model of emotion-based norm enforcement and maintenance.

3. PETRI NETS MODELING

In this section we follow a socionic approach [12] to represent the main arguments in a Petri Net based model. Figure 1 shows a Petri Net representation of sanctioning non-complying behavior by means of social emotions, as suggested in [7] and [8]. Rectangles (transitions) represent actions, whereas circles (places) denote available or unavailable resources or conditions that might be met. Arcs directed from transitions to places represent preconditions for action, whereas arcs directed from places to transitions represent an action's outcome. A firing transition (i.e., an action that is implemented) will remove resources or conditions (tokens) from places and insert them into some other place.

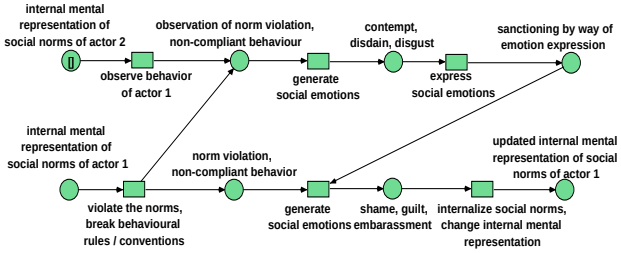

Fig. 1. Internalization [4, 8]

The bottom thread of the net represents the violator's (1) course of action, the upper thread that of an observer / punisher (2). Actor 2 observes the behaviour of actor 1 and perceives a norm transgression (transition "violate the norms, break behavioral rules / conventions"). Social emotions of contempt, disdain or disgust are elicited (transition "generate social emotions") and their expression (transition "express social emotions") constitutes the sanctioning of a norm violator [6, 8] in giving rise (place "sanctioning by way of emotion expression") to negative emotions in the violator (transition "generate social emotions") and induce states of shame, guilt or embarrassment. To integrate the concept of emotion-driven internalization of social norms [4] (s.a.), we extend this model with an additional transition "internalize social norms, change internal mental representation", indicating that certain negative emotions (s.a.) become associated with a situation of norm violation. Occurrence of a similar event would then automatically induce the associated emotions [4]. Associations between negative emotion and norm transgression thus foster the (re-)internalization and reinforcement of social norms and at the same time also update the corresponding internal representation of the norm ("updated internal mental representation of social norms").

Reinforcement of norm-compliant behavior through positive emotions [4, 7, 8] can be modeled in analogy: situations of norm-compliance are associated and internalized along with positive emotions, motivating an actor to seek out situations in which compliance with the (updated) internal representation of a norm leads to intrinsically rewarding positive emotions. Referring to the problem of agent cooperation, this mechanism can be exemplified as cooperative behavior based on adopted social norms within a multi-agent society. In this case, cooperation is mutually rewarded

with different positive emotions, i.e. acknowledgement, gratefulness, or admiration on one side, and pride or satisfaction on the other side. Incentives to cooperate are reinforced on the micro level within a single agent, consequently also reinforcing the norm of cooperation on the macro level of an entire MAS.

Figure 2 integrates processes of sanctioning and reinforcement in a general Petri Net model of emotion-driven norm enforcement and maintenance on the macro level by means of internalization of norms and emotions on the micro level. Here, a powerful variant of Petri Nets – a reference net [17] is used. A notable property of a reference net is the possibility that tokens located on a place in a net (the system net) may again be a reference net (an object net) (or some arbitrary Java object) [17]. Further details on reference nets modeling are omitted here (see [11] for details).

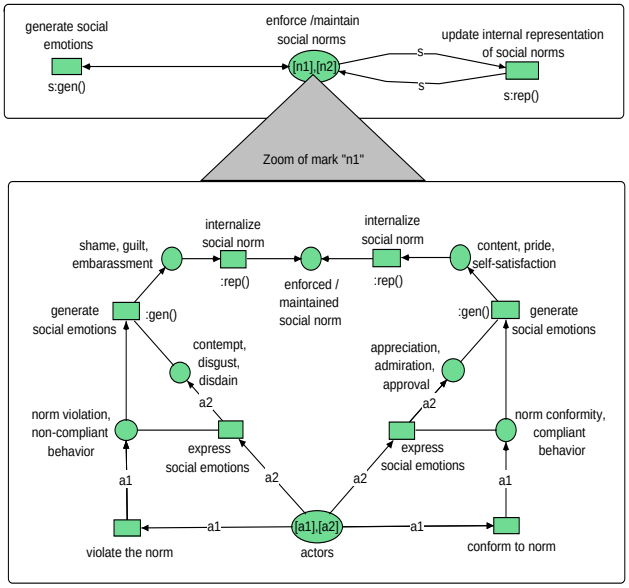

Fig. 2. Emotion-based enforcement and maintenance of norms

4. DISCUSSION

Modeling the social functions of emotion is supposed to improve MAS, e.g. in view of alternative coordination solutions and structuration. Our approach allows modeling the interrelation of social norms and emotion at different levels of abstraction. On the one hand, norms can be modeled on the micro-level, reflecting implications of the internal representation of norms for agents' de facto behavior. On the other hand, norms can also be modeled on the macro-level, thereby focusing on the social mechanisms of norm enforcement and maintenance. A detailed analysis of these approaches and their implications for the dynamics of MAS are clearly beyond the scope of this paper. We basically aimed to show the general role of emotions in enforcing norms in MAS and to evaluate the Petri Net modeling formalisms in view of the interrelation of norms and emotion. The quantitative representation and functions of emotion in agent architectures are expressly *not* addressed herein. Embedding the models into our general multi-agent framework MULAN is the subject of future work.

ABSTRACT

In this paper we present an agent-based simulation of pedestrian dynamics based on cellular automata models. Differently from the cellular automata, our model represents different pedestrian characteristics: gender, speed, room geometry knowledge, and herding and obstacle avoidance behavior. We study how different room geometries, different pedestrian groups sizes and characteristics influence the pedestrian dynamics and the macroscopic behavior of the system. With this agent-based approach we expect to obtain more realistic results than the cases where the pedestrians are uniformly modeled. Our analysis indicates that pedestrian groups with different features contribute in different ways to the macroscopic behavior.

1. INTRODUCTION

Modeling and simulating pedestrian dynamics is more complex than simulating vehicles. Computer simulations of pedestrian dynamics are able to show a high number of characteristics that exist in the real world and contribute for a better understanding of basic pedestrian traffic principles. This way, researchers can explore the effects of new traffic rules, changes in rooms geometry and exit paths avoiding dangerous and expensive experiments.

In classical models such as continuous and cellular automata all pedestrians are modeled uniformly, disregarding notable pedestrian differences. In this paper we propose an agent-based modelling that represents different pedestrian characteristics: gender, speed, room geometry knowledge, herding behavior, obstacle avoidance behavior, etc.

2. RELATED WORK

The three classes of models for pedestrian dynamics – continuous, agent-based, and cellular automata based – represent important pedestrian dynamics features and each has its own characteristics, as well as advantages and disadvantages. In **continuous models** [2], pedestrians behavior is represented by differential equations describing their movement and pedestrian are treated as particles affected by repulsion and attraction forces. This approach is successful when simulating pedestrian dynamics and space-time self-organized patterns, such as lane formations and oscillations on bottlenecks. Regarding **cellular automata models** (CA), in [1] pedestrians have different speeds and are represented by an automata aiming to maximize their frontal movement. In the model by Schadschneider and coworkers (see chapters of Burstedde et all. and Schadschneider in [5]), pedestrians move influenced by a pheromone trail. In **agent-based models** [4] pedestrians are simulated as agents that seek to minimize their mental stress improving their comfort while walking. This last model is the closest to ours in the sense that it is also agent based. However it is less focused on dynamics and more on stress and comfort of the agents, an issue particular to their scenario.

Next we briefly review features such as lane formation, attractive and repulsive effects and make a comment on implementation issues of those models.

Pedestrian flow is more efficient when pedestrians are organized in lanes. Besides, **lane formation** does not arise from the pedestrian initial spatial configuration but is a consequence of pedestrian interactions. Pedestrian dynamics space-time patterns appear due to the non-linear interactions among them. These interactions are caused by model's **attractive and repulsive effects**. Therefore these effects are important to pedestrian dynamics simulation. Attractive and repulsive effects are present in [2]. Pedestrians are attracted to their destination, other pedestrians, or objects. They maintain a certain distance from other pedestrians and objects to avoid collisions. This repulsive effect depends on the pedestrian density and desired speed. The model proposed in [4] has attractive and repulsive effects, represented in the agent's objective of minimizing the *destination*

stress (*D-stress*), that is the mental stress perceived when the agent cannot go through the shortest way to his destination. Repulsive effect is represented in the agent's objective of minimizing the *pedestrian stress* (*P-stress*), that is the mental stress perceived by the agent from others pedestrians while walking. The model proposed by Adler and Blue represents in the CA rules only attractive effects, but no repulsive effect is simulated. The CA model from Schadschneider and coworkers represents in the *dynamic floor field* and in the *static floor field* attractive effects, however no repulsive effect is modeled.

Regarding **performance**, in continuous models, each pedestrian must be compared with all others in order to perform the attractive and repulsive forces calculation, representing a large effort. In CA models, as they are discrete in time, space, and state variables, plus pedestrian interactions only occur in the local neighborhood, this makes them good for high performance computer simulations such as evacuations of stadiums with thousands of pedestrians. In the model by Osaragi, each agent cannot be too complex, because if it takes too much time to deliberate. Thus, in a simulation with hundreds or thousands of pedestrians the simulation time would be excessively long.

3. MODEL DEFINITION AND DYNAMICS

Our model is based on a CA but represents different pedestrian characteristics. Several underlying concepts are: Preferences Matrix, Floor Field, Sensitivity Coefficients, Speed, Hindrance Coefficient, Transition Probabilities and Collision Resolution.

Each pedestrian Ω has a **preference matrix** M^{Ω} which represents the pedestrian probability of movement in all directions: $\{M^{\Omega}_{i-1,j}; M^{\Omega}_{i,j-1}; M^{\Omega}_{i,j}; M^{\Omega}_{i,j+1}; M^{\Omega}_{i+1,j}\} \in [0,1]$. $M^{\Omega}_{i,j}$ represents pedestrian probability of remaining in his current position. The preferences matrix may be calculated, for example, by a route selection algorithm.

Attractive and repulsive effects are important to reproduce self-organized collective effects in pedestrian dynamics. We avoid explicitly modeling attractive long ranged interactions. Instead, we use the *floor field* concept. Through the *dynamic*, *static* and *repulsion floor fields*, we can simulate pedestrian interactions and attractive geometry effects in a simple and unified way.

The **dynamic floor field** represents the virtual path created by pedestrians while they walk. It models the long ranged attractive interaction among pedestrians. The dynamic field ($D_{ij} = 0$) is zero for all cells (i,j) in the grid at the initial time ($t = 0$). Whenever a pedestrian moves from one cell (i,j) to one of the neighboring cells, the dynamic floor field at cell (i,j) is increased by one: $D_{ij} = D_{ij} + 1$. Besides, the dynamic floor field is time dependent. It has diffusion parameter $\alpha \in [0,1]$ and decay parameter $\delta \in [0,1]$.

The **static field** models space regions that have a higher attractive effect, such as exit doors. It does not change over time, even with pedestrian movement.

The values for the static floor field $S_{i,j}$ used in this paper are calculated as in [3]. The static field has the maximum value at the door cells. It decreases with distance and is zero for the cell farthest away from the door.

The explicit values of $S_{i,j}$ at cell (i,j) is $S_{i,j} = MD - DIST_{i,j}$ with MD being the maximum distance from any cell to a door and $DIST_{i,j}$ being the minimum distance from cell (i,j) to the nearest door.

A pedestrian feels uncomfortable when s/he walks in a strange person's direction. This repulsive effect keeps a pedestrian from getting too close to another person. The original model from Schadschneider and coworkers does not take such repulsive effects into account. The **repulsion field** is our contribution to model the repulsive short ranged interaction among pedestrians. Each pedestrian creates a individual repulsion field. The repulsion field has its maximum value at $E1$ and obeys the relation $E1 > E2$. The resulting repulsion field at position R_{ij} is the sum from all individuals repulsion fields all over the grid and has the following domain: $R_{ij} \in [0, \infty[$.

Each individual in a crowd has a different reaction to long ranged interactions (dynamic floor field and static floor field) and short ranged interactions (repulsive floor field). The model represents each pedestrian in a different way using **sensitivity coefficients**. For each floor field, a sensitivity coefficient is created: $K_s \in [0, \infty[$ is a static floor field sensitivity coefficient; $K_d \in [0, \infty[$ is a dynamic floor field sensitivity coefficient; and $K_r \in [0, \infty[$ is a repulsion field sensitivity coefficient.

Through the sensitivity coefficients, it is possible to model different characteristics such as herding behavior, knowledge about room geometry and obstacle avoidance behavior. For example, a large K_s implies a motion toward the exit via the shortest path. For decreasing K_s a pedestrian performs a random walk and just find the door by chance. This is important for simulations on a dark or smoke-filled room where pedestrians do not have full knowledge about the exit location. The dynamic floor field coefficient K_d controls the herding behavior. A large K_d implies a strong herding behavior, such as the one observed in the panic situation. A full explanation about K_s and K_d may be found in [3]. The repulsion field coefficient K_r controls the obstacle avoidance behavior. A large K_r implies a pedestrian strongly avoidance other pedestrians.

Pedestrians can also have different **speeds**. Differently from [1], the speed values and speed probability distribution are based on real empiric observations about men's and women's speeds. We first generate a Gaussian distribution (mean 1.62 and 1.38 m/s and variance 0.22 and 0.17 for men and women respectively).

During a panic situation, objects that usually hinder the way may be jumped. Chairs, auditorium seats, and other minor objects are common examples. Other models do not take this effect in account during panic simulations. We introduce a **hindrance coefficient** $T_{ij} \in [0,1]$ to represent the possibility of a pedestrian jumping over an obstacle. An obstacle is fully not passable if $T_{ij} = 1$. For decreasing values of T_{ij} it is easier to jump the obstacle.

The **transition probability** P_{ij} to (i,j) for the pedestrian Ω depends on all other concepts presented. With these factors we propose a modified transition probability which is different for distinct situations: normal (Equation 1) and under panic (Equation 2). These formulas are modifications of those proposed by Schadschneider and colleagues and include the repulsion field $exp(K_r \cdot R_{ij})$ to represent the repulsive short ranged interaction among pedestrians, and the hindrance coefficient T_{ij} for panic scenarios.

$$P_{ij} = \frac{N \cdot M_{ij} \cdot (1 - n_{ij}) \cdot exp(K_d \cdot D_{ij}) \cdot exp(K_s \cdot S_{ij})}{exp(K_r \cdot R_{ij})} \quad (1)$$

$$P_{ij} = \frac{N \cdot M_{ij} \cdot (1 - n_{ij}) \cdot exp(K_d \cdot D_{ij}) \cdot exp(K_s \cdot S_{ij}) \cdot (1 - T_{ij})}{exp(K_r \cdot R_{ij})} \quad (2)$$

where N is the normalization factor to ensure that the sum over all the matrix cells is 1 ($\sum_i \sum_j P_{ij} = 1$).

A **collision** occurs when two or more pedestrian choose to move to the same cell. The conflict is solved according to the relative probabilities which each pedestrian chooses the target cell (i, j).

4. SIMULATIONS

Due to lack of space, here we do not show details of all simulations performed (lane formation in a corridor, variable door size evacuation simulation, room evacuation, and auditorium evacuation under panic). Instead, we concentrate on the parameters employed and the results achieved. Mostly, each cell represents 40 x 40 cm^2 and each iteration step is 1 second.

First, one experiment by Schadschneider and colleagues was reproduced for the sake of verification of the correctness of our model. It is the evacuation of a room of 25.2 m^2 or $63X63$ cells, with an exit of one cell in the middle of one wall. All 1116 pedestrians are initially distributed randomly and try to leave the room. It was verified that our results are close to the ones found by Kirchner.

Next, we have performed the simulation regarding lane formation on a corridor (30 X 15 cells) with 65 pedestrians (50% men and 50% women). The dynamical floor field diffusion is $\alpha = 0.05$ and the decay is $\delta = 0.15$. With these parameters, the dynamical field lasts longer and has little diffusion. The repulsion field is: $E1 = 0.6$, $E2 = 0.2$. All pedestrians have herding behavior ($K_d = 1$) and sensitivity to the repulsion field ($K_r = 1$). The kind of experiment can be assessed from the qualitative point of view: our model is able to achieve lane formation (Fig. 1) and pedestrian flow is more organized than a random pedestrian distribution.

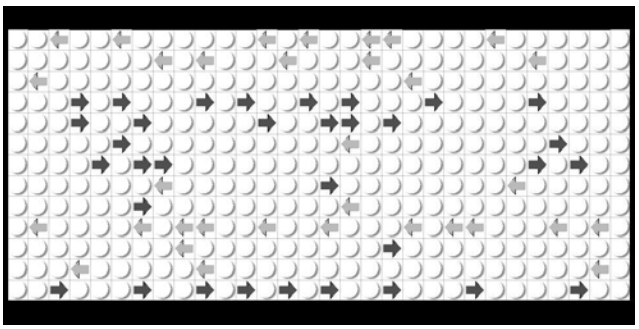

Figure 1: Lane formation

We have then simulated the evacuation of a room, 84.64 m^2 or 23 X 23 cells, varying the door size from 1 to 21 cells. The parameters are $\alpha = 0.05$, $\delta = 0.15$, $E1 = 0.6$, and $E2 = 0.2$. All 132 pedestrians (50% men and 50% women) are assumed to be in the *optimal regime* (they have a combination of knowledge about room geometry ($K_s = 1.3$) and herding behavior ($K_d = 0.5$) that minimizes the evacuation time). The repulsion floor field sensitivity coefficient is $K_r = 1$. We have measured the average pedestrian flow, the evacuation time, and the escape probability. The former increases with the door size (notice that this is not obvious: there are reports showing that pedestrian flow decreases for door size greater than 1 and smaller than 4, when there are conflicts near near the exit door).

In the last experiment, we have simulated the evacuation of an auditorium, 27 X 43 cells, in a panic scenario. The auditorium's chairs have hindrance coefficient $T_{i,j} = 0.9$ and the transition probability in panic scenario is as described in Equation 2. At $t = 0$ there are 237 individuals (50% men and 50% women) distributed in the auditorium chairs. Individuals are in the *disordered regime* after the announcement of a need to evacuate the auditorium quickly. According to [3], pedestrians in this regime are under panic and have a strong herding behavior ($K_s = 0.8$, $K_d = 2$ and $K_r = 1$). The dynamical floor field diffusion is $\alpha = 0.05$ and the decay is $\delta = 0.15$. Pedestrian flow increases at a maximum near time step 50 and begin to decrease near time step 125.

5. CONCLUSIONS AND FUTURE WORK

In continuous and cellular automata models all pedestrians are modeled uniformly, disregarding pedestrian differences. Differently from these, we proposed an agent-based model that represents different pedestrian characteristics: gender, speed, room geometry knowledge, herding behavior, and obstacle avoidance behavior. The motivation to use agent-based approaches is to achieve more realistic results than those from cellular automata and continuous models where the pedestrians are uniformly modeled. Our results indicate that when the pedestrian population is heterogeneous, the macroscopic behavior is different from a uniformly modeled population of pedestrians. Analysis indicate that pedestrian groups with different features (such as the group in the *optimal regime* and the group in the *normal regime*) have different escape probabilities and contribute in different ways to the macroscopic behavior. For future work, we intend to perform simulations with more than two pedestrian groups to investigate how the pedestrian dynamics behavior is affected by mixed classes of pedestrian.

ABSTRACT

Agents are a powerful tool for systems modeling. Instantiating each domain entity with an agent captures many aspects of system dynamics and interactions that other modeling techniques do not. However, an entity's agent can execute only one trajectory per run, and so does not capture the alternative trajectories accessible in the evolution of any realistic system. Averaging over multiple runs does not capture the range of individual interactions. We address these problems with a new modeling construct, the *polyagent*, which represents each entity with a single persistent *avatar* supported by a swarm of transient *ghosts*. Each ghost interacts with the ghosts of other avatars through digital pheromone fields, capturing a wide range of alternative trajectories in a single run of the system that can proceed faster than real time.

1. INTRODUCTION

The fundamental entity in an agent-based model is the agent, corresponding to a discrete entity in the domain being modeled, and the fundamental operator is the interaction among agent behaviors. The fundamental entity in an equation-based model [9] is some system observable, and the fundamental operator is the evolution of that observable. Agent-based models often map more naturally to the structure of a problem than do equation-based models, have representations that are more naturally constructed and explored, and provide more realistic results [8], but have a shortcoming. The observables in an equation-based model are often averages across many agents, and so implicitly capture the range of agent variation (although at an aggregate level). The software agent representing an entity in an agent-based model can execute only one trajectory in each run of the system, and so does not capture the alternative trajectories accessible to the entity in the evolution of any realistic system. Good modeling practice calls for averaging over multiple runs, but this approach still does not capture the range of individual interactions involved.

A new construct, the *polyagent*, represents each entity with a single persistent *avatar* and a swarm of transient *ghosts*. Each ghost interacts with ghosts of other avatars through digital pheromone fields, capturing a wide range of alternative trajectories in a single run that can proceed faster than real time for many reasonable domains.We have used this approach in a number of systems that we have constructed over the years. The purpose of this paper is to articulate the polyagent as a explicit modeling construct and provide some guidance concerning its use.

Section 2 reviews the challenge of adequate sampling in multi-agent modeling of complex domains. Section 3 proposes a new modeling construct, the polyagent, as an answer to this challenge. Section 4 discusses systems we have constructed that can be understood as instances of polyagents. Section 5 concludes.

2. THE CHALLENGE OF MODELING MULTI-AGENT INTERACTIONS

Imagine $n + 1$ entities in discrete time. At each step, each entity interacts with one of the other n entities. Thus at time t its interaction history $h(t) \in n^t$. Its behavior is a function of $h(t)$. This toy model generalizes many interesting domains, including predator-prey systems, combat models, innovation and diffusion of ideas, and disease propagation.

An equation-based model typically reasons at the level of aggregate or average observables across the agent population (e.g., in the predator-prey example, predator population, prey population, average predator energy level, or average prey energy level, all as functions of time). No attempt is made to model the trajectory of an individual entity.

An agent-based model must explicitly describe the trajectory of each agent. In our general model, during a run of length τ, each entity will experience one out of n^τ possible histories. The population of $n + 1$ entities will sample $n + 1$ of these possible histories. The length of a run is often orders of magnitude larger than the number of modeled entities ($\tau >> n$).

Good practice recommends that such models be run many times, with different random seeds, to explore the range of possible outcomes. Each such run only samples one set of possible interactions. For large populations and scenarios that permit multiple agent interactions, the number of runs needed to sample the pos-

sible alternative interactions thoroughly can quickly become prohibitive, and the portion of the space of possible entity histories actually sampled by a single run is vanishingly small. We would need a number of runs on the order of τ to generate a meaningful sample. Polyagents can capture the outcome of multiple possible interactions in a single run.

3. THE POLYAGENT CONSTRUCT

A polyagent represents each domain entity with a single *avatar* that manages its correspondence with the domain, and a swarm of *ghosts* that explore its alternative behaviors.

The *avatar* persists as long as its entity is active, and maintains state information reflecting its entity's state. Its computational mechanisms may range from simple stigmergic coordination to sophisticated BDI reasoning. Each avatar generates a stream of *ghosts*. Ghosts have limited lifetime, dying off after a fixed period of time or after some defined event to make room for more ghosts. The avatar controls the rate of generation of its ghosts, but typically has several ghosts concurrently active.

Ghosts explore alternative possible behaviors for the avatar that generated them. They are computationally very simple, and interact with one another through a digital pheromone field, a vector of scalar values that is a function of both location and time. That is, each ghost chooses its actions stochastically based on a weighted function of the strengths of the various pheromones in its immediate vicinity, and deposits its own pheromone to record its presence. A ghost's "program" consists of the vector of weights defining its sensitivity to various pheromones.

Multiple ghosts multiply the number of interactions that a single run of the system can explore. Instead of one trajectory for each avatar, we now have one trajectory for each ghost. If each avatar has k concurrent ghosts, we explore k trajectories concurrently. But the multiplication is in fact greater than this.

The environment maintains the digital pheromone field, supporting three functions [1]: It *aggregates* deposits from individual agents, fusing information across multiple agents and through time. Aggregation of pheromones enables each ghost to interact with multiple other ghosts at the same time through their pheromone field, which summarizes their individual behaviors. It *evaporates* pheromones over time, an innovative alternative to traditional truth maintenance in artificial intelligence. Traditionally, knowledge bases remember everything they are told unless they have a reason to forget something. Detecting inconsistencies is NP-complete. Pheromones constantly forget everything they learn, unless it is continually reinforced, so inconsistencies automatically remove themselves. It *propagates* pheromones to nearby places, disseminating information for access by nearby agents.

Propagation enables each ghost to sense the presence of multiple other agents. If n avatars deposit pheromones, each ghost's actions are influenced by up to n other agents (depending on the propagation radius), so that we are exploring in effect nk interactions for each entity, or n^2k interactions overall. If individual ghosts deposit pheromones, the number of interactions being explored is even greater, on the order of k^n. The interactions are not played out in the detail they would be in a conventional multi-agent model. But empirically, they are reflected with a fidelity that is adequate for the problems we have addressed.

The avatar can *activate* its ghosts when it wants to explore alternative possible futures, modulating their generation rate to determine the number of alternatives explored and initializing the ghosts' weight vectors to reflect the breadth of alternatives it wishes to explore. It can *evolve* its ghosts to learn the best parameters for a given situation, monitoring the performance of existing ghosts against some fitness parameter, and then breeding the most successful to determine the parameters of the next generation. It can *review* its ghosts' behavior to estimate the direction and likely variation in how its own future behavior.

The polyagent bears comparison with functionally decomposed multi-agent architectures, population-based search, fictitious play, and two previous uses of the term "polyagent" (**Error! Reference source not found.**).

Our polyagent is distinct from the common use of multiple agents to model different functions of a single domain entity. In a polyagent, each ghost has the same function: to explore one possible behavior of the domain entity. The plurality among ghosts provides, not functional decomposition, but a range of estimates of alternative likely behaviors.

Many forms of evolutionary computation [3] allow multiple representatives of a single entity to execute concurrently, to evaluate their fitness. In these systems, each agent samples only one possible series of interactions with other entities in the domain. Pheromone-based coordination in the polyagent construct permits each ghost to adjust its behavior based on many possible alternative behaviors of other entities in the domain.

Similarly, the multiple behaviors contemplated in fictitious play [5] take place against a static model of the rest of the world.

Like the polyagent, ant-colony optimization (ACO) [2] uses pheromones to integrate the experiences of parallel searchers. The novel contribution of the polyagent is the avatar as a single point of contact for the searchers representing a single domain entity.

"Polyagent" is a neologism to capture the concept of several software agents that collectively represent a domain entity and its alternative behaviors. The term is used in two other contexts that should not lead to any confusion. In medicine, "polyagent therapy" uses multiple treatment agents (notably, multiple drugs combined in chemotherapy). K. Kijima [4] uses the term in analyzing

Table 1: The Polyagent and Other Technologies	Multiple agents / entity	Avatar/Ghost dualism	Parallel search of alternate behaviors	Parallel search of multiple interactions
Polyagent	X	X	X	X

multiple decision-makers. In Kijima's approach, the term "polyagent" makes sense only as a description of a system, and does not describe a single agent. In our approach, it makes sense to talk about a single modeling construct as "a polyagent."

4. EXAMPLES OF POLYAGENTS

We discovered the value of polyagents as a modeling construct by reflecting on several applications that we have constructed and observing their common features. The full paper discusses these applications, which are summarized in Table 2.

Our current use of polyagents involves a fair amount of art. There is much room for theoretical work to make the technique more rigorous. Perhaps the most challenging question has to do with the legitimacy of merging pheromones of multiple ghosts representing agent A into a single field that then guides the behavior of agent B. This process enables B to explore concurrently its possible interactions with multiple alternative realizations of A, but the formal legitimacy of this process is open to question.

Pheromone field strength depends on the frequency with which agents visit various locations. It may be viewed as a probability field describing (for instance) the likelihood of finding an agent of a given type at a given location. If those agents are ghosts representing alternative futures of an entity's trajectory, the probability field represents the likelihood of different future states. An analogous situation arises in quantum mechanics (Table 3), which we are exploring as an intellectual and formal model for engineering polyagent systems and interpreting their behavior.

5. CONCLUSION

One strength of agent-based over equation-based modeling is that it captures the details of the trajectory experienced by each entity. In uncertain domains, this strength is also a weakness, because any single set of entity trajectories is only a sample from a space of possible trajectories that is much too large to explore thoroughly by repeated experiments. Polyagents can sample multiple interactions in a single simulation run. An avatar mediates between the entity being modeled and a swarm of ghosts that sample alternative possible trajectories. The avatar may employ sophisticated cognitive reasoning, but the ghosts interact entirely through digital pheromone fields that they deposit and sense in their shared environment. The avatar modulates the continual generation of ghosts, and interprets their aggregate behavior to provide an estimate of its entity's likely behavior.

Table 3: Parallels between Quantum Physics and Polyagents

Quantum Physics	Polyagents
Duality between (single, localized) particle and (distributed) wave function	Duality between (single, localized) avatar and (distributed) swarm of ghosts
Interactions among wave functions' amplitude fields model interactions among particles	Ghosts' pheromone fields can be interpreted as probability densities that model interactions of agents
Wave function captures a range of possible behaviors	Swarm of ghosts captures a range of possible behaviors
Observation collapses the wave function to a single behavior	Avatar interprets the aggregate behavior of the ghosts and yields a single prediction of behavior

We have applied polyagents to several problems. Empirically, the construct functions very well, but it opens a wide range of questions about the relation between multiple ghosts interacting with a pheromone field that represents multiple alternative realizations of other entities. The system exhibits several parallels with quantum physics that suggest the latter discipline may be a useful basis for a more formal model of polyagents.

ABSTRACT
The management of a complex engineering project is a difficult task that initially involves the division of the project into tasks; the selection of the right people; and the correct allocation of those tasks for the selected people. Team configuration process is typically performed by a manager based on his/her past experience and the available (though frequently scarce, uncertain and dynamic) information about the cognitive, personal and social characteristics of the potential team members. To support this decision-making process we propose TEAKS, a knowledge-based tool that given an initial team configuration and a set of tasks, simulates the most possible team performance. Its formal bases are Fuzzy Set Theory and Fuzzy Logic and it is implemented using Multi-Agent Systems technology in Java, JADE, JESS and FuzzyJESS. This tool was validated with an industrial project involving 23 team members and 23 tasks (ranging from task assignment to SAP administration, SQL programming and equipment connectivity).

1. INTRODUCTION
When a new complex project starts, a project manager is put in charge of partitioning this project into tasks and selecting the people who will perform them. The success of a project is greatly due to the personal responsibility of each member, but also to an adequate communication, collaboration and co-operation between them [2]. In addition to social factors, the emotional state of a person plays a critical role in rational decision-making, perception, human interaction, and human intelligence [11]. The computational simulation of human intelligent behaviour has been one of the main research topics in Artificial Intelligence, and therefore, some of these techniques can be employed to simulate social human behaviour as well, particularly human social interaction and behaviour in a team. In this paper we present TEAKS (TEAm Knowledge-based Structuring), a fuzzy agent-based tool that can be used to simulate team-working performance.

2. RELATED WORK
The simulation of human behaviour has been one of the most interesting areas of research and application since early 70's [6]. More recently, the computational simulation of work groups to predict group performance has started to emerge. For instance, each worker can be modelled as a self-running process that controls a worker entity through data and rules embedded in each process as is proposed in [1].

Given the characteristics of the Multi-Agent Systems [13], they can be seen as a very useful tool for modelling human behaviour and in particular social behaviour. The agent-based approach enhanced the potentialities of computer simulation as a tool for theorising about social scientific issues, since it facilitates the modelling of artificial societies of autonomous intelligent agents [5]. In [10] an agent-based model to represent human behaviour is presented where the agents can be characterised by a set of attributes and their behaviour can be described by a set of simple decision heuristics. Additionally, in [12] an application-independent agent architecture called PECS (Physics, Emotion, Cognition, Social Status) to simulate human behaviour within groups is proposed.

Fuzzy logic can also be considered to represent some human characteristics. In [7] a fuzzy emotional agent for decision-making in a mobile robot is described. Another interesting work is presented in [9] where fuzzy agents with dynamic personalities are proposed. Our TEAKS model is based on fuzzy agents; fuzzy parameters represent human characteristics and fuzzy rules model

[1] The first author is a Ph.D. student of the Artificial Intelligence Program at the Technical University of Catalonia (SPAIN).

the human performance within a work team. The agent architecture is based on the PECS model.

3. TEAKS PARAMETERS TO SIMULATE HUMAN PERFORMANCE

To simulate the human behaviour at work, those relevant human characteristics that affect a person performance at work should be identified. In this research we have decided to incorporate the following characteristics to our team members: personality trends, a set of basic emotions, social characteristics and cognitive capabilities.

3.1 Personality Trends

There are several studies that show the importance of the personality traits in the job performance [4]. We have taken into account the CLEAVER technique to identify behaviour styles in front of different work situations [3]. The CLEAVER technique is applied to the candidates through several psychometric questions. The result of this questionnaire is a numeric value between 1 and 99 for each of the following personality trend parameters (DISC): **Drive, Influence, Steadiness** and **Compliance:** capability to develop the work following establish rules or procedures.

3.2 Emotional State

Emotions have been proven to be an important factor at work place [8]. Given the importance of the emotions in the human work behaviour, the critical decision is to select the set of basic emotions to model them into the agents. From the extended psychology classification of the basic emotions, we select a little set of four basic emotions to model the agents' emotional state at work. Two of them are positive emotions and the other two have a negative influence over the people's performance: **Positive emotions**: ***desire*** and ***interest*** of the person to develop a specific task in a given moment. **Negative emotions**: ***disgust*** and ***anxiety*** generated by a given task in specific moment.

3.3 Social Characteristics

The characteristics of human relations in groups and teams (such as competence, trust, co-operation, among others) are the main topic of research in areas such as social psychology, social sciences and organisational behaviour. Modelling all these characteristics is out of the scope of this research, but nevertheless, we considered a small set of social characteristics: **introverted / extroverted,** and **prefers to work alone / in team:** when a person is working, he/she may prefers to work alone to develop a specific task(s) even though this person can be extroverted, and vice versa.

3.4 Cognitive Capabilities

Human cognitive capabilities involve several brain processes such as learning and memory among others. Modelling these brain processes and their interactions to generate an intelligent behaviour has been one of the main goals of Artificial Intelligence and it is, as well as human social characteristics, out of the scope of this research. The cognitive capabilities of a person were taken into account in our model by considering the person degree of expertise in a particular domain: **Project Manager:** a person in charge of managing the project and assigning tasks to the other team-members. **Co-ordinator:** person in charge of specialised tasks, re-configuration of tasks and re-location of resources. **Specialist:** person in charge of complex and specialised tasks. **Technician:** Person who can deal with technical and no-specialised tasks. **Assistant:** Person in charge of not complex, routine and repetitive tasks. In addition of each person's role, every team-member has two other independent-role parameters to represent his/her cognitive capabilities: **experience level** and **creativity level**.

3.5 Performance Parameters

The resulting team members' performance is calculated by taking into account its internal characteristics, the interaction with its assigned task and the interaction with the rest of team-members. We have proposed six parameters to evaluate the expected final performance of each team member: **goals achievement**, **timeliness** and **quality** of the performed task, **team collaboration level**, **individual contribution level** and **required supervision level**. These six parameters had been taken from the existent formats used by project leaders of the Mexican Petroleum Institute (IMP), (the institution which provides us the case study described in section 7).

3.6 The Project

In the TEAKS model a project is represented by its division into tasks, every task is then represented by the following parameters: **number of participants** in the task, **estimated duration** (measured in days), **sequence** (two or more tasks could be executed sequentially or in parallel), **priority within the project**, **deadline**, **cost**, **quality**, **application domain**, **task description**, **level of difficulty** and **type** (required specialisation level).

4. TEAKS FUZZY AGENTS

The behaviour of a person, i.e. the simulation of his/her performance within the project individually and as a team-member, is generated by the combination of all the previously mentioned characteristics. It is difficult to accept that a numerical value could be used to measure the intensity of either human emotion, experience or creativity level. However, we frequently use qualitative attributes to describe properties of human moods, features and emotions. Following this fact, we propose that it is more natural and intuitive to associate qualitative values to the person's internal parameters.

4.1 Fuzzy Rules

Once the fuzzy sets for the agent and task parameters have been defined, the next step is to build the fuzzy rules that are required to simulate the agent behaviour. Fuzzy rules are used to update the values in the internal state of the agents and the agents' performance.

An example of the fuzzy rules used in this process is shown below (where T1 represents a task and A1 an agent):

IF T1 presents a *high_delay* AND A1 has a *driver* personality with *high_intensity* THEN

The *desire* emotion will have a *high_increase*
The *interest* emotion will have a *high_increase*
The *disgust* emotion wills *stay_equal*
The *anxiety* emotion will have a *low_increase*

5. TEAKS VALIDATION

TEAKS was implemented over the JADE Multi-Agent framework (see http://jade.tilab.com/). JESS (see http://herzberg.ca.sandia.gov/jess/) and FuzzyJess (http://www.iit.nrc.ca/IR_public/fuzzy/fuzzyJToolkit2.html) rule engines were used to implement the fuzzy sets and the reasoning mechanism required to simulate the agent performance. TEAKS initial test and validation was performed at the Mexican Institute of Petroleum (IMP, www.imp.mx), a research and technological development centre. At the IMP, like in other organisations, the configuration of the project team is fundamental to success in large and complex projects.

An Information Technology project was selected for validation due to the availability of the project manager, the accessibility to confidential documents that evaluate the performance of some of the people involved in the project; and the recent finalisation of that project. In particular, this case study was a project on the development and implementation of a Geographical Information System (GIS) for internal use at the IMP. This project was divided into 23 tasks and assigned (coincidentally) to 23 team-members (1 project manager, 1 coordinator, 15 specialists and 6 technicians). The results generated by our simulation tool were compared with the evaluation reports provided by the project manager.

6. DISCUSSION

The people (and agents) performance is strongly affected by the values of the CLEAVER parameters. Low values for these parameters generate low values in most of the other evaluation parameters. On the other hand, high values of CLEAVER parameters and high values in the parameters related to the social characteristics give rise to a better performance. The difficult of the task parameter influences the team member behaviour. Agent 11 was in charge of 2 tasks (without team-mates in both tasks), and one of these tasks was of medium difficulty. The result of its behaviour for each of the six parameters was better for the *low difficulty task* than for the *medium difficulty task*.

It can be argued that most of the results depend on the rules configuration, despite that, in most cases, the simulation and the GIS/IMP project results were similar. Nevertheless, we must take into account the following:

- We could not access the information for all the team members involved in the project. Nevertheless, we had the opportunity to talk with the project manager and some of the people who worked in the project. Their comments were that, given the software limitations (absence of some of the policies of the institution, such as involvement of the client and manager services among others), the initial predictions can be considered useful and resemble a part of the reality.
- The project manager filled the evaluation documents where the results of the team-members performance are recorded. This evaluation is according to the project manager perception and, in many cases, he/she did not work directly with some of the team members.
- The personality type parameters for each agent were set according to the results of the application of the CLEAVER technique. Nevertheless, the values of parameters such as creativity and experience were configured according to the perception and experience of one of the project co-ordinators regarding his/her interaction with the other team members.
- We have compared the results for only one project. As a result of these initial results, the managers of IMP have shown a huge interest in applying this model for more projects. Once the new information becomes available, we plan to use it for further comparisons and validation (IMP plans to finish this job in the next months).

Even with this set of encouraging results of the initial validation, more tests with other case studies are obviously needed to enhance TEAKS and improve its validation.

ABSTRACT
In the development of disciplines addressing dynamics, such as Mathematics and Physics, a major role was played by the assumption that processes can be modelled by introducing certain state properties (also called potentialities) that anticipate in which respect a next state will be different. The current paper is a first exploration of this perspective to analyse and model dynamics. Potentiality-based modelling subsumes quantitative, numerical modelling approaches, such as Dynamical Systems Theory (DST), and qualitative or symbolic modelling approaches to dynamics, such as BDI-modelling, and is applicable to model dynamics in a wide variety of (cognitive and noncognitive) disciplines. Thus, the modelling of dynamics of cognitive agents can be fully integrated with the modelling of other phenomena in Nature.

1. INTRODUCTION
Dynamics of the world shows itself by the occurrence of different world states, i.e., states at different points in time that differ in some of their state properties. In recent years, within Cognitive Science dynamics has been recognised and emphasised as a central issue in describing cognitive processes [9]. Van Gelder and Port [6] propose the Dynamical Systems Theory (DST) as a new paradigm that is better suited to the dynamic aspects of cognition than symbolic modelling approaches. However, as DST commits to the use of quantitative methods (differential and difference equations), it is often considered less suitable to model higher cognitive processes such as reasoning and language processing. DST is based on the notion of a state-determined system: a system in which properties of a given state fully determine the properties of future states; cf. [3], p. 25; [6], p. 6. This means that for state properties that are different in a future state, state properties in the given state can be found that somehow indicate or anticipate these differing (changed) properties in the future state. This idea closely relates to the concept of *potentiality* that goes back to Zeno and Aristotle [1]: if a potentiality *p* for a state property *a* occurs in a given state, then in a next state, property *a* will occur. A potentiality can be considered a kind of anticipatory state property: a state property anticipating the different state property (in the changed state).

The current paper contributes a first exploration of the notion of potentiality with respect to its use as a basis for modelling the dynamics of cognitive agents. A methodological perspective is described to analyse and model these dynamics in terms of potentialities. This modelling perspective subsumes both quantitative approaches (such as DST) and qualitative or symbolic approaches to modelling of dynamics. Given that the perspective subsumes DST, which since long has proved its value for quantifiable areas within a wide variety of disciplines, the scope of applicability of the proposed method includes disciplines such as Physics, Chemistry, Biology, and Economics.

2. POTENTIALITIES
Given a particular state that just changed with respect to some of its state properties, it is natural to ask for an explanation of why these new state properties occurred. In a state-based approach, as a source for such an explanation, state properties found in the previous state form a primary candidate. A main question becomes how to determine for a certain state that it is going to change to a different state, and, more specifically, how to determine (on the basis of some of the state properties in the given state) those state properties for which the new state will differ from the given one. This poses the challenge to identify state properties occurring in a given state that in some way or the other indicate which of the (other) occurring state properties will be different in a subsequent state; by having these properties, the state anticipates the next state: anticipatory state properties. If such state properties are given, anticipation to change is somehow encoded in a state. The existence of such properties is the crucial factor for the validity of the assumptions underlying the Dynamical Systems Theory [3, 6]. It indicates the possibility to include concepts in the state ontology to conceptualise state properties that are useful to describe properties of changed states. Aristotle did introduce such a type of concept; he called it *potentiality* (to move), or movable. For example, the difference between an arrow at rest at position *P* and the snapshot of a moving arrow at time *t* at position *P* is that the former has no potentiality to be at some different position *P'*, whereas the latter has. This explains why at a next instant *t'* the former arrow is still where it was, at *P*, while the latter arrow is at *P'*.

3. HIGHER-ORDER POTENTIALITIES
The effect of a potentiality on a future state can be described by relating its occurrence in the present state to the occurrence of a certain state property in the future state. This specification can be viewed as the definition of what it is a potentiality for. A more complicated question is how to specify when (under which past and present circumstances) a potentiality itself will occur. For the case of empty space, where an object is assumed to have no interaction with other objects, a potentiality to change position is present because it was present at an earlier point in time and persisted until *t* (inertia of motion). However, if the potentiality in a new state is different from the earlier one, a question becomes why this is so. This leads to the question addressed in this section of how a *changed potentiality* can be explained. An answer to this question is the use of *higher-order potentialities*. The idea behind this is simple: to

obtain an explanation of changed state properties over time, potentialities were introduced. Potentialities are also changing over time. As they are considered state properties themselves, it would be reasonable to treat them just like any other state property that changes over time. This means that for a potentiality $p^{(1)}$ a so-called *second-order potentiality* $p^{(2)}$ is introduced to explain why $p^{(1)}$ may become changed over time. And of course this process can be repeated for $p^{(2)}$, and so on. This leads to an infinite sequence of *higher-order* potentialities, $p^{(1)}$, $p^{(2)}$, $p^{(3)}$, $p^{(4)}$, …, where for each natural number n the potentiality $p^{(n)}$ is called an *n-th-order potentiality*. Using such higher-order potentialities, the idea is the following:

- for a certain point in time *t0* the occurrence of a state property *a* is determined by the state at a previous time point *t1* < *t0*, in particular, by the occurrence of the first-order potentiality $p^{(1)}$ for *a* at that time point *t1*.
- the occurrence of the first-order potentiality $p^{(1)}$ at *t1* can be determined by the state at a time point *t2* < *t1*, in particular by the occurrence of its own potentiality which is the second-order potentiality $p^{(2)}$ for *a* at *t2*.
- and so on.

This process can be visualised as depicted in Figure 1. In this figure, the *x* at the lower-left can be ignored for the moment.

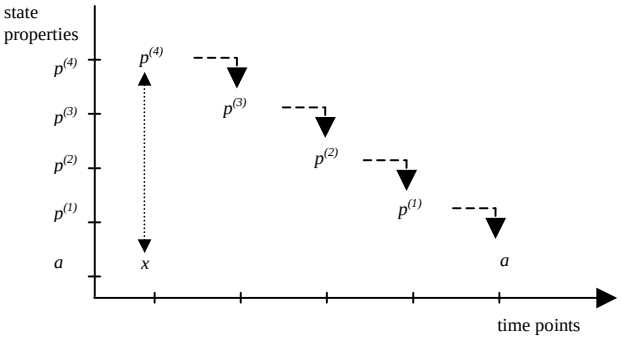

Figure 1. Dynamics based on higher order potentialities

This shows how the concept of potentiality to explain change of a certain basic state property *a* can take the form of a single entity, for example one number, to indicate what a changed property in an immediate subsequent state will be. Moreover, this can be extended by a large number of other (higher-order) entities, the occurrence of which can explain changed basic state properties *a* in future states.

Strange as the idea of an infinite number of higher-order potentialities may seem at first sight, in mathematical context (in particular in calculus) this has been worked out well (using infinite summations). For the discrete case, the idea of difference tables for functions has been developed. These differences play the role of relative potentialities: they indicate the next value not in an absolute sense, but in comparison to the current value. For the continuous case, higher-order potentialities have been formalised in the form of (higher-order) derivatives of a function. The (first-order) derivative of a function at a time point t gives an estimated measure of how the function will change its value in a next time point. The well-known Taylor series [12] for sufficiently smooth functions (at least infinitely often differentiable) shows how changes of the value from *t* to *t'* (within some given neighbourhood of *t*) depend on all (higher-order) derivatives:

$$f(t') = f(t) + \Sigma_k \; f^{(k)}(t)(t' - t)^k / k!$$

This expression shows how the (relative) potentiality at *t*, defined by the combination of all (infinitely many) higher-order potentialities, determines the changed state at the future time points *t'*.

In later times, successors of Aristotle have addressed the question how to further develop the phenomenon of dynamics (or change), in particular within Physics. They developed classical mechanics based on certain types of potentialities. For example, Descartes [4] took the product of mass and velocity of an object as an appropriate foundation for its potentiality to be in a changed position, or 'quantity of motion'. In modern physics this 'quantity of motion' concept is called *(linear) momentum*. This is one way in which a concept 'potentiality' (for change of position) was formalised in physics, thus providing one of the cornerstones of classical mechanics. Leibniz [7] formalised the notion of potentiality for changed position in a different manner by the product of mass and the square of velocity, what later got the form of the notion of kinetic energy, another cornerstone in Physics.

Also second-order potentialities played a crucial role in the development of Physics, for example, to obtain the concept 'force'. Newton uses the term 'impressed motive force' to express the change of motion in his second law: 'The change of motion is proportional to the motive force impressed; and is made in the direction of the right line in which that force is impressed' [8]. This law expresses that the concept of force used by Newton directly relates to change of motion. For (quantity of) motion he gives the same definition as Descartes, i.e., momentum. For an impressed force the following definition is given: 'An impressed force is an action exerted upon a body, in order to change its state, either of rest, or of uniform motion in a right line'. These definitions show that the concept 'force' used by Newton as an addition to state ontology can be given a definitional relationship to 'motion generated in a given time'. This 'motion generated in a given time' can be considered a second-order potentiality for the first-order potentiality 'motion' or momentum. So, within classical mechanics, after the concepts 'momentum' and 'kinetic energy' which were added to the state ontology as specific types of (first-order) potentiality, the concept 'force' can be considered a third property added to the state ontology, this time as a second-order potentiality. Using this state ontology, Newton (and also Leibniz) developed mathematical techniques of calculus, such as differentiation and integration.

4. REDUCERS

As indicated in the previous sections, the idea of explaining changed states in terms of higher-order potentialities can be very useful. However, when each potentiality can only be explained by introducing another (higher-order) potentiality, the approach risks ending up with an infinite chain of explanations. Then infinitary mathematical techniques such as infinite summations are needed, as shown in the Taylor series. To avoid this, one of the higher-order potentialities often can be connected somehow to lower level potentialities and/or basic state properties of the world. To this end, the notion of *reducer* of a higher-order potentiality is introduced: a combination of lower level potentialities and/or basic world state properties that is equivalent to this higher-order potentiality.

An example in the domain of Physics illustrates this notion. Analysing the motion of planets around the sun, Newton found out that they can only follow their orbit if a second-order potentiality (i.e., a force) is assumed, in the direction of the sun [8]. Newton calculated (using his calculus under development) in detail that this force was proportional to 1 divided by the square of the distance. For example, for an object in space with mass *m* approaching earth (with mass *M*), Newton's law of

gravitation for the motive force on the object is as follows (here x is the distance between the object and the earth, and c is a constant): $F = c\ mM/x^2$. Such a relation between the second-order potentiality force and basic state properties such as mass and distance shows how a higher-order potentiality can be reduced: in this case $c\ mM/x^2$ is a reducer for F.

To explain the idea of reduction, consider Figure 1 again. This time, pay attention to the additional (world) state property x, which is the reducer of $p^{(4)}$. For simplicity of the presentation we take an example where reduction only involves a basic state property, and no lower level potentialities.

5. POTENTIALITY-BASED MODELLING

Based on the idea of reduction, a generic method can be formulated to describe dynamics in terms of higher-order potentialities. The method involves a number of steps (also see Figure 1), roughly expressed as follows:

1. pick a basic world state property a of which the change over time needs to be modelled.
2. introduce a potentiality $p^{(1)}$ that explains the change over time of a.
3. can a reducer be found for the potentiality $p^{(n)}$ in the model that has the highest order?
   - 3a. *yes* -> introduce a reducer x that connects $p^{(n)}$ to a lower-level state property: in terms of world state properties and lower level potentialities; then end.
   - 3b. *no* -> introduce a potentiality $p^{(n+1)}$ that explains the change over time of $p^{(n)}$; then go to step 3.

To illustrate the idea of the method, suppose one wants to explain the fact that an object approaching the earth changes position over time (due to gravitation). In that case the basic world state property a would be something like 'object O is in position P' (step 1). Then, to explain the change over time of this state property, for the first-order potentiality $p^{(1)}$ a concept 'momentum' can be introduced (step 2). However, since no reducer of this potentiality can be found, a second-order potentiality $p^{(2)}$ is introduced to explain the change over time of a momentum, i.e. a concept 'force' (step 3b). Finally, a reducer is introduced for this second-order potentiality force: the expression $c*mM/x^2$ (step 3a). To summarise, this example shows how the change of a world state property in the domain of Physics can be explained and modelled in terms of higher-order potentialities.

6. DISCUSSION

In this paper, the perspective to analyse and model dynamics in terms of (first- and higher-order) potentialities has been explored. This potentiality-based perspective played a crucial role in the development of Physics. These examples refer to motion of non-living objects. Another type of motion to be explained is motion of a living being. Often used explanations of human (or animal) actions refer to internal mental states: e.g., an explanation of human behaviour from internal mental state properties such as desires. The desire to be at P' plays a role similar to that of the potentiality for being at P'. Indeed, this similarity can be traced back in history, for example, to Aristotle: 'Now we see that the living creature is moved by intellect, imagination, purpose, wish, and appetite. And all these are reducible to mind and desire.' [2], Part 6. Here properties of 'mind and desire' are mentioned as the source of motion of a living being. He shows how the occurrence of certain internal (mental) state properties (e.g., desires) within the living being entails or causes the occurrence of an action in the external world. This indicates hoe the potentiality-based perspective can be used to model BDI-agents. Thus, the use of potentialities in a sense unifies different types of approaches (both symbolic approaches, such as BDI-modelling [10], and nonsymbolic approaches, such as DST [9]) to cognitive modelling that are often seen as mutually exclusive. For every (basic) state property that is changing over time, a potentiality can be added to anticipate its changes. As this (first-order) potentiality may also change, a second-order potentiality may be introduced to anticipate these changes. In principle, this can be continued indefinitely. However, in many cases there is no need to go this far. Often, after a few steps a reduction can be made in the sense that a higher-order potentiality turns out to be equivalent to a combination of basic state properties and/or lower level potentialities. Within DST this is where a differential equation comes in, reducing an nth-order derivative to lower level properties: the assumption of reduction is another assumption underlying DST. All in all, the proposed modelling perspective places the modelling of cognitive phenomena not in an isolated position, but fully integrates it with the modelling of other phenomena in Nature.

Analysing dynamics of a process in terms of basic world state properties and higher-order potentialities opens up the possibility to create an executable *formal specification* (and subsequently, *simulation*) of the process. This is the subject of current research. In addition, an interesting challenge is to apply the presented method to affective agent states (such as emotions and moods). It is claimed by many authors (e.g., [11]) that affective states have the potential to control agent behaviour; see [5] for an example application. Therefore, an obvious next step is to model affective states as potentialities as well, thereby providing more formal evidence of the above claims. This option will be explored in future work.

ABSTRACT

Agent-based simulations form a valuable tool for learning about real world societies and global behaviors of systems emerging from microscopic relationships. Calibration of model parameters for detailed agent-based models is a big problem for standard calibration techniques, due to the large parameter search spaces, long simulation run times, uncertainties in the structural model design and different observation levels upon which the model needs to be calibrated. In this paper we propose several methods to improve the calibration process of agent-based simulations.

Agent-based Simulation, Simulation Calibration

1. INTRODUCTION

Agent-based simulations (ABS) form a valuable tool for studying real world societies and global behaviors of multi-agent systems (MAS) emerging from microscopic relationships. In ABS agents and societies of a real world system are represented explicitly in a simulation model. Autonomous actors are reproduced by agents with their autonomy, individual goals etc. This allows a close mapping between real and modeled system and leads to advantages in relation to macroscopic simulation techniques and also to other micro modeling paradigms like object-oriented simulation, cellular automatons or petri networks.
To derive valid results and knowledge from an ABS great care needs to be put in the model development process. The main problem does not relate to particular specification and implementation languages, but more generally to the (missing) link between macroscopic aggregate behavior and microscopic agent-level model. One major advantage of ABS is that the observation element "individual" equals the modeling element "agent". However it is not clear what properties and behavior, i.e. modeled structure of the real-world agent, actually lead to the measurable aggregate values. This leads to a rather high uncertainty about a valid model structure and consequently about a valid parameter setting. However, parameter calibration can only be done with an appropriate model structure as starting point. On the other hand, whether a model structure is valid can only be assessed with parameter settings. This dilemma is particular to ABS and cannot be addressed by parameter calibration or optimization that take the model and its structure as a black box. Therefore, new methods and techniques have to be developed that combine parameter calibration with model structure refinement for ABS.

2. RELATED WORK

In 1 we described the need for treating parameter calibration and structural refinement of ABS in a combined fashion. As a result the related work is described in three parts:
Black box calibration techniques: In general parameter calibration of simulation models is treated as an optimization problem [4]. The simulation models are adopted as black boxes computing a predefined objective function which measures the overall simulation validity. The problem for direct application of these techniques in ABS is the potentially large level of detail in such simulation models resulting in huge parameter search spaces.
Structural model refinement of ABS: ABM can be designed in a goal-oriented top-down fashion, i.e. starting with an abstract model with the desired macro behavior and adding model detail as required to answer the simulation question, or bottom-up based on the design of local agent relationships. In both cases the step of tuning and refining model structures in case of invalid simulation results is generally handled rather arbitrarily [2].
Systematic Calibration: The calibration issue is not tackled in most agent-oriented engineering methods. Two examples from ABM engineering dealing with calibration are the SADDE methodology [7] which treats the simulation model as a black box employing genetic algorithms (GA) for parameter estimation and the approach described by Calvez

et al. [1] which also uses black box GA.

3. EXAMPLE MODEL: SHOPSIM

Our application example is an ABS of grocery shopping-behavior in Northern Sweden. In the model stores are defined by their position and seven characterizing attributes like price level, assortment size, quality etc. The shopping agents perceive the store attributes and their individual distance to the stores using some perception functions. They combine the different perceptions into a personal store ranking. Based on this ranking the agents spend their yearly grocery shopping budget. The global objective function of the model measures how precisely the empirical turnovers of the stores are reproduced by the model.

The empirical data for the model validation consists of original statistics of store turnovers and estimations of shopping budgets for the shopping agents. The data used to design and calibrate the target model is fuzzy or simply missing. Many stores attributes are based on subjective expert estimations. Further it is unknown which store attributes are actually important for shopping decisions, i.e. whether all or only a subset of the store attributes need to be perceived by the agents. Finally, the potentially over 100,000 agents, evaluating 132 stores each, greatly limits the number of possible parameter configuration evaluations during calibration.

4. MODEL DESIGN AND CALIBRATION

We call our approach a white box calibration approach as opposed to standard black box search (BBS) methods. Our goal is to enhance the efficiency of applied BBS methods by exploiting available expert knowledge and by using calibration methods that explicitly deal with ABM structure.

We suggest a top-down goal oriented analysis of the model and calibration problem. Starting with the conceptual model design, the simulation question(s) to be answered and the necessary level of detail are defined. These form the first two observation levels (macro and micro) upon which we need to ensure model validity. From the simulation question we specify the global objective function for calibration. Based on the analysis of the calibration problem we apply decomposition and abstraction techniques, analyze simplified models and successively refine the model until the desired level of detail has been reached. We do this to overcome arbitrary model changes on local levels.

4.1 Model Abstraction and Decomposition

Based on an analysis of the complexity of the calibration problem one can identify possibilities for increasing the efficiency of applying BBS techniques. The goal is to reduce computational model complexity, to be able to apply individual objective functions for decomposed submodels and to study model relationships on different abstraction levels.

Proposed Proceeding We employ a set of abstraction and decomposition techniques to explore simplified models, create computationally less complex models and analyze local relationships. Abstractions can be aggregations of model units, metamodeling, reductions of heterogeneity or analysis of local interactions. Decompositions can be goal-oriented and on functional, behavioral or temporal levels. A detailed description can be found in Fehler et al.[3].

4.2 Structure and parameter refinement

Several structural model aspects and combinations of these can be responsible for a certain system behavior. We require a technique to efficiently search through possible structural configurations with combined parameter estimation. An example is the calibration of agent perception functions. Agents can potentially perceive several aspects of their environment and act according to reasoning based on these perceptions. However, it may not be known which environmental properties need to be perceived by the agents and if some perception combinations have increased influence on agent behavior. In SHOPSIM we have to identify relevant store attributes and calibrate the associated perception functions.

Proposed Proceeding Our goal is to explore as few perception function subsets (PFS) as possible while identifying the most valid perception model. To search the space of possible PFS we propose to use a combination of a beam search strategy in PFS space, a simulated annealing (SA) search in perception function parameter space and effect analysis using Design of Experiments (DoE) techniques [5]. We start with a subset containing all possible perception functions and optimize its parameters using SA. The next step is to identify the perception functions that are actually responsible for agent behavior. We do this using factorial experiments to determine major and combinational effects up to a preestimated degree using a minimal number of required simulations. Once promising PFS have been determined the experimenter may choose a set of PFS for further investigation following the beam search strategy. The search in structure space may be cut off at any time, if effect analysis suggests no further improvements for certain PFS. Following this procedure in SHOPSIM we explored only 12 instead of potential 127 perception models in order to identify the most valid candidates.

4.3 Validity on multiple observation levels

We want to enforce model validity not only on a global but on several observation levels. Parameter calibration on a single observation level is generally done using objective functions describing degrees of validity on this level.

Proposed Proceeding To ensure model validity on several observation levels we employ behavioral constraints on simulation behaviors during model calibration. Standard constrained parameter optimization uses constraints on the model input parameters, which are tested before and after each parameter configuration evaluation, to guide the search process [6]. We employ behavioral constraints during individual simulation runs. This way we can simply cancel invalid simulation runs, which decreases total calibration time.

4.4 Reasonable introduction of heterogeneity

To keep the parameter search space as small as possible we want to determine small sets of model properties that can be used to describe relevant heterogenous model aspects, like groups of agents or resources. Additionally we want to determine the error inherent in the available fuzzy empirical data. This is important as we derive information of how good we can actually get during parameter calibration in respect to an objective function comparing simulation output to fuzzy empirical data values.

Proposed Proceeding We explore equivalence classes in model properties to determine relevant heterogeneous model aspects which require additional detail, i.e. parameters. In

SHOPSIM this means that all stores with the same attribute values for a given subset of all possible attributes form a single equivalence class. We seek classes which correctly group stores with similar turnovers. If we measure the deviation of individual store turnovers within valid equivalence classes from the mean class turnover, we can derive information of the calibration error inherent in the fuzzy empirical data. In SHOPSIM we see that for the most appropriate equivalence classes the error inherent in the data leads to a quality of only 60% in global turnover reproduction. This helps us in calibrating the actual model parameters as we now know that we will not be able to reduce the error in turnover reproduction to less than 40% during parameter optimization.

4.5 Reverse engineering approach

Suppose we have a bottom-up designed ABM including expert specified structural aspects and parameters. The simulation results are not satisfying. We need to determine required changes in the simulation model without arbitrary changes in the ABM structure.

Proposed Proceeding We propose to invert the calibration process. Instead of fitting agent model parameters to a given environmental model we reverse engineer an environmental model with properties that fit the predefined agent model. On the one hand the resulting model can be analyzed by the domain expert to identify anomalies and thus required model changes. On the other the reverse engineering approach can be used to abstract certain heterogeneous model relationships allowing faster model calibration.

In SHOPSIM we may have expert designed distance perception functions. The parameters of the remaining perception functions need to be calibrated to complement the heterogenous distance perception. Here, we abstract the different possible store attributes into a general store "attractiveness" attribute. The idea is to reverse engineer an attractiveness for each store that fits the agents distance perception. Section 4.6 describes an efficient way to do this.

The first gain is that the resulting store attractivenesses can by analyzed for correlation with original store properties. This allows a more directed adaption of model structures and identification of bad empirical data about store attributes. Suppose we want to analyze the micro validity of agent shopping trips based on different bottom up designed distance perception functions. We do this by analyzing them in environmental models theoretically fitted to the agent perception model using reverse engineering. This means we compute what the attractiveness of each store would have to be in order to correctly reproduce store turnovers, if we assume that the local agent model is correct. This allows to focus local behavior validity analysis on the designed distance perception function without having to deal with possible distortions of agent behavior resulting from behavior based on fuzzy data on the non-distance store attributes.

The second gain is that, by reverse engineering, we abstracted the heterogenous distance attribute of the stores into the store attractiveness attribute which is then perceived homogenously by the agents. To calibrate the original model, the original non-distance store attributes need to be perceived in such a way that the engineered attractiveness is produced. However, we can now use a simple linear model instead of the computationally expensive ABS to calibrate the parameters of the non-distance perception functions. This allows a much faster evaluation of possible parameter configurations and thus the application of more exact estimation techniques like gradient based search.

4.6 Calibration of many local parameters

Suppose we want to calibrate numerous local (agent) parameters as in 4.5. The number of parameters exceeds the size that can be sensibly treated using global BBS. We have an estimation of domain expert knowledge how the local environment of an agent influences its parameter values.

Proposed Proceeding We design local update functions which change the agents parameters based on deviation from desired local properties or behaviors. The functions are based on knowledge about local relationships from the domain expert. We update the parameters in an iterative fashion until the values converge. In the SHOPSIM reverse engineering example from the last section we have to calibrate local attractiveness for 132 stores, i.e. 132 parameters, based on a heterogenous distance agent perception. We defined update functions for each store attractiveness. Depending on the deviation of simulated from the target turnovers the store attractiveness values were adapted. Depending on the chosen perception model 2-5 update iterations were sufficient to calibrate the 132 attractiveness parameters so that the original store turnovers could be perfectly reproduced for given heterogeneous agent distance perception.

5. SUMMARY AND OUTLOOK

In this paper we proposed a framework and associated methods for calibrating ABS designed for prediction and exploration of real world MAS. A main focus was put on the sensible introduction of heterogeneity into the model and the analysis of bottom-up model designs, to overcome the often infeasible trial and error step of parameter and micro level structure refinement. In the future we will further focus on the problem of the introduction of heterogeneity into ABM as this poses a very hard problem to parameter calibration due to the significantly increasing search space size.

ABSTRACT

To realize large scale socially embedded systems, this paper proposes a multiagent-based participatory design that consists of steps called 1) *participatory simulation*, where scenario-guided agents and human-controlled avatars coexist in virtual space and jointly perform simulations, and 2) *augmented experiment*, where an experiment is performed in real space by human subjects and scenario-guided extras. In this methodology, we use production rules to describe *agent models* for approximating users, and multiagent scenarios to describe *interaction models* among services and their users. To learn agent and interaction models incrementally from simulations and experiments, we establish the *participatory design loop* with deductive machine learning technologies.

1. INTRODUCTION

Ubiquitous computing systems in the public space often interact with anonymous users and form socially embedded systems. We propose to apply multiagent technologies to the participatory design of ubiquitous computing systems that are to be embedded in society. To this end, we separate agent models from interaction models: the former covers beliefs, desires, intentions and emotions of human users of ubiquitous computing systems, and the latter covers protocol, method, rule or law that guides users when interacting with the ubiquitous computing systems. We view interaction models as behavioral guidelines of human users playing with socially embedded systems; users keep autonomy within the given guidelines. The question is whether or not users will follow the guidelines in an actual ubiquitous environment. The effectiveness of guidelines depends on agent models, which include the personalities of the users (deliberative, reactive, etc.).

We call the descriptions of interaction models *scenarios*. We have developed a scenario description language *Q* and its processor, which can simultaneously interpret scenarios for a large number of agents [4]. *Q* has been already connected to Microsoft agents for Web navigation, FreeWalk [8] for digital city experience [3], Cormas for natural resource simulation [1], and Caribbean for a massively multiagent simulation [11]. We have used *Q* and FreeWalk to conduct crisis management field studies [5,6,7].

In this paper, we pursue *multiagent-based participatory design methodologies* (*participatory design* hereafter) to confirm the adequateness of socially embedded systems; the following steps outline our approach.

1. Describe *interaction models* among ubiquitous computing systems and their users so as to define the expected behaviors of socially embedded systems. We use multiagent scenarios for this purpose, while using production rules to describe *agent models* for approximating users.
2. Perform a *multiagent-based simulation* by modeling users under the given interaction protocols. The simulation takes place in virtual space and involves simulated users, i.e. scenario-guided agents, whose internal models are described in production rules. Results of the simulation can predict how the entire system would work in society.
3. Replace some of the simulated users by human-controlled avatars to perform a *multiagent-based participatory simulation* (*participatory simulation* hereafter). The simulation is performed in virtual space, and the avatars are controlled by the humans sitting in front of their desktop computers. From the results of the participatory simulation, we can improve the models of users, as well as the interaction protocols: i.e. both agent and interaction models.
4. Perform experiments in real space to try out the entire system with human subjects. Since the number of human subjects is often limited, the experiment should be augmented by scenario-guided agents in virtual space and scenario-guided human extras in real space. We called this the *multiagent-based augmented experiment* (*augmented experiment* hereafter); note that most participants will be virtual constructs.

2. PARTICIPATORY SIMULATION

In our participatory design methodology, we first conduct multiagent-based simulations. Figure 1(a) illustrates how a multiagent-based simulation is realized. The scenario processor interprets interaction protocols and requests agents in virtual space to perform sensing and acting functions. Note that, since agents are inherently autonomous, though agents are guided by scenarios, there is no guarantee that they will behave as requested.

We can easily extend multiagent-based simulations to yield *participatory simulations* by replacing some of scenario-guided agents with human-controlled avatars. Figure 1(b) illustrates how humans and agents can cooperatively perform a simulation. Just as video games, human subjects can join simulation by controlling avatars by joy sticks, mice or other input devices. To analyze simulation results, we monitor the entire process of the simulation by visualizing the virtual space. In addition of video taping the virtual space, we record how the human subjects control their avatars. Recording human behavior is often useful for analyzing simulation results.

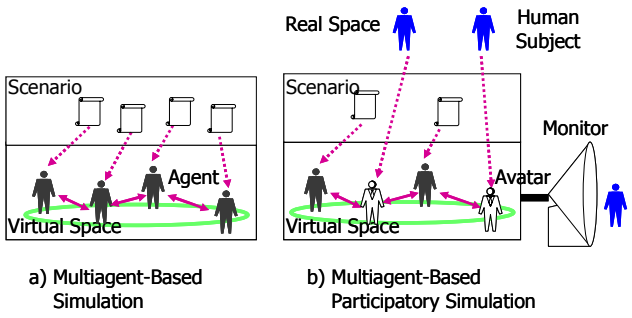

Fig. 1. Participatory Simulation

We conducted a multiagent-based simulation in the evacuation domain. We simulated the controlled experiments conducted by Sugiman [9]. He established a simple environment with human subjects to determine the effectiveness of two evacuation methods: the *Follow-direction method* and the *Follow-me method*. In the former, the leader shouts out evacuation instructions and eventually moves toward the exit. In the latter, the leader tells a few of the nearest evacuees to follow him and actually proceeds to the exit without verbalizing the direction of the exit. Sugiman used university students as evacuees and monitored the progress of the evacuations with different number of leaders. The experiment was held in a basement that was roughly ten meters wide and nine meters long; there were two exits, one of which was not obvious to the evacuees.

Our first evacuation simulation used scenarios with simulated leaders and evacuees in a two-dimensional virtual space. Since the simulation results closely parallel those recorded in Sugiman's controlled experiment, we could conclude that the agents were reasonably well modeled [5]. We then examined the same scenario in the three-dimensional virtual space FreeWalk. One difference between the two-dimensional and three-dimensional simulations is that the latter allowed humans to join the simulation: human subjects can sense their environment and control their avatars in the virtual space.

A participatory simulation was then performed with twelve human subjects: we replaced twelve out of twenty scenario-guided agents by human-controlled avatars. The virtual space is designed so that the human subjects could not distinguish agents from avatars. During the participatory simulation, we found humans behaved differently from their model used in the multiagent-based simulation. We thus adopted machine learning technology to develop agent models from the logs of the participatory simulation. By analyzing the logs and the videos of the simulation, we leaned that a) evacuees use their eyes, not their ears, to identify the leaders, b) upon finding a leader, evacuees tend to approach the leader, even if the Follow-direction method is performed, and c) if contact with the leader is lost, they follow other evacuees that are moving in a group.

Once an accurate model is acquired from participatory simulations, it becomes possible to simulate experiments that cannot be conducted in real space. For example, Sugiman's experiment was performed using two or four leaders, but we can vary this number to clarify the relation between the number of leaders and the time required for evacuation. Moreover, we can explore an effective combination of the Follow-me and Follow-direction methods. Given accurate agent models, participatory simulations are also useful in educating or training people. People can be provided with an experiential learning environment wherein evacuations or other drills can be experienced.

3. AUGMENTED EXPERIMENT

To understand how people behave with socially embedded systems, real-world experiments are often conducted. In the case of video phones, for example, since user behavior in everyday life is not easy to simulate, it is essential to observe how users utilize video phones in real space. In ubiquitous computing, however, because a large number of electronic devices are embedded in public space like railway stations and are continuously in service, it is often impossible to conduct experiments with large number of human subjects. *Augmented experiments* offer ability to perform experiments with a small number of human subjects through augmentation of multiagent-based simulations.

Figure 2 illustrates how augmented experiments are realized. Figure 2(a) represents a real world experiment, where human subjects communicate and perform an experiment in real space. Figure 2(b) shows how we introduce virtual space into a real world experiment. Using sensors in real space, behavior of human subjects are reproduced in virtual space. The sensors can be cameras, RFIDs or GPS depending on the environment. By using virtual space, we can monitor the entire experiment from various viewpoints. Furthermore, we can communicate with human subjects in real space by selecting their avatars in virtual space. *Transcendent communication* is a new monitoring interface, where a visually simulated public space provides a more flexible and consistent view than regular surveillance systems [7].

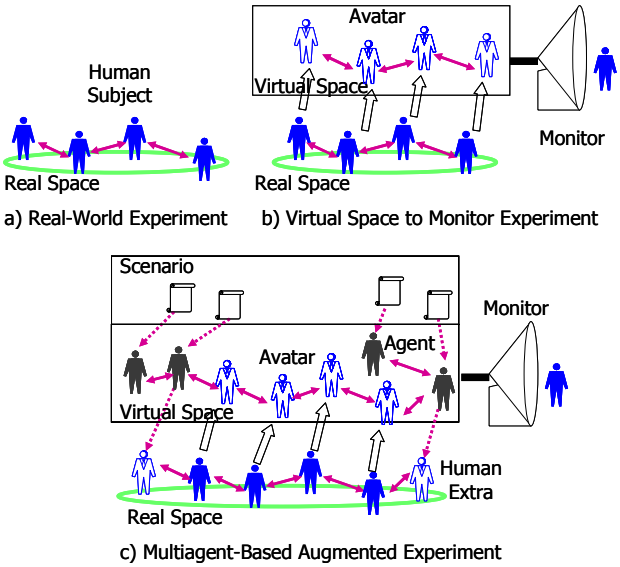

Fig. 2. Augmented Experiment

Figure 2(c) illustrates an augmented experiment. In parallel with a real world experiment, a large scale multiagent-based simulation is conducted in virtual space: the experiment is augmented by the simulation. To combine real and virtual spaces, sensors are used to project human behavior into the virtual space as shown in Figure 2(b). Furthermore, to provide social reality to the human

subjects, scenario-guided extras are placed around the subjects. In contrast to participatory simulations, the human extras do not control avatars: the human extras in the real space are controlled by the scenario-guided agents. For example, we may use human extras acting bus drivers to conduct a demand bus experiment. Conducting an augmented experiment is possible if the real space is equipped with enough sensors. Though we can monitor the experiment via virtual space, video capture of the human subjects in real space is also indispensable for analyzing the entire experiment.

Augmented experiments are needed for testing evacuation methods in railway stations, because there is no other way to conduct experiments with enough reality. To conduct an augmented experiment, we placed twenty eight cameras in Kyoto station, and captured the movements of passengers in real time. Those cameras are specially designed to detect passengers' behavior but not personal features.

We then reproduced the passengers' behavior in virtual space. The evacuees on the station platform are projected into virtual space. The bird's-eye view of real space is reproduced on the screen of the control center so that a leader in the center can easily monitor the experiment [7]. Furthermore the leader can point at particular passengers on the screen, and talk to them through their mobile phones. When the monitor detects pointing operations, a wireless connection is immediately activated between the control center and the indicated passengers. Dragging operations indicating a rectangular area would enable the leader to broadcast an announcement to a group of passengers.

The difficulty with augmented experiments is to provide the human subjects with a sufficient level of reality. To guide extras by scenarios in a timely fashion, the agents must receive sensing information from the corresponding extras. Learning issues are similar to those in participatory simulations, but the evaluation is more difficult, since the behaviors of human subjects in real space are harder to analyze than those in participatory simulations.

4. Future Work

By analyzing the logs of participatory simulations or augmented experiments, we can refine agent and interaction models. The learning process of multiagent-based participatory design consists of two phases: the *normal design loop* and the *participatory design loop*. At first, scenario writers create agent and interaction models and verify their design by multiagent-based simulations. We call this process the normal design loop and have already proposed its detailed steps [5]. After verifying the agent and interaction models, participatory simulations or augmented experiments are performed. The results of which may be different from those of multiagent-based simulations, because human behaviors are often more variable than those of agents modeled by scenario writers. If it is the case, we first refine the agent models to better express the variation seen in human behavior. We then perform the multiagent-based simulations again with the new agent models. If the new simulations fail to produce the expected effects, we then refine the interaction models: modify protocols, methods, rules, and/or laws. After the improved interaction model is confirmed by multiagent-based simulations, participatory simulation or augmented experiment takes place again. This loop is called the participatory design loop.

At first glance, inductive machine learning technologies can be applied to refine agent models and interaction models. However, it is extremely rare to have a large enough number of human subjects to gather enough data, for inductive learning: deductive methods with domain knowledge are more feasible. To refine agent models, given that the training examples will be limited, explanation-based learning is a reasonable approach. Though variations exist in human behavioral rules such as "escape from crowds" and "follow crowds," observing the behavior of a human-controlled avatar can create a plausible explanation that selects one of the two rules. By combining machine learning technologies with interviews of human subjects, we have successfully refined agent models in several domains [6, 10]. To refine interaction models, if we have enough candidate protocols, we can try them, and select the one that best fits. If we need to invent a new model, however, there is no available technology that can create such an interaction model, while the visualization of simulation processes can support scenario writers in inventing new models.

ABSTRACT

In multi-agent systems, greedly agents can harm the performance of the overall system. This is the case of traffic commuting scenarios: drivers repete their actions trying to adapt to daily changes. In this domain, there are several proposals to achieve the traffic network equilibrium. Recently, the focus has shifted to information provision in several forms as a way to balance the load. Most of these works make strong assumptions such as the traffic authority and/or drivers having perfect information. In reality, the information the central control provides to drivers contains estimation errors. The goal of this paper is to propose a socially efficient load balance by internalizing social costs caused by agents' actions. Two issues are addressed: the model of information provision accounts for information imperfectness, and the equilibrium which emerges out of drivers route choices is close to the system optimum due to mechanisms of road pricing. The model can then be used for traffic authorities to simulate the effects of information provision and toll charging.

1. INTRODUCTION

The increasing demand for mobility in our society causes frequent jams in highways. Control measures have been proposed to better control the utilization of the available infra-structure; among these we find *driver information and guidance systems* (DIGS). Normally, information provision and route guidance strategies aim at achieving the *system* optimum (minimization or maximization of some *global* objective criterion). Note that this does not imply the *user* optimum and vice-versa. User optimum means equal costs for all alternative routes connecting two points in the network, for each road user. This may lead to system' suboptimality. If the focus is on global optimum, then the route guidance system may eventually recommend a route which is more costly (for a single user) than it would be the case if the user optimum were to be recommended. In general, traffic control authorities are interested in the system optimum, while the user seeks its own optimum.

In a more general way, this question relates to emergence of coordination in multiagent systems, in cases where the agents do not communicate and thus have to achieve coordination in a somehow greedy way. This normally causes the system to perform suboptimally. Therefore, it is important to align the user and the system optimum. Previous works have been proposed but mostly they assume some degree of cooperation and communication among the agents. Since drivers are self-interested, this alignment cannot be imposed by the system as it has been proposed in other works.

2. RELATED WORK: TRAFFIC, INFORMATION, AND COLLECTIVES

Modeling traffic scenarios with multi-agent systems techniques is not new. However, the focus has been mainly on coarse-grained level regarding traffic problems as traffic agents monitoring problem areas. On the other hand, our long term work focuses on a fine-grained level or rather on traffic flow control.

Our previous work with a scenario of iterated route choice provides a good opportunity to test learning and emergence of coordination. The main problem is to achieve system optimum or at least acceptable patterns of traffic distribution out of user's own performance strategies, i.e. users trying to adapt to the traffic patterns they experiment every day. There are different means to achieve a certain alignment of system and user optimum without relegating important issues such as lack of knowledge of non-commuter users, traffic information and forecast, etc.

The case of simple user adaptation in a binary route choice scenario, with and without traffic forecast was tackled in [3]. A scenario was simulated where N drivers had to decide for one out of the available routes, in every round. At the end of the round, every driver gets a reward that is computed based on the number of drivers who selected the same route,

in a kind of coordination game. In [4] different forms of traffic information – with different associated costs – were analyzed which may be used to assess the future traffic situation for the selection of one route. Finally, information recommendation and manipulation was tested in [2] with a traffic control center giving manipulated information for drivers in the scenario of the Braess Paradox, in a tentative of diverting drivers to less congested routes.

In all these works, different means of utility alignment were tried. Some were more successful than others regarding the performance of the global metrics. However, in the present paper we want to drop the "perfect information" assumption (both the traffic control center and all individuals having knowledge of all alternatives).

From the perspective of the economics of traffic, road pricing has been proposed as a way to realize efficient road utilization i.e. to achieve a distribution of traffic volume as close as possible to the system optimum. Congestion toll is one of the road pricing methods: considering the system optimum, a toll is computed which is the difference between the marginal social cost and the marginal private cost. Notice that this difference can be negative meaning that drivers actually get a reimbursement.

Regarding the future traffic situation as well as the *effects* of the toll system (and other measures to control the traffic), most of the work published has assumed that the control center has perfect information, meaning that it will know precisely the states of near future traffic conditions. This is a hard assumption given that acurate weather and accident forecasts are not possible. A state-dependent toll pricing system is discussed in [5]. Additionally, it is investigated which are the impacts of two alternatives toll schemas: toll is charged before or after drivers select a route. This distinction is important because congestion tolls, when announced before the drivers make their decisions, carry some meaningful information.

Still related to the quest of user vs. system optimum, Tumer and Wolpert [6] have investigated the use of a multiagent system to control routing of packages in a computer network, as well as the sensitivity of the network to the Braess paradox using the Collective Intelligence (COIN) formalism. In COIN, the world utility, $G(\zeta)$, is an arbitrary function of the state of all agents across all times. The utility for an agent is given by the difference between the total cost accrued by all agents in the network and the cost accrued by agents when all agents sharing the same destination are "erased". The problem with the use of this approach in a road network is that we cannot expect the agents (drivers) to have any idea about the global goal or cost. This is possible in the computer network scenario because the agents are router nodes which have knowledge about the throughput (packages to be routed to different destinations).

3. MODEL AND RESULTS

We have developed a simple model for the adaptive route choice. Since an agent has only qualitative information about the routes, and none about the other agents, each agent needs an expectation of the costs s/he will have if s/he selects a certain route. This can be understood as the probability according to which a driver selects one route. For instance, if it is 1 for route r then the driver always takes route r. With a certain periodicity, driver d updates this heuristic according to the rewards s/he has obtained on the routes s/he has taken so far. The update of the heuristic is done according to the following formula: $heuristics(d, r_i) = \frac{\sum_t utility_{r_i}(d,t)}{\sum_i \sum_t utility_{r_i}(d,t)}$.

The variable $utility_{r_i}(d,t)$ is the reward agent d has accumulated on route r_i up to time t. Therefore an important factor is how often and in which intervals the heuristic is updated. This is especially relevant because the reward depends on the other agents. Using this simple model, we have performed experiments varying the frequency of heuristic adaptation. To prevent that all agents update their heuristics during the same round, each agent adapts with a given probability.

In order to model the imperfectness of information, we follow [1] who represent the traffic conditions as L discrete states. We also consider K information types. For each combination of state and information type, there is a cost function which also depend on the traffic volume. Thus, the dynamics on the routes are simulated according to these abstract cost functions which nonetheless can reproduce the macroscopic behavior *of the system* given that it includes a stochastic component regarding the traffic states.

The cost functions we use were adapted from [5], from which we also use much of the nomenclature, cost functions, and some scenarios, althought these were slightly modified to include the drivers's adaptation to route choice. We also assume R alternative routes between two points in the network. Both have a traffic capacity of M vehicles. Traffic can be in one of L states (e.g. if $L = 2$ we can have congested/non-congested states only). In the model, each state occurs with probability q^l. The control center predicts traffic based on imperfect information and provides information to the drivers which is also imperfect. There can be K types of information. At a given time, one information k is given with probability p^k. There can be any correspondence between K and L but mostly it is assumed that $L \geq K$, $K \geq 2$, and $L \geq 2$.

The probability of a state l to occur after information k is given by $\pi^{k,l}$. If $\pi^{k,l} = 1/L$, the information conveys basically no meaning i.e. it is tantamount to no information. When $L = K$ (i.e. for each k there is an exclusive l) we can have perfect information provided one of the π's is one and the others are zero. For example, if $K = L = 2$, when $\pi^{k,l_1} = 1$ and $\pi^{k,l_2} = 0$ ($l_1 \neq l_2$), this is a situation of *perfect information provision* because it is known for sure which state is expected to occur after the information is provided.

3.1 Parameters and Settings

In the examples discussed here, $R = K = L = 2$, and the travel cost functions used are linear of type $c_i^l = \zeta_i^l + v_i^l \times x_i^k$, where x is the number of drivers. In particular we use the following functions [5]:

$c_1^1 = 1.0 + 0.6 \times 0.001 \times x_1^k \quad c_1^2 = 1.5 + 1.6 \times 0.001 \times x_2^k$
$c_1^2 = 1.0 + 0.4 \times 0.001 \times x_1^k \quad c_2^2 = 1.5 + 0.1 \times 0.001 \times x_1^k$

The meaning of these functions is that the marginal costs (v_i^l) of each route r_i differ. Therefore we expect the number of drivers to be smaller in route 2 when $l = 1$. In [5] the system equilibrium (without any toll etc.) is computed for $M = 3000$ drivers: 2391.5 (route 1) and 608.5 (route 2) for $k = 1$; 1927.3 (route 1) and 1072.7 (route 2) for $k = 2$.

We show here that this equilibrium is never achieved when drivers use greedy strategies such as selection of route based

on average of past travel time. However, when the selection is based on an utility function which includes the toll paid or the amount reimbursed, then traffic volumes are close to the system equilibrium.

3.2 Scenarios

In **scenario I** we are interested in reaching the equilibrium by only allowing users to apply their probabilities to select route r_i, given the information provision k. In our case this is done via adaptation of these probabilities (denotated as $\rho^d_{r,k}$) given the past utilities which are function of the costs. The basic mechanism for each driver d is given by: $\rho^d_{r,k} = \frac{\overline{U^d_{r,k}}}{\sum_{i=1}^{R} \overline{U^d_{i,k}}}, 1 \leq i \leq R$, where $\overline{U^d_{r,k}}$ is the average of past utility for selecting route r_i when the information provided was k.

In **scenario II** a toll is computed by the traffic control center and paid by the driver. This computation depends on the information k so that drivers have to make a relation to their previous choice for the last situation where k was provided. The toll value for each driver on route r_i is calculated as $\tau^k_{r_i} = \frac{x^k_r - x^{k^*}_r}{x^k_r}$ where: $x^{k^*}_{r_i}$ is the number of drivers *in the equilibrium situation* for route r_i given information k, and $x^k_{r_i}$ is the expected number of drivers, estimated by the last time k was provided. Notice that this value can be positive (driver pays) or negative (driver gets a reimbursement).

The reasoning of the driver d is as follows. If information k is provided and the last time this has happened I was reimbursed because I have chosen route r_i, then I better select r_i again with probability $\rho^d_{r_i,k} = 1 - rate_{cur}$. However, if information k is provided and the last time this has happened I had to pay, then I select r_i with probability $\rho^d_{r_i,k} = \tau^d_{r_i,k}$. Here $rate_{cur}$ is the rate of curiosity, i.e. a probability of d experimenting another route (other than r_i) even though r_i was good the last time; and $\tau^d_{r_i,k}$ is the toll paid by driver d when selecting route r_i under information k.

3.3 Results

We have used $M = 3000$ agents in order to compare the results to those in [5]. If we let the drivers select routes only according to the utility they perceive (**scenario I**), then an user stable state is reached, but it is far from the system optimum. Number of drivers in both route (graphic not shown here) are not as mentioned before (Section 3.1). For $k = 2$ the $M = 3000$ drivers select each route with equal probability, so that nearly 1500 end up in each route, at any given time. This happens because the utility of drivers is nearly the same when we substitute $x^k_i = 1500$ in the cost functions. For $k = 1$, the expected system equilibrium is two-thirds in route 1 and one-third in route 2. However, this equilibrium is nerver reached: users are stuck in a suboptimal stable state. Thus, a mechanism is needed which internalizes the externalities caused by the drivers selections.

Our **scenario II** simulates exactly what happens when drivers update their route choice probabilities according to a utility which is based on the past toll. Figure 1 depicts the number of drivers in each route, for each k, when a toll is charged and the curiosity rate is zero, meaning that drivers act only based on the the reward or punishment represented by the toll in the last time information k was provided. As we see in that graph, the user equilibrium is now much closer to the system equilibrium. For $k = 1$ the distribution of drivers is around 2300 to 700 (routes 1 and 2 respectively), and for $k = 2$ this distribution is around 2000 to 1000.

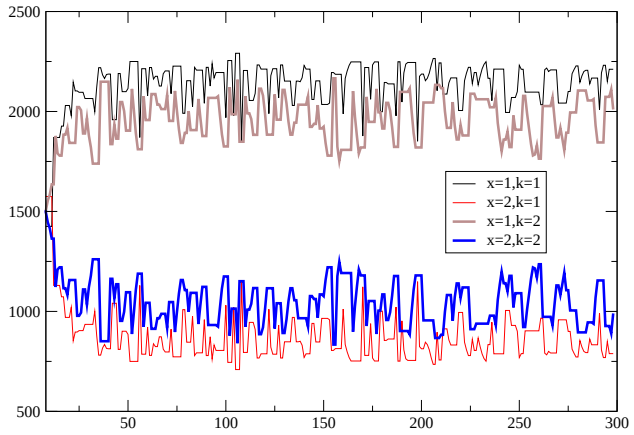

Figure 1: Number of drivers at each route, for each k; with toll and curiosity rate equal 0

Different rates of curiosity of course change these figures. The higher the rate, the more drivers deviate from the system equilibrium.

In summary, this paper shows that congestion tolls are useful to internalize the costs drivers impose to others when they act greedly. Tolls are the equivalent of the utility alignment proposed in the COIN framework, but departing from the assumption that agents are cooperative. For the context of multiagent systems, the present work can contribute to the development of a more general method of mechanism design, specially when agents are self-interested and the system optimum has to be reached without imposing explicit central coordination.

ABSTRACT

Agent-based simulation is increasingly used to analyze the performance of complex systems. There are two main ways agent-based models are built — from equation-based models and directly from data. We are building models in both ways, investigating approaches for creating them and for validating them. In this paper we describe results of our work on one specific agent-based model, showing how it can be validated against the equation-based model from which it was derived, and the extent to which it can be used to derive additional results over and above those that the equation-based model can provide.

1. INTRODUCTION

Agent-based modeling contrasts with traditional approaches to simulation, which typically involve building sets of interrelated differential equations. Such traditional models, commonly called *equation-based models* (EBMs), have been widely applied and generate useful predictions about the behavior of populations. So why use agent-based models? There seem to be four main answers [2]:

- agent-based models are a natural way to describe systems comprised of interacting entities;
- agent-based models are flexible;
- agent-based models capture emergent phenomena; and
- agent-based models provide access to a greater level of useful detail.

In particular, modeling interactions between entities can be much easier in agent-based systems than in EBMs, even when one is comfortable with the concepts of partial differential equations, and can reveal details of the system being modeled that are obscured by EBMs.

In this paper, we describe results of our work on one specific agent-based model, showing how it can be validated against the more traditional model from which it was derived, and highlighting the extent to which it can be used to derive additional results over and above those that the traditional model can provide.

2. A MODEL OF HUMAN CAPITAL

The model that we consider in this paper is drawn from [3], an article that derives a linear model from US census data, and analyzes the aggregate behavior of the model. The model is derived in [3] to identify the effect of the tendency for human societies to stratify by level of education — so-called *human capital*. The model from [3] gives the level of human capital $z_{i,t+1}$ of members of the $t+1$th generation of the ith dynasty as being:

$$z_{i,t+1} = k_{t+1} + \alpha\left(\frac{z_{i,t} + z'_{i,t}}{2}\right) + \beta\left(\frac{\sum_{j=1}^{n} z_{j,t}}{n}\right) + \epsilon_{i,t+1} \quad (1)$$

The first term measures the effect on the level of education ("education" and "human capital" are used more or less interchangeably in this model) of the $t+1$th generation of the education of its parents in the t-th generation. The second term does something similar based upon the neighbors of the parents. The third term is constant across dynasties, but may vary in time to capture exogenous trends in education — for example legislation that requires a certain number of years of additional schooling for given generations. The final term captures a specific "shock" to the human capital in a specific generation of a specific dynasty — for example the early death of a parent, requiring the children to curtail their education.

The notion of "dynasty" and "generation" used here require a little explanation. Each generation of the ith dynasty has two children, one male and one female. Each is assumed to then become the spouse of an opposite sex member of another dynasty, forming a family which in turn produces one male and one female child. One family from a given generation of the ith dynasty remains in the ith dynasty, and one becomes part of another dynasty (the dynasty of the corresponding non-ith partner). Thus there is a constant number of members of each generation, and of each dynasty at each generation.

Based on this model, we have developed an agent-based simulation with a fixed number of agents, n in each generation, with $n/2$ dynasties, and 2 children per family. The basic simulation loop, which executes once for each generation, has three steps:

1. Establish level of z based on:
   (a) Parents
   (b) Neighbors of parents
2. Establish factors that influence z for children
   (a) Spouse
   (b) Neighbors
3. Generate children

Step 1 is fixed by (1), and Step 3 is fixed by the requirement to produce one male and one female child in each generation. Clearly the results are going to depend on the way in which Step 2 is implemented, and our model includes a number of variations described in full in [9].

3. EXPERIMENTS

An agent-based version of the model described in the previous section was implemented in REPAST [5], a Java-based Swarm-like [8] tool developed at the University of Chicago for agent-based modeling in social science applications. We handled the geographic aspects by placing agents on an $n \times n$ grid, where at most one dynasty "lives" in a single grid-square. By varying the size of the grid and number of agents we can create environments of differing population density and have modeled communities of up to 10,000 dynasties.

3.1 Verification

Having constructed an agent-based model of human capital from the equation-based model in [3], we first need to "complete the loop" by performing a statistical analysis of the results from the agent-based model, obtained when using the parameter values assumed in the paper, to show that our agent-based model will achieve the same results as the equation-based model we started with. This verification step is needed in order to justify the further experimental results with the model.

The central result of [3], and the only quantitative result that we can use to check the model against, is the prediction that increasing sorting — which the paper takes to mean increasing the correlation between the human capital values of the parent agents of a generation — will only cause an increase in inequality — which the paper takes to mean that the standard deviation of the human capital distribution grows generation by generation — when the value of α is large. [3] demonstrates this by showing the effect of changing correlation from 0.6 to 0.8 for various values of α. Running experiments on a 50×50 grid — which allows us to deal with a population that is considerably larger than the 1500 individuals analyzed in [3] — we find that our model gives good agreement with the predictions made in [3].

For example, we can plot the effect of parental choice of spouse in terms of the percentage change in inequality (as defined in [3]) against α, the parameter that mediates the effect that parents have on their children's human capital. This gives Figure 1.

3.2 Identifying new features

As we discussed above, one of the advantages that agent-based models have over equation-based models is that one can examine the model in greater detail. Whereas equation-based models can only really be studied in terms of broad statistical features — such as the results from [3] examined above — we can probe agent-based models in considerable detail, discovering what happens to

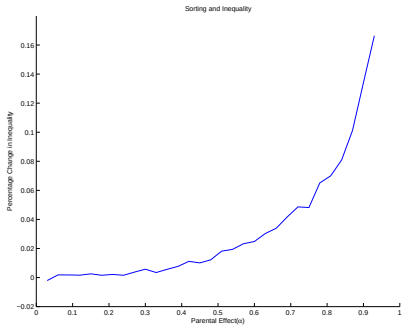

Figure 1: The relationship between the parental effect α and the percentage change in inequality.

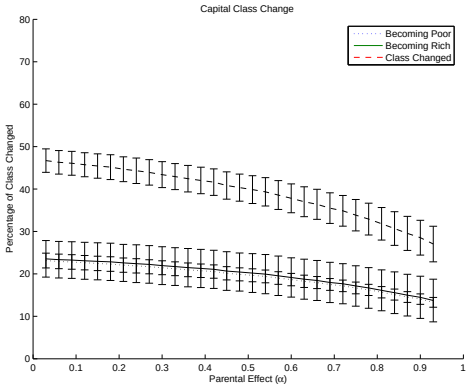

Figure 2: The relationship between the percentage of dynasties that change "class" and α.

individuals as well as to classes of individual. We have carried out such an investigation into the human capital model.

The headline result from [3], replicated by our agent-based model is that *on average* inequality in terms of human capital grows over generations. The widening standard deviation of the human capital distribution suggests that rich dynasties get richer and poor dynasties get poorer. However true this may be at a population level, it is interesting to ask whether it is true for all (or even most) individual dynasties, or whether there is some mobility between dynasties with different levels of human capital.

It turns out that such mobility exists.

We divided our dynasties up into three "classes" — the quotes reminding us that this terminology, while convenient, conflates human capital, basically years of formal schooling, with monetary capital. We call dynasties that fall within one standard deviation above or below the average human capital for the population *middle class*, we call those more than one standard deviation below average *poor*, and those more than one standard deviation above average *rich*. We then examined whether dynasties moved between classes.

The results are given in Figures 2 and 3. These show the way that the number of dynasties that are mobile in this sense changes for two different values of α and β, respectively. When α changes, β is held constant and vice-versa. The graphs plot three values, the total percentage of dynasties that move, the percentage that become richer, and the percentage that become poorer, all data being presented along with standard deviations. The results show that,

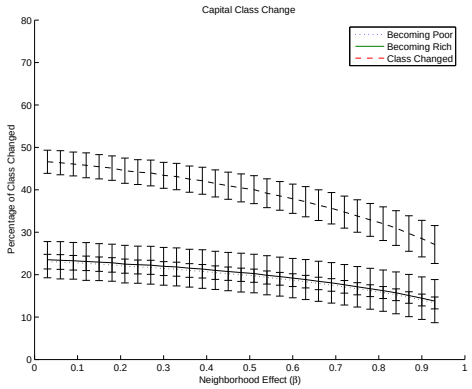

Figure 3: The relationship between the percentage of dynasties that change "class" and β

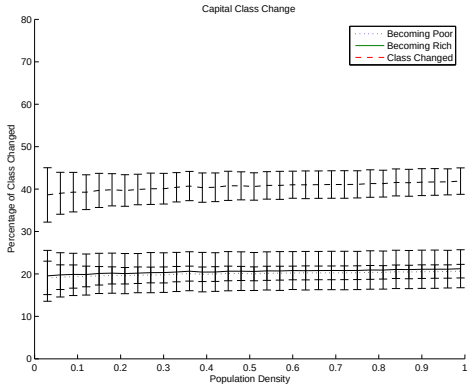

Figure 4: The relationship between the percentage of dynasties that change "class" and population density.

no matter what the value of α and β, there is some mobility (at least 25% of the population, and as much as 45% of the population changes class). Furthermore this change is symmetrical — more or less the same number of dynasties get richer as get poorer.

Note that this effect is separate from the growing inequality — because "middle class" is always defined in terms of the *current* standard deviation, if inequality was the only effect, the percentage of dynasties changing class would be lower than the figure we find. What we see here is the result of mixing, that is, individuals choosing partners or neighbors who are sufficiently far above or below them in human capital terms that their offspring move from one class to another.

We also checked that class mobility was unaffected by other parameters of the model. Since the neighbor effect is based upon a geographic notion of neighborhood, and since neighbors certainly have an effect on class mobility, then one might imagine that changing the density of the population might have some effect on class mobility as well. However, this is not the case. As Figure 4 shows, population density has no systematic effect on class mobility.

For further details of our results, see [9].

4. SUMMARY

This paper set out to show that it was possible to construct an agent-based model from a traditional, equation-based, model, and: (i) verify the agent-based model against the predictions made by the equation-based model; and (ii) use the agent-based model to identify new predictions that cannot be obtained directly from the equation-based model. Both these aims have been achieved.

This work fits into a wider effort that is attempting to model aspects of the education system [7], with the overall aim of being able to identify, and thus establish the impact of, changes in education policy (rather as [1] does for the case of rent control). As described in [7], we have developed a number of models, including a model of interactions in classrooms [6] — which allows us, for example, to model the effects of different pedagogical techniques to overcome absenteeism — and a model of school districts — which, for example, enables us to study the effect of policies like "No child left behind".

Our aim is to tie these models together, and, more ambitiously, to tie them into a comprehensive simulation of the way that education fits into the economy as a whole. One way to think of this is through the model provided in [4]. This describes individuals as making a choice about how much education to receive. This education, combined with their inherent aptitude, equips each agent with a certain level of productivity which, after its education is complete, allows it to pay off its education and purchase units of consumption. Thus education becomes a decision which both enables consumption and constrains it (because education has to be paid for). The kinds of model described in [7] tie in with this approach — the classroom model will affect the way that ability relates to productivity for example — and the human capital model described here provides a means of relating the education decisions made by one generation to those made by the next, giving us a means of projecting the effects of our models over generations.

ABSTRACT

Empirical game theory allows studying the strategic interactions of agents in simulations. Specifically, traditional game theory describes such interactions by an analytical model, while empirical game theory employs simulations. In this paper, we use empirical game theory to study how the more-or-less selfishness of agents affects their behaviour. To this end, we assume that every agent utility can be split in two parts, a first part representing the direct utility of agents and a second part representing agent social consciousness, i.e., their impact on the rest of the multiagent system. An application to supply chains illustrates this approach. In this application, the collaborative strategy is often used by every company-agent at whatever their same level of social consciousness, which may indicate that every agent is strongly related with one other.

1. INTRODUCTION

Walsh and his colleagues [5] have introduced the concept of empirical game theory (GT) by using GT to analyze the behaviour of agents in simulations. In other words, they replaced the analytical model representing strategic interactions in GT by simulation outcomes. Another example of the use of this approach is provided by Wellman and his colleagues [6] who used it to design their agent for the Trading Agent Competition/Supply Chain Management 2003. Our previous work [3] is also such an example of approach suitable for the analysis of interactions in agent-based simulations profitting from GT concepts and applied to supply chains (SC). In our application to SC, we found that the highest level of collaboration was often a Nash equilibrium which incurs the minimum SC cost. We now enhance this previous work in two ways in order to study (Enhan. 1) how the obtained results vary when the utility measuring the achievement of the group goal changes with regard to the individual utility of every agent, and (Enhan. 2) how robust the results are with respect to the stochasticity of some parameters. Our approach is presented in Section 2.

Then, we apply our approach to SC again. In this context, Enhan. 1 is performed by measuring how the SC (i.e., group) goal of delivering products to end-customers is achieved, while the individual goal of every company is to minimize its inventory holding cost. Indeed, companies have to make a trade-off between increasing their inventory level to avoid stock-outs and achieve thus the group goal, and decreasing their inventory level to achieve their individual goal. Finally, the stochastic parameter in Enhan. 2 represents end-customers demand of the two markets buying products to the SC. With Enhan. 2, we check if results depend on the considered instance of a single demand distribution. This application to SC management is described in Section 3.

2. APPROACH

Concerning Enhan. 1, every agent $i \in I$ in our previous work [3] had a common fixed way to calculate its utility u^i that was based on its direct/individual utility u^i_{dir} and on its impact on other agents u^i_{soc}, so that $u^i = ((1-\epsilon^i)u^i_{\text{dir}} + \epsilon^i u^i_{\text{soc}})/(1-\epsilon^i)$, with $\epsilon^i \in [0;1)$; we divide by $(1-\epsilon^i)$ because u^i_{dir} represents realistic costs in our case study. On the contrary, we always kept $\epsilon^i = 2/3$ for each of the $|I|$ agents ($|I|$ denotes the cardinal of the set of agents I) in our previous paper, while Enhan. 1 consists in relaxing this constraint. More precisely, we now verify that agents still have incentives to use the collaborative strategy when ϵ^i varies, or conversely, if every agent behaviour depends on the value of ϵ^i. Notice that $\epsilon^i \to 1$ implements a fully benevolent agent because u^i_{dir} becomes negligible in comparison with u^i_{soc}. In this paper, we only address the case in which $\epsilon^1 = \epsilon^2 = \ldots = \epsilon$ with $\epsilon \in \{1/6, 2/6, 3/6, 4/6, 5/6\}$, which means that all agents have the same level of selfishness ϵ, but that this common level may be different between two of the considered situations. As a consequence, we do not consider the case in which selfish agents cohabit with benevolent agents (the prisonner's dilemma cannot occur), although the presented approach allows doing so. This assumption simplifies the analysis of the simulation outcomes, and we will try to relax it in future work.

Enhan. 2 deals with taking probability distribution for some stochastic parameters into account in replacement of a fixed sequence of numbers, in order to study stochastic models. This means that we generate an instance of the considered distribution, and then, we apply our approach with this fixed sequence of numbers. This is the same method as in our previous paper, except that we repeat the process with other instances of the considered distribution in order to next use statistical tools. In the case study, the stochastic parameter is end-customer demands D^{lumber} and D^{paper} representing the two markets our SC sells in.

Then, our approach may be described as three successive steps, viz **optParam**, **simAllConfig**, and finally **anaSimOut**: (i) **optParam** first optimizes some parameters for every value of ϵ when every agent i uses the same strategy $s^i \in S$ (the strategy set S is unique to all agents), i.e., optimization is only carried our for the strategy profile $(s^i, s^i, \ldots, s^i)$ in order to save computation time. In the case study, these optimized parameters are the inital inventory levels $\{Inv^i_{\text{init}}\}_{i=1}^{i=|I|}$. (ii) Then, **simAllConfig** simulates the SC for the $|S|^{|I|}$ combinations of s^i among the $|I|$ agents with the $\{Inv^i_{\text{init}}\}_{i=1}^{i=|I|}$ found by **optParam**. (iii) Finally, **simAllConfig** builds games in the normal form with the simulation outcomes generated by **simAllConfig**, and looks for the Nash equilibria of these games. Gambit [2] is the set of software tools used to analyze these games. Depending on $\{\epsilon^i\}_{i=1}^{i=|I|}$, different games can be built based from each output of **simAllConfig**.

3. CASE STUDY: APPLICATION TO SUPPLY CHAIN MANAGEMENT

3.1 Adaptation of the approach

We illustrate this approach in the context of the management of a wood SC. We profit from Enhan. 1 to study if selfish as well as benevolent company-agents should collaborate by sharing information concerning market consumption. This shared information is of importance to companies when they place orders, because this information may be distorted by a phenomenon called the "bullwhip effect" [1] that causes an increase of their inventory level and a decrease in their customer service level, and information sharing is the most often proposed solution to the bullwhip effect [4].

Concerning Enhan. 1, we take u^i_{dir} as company-agent i inventory holding cost, and u^i_{soc} as backorder cost, i.e., as stockout cost. Specifically, backorders correspond to orders that were not fulfilled in the past and that have to be shipped as soon as possible, i.e., there are no lost sales in this simulation model because clients wait for product availability. Since backorders are measured in our specific case as negative inventory levels, the calculation of u^i_{dir} and u^i_{soc} are similar, and thus, their aggregation into u^i represents a cost. Of course, every agent tries to minimize its cost u^i (no money can be earned). We think backorders can be used as a measure for social consciousness u^i_{soc} because agents are *not obliged* to consider them when they make decisions (while they always have to take the inventory holding cost into account in u^i_{dir}), but the *goal of the entire* SC should be to satisfy end-customers and avoid thus these backorders. In other words, the SC has not achieved its goal if products are not available by retailers, which is a problem obvious only to retailers. In order to make the other companies internalize the SC goal, we need to have them take backorders into account.

We profit from Enhan. 2 to consider a stochastic market consumption pattern. More precisely, we assume that market demand is a uniform distribution M of integer numbers spread over $\{11, 12, \ldots, 17\}$, and we carry out our experiments with $|M| = 10$ particular instances m_A to m_J of M over the fifty weeks of a simulation run. For instance, m_A corresponds to the two series of fifty numbers $D^{\text{lumber}} = \{16, 13, 16, 11, 15, \ldots, 15, 15, 12, 16, 15\}$ and $D^{\text{paper}} = \{15, 15, 14, 15, 14, \ldots, 13, 14, 14, 11, 13\}$, where the wth number represents the market demand in Week w, e.g., $D^{\text{lumber}}_2 = 13$ means that 13 units are requested to the LumberRetailer in Week 2. We only consider $|M| = 10$ instances of the distribution, because $|M| * |S|^{|I|}$ simulations are required to build the corresponding ten games in the normal form. However, **simAllConfig** carries out $|M| = 10$ times these $|S|^{|I|}$ simulations with one of the ten instances of M in order to build a game. In each of the obtained games, **anaSimOut** changes the ratio ϵ between the u^i_{dir} and u^i_{soc} when Gambit looks for Nash equilibria.

Ordering strategy	Level of collaboration	Type of communication
μ	No collaboration	No communication
β	Information sharing with direct neighbours	Point to point
γ	Information centralization	Bulletin board

Table 1: The three ordering strategies.

3.2 Simulation model

In this case study, we use exactly the same simulation model with $|I| = 6$ agents as in [3]: a LumberRetailer buys from a LumberWholesaler, which buys from a Sawmill, which itself is the only company managing both lumber and paper units. In fact, besides lumbers, the Sawmill can also sell paper units to the PulpMill, which then sells to the PaperWholesaler, which finally sells to the PaperRetailer. Each retailer sells in a different market (lumber and paper), and the Sawmill buys from an infinite source.

Next, each of the six companies i makes its ordering decisions by applying one of $|S| = 3$ ordering strategies s^i called α, β and μ. Once set, s^i remains the same for the fifty weeks of a simulation run. Table 1 outlines these three strategies:

- With ordering strategy μ, company-agents make their decision on their own and can only rely on their incoming orders and shipping to decide what order to place. The only information transmitted with μ are orders and no additional information is shared to help other agents place their own orders. In practice, μ is an (s, S) policy, which is classic in Inventory Management, and in which a company orders $(S - InvP)$ items when the level of its inventory position $InvP$ falls below s. We showed in [3] that taking $s = 0$ and S equals to the current incoming order is optimal.

- There is slight collaboration with strategy β, because agents now transmit the market consumption information to their supplier, which allows every agent to place orders in a more accurate way. From a technical viewpoint, every placed orders is a two-dimension vector, and the quantity ordered is equal to the sum of its two elements: the first element corresponds to the market consumption transmitted by each company to its direct supplier, and the second element represents the products to be ordered in more or in less than the market

Value of ϵ	Nash equilibria
$\epsilon = 1/6$	$(\gamma,\mu,\gamma,\mu,\gamma,\gamma)$, $(\gamma,\gamma,\gamma,\mu,\mu,\gamma)$
$\epsilon = 2/6$	$(\gamma,\mu,\gamma,\mu,\mu,\beta)$, $(\gamma,\gamma,\gamma,\mu,\mu,\gamma)$
$\epsilon = 3/6$	$(\gamma,\beta,\gamma,\mu,\mu,\beta)$, $(\gamma,\gamma,\gamma,\mu,\gamma,\gamma)$
$\epsilon = 4/6$	$(\gamma,\gamma,\gamma,\gamma,\gamma,\gamma)$
$\epsilon = 5/6$	$(\beta,\mu,\beta,\mu,\mu,\beta)$, $(\beta,\beta,\beta,\beta,\beta,\beta)$ $(\beta,\gamma,\beta,\gamma,\beta,\gamma)$, $(\beta,\gamma,\beta,\gamma,\gamma,\beta)$ $(\gamma,\beta,\gamma,\beta,\beta,\beta)$, $(\gamma,\gamma,\gamma,\gamma,\beta,\beta)$

Table 2: Results for Instance m_A.

consumption. Notice that the first element indicates the past market consumption, since this information travels the SC as slowly as orders.

- The highest level of collaboration is implemented in strategy γ, in which retailer-agents write the market consumption information on a bulletin board, and the rest of agents can read this information (this is information centralization). In practice, γ works as β, except that companies take the first element of their two-dimension orders equal to the current market consumption (while it is equal to past data with β).

3.3 Results and analysis

Table 2 enumerates all the Nash equilibria obtained with different values of ϵ with the particular instance m_A of the market demand M. For example, for $\epsilon = 5/6$, there are 6 Nash equilibria, and the first one is the *strategy profile* $(s^1, s^2, s^3, s^4, s^5, s^6) = (\beta,\mu,\beta,\mu,\mu,\beta)$; in this equilibrium, the LumberRetailer ($i = 1$), the LumberWholesaler ($i = 3$) and the Sawmill ($i = 6$) use Strategy β, while all other agents use γ. Note that μ occurs 15 times, β 29 times and γ 40 times in overall Table 2, which represents respectively to frequencies of 20%, 29% and 51%. Therefore, the highest level of collaboration γ occurs in half of the found Nash equilibria.

Next, the question addressed in this paper is to determine at which value of ϵ the Nash equilibria switch from a full-collaborating system (that is, most companies collaborate at the highest level, e.g., $(\gamma,\gamma,\gamma,\beta,\gamma,\gamma)$) to a full non-collaborating one (that is, most companies disagree to collaborate, e.g., $(\mu,\beta,\mu,\ \mu,\mu,\mu)$). To answer this question, we check if the Nash equilibria with low ϵ (selfish agents) often apply the non-collaborative μ, and/or if the Nash equilibria with high ϵ (benevolent agents) frequently use the highly collaborative γ. To see this, we calculate the frequency at which every strategy is used depending on the value of ϵ. That is, we calculate the central column about m_A in Table 3 based on the numbers in Table 2. This calculation is achieved in the following way. In line '$\epsilon = 5/6$' in Table 2, there are 6 equilibria that count a total of 3 μ, 20 β and 13 γ. These three numbers are reported in line $\epsilon = 5/6$ in Table 3 as '$3/36 = 8\% \rightarrow \mu$', which means that 3 of the 36 (=3+20+13) strategies used in a Nash equilibrium are μ. Next, the right column of Table 3 contains the same results, but with the nine other instances m_B to m_J of market consumption. To calculate every frequency in the right column, we take the average of the frequencies obtained with the ten market demands, i.e., these frequencies are not weighted by the number of equilibria: to obtain '$7\% \rightarrow \mu$' with $\epsilon = 5/6$ in the right column of Table 3, the 8% obtained with m_A has the same importance as the percentages obtained with $m_B, \ldots, m_J$, even though they do not represent the same quantity of equilibria.

With both center and right columns in Table 3, we can see that μ only has low occurence frequencies, and that these frequencies do not depend on ϵ. This means that the decision of collaborating does not depend on the level of social consciousness ϵ. The interpretation of this may be that every company-agent is so strongly *dependent* on each other, that they should all collaborate.

Value of ϵ	Frequency of μ, β and γ under Instance m_A	Average frequency of μ, β and γ over Instances m_A to m_J
$\epsilon = \frac{1}{6}$	$4/12 = 33\% \rightarrow \mu$ $0/12 = 0\% \rightarrow \beta$ $8/12 = 67\% \rightarrow \gamma$	$27\% \rightarrow \mu$ $9\% \rightarrow \beta$ $64\% \rightarrow \gamma$
$\epsilon = \frac{2}{6}$	$5/12 = 42\% \rightarrow \mu$ $1/12 = 8\% \rightarrow \beta$ $6/12 = 50\% \rightarrow \gamma$	$22\% \rightarrow \mu$ $6\% \rightarrow \beta$ $72\% \rightarrow \gamma$
$\epsilon = \frac{3}{6}$	$3/12 = 25\% \rightarrow \mu$ $2/12 = 17\% \rightarrow \beta$ $7/12 = 58\% \rightarrow \gamma$	$17\% \rightarrow \mu$ $14\% \rightarrow \beta$ $69\% \rightarrow \gamma$
$\epsilon = \frac{4}{6}$	$0/6 = 0\% \rightarrow \mu$ $0/6 = 0\% \rightarrow \beta$ $6/6 = 100\% \rightarrow \gamma$	$9\% \rightarrow \mu$ $16\% \rightarrow \beta$ $75\% \rightarrow \gamma$
$\epsilon = \frac{5}{6}$	$3/36 = 8\% \rightarrow \mu$ $20/36 = 56\% \rightarrow \beta$ $13/36 = 36\% \rightarrow \gamma$	$7\% \rightarrow \mu$ $43\% \rightarrow \beta$ $50\% \rightarrow \gamma$

Table 3: Relative frequency of the occurence of μ, β and γ in the incurred Nash equilibria.

4. CONCLUSION

This paper studied the impact of social consciousness on individual decision making. As an illustration, we studied if companies in a supply chain would collaborate by sharing the demand when they are more or less benevolent. We found that the benevolence level does not have a great impact, perhaps because companies are tightly linked in our simulation.

5. ACKNOWLEDGMENT

We would like to thank FOR@C, the Research Consortium in E-business in the forest products industry (Université Laval, Québec, Canada), for supporting this research. This work was also partially supported by the National Sciences and Engineering Research Council of Canada (NSERC).

Logics for agent systems

Complexity and Succinctness of Public Announcement Logic

Carsten Lutz
Institute for Theoretical Computer Science
TU Dresden, Germany
lutz@tcs.inf.tu-dresden.de

ABSTRACT

There is a recent trend of extending epistemic logic (EL) with dynamic operators that allow to express the evolution of knowledge and induced by knowledge-changing actions. The most basic such extension is public announcement logic (PAL), which is obtained from EL by adding an operator for truthful public announcements. In this paper, we consider the computational complexity of PAL and show that it coincides with that of EL. This holds in the single- and multi-agent case, and also in the presence of common knowledge operators. We also prove that there are properties that can be expressed exponentially more succinct in PAL than in EL. This shows that, despite the known fact that PAL and EL have the same expressive power, there is a benefit in adding the public announcement operator to EL: it exponentially increases the succinctness of formulas without having negative effects on computational complexity.

1. INTRODUCTION

One of the most prominent applications of logic in agent-based systems is reasoning about the knowledge and belief of agents. Although traditionally, epistemic logic (EL) is the basic logical tool for this purpose [14], it has always been clear that EL is too simple for many relevant applications in this area. Most strikingly, basic EL does not include any syntactic or semantic means for representing dynamic and evolutionary aspects of knowledge. Since it is crucial for almost all agent-based systems that the knowledge and belief of agents are subject to change [1], such expressive means are often indispensible. In the literature, there are two dominant approaches to adding dynamics to EL: first, EL can be extended with a temporal component that allows to reason about the evolution of knowledge over time [9]. And second, EL can be extended with dynamic operators that allow to describe the ramifications of knowledge-changing actions. The latter approach is a relatively recent development, and the resulting extensions of EL are often called *dynamic epistemic logics (DELs)* [8].

By now, a large number of DELs has been proposed, and the various proposals differ considerably in expressive power [2, 11, 16, 3, 4, 6, 7]. However, there is a dynamic operator that is included in almost all proposed logics: the *public announcement* operator that has first been introduced in [16]. This operator allows to state that, after some announcement that is publicly made by an outsider to all agents simultaneously, some property holds true. Both the announcement and the property may include epistemic statements such as "agent a knows fact F" or "agent a believes that agent b knows fact F". The announcement is assumed to be truthful, i.e., the person making the announcement does not lie. The effect of the announcement being public is that everybody knows the announced fact, everybody knows that everybody knows it, and so forth. It is interesting to note that the announced fact is not necessarily true anymore *after* the announcement. For example, this is the case if the announced fact is "agent a knows fact F, but agent b doesn't know that" (because, after the announcement, agent b knows that agent a knows F).

Existing research about the public announcement operator has mainly concentrated on the expressiveness and axiomatics of the obtained extensions of EL. For example, it is known that EL with the public announcement operator has the same expressive power as EL without it.[1] However, performing *actual reasoning* is of great importance when applying DELs in agent-based systems, and thus, the computational properties of such logics need to be analyzed. While the computational complexity of model checking DELs is easily pinpointed, not much is known about deciding satisfiability and validity (henceforth called *reasoning*). Therefore, the purpose of the current paper is to *analyze the computational complexity of reasoning in epistemic logics ex-*

[1]This should not be taken as an indication that the operator is not worth studying; see below.

tended with the public announcement operator. Since computational complexity, expressiveness, and succinctness issues turn out to be intimately and subtly related to computational complexity in the considered logics, we include the latter in our analysis.

We start our investigation with *public announcement logic (PAL)*, the extension of basic EL with the public announcement operator. As noted above, the expressive power of PAL is known to be identical to the expressive power of EL: there exists an equivalence-preserving translation from the former to the latter [16, 8]. Computationally, this translation is only moderately useful: it yields decidability of reasoning in PAL, but it does not produce tight complexity bounds due to an exponential blowup in formula size. More precisely, the known translation yields upper complexity bounds for PAL that are identical to those for EL, but raised by one exponential. In contrast, the best known lower bounds are the ones from EL.

In this paper, we show that the existing upper bounds can be improved by one exponential, and thus reasoning in PAL is of the same complexity as reasoning in EL. To this end, we first propose a novel, equivalence-preserving translation from PAL to EL. Like the existing one, this translation induces an exponential blowup in formula size. The advantage of the new translation is that it can easily be modified such that it becomes only satisfiability-preserving, but avoids the exponential blowup in formula size. The modified translation takes formulas of single-agent PAL to formulas of single-agent EL, and formulas of multi-agent PAL to formulas of multi-agent EL extended with an "everybody knows" operator. Thus, it can be used to prove that (i) single-agent PAL is NP-complete, and (ii) multi-agent PAL is PSPACE-complete. We then extend our equivalence-preserving translation and its satisfiability-preserving modification to PAL extended with (two variants of) common knowledge. In this case, the target language of the translation is propositional dynamic logic (PDL), and we obtain EXPTIME-completeness results.

Due to the fact that PAL and EL are equally expressive and of the same computational complexity, one may be tempted to think that the addition of the public announcement operator to EL is only syntactic sugar and not of much interest. However, it has been convincingly argued in [3, 8] that PAL is a much more intuitive and natural formalism for talking about the dynamics of knowledge than EL. In this paper, we add another, more concrete advantage of PAL: we prove that there are properties that can be expressed exponentially more succinct in PAL than in EL. Thus, the public announcement operator contributes to the succinctness of the logic, and this exponential increase in succinctness is not even penalised by an increase in computational complexity. Of course, our succinctness result also implies that one cannot hope to find an *equivalence-preserving* translation from PAL to EL that avoids an exponential blowup. A limitation of our (current) succinctness result is that it applies only to the class of all Kripke structures, and not to the class of epistemic structures.

2. PUBLIC ANNOUNCEMENT LOGIC

Let PL and N be countable sets of *propositional letters* and *agents*. The formulas of *public announcement logic with common knowledge (PALC)* are built according to the following syntax rule:

$$\varphi ::= p \mid \neg\varphi \mid \varphi \wedge \psi \mid K_a\varphi \mid [\varphi]\psi \mid C_A\varphi$$

where p ranges over PL, a ranges over N, and A ranges over 2^N. The operator $[\varphi]\psi$ is the *public announcement operator*: $[\varphi]\psi$ states that, after φ is publically announced, ψ holds true. A detailed introduction to PALC and how it can be used to model the dynamics of knowledge can be found in [3, 8]. Here, we confine ourselves to a simple example: the formula

$$K_a(K_b\mathsf{secret} \wedge [K_b\mathsf{secret}]K_c\mathsf{leaked}_{a,b}),$$

with secret and $\mathsf{leaked}_{a,b}$ propositional letters, states the following: agent a knows that agent b knows the secret, and if this is publically announced, then agent c will know that agent a has leaked the secret to b.

By dropping the *common knowledge operator* $C_A\varphi$ from PALC, we get formulas of *public announcement logic (PAL)*. By dropping the public announcement operator from PAL, we get formulas of *epistemic logic (EL)*. As usual, we use $\varphi \vee \psi$ as an abbreviation for $\neg(\neg\varphi \wedge \neg\psi)$, $\varphi \rightarrow \psi$ for $\neg\varphi \vee \psi$, $\widehat{K}_a\varphi$ for $\neg K_a\neg\varphi$, $\langle\varphi\rangle\psi$ for $\neg[\varphi]\neg\psi$, and $\top$ for $p \vee \neg p$, with p an arbitrary (but fixed) propositional letter. When talking of *single-agent PAL or EL*, we assume that N is a singleton. In this case, we drop the index $\cdot_a$ from $K_a\varphi$ and $\widehat{K}_a\varphi$.

The semantics of PALC is defined by means of Kripke structures. An *epistemic model* (or *model* for short) is a triple $\mathcal{M} = (S, \sim, V)$ with S a non-empty set of states, $\sim = (\sim_a)_{a\in N}$ a family of equivalence relations on S, and V a function assigning a set of states $V(p) \subseteq S$ with each $p \in \mathsf{PL}$. Given a model $\mathcal{M} = (S, \sim, V)$ and an $s \in S$, we define:

$$\begin{array}{rcl}
\mathcal{M}, s \models p & \text{iff} & s \in V(p) \\
\mathcal{M}, s \models \neg\varphi & \text{iff} & \mathcal{M}, s \not\models \varphi \\
\mathcal{M}, s \models \varphi \wedge \psi & \text{iff} & \mathcal{M}, s \models \varphi \text{ and } \mathcal{M}, s \models \psi \\
\mathcal{M}, s \models K_a\varphi & \text{iff} & s \sim_a t \text{ implies } \mathcal{M}, t \models \varphi, \text{ for all } t \in S \\
\mathcal{M}, s \models [\varphi]\psi & \text{iff} & \mathcal{M}, s \models \varphi \text{ implies } \mathcal{M}|\varphi, s \models \psi \\
\mathcal{M}, s \models C_A\varphi & \text{iff} & s \,(\bigcup_{a\in A} \sim_a)^* \, t \text{ implies } \mathcal{M}, t \models \varphi, \\
 & & \qquad\qquad \text{for all } t \in S
\end{array}$$

where $\cdot^*$ denotes the reflexive-transitive closure operator on binary relations, and the model $\mathcal{M}|\psi := (T, \approx, U)$ is defined as follows:

$$\begin{array}{rcl}
T & := & \{t \in S \mid \mathcal{M}, t \models \psi\} \\
\approx_a & := & \sim_a \cap (T \times T) \\
U(p) & := & V(p) \cap T.
\end{array}$$

It is easily checked that the semantics of the derived modalities is as follows:

$$\begin{array}{rcl}
\mathcal{M}, s \models \widehat{K}_a\varphi & \text{iff} & s \sim_a t \text{ and } \mathcal{M}, t \models \varphi, \text{ for some } t \in S \\
\mathcal{M}, s \models \langle\varphi\rangle\psi & \text{iff} & \mathcal{M}, s \models \varphi \text{ and } \mathcal{M}|\varphi, s \models \psi.
\end{array}$$

Given a model $\mathcal{M}$, we use $S(\mathcal{M})$ to denote the set of states of $\mathcal{M}$. It is not too difficult to see that, by fixing the first argument, the public announcement operator can be conceived as a unary normal modal operator (in the sense of, e.g., [5]) that behaves in many ways like a modal operator for a functional accessibility relation. For example, $\langle\varphi\rangle\psi$ implies $[\varphi]\psi$.

$$
\begin{array}{rcl}
[\varphi]p & \rightsquigarrow & \varphi \to p \\
[\varphi](\psi \wedge \chi) & \rightsquigarrow & [\varphi]\psi \wedge [\varphi]\chi \\
[\varphi]\neg\psi & \rightsquigarrow & \varphi \to \neg[\varphi]\psi \\
[\varphi]K_a\psi & \rightsquigarrow & \varphi \to K_a[\varphi]\psi
\end{array}
$$

Figure 1: The standard translation from PAL to EL.

3. EXPRESSIVITY AND SUCCINCTNESS

As first observed by Plaza [16], the basic epistemic logic with public announcements PAL has exactly the same expressive power as EL. Indeed, by exhaustively applying the rewrite rules in Figure 1, one can convert every PAL formula into an equivalent EL formula [8]. For the purposes of this paper, however, it is convenient to work with a translation that is different from this standard one. To introduce the new translation, we need a bit of notation: for φ a PAL formula and $\sigma = \varphi_1 \cdots \varphi_k$ a finite sequence of PAL formulas, we use

- $|\varphi|$ to denote the length of φ, i.e. the number of symbols needed to write down φ, including symbols such as "[" and "]"; likewise, $|\sigma|$ denotes $|\varphi_1| + \cdots + |\varphi_k|$;
- $\mathcal{M}|\sigma$ as an abbreviation for $(((\mathcal{M}|\varphi_1)|\varphi_2)\cdots|\varphi_k)$ with $\mathcal{M}|\varepsilon = \mathcal{M}$;
- $\mathsf{pre}(\sigma)$ to denote the set of all true prefixes of σ including the empty sequence ε;
- for each $\nu \in \mathsf{pre}(\sigma)$, ν/σ to denote the leftmost symbol of σ that is not in ν.

We now define, for every PAL formula φ and every finite sequence of PAL formulas σ, an EL formula φ^σ. The definition of the formulas φ^σ proceeds by induction on $|\varphi| + |\sigma|$ as shown in Figure 2. In the $K_a\varphi$ case, the conjunction collapses to true if $\sigma = \varepsilon$. To see that we really do induction on $|\varphi| + |\sigma|$, note that the symbols "[" and "]" contribute to the size of the left-hand side of the last line.

The most important property of the formulas φ^σ is given by the following lemma. It can be proved by induction on $|\varphi| + |\sigma|$, for details consult the appendix.

Lemma 1. *For all models $\mathcal{M} = (S, \sim, V)$, PAL formulas φ, finite sequences of PAL formulas σ, and states $s \in S(\mathcal{M}|\sigma)$, we have $\mathcal{M}, s \models \varphi^\sigma$ iff $\mathcal{M}|\sigma, s \models \varphi$.*

Lemma 1 clearly implies that each PAL formula φ is equivalent to the EL formula φ^ε, which gives us the new translation. It can easily be seen that this translation usually produces different formulas than the standard translation given in Figure 1. For example, the result of translating $[p_1][p_2]\cdots[p_k]q$ with our translation results in the formula

$$p_1 \to (p_2 \to (\cdots \to (p_k \to q))),$$

which is of length $\mathcal{O}(k)$. In contrast, the standard translation produces a highly redundant formula of length $2^{\mathcal{O}(k)}$. Thus, there are formulas on which our translation is exponentially more succinct. In general, however, the new translation does not avoid an exponential blowup in formula size. See Theorem 2 below for example formulas.

Given the exponential blowup induced by both translations, it is a natural question whether the exponential blowup in translating PAL to EL can be avoided at all. We answer this question to the negative: PAL is exponentially more succinct than epistemic logic if there are at least two agents and we assume *unrestricted models*, i.e., models whose relations are not required to be equivalence relations. Our aim is to prove the following theorem.

$$
\begin{array}{rcl}
p^\sigma & := & p \\
(\neg\varphi)^\sigma & := & \neg\varphi^\sigma \\
(\varphi \wedge \psi)^\sigma & := & \varphi^\sigma \wedge \psi^\sigma \\
(K_a\varphi)^\sigma & := & K_a(\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu \to \varphi^\sigma) \\
([\varphi]\psi)^\sigma & := & \varphi^\sigma \to \psi^{\sigma\cdot\varphi}
\end{array}
$$

Figure 2: The new translation.

Theorem 2. *For $i \geq 0$, define*

- $\varphi_0 := \top$;
- $\varphi_{i+1} := \langle\langle\varphi_i\rangle\widehat{K}_a\top\rangle\widehat{K}_b\top$.

On unrestricted models, every EL formula ψ equivalent to φ_i is of length at least 2^i, for all $i \geq 0$.

Define a sequence of EL formulas $\psi_0, \psi_0', \psi_1, \psi_1', \psi_2, \ldots$ as follows:

- $\psi_0 := \top$;
- $\psi_i' := \psi_i \wedge \widehat{K}_a\psi_i$;
- $\psi_{i+1} := \psi_{i-1}' \wedge \widehat{K}_b\psi_{i-1}'$.

Using the translation from PAL to EL given above, which also applies to the case of unrestricted models, it is straightforward to prove by induction on i that, for $i \geq 0$, φ_i is equivalent to ψ_i. Thus, for proving Theorem 2 it suffices to prove that every EL formula χ that is equivalent to ψ_i on unrestricted models is of length at least 2^i, for all $i \geq 0$.

In what follows, a *path set* is a subset of N^* (where N is the set of agents). For φ an EL formula φ over the set of agents N, we define the *path-set* P_φ of φ by structural induction as follows:

- $P_p := \{\varepsilon\}$;
- $P_{\neg\varphi} := P_\varphi$;
- $P_{\varphi\wedge\psi} := P_\varphi \cup P_\psi$;
- $P_{K_a\varphi} := \{\varepsilon\} \cup \{aw \mid w \in P_\varphi\}$.

Now, let χ be an EL formula that is equivalent to ψ_i, for some $i > 0$. We show the following:

$$P_{\psi_i} \subseteq P_\chi. \qquad (*)$$

To prove $(*)$, assume to the contrary that there is a $\widehat{w} \in P_{\psi_i} \setminus P_\chi$. Define a model $\mathcal{M} = (S, \sim, V)$ as follows:

- $S = P_{\psi_i}$;
- the relation $\sim_\sigma$, $\sigma \in N$, is defined by setting $w \sim_\sigma v$ if $v = w\sigma$, for $w, v \in S$;
- $V(p) = \emptyset$ for all $p \in \mathsf{PL}$.

$$
\begin{array}{rcl}
R(a) & := & \{(\varepsilon, a)\} \\
R(\neg\varphi) & := & R(\varphi) \cup \{(\varepsilon, \neg\varphi)\} \\
R(\varphi \wedge \psi) & := & R(\varphi) \cup R(\psi) \cup \{(\varepsilon, \varphi \wedge \psi)\} \\
R(K_i\varphi) & := & R(\varphi) \cup \{(\varepsilon, K_i\varphi)\} \\
R([\varphi]\psi) & := & R(\varphi) \cup \{(\varphi \cdot \sigma, \vartheta) \mid (\sigma, \vartheta) \in R(\psi)\} \\
 & & \cup \{(\varepsilon, [\varphi]\psi)\}
\end{array}
$$

Figure 3: The relevant pairs.

$$
\begin{array}{rcl}
B^\sigma_q & := & p^\sigma_q \leftrightarrow q \\
B^\sigma_{\neg\varphi} & := & p^\sigma_{\neg\varphi} \leftrightarrow \neg p^\sigma_\varphi \\
B^\sigma_{\varphi\wedge\psi} & := & p^\sigma_{\varphi\wedge\psi} \leftrightarrow (p^\sigma_\varphi \wedge p^\sigma_\psi) \\
B^\sigma_{K_i\varphi} & := & p^\sigma_{K_i\varphi} \leftrightarrow K_i(\bigwedge_{\nu\in \mathsf{pref}(\sigma)} p^\nu_{\nu/\sigma} \rightarrow p^\sigma_\varphi) \\
B^\sigma_{[\varphi]\psi} & := & p^\sigma_{[\varphi]\psi} \leftrightarrow (p^\sigma_\varphi \rightarrow p^{\sigma\cdot\varphi}_\psi)
\end{array}
$$

Figure 4: The biimplications B^σ_φ.

A second model $\mathcal{M}' = (S', \sim', V')$ is defined as the restriction of $\mathcal{M}$ to the set of states

$$S' := S \setminus \{w \in N^* \mid w = \widehat{w}w' \text{ for some } w' \in N^*\}.$$

It is not too hard to show that $\mathcal{M}$ is a model of ψ_i, but $\mathcal{M}'$ is not. Details are left to the reader.

Lemma 3. *$\mathcal{M}, \varepsilon \models \psi_i$ and $\mathcal{M}', \varepsilon \not\models \psi_i$.*

We now show that χ cannot distinguish ε in $\mathcal{M}$ from ε in $\mathcal{M}'$, i.e., $\mathcal{M}, \varepsilon \models \chi$ iff $\mathcal{M}', \varepsilon \models \chi$. This clearly is a contradiction to Lemma 3 and the fact that χ is equivalent to φ_i. Thus, we have established $(*)$. The fact that χ cannot distinguish ε in $\mathcal{M}$ from ε in $\mathcal{M}'$ is an immediate consequence of the following lemma, which is proved in the appendix.

Lemma 4. *For all $s \in S'$ and $\varphi \in \mathsf{sub}(\chi)$ such that*

$$\{sw \mid w \in P_\varphi\} \subseteq P_\chi,$$

we have $\mathcal{M}, s \models \varphi$ iff $\mathcal{M}', s \models \varphi$.

Finally, $|\chi| \geq 2^i$ is a consequence of $(*)$ together with the following lemma and the fact that, as is easily proved by structural induction, we have $|\varphi| \geq |P_\varphi|$ for all formulas φ.

Lemma 5. *For all $i \geq 0$, $|P_{\psi_i}| \geq 2^i$.*

Proof. It is straightforward to prove by induction on i that, for all $i \geq 0$, we have $\{a, b\}^i \subseteq P_{\psi_i}$. □

This finishes the proof of Theorem 2. We believe that PAL is also exponentially more succinct than EL on epistemic structures, but leave the proof as an open problem.

4. UPPER BOUNDS FOR PAL WITHOUT COMMON KNOWLEDGE

Given the succinctness of PAL established in the previous section, the question arises whether a penalty has to be paid for this succinctness in terms of computational complexity: is reasoning in PAL more expensive than reasoning in epistemic logic? Interestingly, this is not the case. We show that satisfiability in PAL is NP-complete in the single-agent case and PSpace-complete in the multi-agent case, just as in epistemic logic [13]. Lower bounds are immediate since PAL contains EL as a fragment. The idea for obtaining the upper bounds is to convert the equivalence-preserving, but exponential translation given in Section 3 into a satisfiability-preserving and polynomial translation. We start with the single-agent case.

4.1 Reducing Single-Agent PAL

We start with introducing some relevant notions. As these notions will also be useful for dealing with multi-agent PAL, we do not restrict ourselves to single-agent formulas here. Let φ be a PAL formula. With $\mathsf{sub}(\varphi)$, we denote the set of all subformulas of φ, including φ. With $\Sigma(\varphi)$, we denote the set of all pairs (σ, ψ), where $\psi \in \mathsf{sub}(\varphi)$ and σ is a finite (and possibly empty) sequence of formulas from $\mathsf{sub}(\varphi)$. The subset $R(\varphi) \subseteq \Sigma(\varphi)$ of *relevant pairs for* φ is defined inductively as in Figure 3.

Intuitively, $R(\varphi)$ gives us a representation of the subordinate translations that occur when inductively translating the PAL formula φ to the EL formula φ^ε. The central observation is that, while there are exponentially many *calls* to subordinate translations ψ^σ while translating φ into φ^ε, there are only polynomially many sub-translations with different arguments ψ, σ. Using structural induction on φ, it is easy to show that the number of relevant pairs is polynomial in $|\varphi|$ and that each pair in $R(\varphi)$ is of size polynomial in $|\varphi|$.

Lemma 6. *For all PAL formulas φ, we have the following:*

1. *$|R(\varphi)| \leq |\varphi|$;*
2. *for all $(\sigma, \psi) \in R(\varphi)$, the length of the sequence σ is bounded by $|\varphi|$.*

We now convert the equivalence-preserving and exponential translation from PAL to EL into a satisfiability-preserving polynomial one. Intuitively, we introduce a propositional letter p^ψ_σ for each subordinate translation ψ^σ and enforce that p^ψ_σ is true precisely where ψ^σ is true. This can be done in an incremental fashion without actually producing the (exponentially long) formulas of ψ^σ.

Let φ_0 be a single-agent PAL formula whose satisfiability is to be decided. We introduce a set of propositional letters $L_{\varphi_0} := \{p^\sigma_\varphi \mid (\sigma, \varphi) \in R(\varphi_0)\}$. W.l.o.g., assume that no letter from L_{φ_0} occurs in φ_0. For every $(\sigma, \varphi) \in R(\varphi_0)$, we define a biimplication B^σ_φ as in Figure 4. Note that the right-hand side of the biimplications is derived in a straightforward way from the equivalence-preserving translation given in Figure 2. Now define

$$\varphi_0^* := p^\varepsilon_{\varphi_0} \wedge \bigwedge_{(\sigma,\varphi)\in R(\varphi_0)} KB^\sigma_\varphi.$$

Observe that $|\varphi_0^*|$ is polynomial in φ_0: by Point 2 of Lemma 6, $|B^\sigma_\varphi|$ is linear in $|\varphi_0|$ for each $(\sigma, \varphi) \in R(\varphi_0)$. By Point 1 of Lemma 6, $|\varphi_0^*|$ is thus quadratic in $|\varphi|$. Clearly, φ_0^* is an EL formula. As the next lemma shows, we have obtained a satisfiability-preserving reduction as desired. A proof can be found in the appendix.

Lemma 7. *φ_0 is satisfiable iff φ_0^* is satisfiable.*

Taking together Lemma 7, the fact that $|\varphi_0^*|$ is quadratic in $|\varphi_0|$, and the known NP upper bound of single-agent EL (i.e., modal S5 [9]), we obtain an NP upper bound for single-agent PAL.

Theorem 8. *Satisfiability in single-agent PAL is* NP*-complete.*

4.2 Reducing Multi-Agent PAL

The general idea for obtaining a PSPACE-upper bound for multi-agent PAL is to proceed analogously to the single-agent case. However, there is a complication: in the second conjunct of the formula φ_0^* of Lemma 7, we use K as a *master modality* that allows us to access all states that are (directly or indirectly) reachable from some given state. Alas, a master modality is not available in multi-agent PAL. For this reason, we reduce multi-agent PAL to the extension of EL with the *everybody knows operator*. The addition of this operator provides us with a restricted version of the master modality that is sufficient for our purposes.[2] Since adding the everybody knows operator to EL does not increase the computational complexity, we obtain the desired PSPACE upper bound.

Epistemic logic is extended to *epistemic logic with everybody knows (ELE)* by adding the *everybody knows operator* $E_A\varphi$, where A is a finite set of agents. The semantics of the new operator is as follows:

$$\mathcal{M}, s \models E_A\varphi \text{ iff } s \sim_a t \text{ implies } \mathcal{M}, t \models \varphi, \text{ for all } t \in S \text{ and all } a \in A.$$

PSPACE-completeness of satisfiability in multi-agent ELE is folklore. For the sake of completeness, we prove it in the extended version of this paper [15].

We now reduce satisfiability in multi-agent PAL to satisfiability in ELE. Let φ_0 be the PAL formula whose satisfiability is to be decided, and let A be the set of agents used in φ_0. As in the single agent case, we introduce a set of propositional letters $L_{\varphi_0} := \{p_\varphi^\sigma \mid (\sigma, \varphi) \in R(\varphi_0)\}$ that are assumed to be disjoint from the propositional letters used in φ_0. The *modal depth* $\mathsf{md}(\varphi)$ of a PAL formula φ is defined inductively in the usual way:

$$\begin{array}{rcl} \mathsf{md}(p) & := & 0 \\ \mathsf{md}(\neg\varphi) & := & \mathsf{md}(\varphi) \\ \mathsf{md}(\varphi \wedge \psi) & := & \mathsf{md}([\varphi]\psi) := \max(\mathsf{md}(\varphi), \mathsf{md}(\psi)) \\ \mathsf{md}(K_a\varphi) & := & \mathsf{md}(\varphi) + 1. \end{array}$$

Define an ELE formula

$$\varphi_0^* := p_{\varphi_0} \wedge \bigwedge_{j \le \mathsf{md}(\varphi_0)} \bigwedge_{(\sigma,\varphi) \in R(\varphi_0)} E_A^j B_\varphi^\sigma,$$

where B_φ^σ is the biimplication as defined in Figure 4, $E_A^j\varphi$ is an abbreviation for the j-fold nesting $E_A \cdots E_A\varphi$ if $j > 0$, and $E_A^0\varphi$ is simply φ. The proof of the following lemma is analogous to the proof of Lemma 7. The only difference concerns the "if" direction, where we cannot assume anymore that the accessibility relations are universal relations. To compensate for this, it is not hard to argue that the second conjunct of φ_0^* ensures that B_φ^σ is satisfied at all relevant states in models of φ_0^*, for all $(\sigma, \varphi) \in R(\varphi_0)$. Details are left to the reader.

Lemma 9. *φ_0 is satisfiable iff φ_0^* is satisfiable.*

By Lemma 6 and the fact that $\mathsf{md}(\varphi_0)$ is bounded by $|\varphi_0|$, $|\varphi_0^*|$ is polynomial in $|\varphi_0|$. From Lemma 9 and PSPACE-completeness of satisfiability in ELE, we thus obtain the following result.

Theorem 10. *Satisfiability in multi-agent PAL is* PSPACE*-complete.*

5. UPPER BOUNDS FOR PAL WITH COMMON KNOWLEDGE

It is known that (multi-agent) PALC is more expressive than the standard epistemic language extended with a common knowledge operator (ELC). For example, it is shown in [2] that there is no formula of ELC that is equivalent to the PALC formula $[p]\neg C^*\neg q$. Thus, to obtain complexity results for PALC we cannot proceed analogous to the PAL case, i.e., first exhibit an equivalence-preserving translation to the logic obtained by dropping public announcements, and then use this translation to devise a decision procedure. The solution is to establish an equivalence-preserving translation from PALC to a more expressive language than ELC: propositional dynamic logic (PDL). Since satisfiability in both ELC (which is a fragment of PALC) and PDL is EXPTIME-complete, we can then continue as in the previous section.

Recall that PDL formulas and programs are built according to the following syntax rules:[3]

$$\begin{array}{rcl} \varphi & ::= & p \mid \varphi \vee \varphi \mid \neg\varphi \mid [[\alpha]]\varphi \\ \alpha & ::= & a \mid \alpha \cup \alpha \mid \alpha;\alpha \mid \alpha^* \mid \varphi? \end{array}$$

where p ranges over propositional letters and a over agents (usually called *atomic programs* in PDL). We define the semantics of PDL based on epistemic models by simultaneously definining the consequence relation together with accessibility relations $\sim_\alpha$ for complex programs α. Let $\mathcal{M} = (S, \sim, V)$ be an epistemic model. Then, for all $s, t \in S$, we have:

$$\begin{array}{lll} s \sim_{\alpha\cup\beta} t & \text{iff} & s \sim_\alpha t \text{ or } s \sim_\beta t \\ s \sim_{\alpha;\beta} t & \text{iff} & s \sim_\alpha u \text{ and } u \sim_\beta t \text{ for some } u \in S \\ s \sim_{\alpha^*} t & \text{iff} & \exists u_0, \ldots, u_n \in S,\ n \ge 0, \text{ such that} \\ & & s = u_0,\ t = u_n, \text{ and } u_i \sim_\alpha u_{i+1} \text{ for } i < n \\ s \sim_{\varphi?} t & \text{iff} & s = t \text{ and } \mathcal{M}, s \models \varphi \\ \mathcal{M}, s \models [[\alpha]]\varphi & \text{iff} & s \sim_\alpha t \text{ implies } \mathcal{M}, t \models \varphi, \text{ for all } t \in S \end{array}$$

where the clauses for the Booleans are as in Section 2. To distinguish PDL on unrestricted models from PDL on epistemic models, we will from now on call the latter ePDL.

Figure 5 defines, for each PALC formula φ and finite sequence of PALC formulas σ, an ePDL formula φ^σ. Observe that the only difference to Figure 2 is the additional line dealing with the common knowledge operator. As in the case of PAL, we use φ^ε as the ePDL-translation of the PALC formula φ. The following lemma shows that φ^ε is

[2] Adding *everybody knows* does not actually increase the expressive power. However, it allows us to formulate the restricted master modality exponentially more succinct than in standard EL, which is crucial for obtaining a polynomial translation.

[3] We use the notation $[[\alpha]]\varphi$ instead of the more familiar $[\alpha]\varphi$ to distinguish this operator from the public announcement operator.

$$
\begin{array}{rcl}
p^\sigma & := & p \\
(\neg\varphi)^\sigma & := & \neg\varphi^\sigma \\
(\varphi \wedge \psi)^\sigma & := & \varphi^\sigma \wedge \psi^\sigma \\
(K_i\varphi)^\sigma & := & K_i(\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu \to \varphi^\sigma) \\
(C_A\varphi)^\sigma & := & [[(\bigcup_{a\in A} a; (\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu)?)^*]]\varphi^\sigma \\
([\varphi]\psi)^\sigma & := & \varphi^\sigma \to \psi^{\sigma\cdot\varphi}
\end{array}
$$

Figure 5: The formulas φ^σ for PALC.

indeed equivalent to φ. The proof is a straightforward extension of the proof of Lemma 1. Details are given in the appendix.

Lemma 11. *For all models $\mathcal{M} = (S, \sim, V)$, PALC formulas φ, finite sequences of PALC formulas σ, and states $s \in S(\mathcal{M}|\sigma)$, we have $\mathcal{M}, s \models \varphi^\sigma$ iff $\mathcal{M}|\sigma, s \models \varphi$.*

Our aim is to show ExpTime-completeness of PALC. As already the fragment ELC of PALC is ExpTime-hard [10], it remains to establish an upper bound. In the following, we prove this bound by a satisfiability-preserving and polynomial reduction to ePDL. Let us first fix the complexity of this logic.

Lemma 12. *Satisfiability in ePDL is* ExpTime*-complete.*

Proof. The lower bound stems from ELC [10]. The upper bound is easily obtained by a reduction to converse-PDL, which is ExpTime-complete [10, 17, 12]: to decide whether a PDL formula φ is satisfiable in an epistemic model, simply replace all atomic programs a in φ with $(a \cup a^-)^*$, and check whether the resulting IPDL formula is satisfiable in an unrestricted model. □

We may now reduce satisfiability in PALC to satisfiability in ePDL using the same approach as in the previous section. Let φ_0 be the PALC formula whose satisfiability is to be decided. The definition of the set of relevant pairs $R(\varphi_0)$ can be extended to PALC formulas by adding the clause

$$R(C_A\varphi) \quad := \quad R(\varphi) \cup \{(\varepsilon, C_A\varphi)\}.$$

As usual, we then introduce a set of propositional letters $L_{\varphi_0} := \{p^\sigma_\varphi \mid (\sigma, \varphi) \in R(\varphi_0)\}$ that are disjoint from the propositional letters used in φ_0. Let $a_1, \ldots, a_k$ be the agents referred to in φ_0. We define an ePDL-formula

$$\varphi_0^* := p_{\varphi_0} \wedge \bigwedge_{(\sigma,\varphi)\in R(\varphi_0)} [[(a_1 \cup \cdots \cup a_k)^*]]B^\sigma_\varphi,$$

where the biimplications B^σ_φ are defined as in Figure 4, with the following additional clause for common knowledge:

$$B^\sigma_{C_A\varphi} \quad := \quad p^\sigma_{C_A\varphi} \leftrightarrow [[(\bigcup_{a\in A} a; (\bigwedge_{\nu \in \mathsf{pre}(\sigma)} p^\nu_{\nu/\sigma})?)^*]]p^\sigma_\psi.$$

The proof of the following lemma is analogous to the proof of Lemmas 7 and 9.

Lemma 13. *φ_0 is satisfiable iff φ_0^* is satisfiable.*

Since Lemma 6 can easily be extended to the PALC case, $|\varphi_0^*|$ is polynomial in $|\varphi_0|$. From Lemmas 12 and 13, we thus obtain the following result.

Theorem 14. *Satisfiability in PALC is* ExpTime*-complete.*

In [4], van Benthem et al. introduce a generalization of the common knowledge operator $C_A(\varphi, \psi)$ that is called the *relativized common knowledge operator* and has the following semantics:

$$\mathcal{M}, w \models C_A(\varphi, \psi) \quad \text{iff} \quad \mathcal{M}, w \models \varphi \to [[(\bigcup_{a\in B} a; \varphi?)^*]]\psi,$$

where the formula on the right-hand side is to be read as a PDL formula. Clearly, $C_A\varphi$ is equivalent to $C_A(\top, \varphi)$. Intuitively, relativized common knowledge resembles the until operator from temporal logic.

Let PAL-RC denote the variant of PALC in which common knowledge is replaced with relativized common knowledge, and let EL-RC be the extension of EL with the relativized common knowledge operator. The introduction of the new operator is a reaction to the fact that there exists no equivalence-preserving translation from PALC to ELC, i.e, to the logic obtained by dropping the public announcement operator. By moving from common knowledge to the stronger relativized common knowledge, such a translation is recovered: as shown in [4], there exists an equivalence-preserving translation from PAL-RC to EL-RC.

We can easily modify the translation given in Figure 5 such that it maps formulas of PAL-RC to formulas of ePDL:

$$C_A(\varphi, \psi)^\sigma := \varphi^\sigma \to [[(\bigcup_{a\in A} a; (\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu)?; \varphi^\sigma?)^*]]\psi^\sigma$$

Then, we can continue along the lines of the reduction from PALC to ePDL to obtain a reduction from PAL-RC to ePDL. As in the PALC case, we obtain the following theorem.

Theorem 15. *Satisfiability in PAL-RC is* ExpTime*-complete.*

6. CONCLUSION

We have analyzed the succinctness and computational complexity of (several variations of) epistemic logic extended with a public announcement operator. The main results are that, first, there are certain properties that can be expressed exponentially more succinct in PAL than in EL, and, second, despite this succinctness the computational complexity of PAL and EL coincides. As future work, it would be nice to prove the exponential succinctness of PAL as compared with EL also on epistemic structures. It is not clear whether a relatively simple argument such as the one given in Section 3 can be used in this case. Moreover, it would be interesting to analyze the computational complexity of other announcement operators, in particular of private announcements as considered, e.g., in [2, 11].

APPENDIX

Lemma 1. For all models $\mathcal{M} = (S, \sim, V)$, PAL formulas φ, finite sequences of PAL formulas σ, and states $s \in S(\mathcal{M}|\sigma)$, we have $\mathcal{M}, s \models \varphi^\sigma$ iff $\mathcal{M}|\sigma, s \models \varphi$.

Proof. The proof is by induction on $|\varphi| + |\sigma|$. The base case is $|\varphi| + |\sigma| = 1$. Then $\varphi = p \in \mathsf{PL}$ and $\sigma = \varepsilon$. We have $\mathcal{M}|\sigma = \mathcal{M}$ and $\varphi^\sigma = \varphi$ and are done. For the induction step, let $\mathcal{M}|\sigma = (T, \approx, U)$ and make a case distinction on the form of φ:

- $\varphi = p$. Trivial by definition of p^σ.
- $\varphi = \neg\psi$ or $\varphi = (\psi \wedge \vartheta)$. Easy using the definition of $(\neg\psi)^\sigma$, the semantics, and the induction hypothesis.
- $\varphi = K_a\psi$. Let $\mathcal{M}, s \models (K_a\psi)^\sigma$. We have to show that $\mathcal{M}|\sigma, s \models K_a\psi$, i.e. that $\mathcal{M}|\sigma, t \models \psi$ for all $t \in T$ with $s \approx_a t$. Hence, let $t \in T$ with $s \approx_a t$. Then we have $\mathcal{M}, t \models (\nu/\sigma)^\nu$ for all $\nu \in \mathsf{pre}(\sigma)$: assume to the contrary that $\mathcal{M}, t \not\models (\nu/\sigma)^\nu$ for some $\nu \in \mathsf{pre}(\sigma)$. By induction hypothesis, we get $\mathcal{M}|\nu, t \not\models (\nu/\sigma)$. Thus the state t is not present in $\mathcal{M}|\nu \cdot \nu/\sigma$ and consequently $t \notin T$, which is a contradiction. Thus $\mathcal{M}, t \models (\nu/\sigma)^\nu$ for all $\nu \in \mathsf{pre}(\sigma)$, implying $\mathcal{M}, t \models \bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu$. Since $s \approx_a t$, we additionally have $s \sim_a t$. Together with $\mathcal{M}, s \models (K_a\psi)^\sigma$, we get $\mathcal{M}, t \models \psi^\sigma$. By induction hypothesis, we obtain $\mathcal{M}|\sigma, t \models \psi$ as required.
  Now let $\mathcal{M}|\sigma, s \models K_a\psi$. We have to show that $\mathcal{M}, s \models (K_a\psi)^\sigma$, i.e. that $\mathcal{M}, t \models \psi^\sigma$ for all $t \in S$ with (i) $s \sim_a t$ and (ii) $\mathcal{M}, t \models \bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu$. Hence, let $t \in S$ such that (i) and (ii) are satisfied. We show by induction on the length of ν that t is a state in $\mathcal{M}|\nu$ for all $\nu \in \mathsf{pre}(\sigma) \cup \{\sigma\}$.
  - $\nu = \varepsilon$. Trivial since $\mathcal{M}|\varepsilon = \mathcal{M}$.
  - $\nu = \nu' \cdot \vartheta$. By induction hypothesis, t is a state in $\mathcal{M}|\nu'$. By (ii), we have $\mathcal{M}, t \models (\nu'/\sigma)^{\nu'}$. By (outer) induction hypothesis, this yields $\mathcal{M}|\nu', t \models (\nu'/\sigma)$. Thus, t is a state in $(\mathcal{M}|\nu')|(\nu'/\sigma) = \mathcal{M}|\nu$.

  Thus, $s, t \in T$. Hence, (i) yields $s \approx_a t$. Together with $\mathcal{M}|\sigma, s \models K_a\psi$, we get $\mathcal{M}|\sigma, t \models \psi$. By induction hypothesis, we get $\mathcal{M}, t \models \psi^\sigma$ as required.
- $\varphi = [\psi]\vartheta$. Then $\mathcal{M}, s \models ([\psi]\vartheta)^\sigma$ iff $\mathcal{M}, s \not\models \psi^\sigma$ or $\mathcal{M}, s \models \vartheta^{\sigma \cdot \psi}$ iff $\mathcal{M}|\sigma, s \not\models \psi$ or $\mathcal{M}|\sigma \cdot \psi, s \models \vartheta$ iff $\mathcal{M}|\sigma, s \not\models \psi$ or $(\mathcal{M}|\sigma)|\psi, s \models \vartheta$ iff $\mathcal{M}|\sigma, s \models [\psi]\vartheta$.
  The first "iff" holds by definition of $([\psi]\vartheta)^\sigma$, the second by induction hypothesis, the third since $\mathcal{M}|\sigma \cdot \psi = (\mathcal{M}|\sigma)|\psi$, and the fourth by the semantics.

□

Lemma 3. For all $s \in S'$ and $\varphi \in \mathsf{sub}(\chi)$ such that

$$\{sw \mid w \in P_\varphi\} \subseteq P_\chi,$$

we have $\mathcal{M}, s \models \varphi$ iff $\mathcal{M}', s \models \varphi$.

Proof. The proof is by induction on the structure of φ. As the induction start and the Boolean cases are trivial, we only treat the case $\varphi = K_\sigma\psi$.

"$\Leftarrow$". Let $\mathcal{M}', s \models \varphi$. We have to show that, for all $t \in S$, $s \sim_\sigma t$ implies $\mathcal{M}, t \models \varphi$. Hence, let $t \in S$ with $s \sim_\sigma t$. Then $t = s\sigma$. We first show that t does no have prefix $\widehat{w}$. Assume that the contrary holds. Since $s \in S'$ and thus s does not have prefix $\widehat{w}$, we have $t = \widehat{w}$. Since $\sigma \in P_\varphi$

and $\{sw \mid w \in P_\varphi\} \subseteq P_\chi$, the latter yields $\widehat{w} \in P_\chi$, in contradiction to $\widehat{w} \notin P_\chi$. Thus, t does not have prefix $\widehat{w}$, i.e., $t \in S'$. We have $P_\psi = \{w \mid \sigma w \in P_\varphi\}$. Thus, $t = s\sigma$ and $\{sw \mid w \in P_\varphi\} \subseteq P_\chi$ yield $\{tw \mid w \in P_\psi\} \subseteq P_\chi$. Finally, IH, $\mathcal{M}', s \models \varphi$, and $s \sim'_\sigma t$ yield $\mathcal{M}, t \models \psi$ as required.

"$\Rightarrow$". Let $\mathcal{M}, s \models \varphi$. We have to show that, for all $t \in S'$, $s \sim'_\sigma t$ implies $\mathcal{M}', t \models \varphi$. Hence, let $t \in S'$ with $s \sim'_\sigma t$. Then $t = s\sigma$. We have $P_\psi = \{w \mid \sigma w \in P_\varphi\}$. Thus, $t = s\sigma$ and $\{sw \mid w \in P_\varphi\} \subseteq P_\chi$ yield $\{tw \mid w \in P_\psi\} \subseteq P_\chi$. Finally, IH, $\mathcal{M}, s \models \varphi$, and $s \sim_\sigma t$ yield $\mathcal{M}', t \models \psi$ as required. □

Lemma 7. The single-agent PAL formula φ_0 is satisfiable iff the single-agent EL-formula φ_0^* is satisfiable.

Proof. "if". Let $\mathcal{M} = (S, \sim, V)$ be a model of φ_0^*, and let $s_0 \in S$ with $\mathcal{M}, s_0 \models \varphi_0^*$. By standard results on the unimodal logic S5, we may w.l.o.g. assume that $\sim = S \times S$ [5]. Thus, the second conjunct of φ_0^* implies that $K, s \models B_\varphi^\sigma$ for all $s \in S$ and all $(\varphi, \sigma) \in R(\varphi_0)$.

We show that, for all $s \in S$ and all $(\sigma, \varphi) \in R(\varphi_0)$, we have

$$\mathcal{M}, s \models \varphi^\sigma \text{ iff } \mathcal{M}, s \models p_\varphi^\sigma.$$

By Lemma 1, from this we get $\mathcal{M}|\sigma, s \models \varphi$ iff $\mathcal{M}, s \models p_\varphi^\sigma$. Since $\mathcal{M}, s_0 \models p_{\varphi_0}^\varepsilon$, this yields $\mathcal{M}, s_0 \models \varphi_0$ as required. The proof is by induction on $|\varphi| + |\sigma|$. For the induction start, we have $\varphi = q$ and $\sigma = \varepsilon$. Then $\varphi^\sigma = q$. Since $\mathcal{M}, s \models B_\varphi^\sigma = p_q^\sigma \leftrightarrow q$, we are done. For the induction step, we make a case distinction according to the structure of φ:

- $\varphi = q$. Identical to the induction start.
- $\varphi = \neg\psi$. Then $\mathcal{M}, s \models (\neg\psi)^\sigma$ iff $\mathcal{M}, s \models \neg\psi^\sigma$ iff $\mathcal{M}, s \not\models \psi^\sigma$ iff $\mathcal{M}, s \not\models p_\psi^\sigma$ iff $\mathcal{M}, s \models \neg p_\psi^\sigma$ iff $\mathcal{M}, s \models p_{\neg\psi}^\sigma$.
  The first "iff" holds by definition of $(\neg\psi)^\sigma$, the second by the semantics, the third by induction hypothesis, the fourth by the semantics, and the last since $\mathcal{M}, s \models B_{\neg\psi}^\sigma = p_{\neg\psi}^\sigma \leftrightarrow \neg p_\psi^\sigma$.
- $\varphi = \psi \wedge \vartheta$. Similar to the previous case.
- $\varphi = K\psi$. We have $\mathcal{M}, s \models (K\psi)^\sigma$ iff
  $$\mathcal{M}, s \models K(\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu \to \varphi^\sigma),$$
  which is the case iff, for all $t \in S$,
  $$s \sim t \text{ implies } \mathcal{M}, t \models (\bigwedge_{\nu \in \mathsf{pre}(\sigma)} (\nu/\sigma)^\nu \to \varphi^\sigma). \qquad (\dagger)$$
  By induction hypothesis, we get that, for all $t \in S$, (i) $\mathcal{M}, t \models \nu/\sigma^\nu$ iff $\mathcal{M}, t \models p_{\nu/\sigma}^\nu$ for all $\nu \in \mathsf{pre}(\sigma)$ and (ii) $\mathcal{M}, t \models \varphi^\sigma$ iff $\mathcal{M}, t \models p_\varphi^\sigma$. Thus, (†) holds iff, for all $t \in S$,
  $$s \sim t \text{ implies } \mathcal{M}, t \models (\bigwedge_{\nu \in \mathsf{pre}(\sigma)} p_{\nu/\sigma}^\nu \to p_\varphi^\sigma). \qquad (\ddagger)$$
  Since $\mathcal{M}, s \models p_{K\varphi}^\sigma \leftrightarrow K(\bigwedge_{\nu \in \mathsf{pref}(\sigma)} p_{\nu/\sigma}^\nu \to p_\varphi^\sigma)$, (‡) holds iff $\mathcal{M}, s \models p_{K\varphi}^\sigma$ and we are done.
- $\varphi = [\psi]\vartheta$. We have $\mathcal{M}, s \models ([\varphi]\psi)^\sigma$ iff $\mathcal{M}, s \models \varphi^\sigma \to \psi^{\sigma\cdot\varphi}$ iff $\mathcal{M}, s \models p_\varphi^\sigma \to p_\psi^{\sigma\cdot\varphi}$ iff $\mathcal{M}, s \models p_{[\varphi]\psi}^\sigma$.
  The first "iff" holds by definition of $([\varphi]\psi)^\sigma$, the second by induction hypothesis, and the third since $\mathcal{M}, s \models p_{[\varphi]\psi}^\sigma \leftrightarrow (p_\varphi^\sigma \to p_\psi^{\sigma\cdot\varphi})$.

"only if". Let $\mathcal{M} = (S, \sim, V)$ be a model of φ_0, and let $s_0 \in S$ with $\mathcal{M}, s_0 \models \varphi_0$. Define a model $\mathcal{M}'$ as $\mathcal{M}$ by additionally setting, for $(\sigma, \varphi) \in R(\varphi_0)$,

$$V(p_\varphi^\sigma) := \{s \in S \mid \mathcal{M}, s \models \varphi^\sigma\}.$$

Using the definition of the translation φ^σ and the implications B_φ^σ, it is straightforward to show by induction on $|\varphi| + |\sigma|$ that

$$\mathcal{M}', s \models B_\varphi^\sigma \text{ for all } (\sigma, \varphi) \in R(\varphi_0) \text{ and } s \in S.$$

Since $\mathcal{M}, s_0 \models \varphi_0$, we have $\mathcal{M}', s_0 \models p_{\varphi_0}^\varepsilon$. Thus, $\mathcal{M}', s_0 \models \varphi_0^*$. □

Lemma 11. For all models $\mathcal{M} = (S, \sim, V)$, PALC formulas φ, finite sequences of PALC formulas σ, and states $s \in S(\mathcal{M}|\sigma)$, we have $\mathcal{M}, s \models \varphi^\sigma$ iff $\mathcal{M}|\sigma, s \models \varphi$.

Proof. The proof is analogous to that of Lemma 1. We only treat the additional case for common knowledge:

- $\varphi = C_A\psi$. Let $\mathcal{M}, s \models (C_A\psi)^\sigma$. We have to show that $\mathcal{M}|\sigma, s \models C_A\psi$, i.e. that $\mathcal{M}|\sigma, t \models \psi$ for all $t \in T$ with $s\,(\bigcup_{a\in A} \approx_a)^*\, t$. Hence, let $t \in T$ with $s\,(\bigcup_{a\in A} \approx_a)^*\, t$. Then there are $s_1, \ldots, s_k \in T$ with $s_1 = s$, $s_k = t$, and $(s_i, s_{i+1}) \in \bigcup_{a\in A} \approx_a$ for $1 \le i < k$. We have $\mathcal{M}, s_i \models (\nu/\sigma)^\nu$ for all $\nu \in \mathsf{pre}(\sigma)$ and $1 < i \le k$: assume to the contrary of what is to be shown that $\mathcal{M}, s_i \not\models (\nu/\sigma)^\nu$ for some $\nu \in \mathsf{pre}(\sigma)$ and some i with $1 < i \le k$. By induction hypothesis, we get $\mathcal{M}|\nu, s_i \not\models (\nu/\sigma)$. Thus the state s_i is not present in $\mathcal{M}|\nu\cdot\nu/\sigma$ and consequently $s_i \notin T$, which is a contradiction. Thus $\mathcal{M}, s_i \models (\nu/\sigma)^\nu$ for all $\nu \in \mathsf{pre}(\sigma)$ and $1 < i \le k$. Moreover, we clearly have $(s_i, s_{i+1}) \in \bigcup_{a\in A} \sim_a$ for $1 \le i < k$. It follows that $(s, t) \in \sim_{\alpha^*}$, where
  $$\alpha := \bigcup_{a\in A} a; (\bigwedge_{\nu\in\mathsf{pre}(\sigma)} (\nu/\sigma)^\nu)?.$$
  Together with $\mathcal{M}, s \models (C_A\psi)^\sigma$, we get $\mathcal{M}, t \models \psi^\sigma$. By induction hypothesis, we obtain $\mathcal{M}|\sigma, t \models \psi$ as required.
  Now let $\mathcal{M}|\sigma, s \models C_A\psi$. We have to show that $\mathcal{M}, s \models (C_A\psi)^\sigma$, i.e. that $\mathcal{M}, t \models \psi^\sigma$ for all $t \in S$ with $(s, t) \in \sim_{\alpha^*}$. Hence, let $t \in S$ with $(s, t) \in \sim_{\alpha^*}$. Then there are $s_1, \ldots, s_k \in T$ with $s_1 = s$, $s_k = t$, and $(s_i, s_{i+1}) \in \sim_\alpha$ for $1 \le i < k$. We show by induction on the length of ν that s_i is a state in $\mathcal{M}|\nu$ for all $\nu \in \mathsf{pre}(\sigma) \cup \{\sigma\}$ and all i with $1 < i \le k$.
  - $\nu = \varepsilon$. Trivial since $\mathcal{M}|\varepsilon = \mathcal{M}$.
  - $\nu = \nu' \cdot \vartheta$. By induction hypothesis, s_i is a state in $\mathcal{M}|\nu'$. Since $(s_{i-1}, s_i) \in \sim_\alpha$, we have $\mathcal{M}, s_i \models (\nu'/\sigma)^{\nu'}$. By (outer) induction hypothesis, this yields $\mathcal{M}|\nu', s_i \models (\nu'/\sigma)$. Thus, s_i is a state in $(\mathcal{M}|\nu')|(\nu'/\sigma) = \mathcal{M}|\nu$.

  Thus, we have $s_1, \ldots, s_k \in T$. As $(s_i, s_{i+1}) \in \sim_\alpha$ implies $(s_0, s_{i+1}) \in \bigcup_{a\in A} \sim_a$, this yields
  $$(s, t) \in (\bigcup_{a\in A} \approx_a)^*.$$
  Together with $\mathcal{M}|\sigma, s \models C_A\psi$, we get $\mathcal{M}|\sigma, t \models \psi$. By induction hypothesis, we get $\mathcal{M}, t \models \psi^\sigma$ as required.

□

A complete and decidable security-specialised logic and its application to the TESLA protocol

Alessio Lomuscio and Bożena Woźna*

ABSTRACT

We examine a logic to reason about security protocols by means of temporal and epistemic concepts. We report results on completeness and decidability of the formalism as well as its expressiveness. As a case study we apply the formalism in the analysis of TESLA, a secure stream multi-cast protocol.

1. INTRODUCTION

There is a long tradition in the use of formal tools (process algebras, theorem proving, model checking, formal logics, etc) to analyse cryptographic protocols. In particular, since the late 80s there has been an attention to modelling security protocols in terms of the evolution of the states of knowledge of the principals. The work on BAN logic [6] was the seminal contribution in this line. BAN logic provides primitives to represent and reason about principals' beliefs, reception of messages, an array of cryptographic-specific concepts such as freshness, keys, etc, as well as axioms and rules tailored to the particular protocol under analysis governing the evolution of these.

It is nowadays customary ([18, 4], etc) to point out that BAN logic lacks several essential technical features (no representation of temporal flows, no well-defined semantics, no models for the intruder, etc) thereby making it impossible to use it consistently to prove that a particular protocol is correct or otherwise. Advances and improvements over the original formulation [1, 12, 15] have not solved this crucial concern.

Given that the emphasis in BAN logic was analysing whether particular protocols established *authentication* of the principals participating in it, one crucial assumption was the benevolence of principals. On the contrary, more recently attention has shifted to analysing whether or not a particular protocol can be exploited by an *adversary*, or *intruder*, achieving a property originally not intended by the protocol designer. In this line perfect encryption is normally assumed, and the intruder follows the Dolev-Yao model [9], i.e. it can read and compose messages but cannot break encrypted messages. This analysis is often carried out in combination with verification techniques, notably model checking, and epistemic notions are not analysed.

Recently, attention has been given again to modelling epistemic states of the principals in a protocol. In [14] a notion of algorithmic knowledge has been proposed. The semantics of the logic assumes that adversaries use algorithms to compute their knowledge. A related paper [20] explores an epistemic logic where the notion of explicit knowledge is linked to deductions in a logical framework. Similarly, in [2] a logic for awareness (originally introduced in [10]) is augmented with security-specialised predicates.

The referenced papers above do not treat temporal concepts explicitly. In [8] a linear time temporal epistemic logic is proposed, where properties of a protocol may be shown via resolution, although an explicit model of the adversary is not provided. In [21] it is shown that the verification problem for a linear temporal epistemic logic augmented with the past operators and security-specific predicates, and *tagged protocols* is decidable.

Many of the papers discussed above [1, 6, 12, 15], do not provide completeness results for the language and/or do not provide a grounded semantics [22] for the modalities. The main aim of the present paper is to propose a decidable security-specialised logic to reason about security concepts, that:

- has an intuitive, computationally-grounded semantics,
- offers a model of the adversary,
- enables the representation of epistemic and temporal concepts,
- enjoys soundness and completeness.

The logic presented in this paper is a combination of CTL [7], and a standard epistemic logic [11] augmented to include an additional epistemic operator representing explicit knowledge. It is further shown that the expressivity of the resulting system enables us to represent a non-standard notion of deductive knowledge. In addition we show how to apply the logic to model properties of the TESLA protocol [19], a protocol so far analysed only via process algebras [5] and Lynch-Vaandrager automata [3].

The rest of the paper is organised as follows. In Section 2 we present our security-specialised logic. Section 3 describes the standard Dolev-Yao adversary model in the logic of Section 2. In Section 4 we describe a scheme of the TESLA protocol, and analyse it formally in Section 5. We conclude in Section 6 with some final remarks.

2. A TDL LOGIC

In this section we present the syntax and semantics of a multi-modal temporal epistemic logic with security-specialised primitives, and we show that this logic is finitely axiomatisable. We call the logic *a temporal deductive logic* (TDL).

2.1 Syntax

We assume familiarity with the basic concepts of security protocols and we take $\mathbb{K} = \{k_1, k_2, \ldots\}$ to be a set of symmetric and asymmetric keys, $\mathbb{N}$ to be a set of nonces, $\mathbb{T} = \{t_1, t_2, \ldots\}$ to be a set of plain-texts, and $\mathbb{F} = \{f(k) \mid k \in \mathbb{K}$ and $f : \mathbb{K} \to \{0, 1, \ldots\}$ is a pseudo-random function$\}$ to be a set of commitments to keys. The commitment to a key k is an integer value that is computed by applying a pseudo-random function f to key k. It is assumed that f is effectively impossible to invert, so key k cannot be computed from the commitment to k. We assume that keys, nonces, texts, and commitments can be distinguished, that is, $\mathbb{K}$, $\mathbb{N}$, $\mathbb{T}$ and $\mathbb{F}$ are disjoint sets. A set of *messages* $\mathbb{M}$ is defined inductively by the following grammar:

$$m := t \mid k \mid n \mid f(k) \mid m \cdot m \mid \{m\}_k \mid \mathtt{MAC}(k, m)$$

where $t \in \mathbb{T}$, $k \in \mathbb{K}$, $n \in \mathbb{N}$, $f(k) \in \mathbb{F}$, m is a generic message, and $\mathtt{MAC} : \mathbb{K} \times \mathbb{M} \to \{0, 1, \ldots\}$ is a pseudo-random function, called *message authentication code*. It is assumed that MAC is effectively impossible to invert, so key k cannot be computed from the MAC value.

We write $m \cdot m'$ for the concatenation of m and m', $\{m\}_k$ for encryption of m with the key k, and $\mathtt{MAC}(k, m)$ for the message authentication code of m and k. We assume that the set $\mathbb{K}$ is closed under inverses, i.e. for a given key $k \in \mathbb{K}$ there is an inverse key $k^{-1} \in \mathbb{K}$ such that $\{\{m\}_k\}_{k^{-1}} = m$. If the cryptosystem uses symmetric keys, then $k = k^{-1}$; for the public cryptosystem k and k^{-1} are different. We also define a *submessage* binary relation $\sqsubseteq$ on $\mathbb{M}$ as the smallest reflexive and transitive relation satisfying the following conditions: (1) $m \sqsubseteq m \cdot m'$, (2) $m \sqsubseteq m' \cdot m$, (3) $m \sqsubseteq \{m\}_k$.

Let $\mathcal{PV}$ be a set of propositional variables. We assume that $\mathcal{AG} = \{1, \ldots, N\}$ is a finite set of agents. The set $\mathcal{WF}(TDL)$ of well-formed TDL formulas is defined by the following grammar:

$$\varphi := p \mid has_i(m) \mid sent_i(m) \mid received_i(m) \mid faked_i(m) \mid dropped_i(m) \mid \neg\varphi \mid \varphi \vee \varphi \mid \mathrm{E}\bigcirc\varphi \mid \mathrm{E}(\varphi \mathcal{U} \varphi) \mid \mathrm{A}(\varphi \mathcal{U} \varphi) \mid \mathcal{K}_i\varphi \mid \mathcal{X}_i\varphi \mid \mathcal{A}_i\varphi$$

where $p \in \mathcal{PV}$, $i \in \mathcal{AG}$, $m \in \mathbb{M}$. The terms $has_i(m)$, $sent_i(m)$, $received_i(m)$, $dropped_i(m)$, and $faked_i(m)$ are security-specialised propositional variables, which, as one would expect, are read as "*agent i has message m*", "*agent i sent message m*", "*agent i received message m*", "*agent i dropped message m*, and "*agent i faked message m*", respectively. $has_i(m)$ means that agent i has in his explicit possession the message m. What "explicit possession" means depends on the application, the capabilities of the principals, and the protocol they are running. In Section 3 we provide a concrete implementation of the $has_i(m)$ that captures Dolev-Yao capabilities.

We would like to emphasise that the above security-specialised propositional variables are *propositions*, not predicates. This is because we assume that the message m, which is carried by $has_i(m)$, $sent_i(m)$, $received_i(m)$, $dropped_i(m)$, and $faked_i(m)$, is not a value, but rather an intrinsic part of the propositions.

The above syntax extends CTL [7] with a standard epistemic modality $\mathcal{K}_i$ as well as operators for explicit knowledge ($\mathcal{X}_i$) and awareness ($\mathcal{A}_i$) as in [11]. The formula $\mathcal{X}_i\alpha$ is read as "*agent i knows explicitly that α*", $\mathcal{A}_i\alpha$ is read as "*agent i is aware of α*", and $\mathcal{K}_i\alpha$ is read as "*agent i knows (implicitly) that α*". The formula $\mathrm{E}\bigcirc\alpha$ is read as "*there exists a computation path such that at the next step of the path α holds*", $\mathrm{E}(\alpha\mathcal{U}\beta)$ is read as "*there exists a computation path such that β eventually occurs and α continuously holds until then*", and $\mathrm{A}(\alpha\mathcal{U}\beta)$ is read as "*for all computation paths β eventually occurs and α continuously holds until then*". We shall further use the shortcut $\mathcal{D}_i\alpha$ to represent $\mathrm{E}(\mathcal{K}_i\alpha\mathcal{U}\mathcal{X}_i\alpha)$. The formula $\mathcal{D}_i\varphi$ is read as "*agent i may deduce α (by some computational process)*". Note that TDL differs from [16] only in a security-specialised subset of the set $\mathcal{PV}$.

2.2 Interpreted Systems

In this section we will briefly review the multi-agent framework from [11]; especially we will focus on *interpreted systems*, over which a semantics for TDL will be given.

A multi-agent system (MAS) consists of n agents and an environment, each of which is in some particular local state at a given point in time. We assume that an agent's local state encapsulates all the information the agent has access to. In the security settings, the local state of an agent might include some initial information about keys, the messages that the agent has sent and received so far, and so on. The local states of the environment describe information that is relevant to the system but that is not included in any local agent's state. Note also that the environment can be viewed as just another agent, as we will do here.

A multi-agent system is not a static entity. Its computations are usually defined by means of runs (see [11]), where a *run* is a function from the natural numbers to the set of all the possible global states. Thus, in these settings, an *interpreted system* for a multi-agent system is defined as a set of runs together with a valuation function for the propositional variables of the language under consideration. More formally, let each agent $i \in \mathcal{AG}$ be associated with a set of local states L_i, and the environment be associated with a set of local states L_e. Then, an *interpreted system* is a tuple $IS = (S, T, \sim_1, \ldots, \sim_n, \mathcal{V})$, where $S \subseteq \prod_{i=1}^{n} L_i \times L_e$ is a set

of global states; $T \subseteq S \times S$ is a serial (temporal) relation on S; for each agent $i \in \mathcal{AG}$, $\sim_i \subseteq S \times S$ is an equivalence (epistemic) relation defined by: $s \sim_i s'$ iff $l_i(s') = l_i(s)$, where $l_i : S \to L_i$ is a function that returns the local state of agent i from a global state; $\mathcal{V} : S \longrightarrow 2^{\mathcal{PV}}$ is a valuation function. $\mathcal{V}$ assigns to each state a set of proposition variables that are assumed to be true at that state. For more details we refer to [11].

In order to give a semantics to TDL we extend the above definition by means of local awareness functions, used to indicate the facts that agents are aware of. As in [11], we are not very specific with the notion of awareness, but by being aware we intutively mean "*to be able to figure out the truth*", or "*to be able to compute the truth within time T*", etc.

DEFINITION 1 (MODEL). *Given $\mathcal{AG} = \{1, \ldots, n\}$, a* model *is a tuple $M = (S, T, \sim_1, \ldots, \sim_n, \mathcal{V}, \mathbb{A}_1, \ldots, \mathbb{A}_n)$, where S, T, $\sim_i$, and $\mathcal{V}$ are defined as above, and $\mathbb{A}_i : L_i \longrightarrow 2^{\mathcal{WF}(TDL)}$ is an awareness function assigning a set of formulas to each state, for each $i \in \mathcal{AG}$.*

Note that the set of formulas that the agent is aware of can be arbitrary and may not be closed under sub-formulas. Note also that the definition of the model is an extension of the awareness structure (see [11]) by a temporal relation. Moreover, it restricts the standard awareness function to be defined over local states only.

In the paper we focus on a specific class of multi-agent systems, appropriate to modelling security protocols. These are message-passing systems in which one or more of the agents is an adversary controling the communication channel.

We assume that the local state of an agent is a sequence of events of the form $(e_0, \ldots, e_m)$, where e_0 is the initial event, and for $i \in \{1, \ldots, m\}$, e_i is a term of the form $sent(i, m)$ or $recv(m)$, where m is a message and i is an agent. The term $sent(i, m)$ stands for the agent has sent message m to agent i. Similarly the term $recv(m)$ represents that the agent has received message m. Note that in $recv(m)$ the sender is not specified. This is because the receiver will not in general be able to determine the sender of a message he has received.

2.3 Satisfaction

A *path* in M is an infinite sequence $\pi = (s_0, s_1, \ldots)$ of global states such that $(s_i, s_{i+1}) \in T$ for each $i \in \mathbb{N}$. For a path $\pi = (s_0, s_1, \ldots)$, we take $\pi(k) = s_k$. By $\Pi(s)$ we denote the set of all the paths starting at $s \in S$.

DEFINITION 2 (SATISFACTION). *Let M be a model, s a state, and α, β TDL formulas. The satisfaction relation $\models$, indicating truth of a formula in model M at state s, is defined inductively as follows:*

$(M, s) \models p$ *iff* $p \in \mathcal{V}(s)$,
$(M, s) \models \alpha \vee \beta$ *iff* $(M, s) \models \alpha$ *or* $(M, s) \models \beta$,
$(M, s) \models \neg\alpha$ *iff* $(M, s) \not\models \alpha$,
$(M, s) \models \mathrm{E}\bigcirc\alpha$ *iff* $(\exists \pi \in \Pi(s))(M, \pi(1)) \models \alpha$,
$(M, s) \models \mathrm{E}(\alpha \mathcal{U} \beta)$ *iff* $(\exists \pi \in \Pi(s))(\exists m \geq 0)[(M, \pi(m)) \models \beta$ *and* $(\forall j < m)(M, \pi(j)) \models \alpha]$,
$(M, s) \models \mathrm{A}(\alpha \mathcal{U} \beta)$ *iff* $(\forall \pi \in \Pi(s))(\exists m \geq 0)[(M, \pi(m)) \models \beta$ *and* $(\forall j < m)(M, \pi(j)) \models \alpha]$,
$(M, s) \models \mathcal{A}_i\alpha$ *iff* $\alpha \in \mathbb{A}_i(l_i(s))$,
$(M, s) \models \mathcal{K}_i\alpha$ *iff* $(\forall s' \in S)$ $(s \sim_i s'$ *implies* $(M, s') \models \alpha)$,
$(M, s) \models \mathcal{X}_i\alpha$ *iff* $(M, s) \models \mathcal{K}_i\alpha$ *and* $(M, s) \models \mathcal{A}_i(\alpha)$.

Henceforth, we will only consider models with a fixed interpretation for the security-specialised propositional variables $sent_i(m)$ and $received_i(m)$; in particular, we take $\models$ to be defined for these propositions as follows:

$(M, s) \models sent_i(m)$ iff $(\exists m' \in \mathbb{M})(\exists j \in \mathcal{AG})$ such that $m \sqsubseteq m'$ and $sent(j, m') \in l_i(s)$,
$(M, s) \models received_i(m)$ iff $recv(m) \in l_i(s)$.

We leave definitions of the other security-specialised propositions open. Namely, for distinct protocols these propositions will be defined differently.

Note that since $\mathcal{D}_i\alpha$ is a shortcut for $\mathrm{E}(\mathcal{K}_i\alpha \mathcal{U} \mathcal{X}_i\alpha)$, as defined on page 2, we have that $(M, s) \models \mathcal{D}_i\alpha$ iff $(M, s) \models \mathrm{E}(\mathcal{K}_i\alpha \mathcal{U} \mathcal{X}_i\alpha)$. We would like to emphasise that satisfaction for $\mathcal{X}_i$ can be defined using only the $\sim_i$ relation and the $\mathbb{A}_i$ function, but we will find it convenient in the axiomatisation to have a dedicated operator $\mathcal{A}_i$ for awareness of agent i. This is in line with [11]. Note also that the definition of the satisfaction relation is quite general; in particular, it contains nothing that is specific to security protocols, except the interpretation of the security-specialised propositional variables.

The remaining operators can be introduced as abbreviations in the usual way, i.e., $\alpha \wedge \beta \stackrel{def}{=} \neg(\neg\alpha \vee \neg\beta)$, $\alpha \Rightarrow \beta \stackrel{def}{=} \neg\alpha \vee \beta$, $\alpha \Leftrightarrow \beta \stackrel{def}{=} (\alpha \Rightarrow \beta) \wedge (\beta \Rightarrow \alpha)$, $\mathrm{A}\bigcirc\alpha \stackrel{def}{=} \neg\mathrm{E}\bigcirc\neg\alpha$, $\mathrm{E}\Diamond\alpha \stackrel{def}{=} \mathrm{E}(\top \mathcal{U} \alpha)$, $\mathrm{A}\Diamond\alpha \stackrel{def}{=} \mathrm{A}(\top \mathcal{U} \alpha)$, $\mathrm{E}\Box\alpha \stackrel{def}{=} \neg\mathrm{A}\Diamond\neg\alpha$, $\mathrm{A}\Box\alpha \stackrel{def}{=} \neg\mathrm{E}\Diamond\neg\alpha$, $\mathrm{A}(\alpha \mathcal{W} \beta) \stackrel{def}{=} \neg\mathrm{E}(\neg\alpha \mathcal{U} \neg\beta)$, $\mathrm{E}(\alpha \mathcal{W} \beta) \stackrel{def}{=} \neg\mathrm{A}(\neg\alpha \mathcal{U} \neg\beta)$.

Let M be a model. We say that a TDL formula φ is *valid in M* (written $M \models \varphi$), if $M, s \models \varphi$ for all states $s \in S$, and that a TDL formula φ is *valid* (written $\models \varphi$), if φ is valid in all the models M .

2.4 A Complete Axiomatic System for TDL

An *axiomatic system* consists of a collection of *axioms* and *inference rules*. An axiom is a formula, and an inference rule has the form "from previously derived formulas $\varphi_1, \ldots, \varphi_m$ infer formula φ". We say that φ is *provable* (written $\vdash \varphi$) if there is a sequence of formulas ending with φ, such that each formula is either an instance of an axiom, or follows from other provable formulas by applying an inference rule. An axiom system is said to be *sound* with respect to the models defined as in Definition 1, if $\vdash \varphi$ implies $\models \varphi$. An axiom system is said to be *complete* with respect to the models defined as in Definition 1, if $\models \varphi$ implies $\vdash \varphi$.

Let $i \in \{1, \ldots, n\}$. Consider an axiom system for TDL as defined below:

PC. All substitution instances of classical tautologies.
T1. $\mathrm{E}\bigcirc\top$ T2. $\mathrm{E}\bigcirc(\alpha \vee \beta) \Leftrightarrow \mathrm{E}\bigcirc\alpha \vee \mathrm{E}\bigcirc\beta$
T3. $\mathrm{E}(\alpha \mathcal{U} \beta) \Leftrightarrow \beta \vee (\alpha \wedge \mathrm{E}\bigcirc\mathrm{E}(\alpha \mathcal{U} \beta))$
T4. $\mathrm{A}(\alpha \mathcal{U} \beta) \Leftrightarrow \beta \vee (\alpha \wedge \mathrm{A}\bigcirc\mathrm{A}(\alpha \mathcal{U} \beta))$
K1. $(\mathcal{K}_i\alpha \wedge \mathcal{K}_i(\alpha \Rightarrow \beta)) \Rightarrow \mathcal{K}_i\beta$ K2. $\mathcal{K}_i\alpha \Rightarrow \alpha$
K3. $\neg\mathcal{K}_i\alpha \Rightarrow \mathcal{K}_i\neg\mathcal{K}_i\alpha$ X1. $\mathcal{X}_i\alpha \Leftrightarrow \mathcal{K}_i\alpha \wedge \mathcal{A}_i\alpha$
A1. $\mathcal{A}_i\alpha \Rightarrow \mathcal{K}_i\mathcal{A}_i\alpha$ A2. $\neg\mathcal{A}_i\alpha \Rightarrow \mathcal{K}_i\neg\mathcal{A}_i\alpha$
R1. From α and $\alpha \Rightarrow \beta$ infer β
R2. From α infer $\mathcal{K}_i\alpha$, $i = 1, \ldots, n$
R3. From $\alpha \Rightarrow \beta$ infer $\mathrm{E}\bigcirc\alpha \Rightarrow \mathrm{E}\bigcirc\beta$
R4. From $\gamma \Rightarrow (\neg\beta \wedge \mathrm{E}\bigcirc\gamma)$ infer $\gamma \Rightarrow \neg\mathrm{A}(\alpha \mathcal{U} \beta)$
R5. From $\gamma \Rightarrow (\neg\beta \wedge \mathrm{A}\bigcirc(\gamma \vee \neg\mathrm{E}(\alpha \mathcal{U} \beta)))$ infer $\gamma \Rightarrow \neg\mathrm{E}(\alpha \mathcal{U} \beta)$

THEOREM 1 ([16]). *The system TDL is sound and complete, i.e. $\models \varphi$ iff $\vdash \varphi$, for any formula $\varphi \in \mathcal{WF}(TDL)$.*

3. THE DOLEV-YAO ADVERSARY

The Dolev-Yao adversary [9] can compose messages, replay them, or decipher them if he has the right keys. In

the paper we use a formalisation of the Dolev-Yao adversary given in [14]. Namely, we define a derivation relation $H \vdash_{DY} m$ between a set of messages H and a message m. Intuitively, $\vdash_{DY}$ means that an adversary can "extract" message m from a set H of received messages and keys, using the admissible operations.

The derivation relation $\vdash_{DY}$ is defined as follows:

- if $m \in H$, then $H \vdash_{DY} m$
- if $H \vdash_{DY} \{m\}_k$ and $H \vdash_{DY} k^{-1}$, then $H \vdash_{DY} m$
- if $H \vdash_{DY} m \cdot m'$, then $H \vdash_{DY} m$
- if $H \vdash_{DY} m \cdot m'$, then $H \vdash_{DY} m'$

In our framework, to capture the capabilities of the Dolev-Yao adversary, we specify how the adversary can extract a message, by defining an awareness function $\mathbb{A}_i^{DY}$ for the intruder i, and by introducing the following fixed interpretation for the proposition $has_i(m)$:

$M, s \models has_i(m)$ iff there exists m' such that $m \sqsubseteq m'$ and $recv(m') \in l_i(s)$.

The function $\mathbb{A}_i^{DY} : L_i \rightarrow 2^{\mathcal{WF}(TDL)}$ is defined by: $has_i(m) \in \mathbb{A}_i^{DY}(l)$ iff one of the following conditions holds:

- $recv(m) \in l$.
- $m \in e_0(l)$, where the function e_0 returns the set of messages contained in the initial event of the local state l.
- there exists m' such that $has_i(m \cdot m') \in \mathbb{A}_i^{DY}(l)$ or $has_i(m' \cdot m) \in \mathbb{A}_i^{DY}(l)$.
- there exists an asymmetric key k such that $has_i(\{m\}_k) \in \mathbb{A}_i^{DY}(l)$ and $has_i(k^{-1}) \in \mathbb{A}_i^{DY}(l)$.
- there exists a symmetric key k such that $has_i(\{m\}_k) \in \mathbb{A}_i^{DY}(l)$ and $has_i(k) \in \mathbb{A}_i^{DY}(l)$.
- $m = m_1 \cdot m_2$ and $has_i(m_1) \in \mathbb{A}_i^{DY}(l)$ and $has_i(m_2) \in \mathbb{A}_i^{DY}(l)$.
- $m = \{m_1\}_k$ and $has_i(m_1) \in \mathbb{A}_i^{DY}(l)$ and $has_i(k) \in \mathbb{A}_i^{DY}(l)$.

We can now show that using $\mathbb{A}_i^{DY}$ an adversary can check that he explicitly knows $has_i(m)$ in a state s iff m can be derived from the messages received in the states s together with the messages initially known via the relation $\vdash_{DY}$.

LEMMA 1. *Let $M = (S, T, \sim_1, \ldots, \sim_n, \mathcal{V}, \mathbb{A}_1, \ldots, \mathbb{A}_n)$ be a model such that $\mathbb{A}_i = \mathbb{A}_i^{DY}$. Then, $M, s \models \mathcal{X}_i(has_i(m))$ iff $\{m' \mid recv(m') \in l_i(s)\} \cup e_0(l_i(s)) \vdash_{DY} m$.*

Proof. (Left to right). Assume $M, s \models \mathcal{X}_i(has_i(m))$ hold. By the definition of $\models$, we have that $M, s \models \mathcal{K}_i(has_i(m))$ and $has_i(m) \in \mathbb{A}_i(l_i(s))$. Since $has_i(m) \in \mathbb{A}_i(l_i(s))$, by the definition of $\mathbb{A}_i^{DY}$ we have that either $m \in \{m' \mid recv(m') \in l_i(s)\} \cup e_0(l_i(s))$, or there exists m'' such that $m \sqsubseteq m''$ and $m'' \in \{m' \mid recv(m') \in l_i(s)\} \cup e_0(l_i(s))$. This implies that $\{m' \mid recv(m') \in l_i(s)\} \cup e_0(l_i(s)) \vdash_{DY} m$.
(Right to left). Assume $\{m' \mid recv(m') \in l_i(s)\} \cup e_0(l_i(s)) \vdash_{DY} m$ hold. Then, we have that either $recv(m) \in l_i(s)$ or there exists m' such that $m \sqsubseteq m'$ and $recv(m') \in l_i(s)$. So, by the definition of $\mathbb{A}_i^{DY}$ we have that $has_i(m) \in \mathbb{A}_i^{DY}(l_i(s))$. Moreover, by the definition of $\models$ we have that $M, s \models has_i(m)$. Since $\mathbb{A}_i^{DY}$ is defined over the local states of agent i, we have that for all $t \in S$ such that $s \sim_i t$, $M, t \models has_i(m)$ holds. Hence, by the definition of $\models$ we have that $M, s \models \mathcal{K}_i(has_i(m))$. Hence, we conclude that $M, s \models \mathcal{X}_i(has_i(m))$. □

A model of the Dolev-Yao adversary was already considered in the interpreted system framework in [14, 20]. However, in those papers, the notion of *algorithmic knowledge* was used to capture the capabilities of the Dolev-Yao adversary instead.

4. TESLA

The *timed efficient stream loss-tolerant authentication* (TESLA) protocol was developed by A. Perrig et al. [19]. It was designed to enable authentication of a continuous stream of packets over an unreliable channel. The developers of TESLA proposed five variants of the protocol; only the first of these is discussed here.

Every variant of the TESLA protocol assumes a single sender broadcasting a continuous stream of packets. Since receivers act independently of one another, only one receiver will be considered below. TESLA uses cryptographic primitives like *commitments* to keys and `MAC` values. Recall that the commitment to a key k is computed by applying a pseudo-random function f to k, and the `MAC` value is computed by applying a *message authentication code* function `MAC` to a part of the packet content and a key. It is assumed that both the sender and the receiver know the pseudo-random function f, and the message authentication code function `MAC`. With the exception of the two initial packets, each TESLA packet (in the variant we analyse here) contains: (1) the message to be delivered; (2) a *commitment* to the key to be used to encode the `MAC` of the next packets; (3) the key that was used to encode the `MAC` of the previous sent packet; (4) the `MAC` of the current packet.

We now introduce a TESLA variant assuming that the protocol uses one pseudo-random function only. We have introduced such a simplification, because in our opinion the extra pseudo-random function does not provide any additional security; the same assumption is made in [3, 5].

Let $\mathbf{S}$ stand for the sender, $\mathbf{R}$ stand for the receiver, and $[x, y]$ denote the concatenation of x and y. Moreover, assume that $\mathbf{S}$ has a digital signature key pair, with private key $k_{\mathbf{S}}^{-1}$ and public key $k_{\mathbf{S}}$ known to $\mathbf{R}$. Further, assume that $\mathbf{R}$ chooses a random and unpredictable nonce. Then, the initial n steps, for $n > 1$, of the protocol for one sender and one receiver are the following:

(-1) $\mathbf{R} \rightarrow \mathbf{S} : n_{\mathbf{R}}$
(0) $\mathbf{S} \rightarrow \mathbf{R} : \{f(k_1), n_{\mathbf{R}}\}_{k_{\mathbf{S}}^{-1}}$
(1) $\mathbf{S} \rightarrow \mathbf{R} : [P_1, \mathtt{MAC}(k_1, P_1)]$, for $P_1 = [t_1, f(k_2)]$
(2) $\mathbf{S} \rightarrow \mathbf{R} : [P_2, \mathtt{MAC}(k_2, P_2)]$, for $P_2 = [t_2, f(k_3), k_1]$
...
(n) $\mathbf{S} \rightarrow \mathbf{R} : [P_n, \mathtt{MAC}(k_n, P_n)]$, for $P_n = [t_n, f(k_{n+1}), k_{n-1}]$

In the first step (i.e. step (-1.)) $\mathbf{R}$ sends a nonce $n_{\mathbf{R}}$ to $\mathbf{S}$ in order to ensure freshness of the session. In step (0), $\mathbf{S}$ encodes with $k_{\mathbf{S}}^{-1}$ the pair composed by the nonce just received and the commitment to key k_1 (i.e. $f(k_1)$), produced by the agreed pseudo-random function f. This is sent to $\mathbf{R}$. $\mathbf{R}$ knows $k_{\mathbf{S}}$, so he can decode the message $\{f(k_1), n_{\mathbf{R}}\}_{k_{\mathbf{S}}^{-1}}$. Given this, $\mathbf{R}$ knows that commitment $f(k_1)$ is authentic; however, because he does not know the reverse of f, he cannot compute the value of the key k_1. In step (1), $\mathbf{S}$ transmits in clear the first packet P_1 together with its `MAC`, i.e. the value $\mathtt{MAC}(k_1, P_1)$. P_1 contains message t_1 and commitment to key k_2 only. k_2 is used to compute the `MAC` of the next packet. After this step $\mathbf{R}$ knows the content of t_1, but he cannot be sure of its authenticity. This is because he does not know the value of the key k_1, and so he cannot check the `MAC` value. The authentication of packet P_1 is done by the sender's disclosing of k_1 in step (2). In steps (2),...,(n) $\mathbf{S}$ sends packet P_i, for $i \in \{1, \ldots, n\}$, authenticated by the `MAC` value computed from key k_i and P_i (i.e. the value $\mathtt{MAC}(k_i, P_i)$). P_i contains message t_i, commitment

to key k_{i+1} that is computed by applying pseudo-random function f to k_{i+1} , and key k_{i-1} thereby enabling $\mathbf{R}$ to verify the commitment $f(k_{i-1})$ and the MAC of packet P_i.

The TESLA scheme is susceptible to packet loss. In particular, once a packet is dropped no further packets can be authenticated; in the next section we will formally show that TESLA satisfies this property. Moreover, the scheme can be subverted if an attacker gets packet P_{i+1} before the receiver gets P_i. This is because the attacker would then know the secret key k_i that is used to compute the MAC value of P_i, and use this to forge all subsequent traffic by impersonating $\mathbf{S}$. To prevent this attack, the TESLA participants are initially synchronised, they know the precise schedule of packets, and $\mathbf{S}$ has to send packets at regular intervals that were agreed with $\mathbf{R}$ during the synchronisation process. More details are in [19]. This is not essential for our analysis.

TESLA guarantees the following security property: "*the receiver does not accept as authentic any message unless it was actually sent by the sender*". A streaming scheme that provides this guarantee is usually called a *secure stream authentication scheme* [19]. The main aim of the rest of the paper is to analyse this statement formally.

5. MODELLING OF TESLA IN TDL

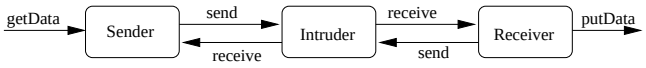

Figure 1: The Dolev-Yao assumption

So far, the TESLA protocol has been modelled and checked via process algebras [5] and Lynch-Vaandrager automata [3] only. Here, we are interested in applying the interpreted systems framework and the TDL language, which has a computationally-grounded semantics, to perform a *semantic* analysis of this protocol. So, let us begin by building a model $M = (S, T, \sim_{\mathbf{S}}, \sim_{\mathbf{R}}, \sim_{\mathbf{I}}, \mathcal{V}, \mathbb{A}_{\mathbf{S}}, \mathbb{A}_{\mathbf{R}}, \mathbb{A}_{\mathbf{I}})$ for TESLA. In order to perform this task, we have to provide definitions of the set of reachable global states S, the transition relation T, the valuation function $\mathcal{V}$, and the awareness functions $\mathbb{A}_{\mathbf{S}}$, $\mathbb{A}_{\mathbf{R}}$ and $\mathbb{A}_{\mathbf{I}}$.

There are three active components in the TESLA protocol: a sender, a receiver, and an intruder. In the formalism of interpreted systems, it is convenient to see the sender and the receiver as agents, and the intruder as the environment. We assume that the communication channel is under complete control of the intruder, hence all messages from the sender to the receiver and vice versa go through the intruder (see Figure 1). The intruder can overhear, capture, drop, resend, delay and fake messages. We do not allow the intruder to encrypt and decrypt messages unless he has the appropriate key, and we force the intruder to send well-formed packets only. Namely, a packet sent (re-sent, faked) by the intruder has to contain a message body, a key commitment, a key, and a MAC value computed from the packet and some key. Moreover, we assume that the sender, the receiver, and the intruder use a shared pseudo-random function f and a shared message authentication code function MAC. Namely, they can all compute $f(m)$ and $\mathtt{MAC}(m, n)$, if they have m and n. Further, we assume that the receiver and the intruder know the public key of the sender, and that the sender and the intruder start off with disjoint sets of keys.

Each of the principals as well as the intruder can be modelled by considering their local states. Before we define them, we first introduce the following notion. For $t_i \in \mathbb{M}$, $f(k_{i+1}) \in \mathbb{F}$, $k_i \in \mathbb{K}$, $n_{\mathbf{R}} \in \mathbb{N}$ we define a message P_i, called a *packet*, as follows:

$$P_i = \begin{cases} (t_i \cdot f(k_{i+1}) \cdot k_{i-1}) \cdot \mathtt{MAC}(k_i, (t_i \cdot f(k_{i+1}) \cdot k_{i-1})), \\ \text{if } i > 1; \\ (t_i \cdot f(k_{i+1})) \cdot \mathtt{MAC}(k_i, (t_i \cdot f(k_{i+1}))), \text{ if } i = 1; \\ \{f(k_{i+1}) \cdot n_{\mathbf{R}}\}_{k_{\mathbf{S}}^{-1}}, \quad \text{if } i = 0. \end{cases}$$

We assume that the receiver knows the precise sending schedule of packets, and that this information is incorporated into packet P_0. Notice, that from this assumption it follows that P_0 always has to arrive to the receiver safely for the protocol to function. Further, we assume the sender and the receiver to keep the three most recent packets, and the intruder to keep five.

For the sender $\mathbf{S}$ we take the following set of local states:

$$L_{\mathbf{S}} = \{[\cdot], [recv(n_{\mathbf{R}})], [sent(\mathbf{R}, P_0)]\} \cup \\ \{[sent(\mathbf{R}, P_{i-1}), sent(\mathbf{R}, P_i)] \mid i > 0\} \cup \\ \{[sent(\mathbf{R}, P_{i-1}), sent(\mathbf{R}, P_i), sent(\mathbf{R}, P_{i+1})] \mid i > 0\}$$

$[\cdot]$ represents $\mathbf{S}$'s initial state in the protocol. In any state, we assume that $\mathbf{S}$ has all the information he needs to prepare a packet, i.e. he has a complete set of messages $M_{\mathbf{S}} \subseteq \mathbb{M}$. Further, we assume that $M_{\mathbf{S}}$ constitutes $\mathbf{S}$'s initial database that remains accessible to him throughout the run. For convenience we do not add this explicitly to the local states. The local state $[recv(n_{\mathbf{R}})]$ represents the message from $\mathbf{R}$ to establish communication, whereas $[sent(\mathbf{R}, P_0)]$ represents the state in which $\mathbf{S}$ has just sent P_0 to $\mathbf{R}$. $[sent(\mathbf{R}, P_{i-1})$, $sent(\mathbf{R}, P_i)]$ and $[sent(\mathbf{R}, P_{i-1})$, $sent(\mathbf{R}, P_i)$, $sent(\mathbf{R}, P_{i+1})]$ represent states, in which $\mathbf{S}$ has sent packets P_j, where $j \leq i + 1$ and $i > 0$.

We take the following set of local states for the receiver $\mathbf{R}$:

$$L_{\mathbf{R}} = \{[\cdot], [sent(\mathbf{S}, n_{\mathbf{R}})], [stop], [recv(P_0)]\} \cup \\ \{[recv(P_0), recv(P_2)]\} \cup \{[recv(P_i), recv(P_{i+1})] \mid i \geq 0\} \cup \\ \{[recv(P_{i-1}), recv(P_i), recv(P_{i+1})] \mid i > 0\} \cup \\ \{[recv(P_{i-1}), recv(P_i), recv(P_{i+2})] \mid i > 0\} \cup \\ \{[recv(P_i), recv(P_{i+1}), recv(P'_{i+2})] \mid i \geq 0\} \cup \\ \{[recv(P_0), recv(P'_1)]\} \cup \{[recv(P_0), recv(P'_1), recv(P'_2)]\} \\ \cup \{[recv(P_0), recv(P'_1), recv(P_2)]\}$$

$[\cdot]$ represents $\mathbf{R}$'s initial state in the protocol, in which $\mathbf{R}$ has his set of nonces only. $[sent(\mathbf{S}, n_{\mathbf{R}})]$ represents the local state in which $\mathbf{R}$ has just sent the nonce $n_{\mathbf{R}}$ to $\mathbf{S}$, and he is waiting for packets. $[stop]$ represents the local state, in which $\mathbf{R}$ has just stopped collecting packets. The local states $[recv(P_0)]$, $[recv(P_0), recv(P_2)]$, $[recv(P_i)$, $recv(P_{i+1})]$ for $i \geq 0$, $[recv(P_{i-1}), recv(P_i)$, $recv(P_{i+2})]$ and $[recv(P_{i-1})$, $recv(P_i), recv(P_{i+1})]$ for $i > 0$ represent the packets $\mathbf{R}$ has received from $\mathbf{S}$, whereas $[recv(P_0)$, $recv(P'_1)]$, $[recv(P_0)$, $recv(P'_1), recv(P'_2)]$, $[recv(P_0), recv(P'_1)$, $recv(P_2)]$, and $[recv(P_i), recv(P_{i+1}), recv(P'_{i+2})]$ for $i \geq 0$ represent the faked packets $\mathbf{R}$ has received. Specifically, these states represent situations in which $\mathbf{I}$ has produced a new packet, say P'_i, and has sent it to $\mathbf{R}$ instead of forwarding the intercepted packet P_i.

It remains to model the intruder's set of local states. For $\mathbf{I}$ we take the following set:

$$L_{\mathbf{I}} = \{[\cdot], [recv(n_{\mathbf{R}})], [recv(P_0)]\} \cup \\ \{[recv(P_i), recv(P_{i+1})] \mid i \geq 0\} \cup \\ \{[recv(P_{i-1}), recv(P_i), recv(P_{i+1})] \mid i > 0\} \cup$$

$$\{[recv(P_0), recv(P_1), send(\mathbf{R}, P_1')]\} \cup$$
$$\{[recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2)]\} \cup$$
$$\{[recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2), send(\mathbf{R}, P_2')]\} \cup$$
$$\{[recv(P_{i-1}), recv(P_i), recv(P_{i+1}), send(\mathbf{R}, P_{i+1}')] \mid i > 0\}$$

$[\cdot]$ represents $\mathbf{I}$'s initial state in the protocol. In any state, we assume that $\mathbf{I}$ has all the information needed to prepare well-formed packets, with $M_{\mathbf{I}} \subseteq \mathbb{M}$ such that $M_{\mathbf{I}} \cap M_{\mathbf{S}} = \emptyset$. Further, we assume that $M_{\mathbf{I}}$ can grow during the run. $[recv(n_{\mathbf{R}})]$ represents $\mathbf{I}$'s state following the interception of $\mathbf{R}$'s initial message to $\mathbf{S}$. $[recv(P_0)]$, $[recv(P_i), recv(P_{i+1})]$ and $[recv(P_{i-1}), recv(P_i),\ recv(P_{i+1})]$ represent the packets intercepted by $\mathbf{I}$ sent by $\mathbf{S}$ to $\mathbf{R}$. $[recv(P_0), recv(P_1), send(\mathbf{R}, P_1')]$, $[recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2)]$, $[recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2), send(\mathbf{R}, P_2')]$, and $[recv(P_{i-1}), recv(P_i), recv(P_{i+1}), send(\mathbf{R}, P_{i+1}')]$ for $i > 0$, represent the packets intercepted by $\mathbf{I}$ sent by $\mathbf{S}$ to $\mathbf{R}$ and their faked versions.

Given the sets of local states for the TESLA agents, i.e. the sets $L_{\mathbf{S}}$, $L_{\mathbf{R}}$ and $L_{\mathbf{I}}$, the following sets of actions are available to the agents:

- $Act_{\mathbf{S}} = \{sendP_i \mid i \geq 0\} \cup \{acceptP_i \mid i \geq 0\} \cup \{\lambda\}$,
- $Act_{\mathbf{R}} = \{\lambda, nonce, stop\} \cup \{acceptP_i \mid i > 0\}$,
- $Act_{\mathbf{I}} = \{\lambda\} \cup \{dropP_i \mid i > 0\} \cup \{fakeP_i \mid i > 0\} \cup \{acceptP_i \mid i > 0\}$,

where λ stands for no action.

The protocols executed by agents are defined as follows:

Sender:

- $P_{\mathbf{S}}([\cdot]) = \{\lambda\}$
- $P_{\mathbf{S}}([recv(n_{\mathbf{R}})]) = \{sendP_0\}$
- $P_{\mathbf{S}}([sent(\mathbf{R}, P_0)]) = \{sendP_1\}$
- $P_{\mathbf{S}}([sent(\mathbf{R}, P_{i-1}), sent(\mathbf{R}, P_i)]) = \{sendP_{i+1}\}$,
- $P_{\mathbf{S}}([sent(\mathbf{R}, P_{i-1}), sent(\mathbf{R}, P_i), sent(\mathbf{R}, P_{i+1})]) = \{acceptP_{i-1}, \lambda\}$, for $i \geq 0$.

Intruder:

- $P_{\mathbf{I}}([\cdot]) = P_{\mathbf{I}}([recv(n_{\mathbf{R}})]) = \{\lambda\}$
- $P_{\mathbf{I}}([recv(P_0)]) = \{\lambda, dropP_1, fakeP_1\}$
- $P_{\mathbf{I}}([recv(P_i), recv(P_{i+1})]) = \{\lambda, dropP_{i+2}, fakeP_{i+2}\}$, for $i \geq 0$
- $P_{\mathbf{I}}([recv(P_{i-1}), recv(P_i), recv(P_{i+1})]) = \{acceptP_{i-1}, \lambda\}$, for $i > 0$
- $P_{\mathbf{I}}([recv(P_0), recv(P_1), send(\mathbf{R}, P_1')]) = \{fakeP_2\}$,
- $P_{\mathbf{I}}([recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2)]) = \{\lambda\}$,
- $P_{\mathbf{I}}([recv(P_0), recv(P_1), send(\mathbf{R}, P_1'), recv(P_2), send(\mathbf{R}, P_2')]) = \{\lambda\}$,
- $P_{\mathbf{I}}([recv(P_{i-1}), recv(P_i), recv(P_{i+1}), send(\mathbf{R}, P_{i+1}')]) = \{\lambda\}$, for $i > 0$

Receiver:

- $P_{\mathbf{R}}([\cdot]) = \{nonce\}$
- $P_{\mathbf{R}}([sent(\mathbf{S}, n_{\mathbf{R}})]) = P_{\mathbf{R}}([recv(P_0)]) = \{\lambda\}$
- $P_{\mathbf{R}}([recv(P_i), recv(P_{i+1})]) = \{\lambda\}$, for $i \geq 0$
- $P_{\mathbf{R}}([recv(P_{i-1}), recv(P_i), recv(P_{i+1})]) = \{acceptP_i\}$, for $i > 0$
- $P_{\mathbf{R}}([stop]) = P_{\mathbf{R}}([recv(P_0), recv(P_2)]) = \{stop\}$,
- $P_{\mathbf{R}}([recv(P_{i-1}), recv(P_i), recv(P_{i+2})]) = \{stop\}$, for $i > 0$
- $P_{\mathbf{R}}([recv(P_0), recv(P_1')]) = \{\lambda\}$,
- $P_{\mathbf{R}}([recv(P_0), recv(P_1'), recv(P_2')]) = \{stop\}$,
- $P_{\mathbf{R}}([recv(P_0), recv(P_1'), recv(P_2)]) = \{stop\}$,
- $P_{\mathbf{R}}([recv(P_{i-1}), recv(P_i), recv(P_{i+1}')]) = \{stop\}$, for $i > 0$

The evolution of the system during the execution of TESLA is defined by means of an evolution function $t : (L_{\mathbf{S}} \times L_{\mathbf{R}} \times L_{\mathbf{I}}) \times Act \rightarrow 2^{L_{\mathbf{S}} \times L_{\mathbf{R}} \times L_{\mathbf{I}}}$, where Act is a subset of $Act_{\mathbf{S}} \times Act_{\mathbf{R}} \times Act_{\mathbf{I}}$. More precisely, let us assume that the system starts from the initial state $([\cdot], [\cdot], [\cdot])$, and let rv denote the even *recv*, and st the even *sent*. Then, the evolution function for TESLA is defined as follows:

Intruder forwards all packets

1. $t(([\cdot], [\cdot], [\cdot]), (\lambda, nonce, \lambda)) = ([rv(n_{\mathbf{R}})], [st(\mathbf{S}, n_{\mathbf{R}})], [rv(n_{\mathbf{R}})])$;
2. $t([rv(n_{\mathbf{R}})], [st(\mathbf{S}, n_{\mathbf{R}})], [rv(n_{\mathbf{R}})]), (sendP_0, \lambda, \lambda))$ $= ([st(\mathbf{R}, P_0)], [rv(P_0)], [rv(P_0)])$;
3. $t([st(\mathbf{R}, P_0)], [rv(P_0)], [rv(P_0)]), (sendP_1, \lambda, \lambda)) =$ $([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0), rv(P_1)], [rv(P_0), rv(P_1)])$;
4. $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0), rv(P_1)], [rv(P_0), rv(P_1)])$, $(sendP_2, \lambda, \lambda)) = ([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)]$, $[rv(P_0), rv(P_1), rv(P_2)], [rv(P_0), rv(P_1), rv(P_2)])$;
5. $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)],\ [rv(P_0), rv(P_1), rv(P_2)]$, $[rv(P_0), rv(P_1), rv(P_2)]), (acceptP_0, acceptP_1, acceptP_0)) =$ $([st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [rv(P_1), rv(P_2)], [rv(P_1), rv(P_2)])$;
6. $t([st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [rv(P_1), rv(P_2)], [rv(P_1), rv(P_2)])$, $(sendP_3, \lambda, \lambda)) = ([st(\mathbf{R}, P_1), st(\mathbf{R}, P_2), st(\mathbf{R}, P_3)]$, $[rv(P_1), rv(P_2), rv(P_3)], [rv(P_1), rv(P_2), rv(P_3)])$;
7. $t([st(\mathbf{R}, P_1), st(\mathbf{R}, P_2), st(\mathbf{R}, P_3)],\ [rv(P_1), rv(P_2), rv(P_3)]$, $[rv(P_1), rv(P_2), rv(P_3)]), (acceptP_1, acceptP_2, acceptP_1)) =$ $([st(\mathbf{R}, P_2), st(\mathbf{R}, P_3)], [rv(P_2), rv(P_3)], [rv(P_2), rv(P_3)]])$;

...

- $t([st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})], [rv(P_n), rv(P_{n+1})]$, $[rv(P_n), rv(P_{n+1})]), (sendP_{n+2}, \lambda, \lambda)) =$ $([st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1}), st(\mathbf{R}, P_{n+2})],\ [rv(P_n), rv(P_{n+1})$, $rv(P_{n+2})], [rv(P_n), rv(P_{n+1}), rv(P_{n+2})])$, for $n > 0$;
- $t([st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1}), st(\mathbf{R}, P_{n+2})]$, $[rv(P_n), rv(P_{n+1}), rv(P_{n+2})], [rv(P_n), rv(P_{n+1}), rv(P_{n+2})])$, $(acceptP_n, acceptP_{n+1}, dropP_n)) = ([st(\mathbf{R}, P_{n+1}), st(\mathbf{R}, P_{n+2})]$, $[rv(P_{n+1}), rv(P_{n+2})], [rv(P_{n+1}), rv(P_{n+2})])$, for $n > 0$;

Intruder blocks packet P_1

1. $t(([st(\mathbf{R}, P_0)], [rv(P_0)], [rv(P_0)]),\ (sendP_1, \lambda, dropP_1)) =$ $([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0)], [rv(P_0), rv(P_1)])$;
2. $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0)], [rv(P_0), rv(P_1)])$, $(sendP_2, \lambda, \lambda)) = ([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)]$, $[rv(P_0), rv(P_2)], [rv(P_0), rv(P_1), rv(P_2)])$;
3. $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [rv(P_0), rv(P_2)]$, $[rv(P_0), rv(P_1), rv(P_2)]), (\lambda, stop, \lambda)) = ([st(\mathbf{R}, P_0)$, $st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [stop], [rv(P_0), rv(P_1), rv(P_2)])$;
4. $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [stop], [rv(P_0), rv(P_1)$, $rv(P_2)]), (\lambda, stop, \lambda)) = ([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)]$, $[stop], [rv(P_0), rv(P_1), rv(P_2)])$;

Intruder blocks packet P_n, $n > 1$

1. $t(([st(\mathbf{R}, P_{n-2}), st(\mathbf{R}, P_{n-1})], [rv(P_{n-2}), rv(P_{n-1})]$, $[rv(P_{n-2}), rv(P_{n-1})]), (sendP_n, \lambda, dropP_n)) =$ $([st(\mathbf{R}, P_{n-2}), st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n)]$, $[rv(P_{n-2}), rv(P_{n-1})], [rv(P_{n-2}), rv(P_{n-1}), rv(P_n)])$;
2. $t(([st(\mathbf{R}, P_{n-2}), st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n)]$, $[rv(P_{n-2}), rv(P_{n-1})], [rv(P_{n-2}), rv(P_{n-1}), rv(P_n)])$, $(accept_{n-2}, \lambda, accept_{n-2})) = ([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n)]$, $[rv(P_{n-2}), rv(P_{n-1})], [rv(P_{n-1}), rv(P_n)])$;
3. $t(([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n)], [rv(P_{n-2}), rv(P_{n-1})]$, $[rv(P_{n-1}), rv(P_n)]), (sendP_{n+1}, \lambda, \lambda)) = ([st(\mathbf{R}, P_{n-1})$, $st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})], [rv(P_{n-2}), rv(P_{n-1})$, $rv(P_{n+1})], [rv(P_{n-1}), rv(P_n), rv(P_{n+1})])$;
4. $t(([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})], [rv(P_{n-2})$, $rv(P_{n-1}), rv(P_{n+1})], [rv(P_{n-1}), rv(P_n), rv(P_{n+1})])$, $(\lambda, stop, \lambda)) = ([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})]$, $[stop], [rv(P_{n-1}), rv(P_n), rv(P_{n+1})])$;
5. $t([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})], [stop]$, $[rv(P_{n-1}), rv(P_n), rv(P_{n+1})]), (\lambda, stop, \lambda)) =$ $([st(\mathbf{R}, P_{n-1}), st(\mathbf{R}, P_n), st(\mathbf{R}, P_{n+1})], [stop]$, $[rv(P_{n-1}), rv(P_n), rv(P_{n+1})])$;

Intruder fakes packet P_1

1. $t(([st(\mathbf{R}, P_0)], [rv(P_0)], [rv(P_0)]), (sendP_1, \lambda, fakeP_1)) =$ $([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0), rv(P_1')]$, $[rv(P_0), rv(P_1), st(\mathbf{R}, P_1')])$;

2.a $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1)], [rv(P_0), rv(P_1')], [rv(P_0), rv(P_1)$, $st(\mathbf{R}, P_1')]), (sendP_2, \lambda, fakeP_2)) = ([st(\mathbf{R}, P_0)$, $st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [rv(P_0), rv(P_1'), rv(P_2')]$, $[rv(P_0), rv(P_1), st(\mathbf{R}, P_1'), rv(P_2)], st(\mathbf{R}, P_2'))$;

3.a $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [rv(P_0), rv(P_1'), rv(P_2')]$, $[rv(P_0), rv(P_1), st(\mathbf{R}, P_1'), rv(P_2), st(\mathbf{R}, P_2')]), (\lambda, stop, \lambda)) =$ $([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [stop]$, $[rv(P_0), rv(P_1), st(\mathbf{R}, P_1'), rv(P_2), st(\mathbf{R}, P_2')])$;

4.a $t([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)], [stop]$, $[rv(P_0), rv(P_1), st(\mathbf{R}, P_1'), rv(P_2), st(\mathbf{R}, P_2')])$, $(\lambda, stop, \lambda)) = ([st(\mathbf{R}, P_0), st(\mathbf{R}, P_1), st(\mathbf{R}, P_2)]$, $[stop], [rv(P_0), rv(P_1), st(\mathbf{R}, P_1'), rv(P_2), st(\mathbf{R}, P_1')])$;

2.b $t([st(\mathbf{R},P_0),st(\mathbf{R},P_1)],[rv(P_0),rv(P_1')],$
$[rv(P_0),rv(P_1),st(\mathbf{R},P_1')]),(sendP_2,\lambda,\lambda)) =$
$([st(\mathbf{R},P_0),st(\mathbf{R},P_1),st(\mathbf{R},P_2)],[rv(P_0),rv(P_1'),$
$rv(P_2)],[rv(P_0),rv(P_1),st(\mathbf{R},P_1'),rv(P_2)]);$

3.b $t([st(\mathbf{R},P_0),st(\mathbf{R},P_1),st(\mathbf{R},P_2)],[rv(P_0),rv(P_1'),$
$st(\mathbf{R},P_1'),rv(P_2)],[rv(P_0),rv(P_1),rv(P_2)]),(\lambda,stop,\lambda))$
$=([st(\mathbf{R},P_0),st(\mathbf{R},P_1),st(\mathbf{R},P_2)],[stop],$
$[rv(P_0),rv(P_1),st(\mathbf{R},P_1'),rv(P_2)]);$

4.b $t([st(\mathbf{R},P_0),st(\mathbf{R},P_1),st(\mathbf{R},P_2)],[stop],[rv(P_0),rv(P_1),$
$st(\mathbf{R},P_1'),rv(P_2)]),(\lambda,stop,\lambda)) = ([st(\mathbf{R},P_0),st(\mathbf{R},P_1),$
$st(\mathbf{R},P_2)],[stop],[rv(P_0),rv(P_1),st(\mathbf{R},P_1'),rv(P_2)]);$

Intruder fakes packet P_n, $n>1$

1. $t(([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1})],[rv(P_{n-2}),rv(P_{n-1})],$
$[rv(P_{n-2}),rv(P_{n-1})]),(sendP_n,\lambda,fakeP_n)) =$
$([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1}),st(\mathbf{R},P_n)],[rv(P_{n-2}),$
$rv(P_{n-1}),rv(P_n')],[rv(P_{n-2}),rv(P_{n-1}),rv(P_n)]);$
2. $t(([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1}),st(\mathbf{R},P_n)],[rv(P_{n-2}),$
$rv(P_{n-1}),rv(P_n')],[rv(P_{n-2}),rv(P_{n-1}),rv(P_n)]),$
$(\lambda,stop,\lambda)) = ([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1}),st(\mathbf{R},P_n)],$
$[stop],[rv(P_{n-2}),rv(P_{n-1}),rv(P_n)]);$
3. $t([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1}),st(\mathbf{R},P_n)],[stop],$
$[rv(P_{n-2}),rv(P_{n-1}),rv(P_n)]),(\lambda,stop,\lambda)) =$
$([st(\mathbf{R},P_{n-2}),st(\mathbf{R},P_{n-1}),st(\mathbf{R},P_n)],[stop],$
$[rv(P_{n-2}),rv(P_{n-1}),rv(P_n)]);$

The above evolution function determines not only the set of reachable global states $S \subseteq L_{\mathbf{S}} \times L_{\mathbf{R}} \times L_{\mathbf{I}}$, but also gives the transition relation T; namely, for all the s, $s' \in S$, $(s,s') \in T$ iff there exists $act \in Act$ such that $t(s,act) = s'$.

We have now defined states, actions, protocols, and transitions for the model M for TESLA. To conclude, we define a valuation function $\mathcal{V} : S \to 2^{\mathcal{PV}}$ and the awareness functions $\mathbb{A}_X : L_X \to 2^{\mathcal{WF}(TDL)}$, for $X \in \{\mathbf{S},\mathbf{R},\mathbf{I}\}$. We first introduce the following set $\mathcal{PV}$ of propositional variables, which we find useful in analysis of the TESLA scenario:

$$\mathcal{PV} = \{has_{\mathbf{R}}(m), sent_{\mathbf{S}}(m), received_{\mathbf{R}}(m),\\ dropped_{\mathbf{I}}(m), faked_{\mathbf{I}}(m) \mid m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}\}$$

We define $\mathcal{V} : S \to 2^{\mathcal{PV}}$ by assuming that:

- for $i>0$, $has_{\mathbf{R}}(t_i) \in \mathcal{V}(s)$ if there exist packets P_{i-1}, P_i and P_{i+1} such that $f(k_i) \sqsubseteq P_{i-1}$, $t_i \sqsubseteq P_i$, $k_i \sqsubseteq P_{i+1}$, $recv(P_{i-1}) \in l_{\mathbf{R}}(s)$, $recv(P_i) \in l_{\mathbf{R}}(s)$ and $recv(P_{i+1}) \in l_{\mathbf{R}}(s)$,
- $sent_{\mathbf{S}}(m) \in \mathcal{V}(s)$ if there exists packet P_i such that $m \sqsubseteq P_i$ and $sent(\mathbf{R},P_i) \in l_{\mathbf{S}}(s)$, for any $m \in M_{\mathbf{S}}$,
- $received_{\mathbf{R}}(m) \in \mathcal{V}(s)$ if $recv(m) \in l_{\mathbf{R}}(s)$, for any $m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}$,
- $dropped_{\mathbf{I}}(m) \in \mathcal{V}(s)$ if $recv(m) \notin l_{\mathbf{R}}(s)$ and $recv(m) \in l_{\mathbf{I}}(s)$, for any $m \in M_{\mathbf{S}}$,
- $faked_{\mathbf{I}}(m) \in \mathcal{V}(s)$ if there exist packets P_j such that $m \sqsubseteq P_j$ and $send(\mathbf{R},P_j) \in l_{\mathbf{I}}(s)$, for any $m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}$.

For $X \in \{\mathbf{S},\mathbf{I}\}$, we take the following awareness function $\mathbb{A}_X : L_X \to 2^{\mathcal{WF}(TDL)}$: $\mathbb{A}_X(l) = \emptyset$, for any $l \in L_X$. In turn, $\mathbf{R}$'s awareness function $\mathbb{A}_{\mathbf{R}} : L_{\mathbf{R}} \to 2^{\mathcal{WF}(TDL)}$ is defined as follows. For any $l \in L_{\mathbf{R}}$, $\alpha \in \mathbb{A}_{\mathbf{R}}(l)$ if one of the following holds:

- $\alpha = received_{\mathbf{R}}(m)$ and $recv(m) \in l$ and $m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}$,
- $\alpha = faked_{\mathbf{I}}(m)$ and $l = [stop]$ and $m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}$,
- $\alpha = dropped_{\mathbf{I}}(m)$ and $l = [stop]$ and $m \in M_{\mathbf{S}}$,
- $\alpha = has_{\mathbf{R}}(m)$ and ($recv(m) \in l$ or $\exists m'$ such that $m \sqsubseteq m'$ and $recv(m') \in l$) and $m \in M_{\mathbf{S}} \cup M_{\mathbf{I}}$.

We have now completed defining the model M for TESLA.

Note that when we put a bound on the number of packets to be sent, M becomes finite.

Given the model M as defined above, we proceed to the semantical analysis of the TESLA protocol. First, we would like to establish whether or not TESLA satisfies the desired security property: *"the receiver does not accept as authentic any message unless it was actually sent by the sender"*. It can be expressed by the following TDL formula: for any $i>0$,

$$has_{\mathbf{R}}(t_i) \Rightarrow (sent_{\mathbf{S}}(P_{i-1}) \wedge sent_{\mathbf{S}}(P_i) \wedge sent_{\mathbf{S}}(P_{i+1})) \quad (1)$$

It is easy (albeit tedious) to check manually that formula 1 is valid in M.

As one can notice, formula 1 is a pure propositional formula, so in order to verify the TESLA security property there is no need to use strong formalisms like epistemic or temporal logics. Indeed, this property can be checked via process algebras [5] or via Lynch-Vaandrager automata [3]. However, unlike the process algebras and Lynch-Vaandrager automata, the TDL language together with its semantic model is a powerful formalism that allows us to model and verify other properties of TESLA. In particular, using the model M and TDL we can show that TESLA satisfies a much stronger property: *"the receiver does not accept as authentic any message unless he knows that it was actually sent by the sender"*. Indeed it can be checked that, for any $i>0$,

$$M \models \quad has_{\mathbf{R}}(t_i) \Rightarrow \mathcal{K}_{\mathbf{R}}(sent_{\mathbf{S}}(P_{i-1}) \wedge \\ sent_{\mathbf{S}}(P_i) \wedge sent_{\mathbf{S}}(P_{i+1})) \quad (2)$$

Note that our model M of TESLA does not fulfil the contrappositive of the above, i.e. the following holds:

$$M \not\models \quad \mathcal{K}_{\mathbf{R}}(sent_{\mathbf{S}}(P_{i-1}) \wedge sent_{\mathbf{S}}(P_i) \wedge \\ sent_{\mathbf{S}}(P_{i+1})) \Rightarrow has_{\mathbf{R}}(t_i) \quad (3)$$

The above seems reasonable, and it does not violate the security property given the presence of the intruder.

Further, we can check that TESLA actually meets the following property: *"it is always the case that the receiver does not accept as authentic any message unless he knows that it was actually sent by the sender"*.

$$M \models \quad \mathrm{A}\Box(has_{\mathbf{R}}(t_i) \Rightarrow \mathcal{K}_{\mathbf{R}}(sent_{\mathbf{S}}(P_{i-1}) \wedge \\ sent_{\mathbf{S}}(P_i) \wedge sent_{\mathbf{S}}(P_{i+1}))) \quad (4)$$

The principals know about the presence of the intruder, so, the following should holds: for some $i>0$:

$$M \models K_{\mathbf{S}}\mathrm{E}\Diamond(sent_{\mathbf{S}}(P_i) \wedge \neg received_{\mathbf{R}}(P_i)) \quad (5)$$

Indeed, a manual checking of M that we have done confirmed the above observation.

Also, by analysing TESLA one can expect that the protocol should fulfil the following property: *if a packet is faked, then the receiver should discover this.* It expresses the fact that the receiver is able to check the source of messages. This can be formalised as follows:

$$M \models faked_{\mathbf{I}}(P_i) \Rightarrow \mathcal{D}_{\mathbf{R}}(faked_{\mathbf{I}}(P_i)) \quad (6)$$

Again, a manual checking of M confirmed the above.

Investigating the TESLA model M, we could observe that if the receiver obtains some packets P_{i-1}, P_i, and P_{i+1} with a message $t_i \sqsubseteq P_i$, and he does not accept t_i as authentic, then he knows that at least one of the packets was not sent by the intended sender. Moreover, if a packet was indeed faked, the receiver is able to deduce this fact. So, property 7 should hold, and a manual check of M that we have done

confirmed this. For any $i > 0$,

$$M \models (received_{\mathbf{R}}(P_{i-1}) \wedge received_{\mathbf{R}}(P_i) \wedge received_{\mathbf{R}}(P_{i+1}) \wedge \neg has_{\mathbf{R}}(t_i)) \Rightarrow \big(\mathcal{K}_{\mathbf{R}}(\neg sent_{\mathbf{S}}(P_{i-1}) \vee \neg sent_{\mathbf{S}}(P_i) \vee \neg sent_{\mathbf{S}}(P_{i+1})) \wedge (\mathcal{D}_{\mathbf{R}}(fake_{\mathbf{I}}(P_{i-1})) \vee \mathcal{D}_{\mathbf{R}}(fake_{\mathbf{I}}(P_i)) \vee \mathcal{D}_{\mathbf{R}}(fake_{\mathbf{I}}(P_{i+1})))\big) \quad (7)$$

Messages are sent to the receiver according to the schedule. This schedule is known to the intruder as well. So, when the intruder tries to fake the current transmission, he has to follow the sending schedule, otherwise, the receiver will stop the reception immediately. This means that the intruder has to send a packet at each interval, which was agreed by the sender and the receiver at the beginning of the transmission under consideration. This observation can be formalised as follows. For any $i > 0$,

$$M \models \mathrm{A}\Box(dropped_{\mathbf{I}}(P_i) \Rightarrow \mathcal{D}_{\mathbf{R}}(dropped_{\mathbf{I}}(P_i)) \quad (8)$$

It can be checked that property 8 also holds.

6. CONCLUSION

In the paper we have proposed a new security-specialised logic TDL defined on a computationally-grounded semantics, and with a sound and complete axiomatisation. TDL employs different concepts of knowledge (based on the notion of awareness), as well as time in order to represent the knowledge of principals that operate in an environment that is under control of an intruder. Further, we have applied the logic to reason about TESLA, which we have formalised in the interpreted system framework. A temporal epistemic analysis has allowed us not only to reconfirm the TESLA authentication property but also to check more sophisticated specifications.

Obviously we do not suggest one should check security protocols manually as done here. Work is in progress to extend a BDD-based model checker [17] to encode the epistemic notions described here. Since the semantics of TDL is defined on interpreted systems we are hopeful that the exercise conduced here manually can be automated. Since TDL has a computationally-grounded semantics, a model checking technique for it can be defined, which is the scope of a further investigation.

ABSTRACT

We develop a logic for representing and reasoning about coalitional games without transferable payoffs. Although a number of logics of cooperation have been proposed over the past decade (notably Coalition Logic [14] and Alternating-time Temporal Logic [1]), these logics focused primarily on the issue of strategic cooperative ability – what states a coalition can effectively enforce – and have tended to ignore the essential issue of the preferences that agents have over such states; in addition, the connection between such logics and coalitional games, in the sense of cooperative game theory, is left implicit. The Coalitional Game Logic (CGL) that we develop in this paper differs from such previous logics in two important respects. First, CGL includes operators that make it directly possible to represent an agent's preferences over outcomes. Second, we interpret formulae of CGL directly with respect to coalitional games without transferable payoff, thereby establishing an explicit link between formulae of the logic and properties of coalitional games. We show that these coalitional games cannot be seen directly as models for Coalition Logic. We give a complete axiomatization of CGL, prove that it is expressively complete with respect to coalitional games without transferable payoff, show that the satisfiability problem for the logic is NP-complete, and to illustrate its use, we show how the logic can be used to characterise axiomatically a number of well-known solution concepts for coalitional games, including for example non-emptiness of the core.

1. INTRODUCTION

If one aims to build software agents that must inhabit and act within some particular environment, then it is very natural to equip such agents with formal *representations* of the environment, in order to permit them to effectively select and execute actions within it. Previous work on knowledge representation in multi-agent systems may be broadly divided into two distinct categories. In the 1990s, considerable emphasis was placed on representations of the *cognitive structure* of agents – their beliefs, desires, intentions, and so forth. Key issues in such representations include for example the way in which communicative actions (speech acts) affect the mental states of conversation participants, and how we can characterise the mental states of agents engaged in teamwork [5]. More recently, an increasing body of work has focused instead on logics that make it possible to represent the strategic structure of multi-agent environments, and in particular, the powers that agents or groups of agents have in such environments [1, 13]. Such logics have proved to have many important applications, for example in the specification and verification of social choice mechanisms [13].

One significant feature of these cooperation logics is that they have a close link with formal games: the semantic models underpinning Coalition Logic (which corresponds to the next-time fragment of ATL [8]) can be understood as extensive games of almost perfect information [13, p.34]. Further links between logics of strategic ability and formal games have been established elsewhere – for example, van der Hoek and colleagues showed how solution concepts such as Nash equilibrium can be axiomatized in a variant of ATL [16]. However, as a general formalism for reasoning about cooperative games, ATL-like cooperation logics have limitations: their modal structures are only intended to support reasoning about cooperative ability, and they provide no direct mechanism for capturing preferences, which are of course a critical component of all but the very simplest multi-agent scenarios.

Our aim in this paper is to develop a logic that is intended to directly and transparently support reasoning about coalitional games – and more precisely, coalitional games without transferable payoff [11, p.268]. We develop a *Coalitional Game Logic* (CGL). Syntactically, CGL appears quite similar to ATL and Coalition Logic, in that it contains modal cooperation expressions. However, it differs from these previous logics in several important respects. First, CGL includes operators that make it *directly* possible to represent an agent's preferences over outcomes. Second, we interpret formulae of CGL directly with respect to coalitional games without transferable payoff, thereby establishing an explicit link between formulae of the logic and properties of coalitional games. Third, we show that a coalitional game indeed cannot be seen as a model for coalition logic with outcomes of the game as states.

Following the presentation of the syntax and semantics of the

logic in the next section, we give a number of technical results relating to it, as follows. First, we prove that the logic is expressively complete with respect to coalitional games without transferable payoff, in the sense that for any two different coalitional games, there exists a formula of CGL that will be true in one game and false in the other. We then give an axiomatization of CGL, and show that it is complete. With respect to model checking and satisfiability, we show that while model checking for the logic is tractable, the satisfiability problem for CGL is NP-complete. We then compare the semantics of CGL and coalition logic. Finally, to illustrate the utility of the logic, we show how to axiomatically characterise a number of well-known solution concepts for coalitional games, including for example non-emptiness of the core.

2. A LOGIC FOR COALITIONAL GAMES

A *coalitional game* (without transferable payoff) is an $(m+3)$-tuple [11, p.268]:

$$\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle \text{ where:}$$

- $N = \{1, \ldots, m\}$ is a non-empty set of *agents*;
- $\Omega = \{\omega_1, \ldots, \omega_n\}$ is a non-empty set of *outcomes*;
- $V : (2^N \setminus \emptyset) \rightarrow 2^\Omega$ is the *characteristic function* of Γ, which for every non-empty coalition C defines the choices $V(C)$, such that if $\omega \in V(C)$ then C can choose outcome ω; and
- $\sqsupseteq_i \subseteq \Omega \times \Omega$ is a complete, reflexive, and transitive *preference relation*, for each agent $i \in N$.

The above definition also includes the additional assumption, used in this paper, that the set of outcomes is finite.

Readers familiar with ATL [1] or Coalition Logic [14] may be tempted to interpret V as an effectivity function and the outcomes Ω as states of the world. This is *not* the intended interpretation, and indeed, we show in Section 6 that there is no direct mapping between the coalition models of [14] and coalitional games by interpreting outcomes Ω as states and V as an effectivity function. For example, it is perfectly consistent in a coalitional game that, at the same time, disjoint coalitions have the abilities to choose *different* outcomes.

We now define a logic for representing the properties of such games. The language is in two parts. First, given a set of outcome symbols Σ_Ω, we have an *outcome language* $\mathcal{L}_o$, defined by the grammar φ_o, below, which expresses the properties of outcomes. The outcome symbols themselves are the main constructs of this language; a formula such as $\omega_1 \vee \omega_2$ (where $\omega_1, \omega_2 \in \Sigma_\Omega$) means that the outcome corresponds to either ω_1 or ω_2. Next, given a set of agent symbols Σ_N and a set of coalition symbols Σ_C, we have a *cooperation language* $\mathcal{L}_c$, for expressing the properties of coalitional cooperation, and the preferences that agents have over possible outcomes. This language is generated by the grammar φ_c below. $\mathcal{L}_c$ has two main constructs. First, $\omega_1 \succeq_i \omega_2$ (where $\omega_1, \omega_2 \in \Sigma_\Omega$, $i \in \Sigma_N$) expresses the fact that agent i either prefers outcome ω_1 over outcome ω_2, or is indifferent between the two. Second, $\langle C \rangle \varphi$ (where $C \in \Sigma_C$) says that C can choose an outcome in which the formula φ will be true. This construct may seem syntactically similar to counterparts in ATL and Coalition Logic, but it stands here for a fundamentally different concept due to the semantic differences mentioned above. Recall that we construct formulae with respect to a set $\Sigma = \Sigma_N \cup \Sigma_C \cup \Sigma_\Omega$ of symbols, where Σ_N is a set of symbols for agents, Σ_C is a set of symbols for coalitions and Σ_Ω is a set of symbols for outcomes. Formally, we have the following:

$$\begin{array}{lcl} \varphi_o & ::= & \sigma_\omega \mid \neg\varphi_o \mid \varphi_o \vee \varphi_o \\ \varphi_c & ::= & (\sigma_\omega \succeq_{\sigma_i} \sigma_{\omega'}) \mid \langle \sigma_C \rangle \varphi_o \mid \neg\varphi_c \mid \varphi_c \vee \varphi_c \end{array}$$

where $\sigma_i \in \Sigma_N$ is an agent symbol, $\sigma_C \in \Sigma_C$ is a coalition symbol, and $\sigma_\omega, \sigma_{\omega'} \in \Sigma_\Omega$ are outcome symbols.

We will usually exploit the direct correspondence between symbols for outcomes/agents and the outcomes/agents that appear in games. In this paper, we will henceforth assume a one-to-one correspondence between Σ_Ω and Ω, between Σ_N and N and between Σ_C and 2^N. So we assume that $\Sigma_\Omega = \{\sigma_\omega : \omega \in \Omega\}$, $\Sigma_N = \{\sigma_i : i \in N\}$ and $\Sigma_C = \{\sigma_C : C \subseteq N\}$. The languages are parameterised by the sets $\Sigma_\Omega, \Sigma_N, \Sigma_C$, i.e., as a consequence of the assumption, by some set N of agents and set Ω of outcomes. In the following, we assume that these two parameters — and thus the languages — are fixed.

An $\mathcal{L}_c$ formula γ is interpreted in a coalitional game Γ as follows, where $\Gamma \models \gamma$ means that γ is true in Γ. When we write $\Gamma \models \gamma$, it is implicitly assumed that the Γ corresponds to the parameters of the language in the way mentioned above, i.e., that the agents and outcomes in the model are exactly the sets used to parameterise our language. First, we define the satisfaction of a $\mathcal{L}_o$ formula α in an outcome ω of a game Γ, written $\Gamma, \omega \models \alpha$:

$$\Gamma, \omega \models \sigma_{\omega'} \text{ iff } \omega = \omega'$$

$$\Gamma, \omega \models \neg\varphi \text{ iff not } \Gamma, \omega \models \varphi$$

$$\Gamma, \omega \models \varphi \vee \psi \text{ iff } \Gamma, \omega \models \varphi \text{ or } \Gamma, \omega \models \psi$$

Satisfaction of γ in Γ is then defined as follows:

$$\Gamma \models (\sigma_{\omega_1} \succeq_{\sigma_i} \sigma_{\omega_2}) \text{ iff } (\omega_1 \sqsupseteq_i \omega_2)$$

$$\Gamma \models \langle \sigma_C \rangle \varphi \text{ iff } \exists \omega \in V(C) \text{ such that } \Gamma, \omega \models \varphi$$

$$\Gamma \models \neg\varphi \text{ iff not } \Gamma \models \varphi$$

$$\Gamma \models \varphi \vee \psi \text{ iff } \Gamma \models \varphi \text{ or } \Gamma \models \psi$$

To simplify the text that follows, we abuse notation somewhat, and write ω for both an outcome (a semantic construct) and the corresponding symbol σ_ω in the language (a syntactic construct). Similarly, we will write i instead of σ_i for agents in the language, and C instead of σ_C for coalitions. So, we will just write $\langle C \rangle \omega$ for $\langle \sigma_C \rangle \sigma_\omega$, although the reader should be aware of the distinction between our object language $\mathcal{L}_c$ and the objects that live in the semantics: outcomes, agents and their preferences, and coalitions.

We will use the usual derived propositional connectives; $\varphi \wedge \psi$ for $\neg(\neg\varphi \vee \neg\psi)$, $\varphi \rightarrow \psi$ for $\neg\varphi \vee \psi$ and $\varphi \leftrightarrow \psi$ for $(\varphi \rightarrow \psi) \wedge (\psi \rightarrow \varphi)$, as well as $\varphi \nabla \psi$ for $(\varphi \vee \psi) \wedge \neg(\varphi \wedge \psi)$ (exclusive or) and $[C]\varphi$ for $\neg\langle C \rangle \neg\varphi$. We also write $(\omega_1 \succ_i \omega_2)$ to abbreviate $((\omega_1 \succeq_i \omega_2) \wedge \neg(\omega_2 \succeq_i \omega_1)$ and $(\omega_1 =_i \omega_2))$ to abbreviate $((\omega_1 \succeq_i \omega_2) \wedge (\omega_2 \succeq_i \omega_1))$.

Note that $\langle C \rangle \top$ iff C can at least bring about something: $V(C) \neq \emptyset$. $[C]\varphi$ means $\neg\langle C \rangle \neg\varphi$, i.e., every choice of C must involve φ. As an example, suppose $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4\}$ and $V(C) = \{\omega_1, \omega_2\}$. Then:

$$\langle C \rangle \omega_1 \wedge \langle C \rangle (\omega_1 \vee \omega_3) \wedge \neg\langle C \rangle \omega_3 \wedge [C](\omega_1 \vee \omega_2) \wedge \neg[C](\omega_1 \vee \omega_3)$$

Note that if $\omega_1 \neq \omega_2$, then we can have $\langle C \rangle \omega_1 \wedge \langle C \rangle \omega_2$, but the formula $\langle C \rangle (\omega_1 \wedge \omega_2)$ can never be true.

A conjunction $\bigwedge_{\delta \in \emptyset} \varphi$ is, by convention, equal to $\top$, like $\bigvee_{\delta \in \emptyset} \varphi$ equals $\bot$, so that, indeed, we get $\Gamma \models [C]\bot$ iff $\Gamma \models \neg\langle C \rangle \top$ iff

$V(C) = \emptyset$. Let us, for any coalition C and set of outcome symbols Δ, suggestively write $\langle [C] \rangle \Delta$ for $\bigwedge_{\delta \in \Delta} \langle C \rangle \delta \wedge [C] \bigvee_{\delta \in \Delta} \delta$.[1] A formula of this form is said to *fully describe C's choices*. It is easy to see that we have the following. Let $\Delta \subseteq \Omega$.

$$\Gamma \models \langle [C] \rangle \Delta \quad \text{iff} \quad V(C) = \Delta$$

Exclusive disjunctions $\varphi \nabla \psi$ play an important role in our proofs. Note that the negation $\neg(\varphi \nabla \psi)$ is the same as $(\neg\varphi \wedge \neg\psi) \vee (\varphi \wedge \psi)$. Moreover, if Φ is a set of formulas, then we define $\nabla_{\varphi \in \Phi} \varphi$ to be true iff exactly one of the φ's is true. Formally: for any set $\Phi = \{\varphi_1, \ldots \varphi_k\}$,[2]

$$\nabla_{\varphi \in \Phi} \varphi \equiv (\bigvee_{i \leq k} \varphi_i \wedge \bigwedge_{j \neq i, j \leq k} \neg \varphi_j)$$

Note that $\Gamma \models [C](\omega_i \vee \omega_j) \leftrightarrow [C](\omega_i \nabla \omega_j)$ when $i \neq j$: using the definition of $[C]$ and contraposition this is the same as $\Gamma \models \langle C \rangle \neg(\omega_i \nabla \omega_j) \leftrightarrow \langle C \rangle \neg(\omega_i \vee \omega_j)$. Now, syntactically, $\langle C \rangle \neg(\omega_i \nabla \omega_j)$ is equivalent to $\langle C \rangle((\omega_i \wedge \omega_j) \vee \neg(\omega_i \vee \omega_j))$. But, inspecting the truth-definition of $\langle C \rangle$, this is again equivalent to $\langle C \rangle \neg(\omega_i \vee \omega_j)$ since the $\mathcal{L}_o$ formula $\omega_i \wedge \omega_j$ is never true.

So, which properties of a coalitional game can be expressed with our cooperation language? The answer, given by the following theorem, is "all".

THEOREM 1. *The logic* CGL *is expressively complete with respect to coalitional games. That is, for any two coalitional games Γ_1, Γ_2 such that $\Gamma_1 \neq \Gamma_2$, there exists a* CGL *formula ζ such that $\Gamma_1 \models \zeta$ and $\Gamma_2 \not\models \zeta$.*

PROOF. *Our proof is constructive. Given a game Γ, we define a formula ζ_Γ that* completely characterises Γ. *ζ_Γ is constructed from two conjuncts, Π_Γ, which characterises the preference relations of Γ, and Ξ_Γ, which characterises the cooperative properties of Γ. Let $\mathcal{C} = 2^N \setminus \emptyset$ collect all non-empty coalitions from N.*

$$\begin{aligned}
\zeta_\Gamma &\equiv \Pi_\Gamma \wedge \Xi_\Gamma \\
\Pi_\Gamma &\equiv \bigwedge_{i \in N} (\bigwedge_{\substack{\omega, \omega' \in \Omega \\ \omega \sqsupseteq_i \omega'}} (\omega \succeq_i \omega') \wedge \bigwedge_{\substack{\omega, \omega' \in \Omega \\ \omega \not\sqsupseteq_i \omega'}} \neg(\omega \succeq_i \omega')) \\
\Xi_\Gamma &\equiv \Big(\bigwedge_{C \in \mathcal{C}} (\bigwedge_{\omega \in V(C)} \langle C \rangle \omega) \wedge [C](\bigvee_{\omega \in V(C)} \omega)\Big)
\end{aligned}$$

By construction, for any Γ_1, we have $\Gamma_1 \models \zeta_{\Gamma_1}$. Moreover, for any coalitional game $\Gamma_2 \neq \Gamma_1$, we have that $\Gamma_2 \not\models \zeta_{\Gamma_1}$. □

From now on, $\mathcal{C}$ is the set of non-empty coalitions. Given a formula φ, then: let $coal(\varphi)$ denote the set of coalitions named in φ; let $ag(\varphi)$ denote the set of agents named in cooperation expressions in φ; and let $out(\varphi)$ be the set of outcomes named in φ.

3. AXIOMS AND COMPLETENESS

We now present an axiomatic system for the language $\mathcal{L}_c$, and prove its soundness and completeness with respect to the class of all coalitional games without transferable payoff.

Table 1 summarizes the axioms and rules of our logic CGL. Formally, CGL is the set of all $\mathcal{L}_c$-formulas derivable under $\vdash$. In the axioms, $\vdash_c$ denotes derivability of classical logic, and $\varphi_o \in \mathcal{L}_o, \varphi, \psi \in \mathcal{L}_c$. The axiom *Taut* and rule *MP* guarantee that we extend classical logic. On top of that, the axiom K and rule *Nec* determine $[C]$ to be a normal necessity operator. Then, *Lin*, *Ref*, and *Trans* determine the preference of each i to be linear, reflexive and transitive, respectively. The only specific cooperation axiom, *Func*, says that whatever a coalition in the end will chose, it must be a unique alternative from Ω.

Taut	$\vdash \varphi$ φ an instance of a propositional tautology
Lin	$\vdash (\omega_1 \succeq_i \omega_2) \vee (\omega_2 \succeq_i \omega_1)$
Ref	$\vdash (\omega \succeq_i \omega)$
Trans	$\vdash (\omega_1 \succeq_i \omega_2) \wedge (\omega_2 \succeq_i \omega_3) \rightarrow (\omega_1 \succeq_i \omega_3)$
K	$\vdash [C](\varphi \rightarrow \psi) \rightarrow (([C]\varphi) \rightarrow ([C]\psi))$
Func	$\vdash [C](\nabla_{\omega \in \Omega} \omega)$
Nec	$\vdash_c \varphi_o \Rightarrow \vdash [C]\varphi_o$
MP	$\vdash \varphi, \vdash \varphi \rightarrow \psi \Rightarrow \vdash \psi$

Table 1: The logic CGL**.**

The following lemma tells us that in the scope of modal operators, disjunctions over *different* outcomes behave the same as exclusive disjunctions over outcomes. Note that this is in general not true for arbitrary disjunctions: $\langle C \rangle(\omega_1 \vee \omega_1)$ is not the same as $\langle C \rangle(\omega_1 \nabla \omega_1)$, the latter is equivalent to $\langle C \rangle \bot$.

LEMMA 1. *Let $\emptyset \neq C \subseteq N$ and $\Delta \subseteq \Omega$.*

1. *The following are equivalent, in* CGL*: $(i) \langle C \rangle \top$, $(ii) \langle C \rangle \bigvee_{\omega \in \Omega} \omega$, *and* $(iii) \langle C \rangle \nabla_{\omega \in \Omega} \omega$*
2. *In the scope of $\langle C \rangle$ and $[C]$ when exchanging arbitrary occurrences of $\nabla_{\omega \in \Delta} \omega$ with that of $\bigvee_{\omega \in \Delta} \omega$ in a formula φ, the result is equivalent to φ.*
3. $\vdash \bigwedge_{\omega \in \Delta} \neg \langle C \rangle \omega \rightarrow (\langle C \rangle \top \rightarrow \bigvee_{\omega \in \Omega \setminus \Delta} \langle C \rangle \omega)$
4. $\vdash (\bigwedge_{\delta \in \Delta} \neg \langle C \rangle \delta) \leftrightarrow [C] \bigvee_{\delta' \in \Omega \setminus \Delta} \delta'$

PROOF.

1. Since $\nabla_{\omega \in \Omega} \omega \Rightarrow \bigvee_{\omega \in \Omega} \omega \Rightarrow \top$, and the $\langle C \rangle$ is a normal diamond operator, we have $(iii) \Rightarrow (ii) \Rightarrow (i)$. By *Func*, we have $(i) \Rightarrow (iii)$.
2. With induction over φ. The only interesting case $\varphi = \langle C \rangle \psi$ follows from the previous item.
3. From axiom *Func* follows $\vdash \langle C \rangle \top \rightarrow \langle C \rangle \nabla_{\omega \in \Omega} \omega$. By item 1, we have $\vdash \langle C \rangle \top \rightarrow \langle C \rangle \bigvee_{\omega \in \Omega} \omega$. Since $\langle C \rangle$ is a normal diamond, we have $\vdash \langle C \rangle \top \rightarrow \bigvee_{\omega \in \Omega} \langle C \rangle \omega$. Applying *Taut* to this gives the desired property.
4. Follows directly from *Func* and some modal reasoning.

□

LEMMA 2.

1. *Let $C \neq \emptyset$ be a coalition. Then* $\vdash \bigvee_{\Delta \subseteq \Omega} \langle [C] \rangle \Delta$
2. *Let $C \neq \emptyset$ be a coalition. Then* $\vdash \nabla_{\Delta \subseteq \Omega} \langle [C] \rangle \Delta$
3. $\vdash \bigwedge_{C \in \mathcal{C}} \bigvee_{\Delta \subseteq \Omega} \langle [C] \rangle \Delta$
4. $\vdash \bigwedge_{C \in \mathcal{C}} \bigtriangleup_{\Delta \subseteq \Omega} \langle [C] \rangle \Delta$
5. $\vdash \bigvee_{\Delta_C \subseteq \Omega, C \in \mathcal{C}} \bigwedge_{C \in \mathcal{C}} \langle [C] \rangle \Delta_C$

PROOF.

[1] Note that the $\langle [C] \rangle$ modality plays the same role wrt. $[C]$ as Levesque's [9] *only knowing* operator plays wrt. the traditional belief operator.

[2] Note that $\nabla_{p,q,r}$ is not the same as $p \nabla (q \nabla r)$!

1. Note that $\langle C\rangle\omega$ is just an atom in the coalitional language. Let $M = \{1, \ldots, n\}$. Then, even by propositional reasoning, $\vdash \bigvee_{I\cup J=M, I\cap J=\emptyset}(\bigwedge_{i\in I}\langle C\rangle\omega_i \wedge \bigwedge_{j\in J}\neg\langle C\rangle\omega_j)$. Now, take a fixed I and J with $I \cap J = \emptyset$ and $I \cup J = M$. If $I = \emptyset$, then $\bigwedge_{i\in I}\langle C\rangle\omega_i \wedge \bigwedge_{j\in J}\neg\langle C\rangle\omega_j$ equals $\bigwedge_{\omega\in\Omega}\neg\langle C\rangle\omega$, which is equivalent to $\langle[C]\rangle\emptyset$. With Lemma 1 item 4, we have, for fixed I and J, each disjunct in this is equivalent to $\langle[C]\rangle\Delta_I$, with $\Delta_I = \{\omega_i \mid i \in I\}$.
2. Note that, using the notation of the previous item, we even have $\vdash \bigwedge_{I\cup J=M, I\cap J=\emptyset}(\bigwedge_{i\in I}\langle C\rangle\omega_i \wedge \bigwedge_{j\in J}\neg\langle C\rangle\omega_j)$. From this the statement follows directly.
3. This is immediate from item 1: if for an arbitrary C we have $\vdash \langle[C]\rangle\varphi_C$, then also $\vdash \bigwedge_{C\subseteq Z}\langle[C]\rangle\varphi_C$, for any $Z \in \mathcal{C}$.
4. Follows from item 2 in the same way as 3 follows from 1.
5. This follows immediately from item 1 and propositional reasoning: note that for every two coalitions C_1 and C_2 we derive $\vdash \bigvee_{\Delta_1\subseteq\Omega}\langle[C_1]\rangle\Delta_1 \wedge \bigvee_{\Delta_2\subseteq\Omega}\langle[C_2]\rangle\Delta_2$, and use $(p \vee q) \wedge r \equiv (p \wedge r) \vee (q \wedge r)$.

□

DEFINITION 1.

1. *For any agent i, we say that a formula is a preference literal for i if it is either $\omega \succeq_i \omega'$ or $\neg(\omega \succeq_i \omega')$, for some ω and ω'. We say that π_i fully describes i's preferences, if*

$$\pi_i \text{ is of the form } \bigwedge_{\omega,\omega'\in\Omega}(\neg)(\omega \succeq_i \omega')$$

We then say that $\pi \in PossPref(i)$.
2. *Given that we have m agents, a conjunction $\Pi = (\pi_1 \wedge \cdots \wedge \pi_m)$, (where each π_i fully describes i's preferences) is said to fully describe the preferences of all the agents. Similarly for coalitions.*
3. *Recall that $\langle[C]\rangle\Delta$, where C is a coalition and Δ is a set of (atoms for) outcomes $\omega_1, \ldots, \omega_u$, is said to fully describe C's choices. Now let $\mathcal{C} = 2^N \setminus \emptyset$, and let, for each $C \in \mathcal{C}$, Δ_C be a set of outcomes. Then $\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C$ is said to fully describe all of N's choices. (Similarly for subsets of N.) We often will denote such a full description Ξ.*

LEMMA 3.

1. *Let $\Pi_1, \Pi_2, \ldots, \Pi_d$ be all full descriptions of N's preferences. Then: $\vdash \bigvee_{k\leq d}\Pi_k$*
2. *Let $\Pi_1, \Pi_2, \ldots, \Pi_d$ be all full descriptions of N's preferences. Moreover, let $\mathcal{C} = 2^N \setminus \emptyset$ and let*

$$(\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C)_1, \ldots, (\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C)_z$$

enumerate all possible full descriptions of all choices of all coalitions (note that $z = (2^n)^m$). Then:

$$\vdash \bigvee_{k\leq d, t\leq z}(\Pi_k \wedge \bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C)_t$$

THEOREM 2. *Let φ be a formula of the cooperation language.*

1. *Let N be the set of agents, Ω the set of outcomes, and let $\mathcal{C} = 2^N \setminus \emptyset$. Then φ is equivalent to a formula of the form*

$$\bigvee_{k\in K, t\in T}(\Pi_k \wedge (\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C)_t)$$

where each $\Pi_k = (\pi_1 \wedge \cdots \wedge \pi_m)$ fully describes N's preferences, i.e., each π_i fully describes i's preferences, and each $(\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C)_t$ describes fully what N can choose.

2. *The same holds if we take $\Omega = out(\varphi), N = ag(\varphi)$ and we let C range over all $coal(\varphi)$.*

Complex as it may appear, our normal form is nothing more than an enumeration of possible full preferences combined with full descriptions of choices. The range of these possibilities is determined by the index sets K and T, which act as a kind of constraints: the smaller those index sets, the smaller the possible models for the formula. As a reading guide, note that

$$\bigvee_{k\in\{1,2\}, t\in\{a,b\}}(A_k \wedge B_t)$$

equals $(A_1 \wedge B_a) \vee (A_1 \wedge B_b) \vee (A_2 \wedge B_a) \vee (A_2 \wedge B_b)$.

PROOF. Note that the theorem is semantically obvious, the point is that we should be able to *syntactically prove* it from the sole axioms. This is done by induction over φ.

If $\varphi = \omega_1 \succeq_k \omega_2$. Let us say that a π_k is k-compatible with $(\omega_1 \succeq_k \omega_2)$ if the latter occurs as a conjunct in π_k. We then write $(\omega_1 \succeq_k \omega_2) \in \pi_k$ Then, φ is (in propositional logic) equivalent to

$$\bigvee_{\pi_i\in PossPref(i)(i\neq k), (\omega_1\succeq_k\omega_2)\in\pi_k}(\pi_1 \wedge \cdots \wedge \pi_k \wedge \cdots \wedge \pi_m)$$

This if of the form $\bigvee_{k\in K}\Pi_k$. Since by Lemma 2, item 5 we have that $\top$ is equivalent to $\bigvee_{\Delta_C\subseteq\Omega, C\in\mathcal{C}}\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C$ we see that φ is equivalent to

$$\bigvee_{k\in K}\Pi_k \wedge \bigvee_{\Delta_C\subseteq\Omega, C\in\mathcal{C}}\bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C$$

which, by propositional reasoning, is equivalent to

$$\bigvee_{k\in K, \Delta_C\subseteq\Omega, C\in\mathcal{C}}\Pi_k \wedge \bigwedge_{C\in\mathcal{C}}\langle[C]\rangle\Delta_C$$

Suppose $\varphi = \langle E\rangle\varphi_0$. Formula φ_0 regards outcomes, and is equivalent to a disjunction $\bigvee\alpha$ where each α is of the form

$$\alpha = ((\neg)\omega_1 \wedge (\neg)\omega_2 \wedge \cdots \wedge (\neg)\omega_n)$$

Using rule Nec and axiom K, we derive $\vdash \langle E\rangle\varphi_0 \leftrightarrow \langle E\rangle\bigvee\alpha$. Using that $\langle\cdot\rangle$ is a diamond, we then obtain that $\vdash \langle E\rangle\varphi_0 \leftrightarrow \bigvee\langle E\rangle\alpha$. Now we use axiom $Func$ to get rid of every α that contains more than one positive literal ω_i: let β range over all the those α's with at most one positive literal. Then $\vdash \langle E\rangle\varphi_0 \leftrightarrow \bigvee\langle E\rangle\beta$. Now, again in propositional logic, note that every disjunction $\bigvee_{i\in M}\psi_i$ is equivalent to

$$\bigvee_{I\cup J=M, I\cap J=\emptyset}(\bigwedge_{i\in I}\psi_i \wedge \bigwedge_{j\in J}\neg\psi_j).$$

In our case, letting the β's range over $\beta_1, \ldots, \beta_M$,

$$\vdash \langle E\rangle\varphi_0 \leftrightarrow \bigvee_{I\cup J=M, I\cap J=\emptyset}(\bigwedge_{i\in I}\langle E\rangle\beta_i \wedge \bigwedge_{j\in J}\neg\langle E\rangle\beta_j)$$

But, for every fixed $I, J \subseteq M$, $(\bigwedge_{i\in I}\langle E\rangle\beta_i \wedge \bigwedge_{j\in J}\neg\langle E\rangle\beta_j)$ is equivalent to $\langle[E]\rangle\Delta_I$, with $\Delta_I = \{\omega_i \mid i \in I\}$. Hence, we find that $\vdash \langle E\rangle\varphi_0 \leftrightarrow \bigvee_{I\subseteq M}\langle[E]\rangle\Delta_I$. This only limits the abilities of C, and not those of the others: using Lemma 2 item 5 once again:

$$\bigvee_{I\subseteq M}\langle[E]\rangle\Delta_I \leftrightarrow \bigvee_{I\subseteq M, D\neq E, \Delta_D\subseteq\Omega}\langle[E]\rangle\Delta_I \wedge \bigwedge_{D\in\mathcal{C}}\langle[D]\rangle\Delta_D$$

of which the r.h.s. is of the form $\bigvee_{C\in\mathcal{C}, t\in T}(\langle[C]\rangle\Delta_C)_t$, for some index set T. Since $\top$ is provably equivalent with $\bigvee_{k\in K}\Pi_k$ (where now K gives all possible full preference descriptions), the result follows.

Suppose φ is of the form $\varphi_1 \vee \varphi_2$. We can assume that $\varphi_i \equiv \bigvee_{k_i \in K_i, t_i \in T_i}(\Pi_{k_i} \wedge \Xi_{t_i})$, then

$$\varphi \equiv \bigvee_{k \in K_1 \cup K_2, t \in T_1 \cup T_2} (\Pi_k \wedge \Xi_t)$$

which is of the required form.

Let $\varphi = \neg\varphi_1$. Then $\varphi_1 = \bigvee_{k \in K, t \in T}(\Pi_k \wedge \Xi_t)$, for some index sets K and T. From Lemma 3, item 2, we know that $\vdash \bigvee_{k \leq d, t \leq z}(\Pi_k \wedge \Xi_t)$. In words: we know that a big disjunction is valid, but also that φ excludes some of them. Then, using propositional reasoning again, we obtain:

$$\varphi \equiv \bigvee_{k \leq d, k \notin K, t \leq z, t \notin T} (\Pi_k \wedge \Xi_t)$$

□

THEOREM 3 (COMPLETENESS). *We have, for all $\varphi \in \mathcal{L}_c$ over N and Ω: $\models \varphi \Rightarrow \vdash \varphi$*

PROOF. Suppose $\nvdash \varphi$, i.e., $\neg\varphi$ is consistent. We know that

$$\vdash \neg\varphi \leftrightarrow \bigvee_{k \in K, t \in T} (\Pi_k \wedge (\bigwedge_{C \in \mathcal{C}} \langle [C] \rangle \Delta_C)_t)$$

for some index sets K and T. Call the righthandside of this equivalence φ'. Let X be a maximal consistent set around φ'. By virtue of maximal consistent sets, we know that for some k and t, $\varphi'' = (\Pi_k \wedge (\bigwedge_{C \in \mathcal{C}} \langle [C] \rangle \Delta_C)_t) \in X$. But now we can read off the game $\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$ from φ'' immediately:

1. N and Ω are already given;
2. Let $V(C) = \Delta$, where $\langle [C] \rangle \Delta$ is part of φ'
3. every $\sqsupseteq_i$ relation is immediately read off from the component π_i for Π_k in φ''.

Now, it is easy to see, for every subformula ψ of φ'':

$$\Gamma \models \psi \Leftrightarrow \psi \in X$$

□

4. MODEL CHECKING & SATISFIABILITY

It is trivial to see that the *model checking problem* for CGL (i.e., the problem of determining, for any given Γ and φ, whether or not $\Gamma \models \varphi$ [4]) may be solved in deterministic polynomial time: an obvious recursive algorithm for this problem can be directly extracted from the semantic rules of the language.

The *satisfiability problem* is the problem of checking whether or not, for any given φ there exists a game Γ such that $\Gamma \models \varphi$. For most modal logics, the corresponding satisfiability problem has a trivial NP-hard lower bound, since such logics subsume propositional logic, for which satisfiability is the defining NP-complete problem [3, p.374]. However, our logic is specialised for reasoning about coalitional games, and it is not so obvious that it subsumes propositional logic, since we do not have primitive propositions. We must therefore prove NP-hardness from first principles.

For the proof, we need a few additional constructions. A *partial coalitional game* is a structure $\langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$ where all the components are as in regular coalitional games, except that V is a *partial* function, i.e., it is not required to be defined for every possible coalition. Given a partial game $\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$, we can use the semantic rules for CGL to interpret some formulae (although because V is not defined for all coalitions, we cannot necessarily interpret all formulae over N, Ω). Where Γ is a partial game and φ is a formula, let us write $\Gamma \models_p \varphi$ to mean that (i) it is possible to evaluate φ with respect to Γ, and (ii) φ is true under this evaluation. Now, we can prove the following.

LEMMA 4. *A CGL formula φ is satisfiable iff there exists a partial game $\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$ such that:*

1. *$N = ag(\varphi)$,*
2. *$|\Omega| = |out(\varphi)| + 1$ and $out(\varphi) \subseteq \Omega$;*
3. *dom $V = coal(\varphi)$, and*
4. *$\Gamma \models_p \varphi$.*

PROOF. *The right-to-left direction is obvious, so consider the left-to-right direction, and let $\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$ be a game such that $\Gamma \models \varphi$. Let $A = \Omega \setminus out(\varphi)$, i.e., A is the set of outcomes in Γ not named in φ. Let ω^* be an outcome such that $\omega^* \notin \Omega$, and define a partial game $\Gamma^* = \langle N^*, \Omega^*, V^*, \sqsupseteq_1^* , \ldots, \sqsupseteq_o^* \rangle$ as follows:*

- *$N^* = ag(\varphi)$;*
- *$\Omega^* = out(\varphi) \cup \{\omega^*\}$;*
- *The relation $\sqsupseteq_i^*$ is obtained by first restricting $\sqsupseteq_i$ to $out(\varphi)$, and then defining $\omega^* \sqsupseteq_i \omega$ for all $\omega \in out(\varphi)$;*
- *V^* is the partial function such that V^* is only defined for coalitions named in φ (i.e., $C \in$ dom V^* iff $C \in coal(\varphi)$);*
- *$V^*(C) = \begin{cases} V(C) & \text{if } V(C) \subseteq out(\varphi) \\ (V(C) \setminus A) \cup \{\omega^*\} & \text{otherwise.} \end{cases}$*

Notice that Γ^* satisfies conditions (1)–(3) of the lemma. We now prove that Γ^* satisfies condition (4). More precisely, we show that for all sub-formulae ψ of φ: $\Gamma \models \psi$ iff $\Gamma^* \models \psi$. The inductive base is where $\varphi = (\omega_1 \succeq_i \omega_2)$, and is obvious, since $i \in ag(\varphi)$ and $\{\omega_1, \omega_2\} \subseteq out(\varphi)$, and hence $\omega_1 \sqsupseteq_i^* \omega_2$ iff $\omega_1 \sqsupseteq_i \omega_2$.

For the inductive assumption, assume the result is proved for all sub-formulae; in the inductive step, the significant case is where $\varphi = \langle C \rangle \psi$. If $\Gamma \models \langle C \rangle \psi$ then $\exists \omega \in V(C)$ such that $\Gamma, \omega \models \psi$. There are two possibilities: either $\omega \in out(\varphi)$ (in which case $V^*(C) = V(C)$, and the result is obvious), or else $\omega \notin out(\varphi)$. In the latter case, $V^*(C) = (V(C) \setminus A) \cup \{\omega^*\}$; we claim that $\Gamma^*, \omega^* \models \psi$. To see this, assume w.l.o.g. that ψ is in Conjunctive Normal Form. Now, since $\omega \notin out(\varphi)$, then no positive literals can be satisfied by Γ, ω: only negative literals. But such literals must also be satisfied by Γ^*, ω^*, and so $\Gamma^*, \omega^* \models \psi$.

The case for $\Gamma \not\models \langle C \rangle \psi$ implies $\Gamma^* \not\models \langle C \rangle \psi$ is similar. □

Given this, we can prove:

THEOREM 4. *The satisfiability problem for CGL formulae is NP-complete, even for CGL formulae φ such that $|ag(\varphi)| = 1$.*

PROOF. For membership of NP, we know that φ is satisfiable iff it has a "certificate" for this in the form of a partial game Γ as in Lemma 4. This partial game is of size linear in the size of the formula φ. Since we can check whether $\Gamma \models_p \varphi$ in polynomial time, we conclude that CGL satisfiability is in NP.

For NP-hardness, we reduce SAT, the problem of determining whether a formula $\varphi(x_1, \ldots, x_k)$ of propositional logic, over Boolean variables $x_1, \ldots, x_k$, has a satisfying assignment [12]. The basic idea is to map variables x_i to outcomes ω_i, to introduce an additional outcome $\omega_\perp$ to correspond to the truth value "false", so that $(\omega_x \succ_1 \omega_\perp)$ will mean "x takes the value 'true' ". Formally, let $\varphi^\#$ denote the CGL formula obtained from the propositional logic formula φ by systematically replacing every Boolean variable p by the corresponding CGL expression $(\omega_p \succ_1 \omega_\perp)$. Now, we claim that $\varphi^\#$ is CGL satisfiable iff the input SAT instance φ is a satisfiable formula of propositional logic.

For the $\Rightarrow$ direction, assume $\varphi^\#$ is CGL satisfiable, and consider the associated preference relation $\sqsupseteq_1$ in any Γ such that $\Gamma \models \varphi$. From this relation, extract a valuation ξ for the variables $x_1, \ldots, x_k$

as follows: each variable x_i is true under ξ if $\omega_{x_i} \sqsupset_1 \omega_\perp$, and false otherwise. The interpretation ξ is consistent, since we cannot have both $\omega_{x_i} \sqsupset_1 \omega_\perp$ and $\omega_\perp \sqsupset_1 \omega_{x_i}$. The interpretation ξ satisfies φ by a trivial induction on the structure of φ.

For $\Leftarrow$, assume φ is a satisfiable formula of propositional logic, and let ξ be a valuation that satisfies φ. Then we can reconstruct a game Γ_ξ such that $\Gamma_\xi \models \varphi^\#$, as follows. Γ_ξ contains a single agent, (agent 1), and an outcome ω_{x_i} for each variable x_i appearing in φ. We also define an additional outcome $\omega_\perp$. The preference relation $\sqsupseteq_i$ is then defined as follows:

- For each Boolean variable p such that p is true under ξ, define $\omega_p \sqsupset_i \omega_\perp$.
- For each pair of Boolean variables p_1, p_2 such that p_1 and p_2 are both true or both false under ξ, define $\omega_{p_1} =_i \omega_{p_2}$.
- For each Boolean variable p such that p is false under ξ, define $\omega_\perp \sqsupseteq_i \omega_p$.
- For each pair of Boolean variables p_1, p_2 such that p_1 is true (respectively, false) and p_2 is false (respectively, true) under ξ, define $\omega_{p_1} \sqsupset_i \omega_{p_2}$ (respectively, $\omega_{p_2} \sqsupset_i \omega_{p_1}$).

An induction on $\varphi^\#$ proves that $\Gamma_\xi \models \varphi^\#$. $\square$

5. CHARACTERISING COALITIONAL GAMES

We characterise three solution concepts from the theory of coalitional games, viz. *the core* [7], *stable sets* [10] and *the bargaining set* [2], in CGL. We use the formulations of these solution concepts in [11]; there the two latter solution concepts are however defined only for games with real numbered payoffs and transferable utility and below we translate the definitions to the more general games with preference relations over general outcomes and non-transferable utility.

Henceforth, a *C-feasible outcome* is an outcome which can be chosen by the coalition C and a *feasible outcome* is a N-feasible outcome where N is the set of players in the game. We start by looking at the core, which is a, possibly empty, set of outcomes.

DEFINITION 2 (CORE). *The core of a coalitional game is the feasible outcomes ω for which there is no coalition C with a C-feasible outcome ω' such that $\omega' \succ_i \omega$ for all $i \in C$.*

We write $CM(\omega)$ to mean that ω is in the core.

$$CM(\omega) \equiv \langle N \rangle \omega \wedge \neg \left[\bigvee_{C \subseteq N} \bigvee_{\omega' \in \Omega} (\langle C \rangle \omega') \wedge \bigwedge_{i \in C} (\omega' \succ_i \omega) \right]$$

CNE will then mean that the core is non-empty:

$$CNE \equiv \bigvee_{\omega \in \Omega} CM(\omega)$$

THEOREM 5. *The core of Γ is non-empty iff $\Gamma \models CNE$.*

A *stable set* is a set of outcomes. A coalitional game may have several stable sets, but must not necessarily have any. We characterize stable sets in terms of *imputations* and *objections*. An imputation is a feasible outcome that for each agent i is as least as good as any outcome the singleton coalition $\{i\}$ can choose on his own. The CGL formula $IMP(\omega)$ is true whenever ω is an imputation:

$$IMP(\omega) \equiv \langle N \rangle \omega \wedge \bigwedge_{\omega' \in \Omega} \bigwedge_{i \in N} (\langle \{i\} \rangle \omega' \rightarrow \omega \succeq_i \omega')$$

An imputation ω is a C-objection to an imputation ω' if every agent in C prefers ω over ω' and the coalition C can choose an outcome which for every agent in C is as least as good as ω. ω is an objection to ω' if ω is a C-objection to ω' for some coalition C. Next, $OBJ(\omega, \omega', C)$ expresses that outcome ω is an C-objection to outcome ω', when both ω and ω' are imputations:

$$OBJ(\omega, \omega', C) \equiv (\bigwedge_{i \in C} \omega \succ_i \omega') \wedge \bigvee_{\omega'' \in \Omega} (\langle C \rangle \omega'' \wedge \bigwedge_{i \in C} \omega'' \succeq_i \omega)$$

DEFINITION 3 (STABLE SET). *A set of imputations Y is a stable set if it satisfies:*

Internal stability *If $\omega \in Y$, there is no objection to ω in Y.*

External stability *If $\omega \notin Y$, there is an objection to ω in Y.*

Given a set of outcomes $Y \subseteq \Omega$, the CGL formula $STABLE(Y)$ expresses the fact that Y is a stable set:

$$\begin{array}{l} STABLE(Y) \equiv \\ \quad \bigwedge_{\omega \in Y} IMP(\omega) \\ \quad \wedge \Big(\bigwedge_{\omega \in Y} \bigwedge_{C \subseteq N} \bigwedge_{\omega' \in Y} \neg OBJ(\omega', \omega, C) \Big) \\ \quad \wedge \Big(\bigwedge_{\omega \in \Omega \setminus Y} IMP(\omega) \rightarrow \Big(\bigvee_{C \subseteq N} \bigvee_{\omega' \in Y} OBJ(\omega', \omega, C) \Big) \Big) \end{array}$$

THEOREM 6. *Y is a stable set of Γ iff $\Gamma \models STABLE(Y)$.*

PROOF. Given a coalitional game, let $\mathcal{I}$ denote the set of all imputations. First, we argue that $IMP(\omega)$ and $OBJ(\omega, \omega', C)$ have the correct meaning. Every $\omega \in Y$ is an imputation iff $\omega \in V(N)$ (feasibility) and $\omega \succeq_i \omega'$ for all i and $\omega' \in V(\{i\})$ which is exactly when $IMP(\omega)$ holds. If $\omega, \omega' \in \mathcal{I}$ and $C \subseteq N$, ω is a C-objection to ω' iff $\omega \succ_i \omega'$ for every $i \in C$ and there is a $\omega'' \in V(C)$ such that $\omega'' \succeq_i \omega$ for every $i \in C$, which is exactly when $OBJ(\omega, \omega', C)$ holds.

For the main proof, let $Y \subseteq \Omega$. If there is an ω in Y which is not an imputation, Y is not a stable set and $IMP(\omega)$ is not true and we are done, so assume that Y is a set of imputations. Let

$$\hat{Y} = \{\omega \in \mathcal{I} : \text{ there is no objection to } \omega \text{ in } Y\}$$

It is easy to see that if Y is a stable set iff $Y = \hat{Y}$. We argue that the second and third main conjuncts of the formula $STABLE(Y)$ is true whenever $Y \subseteq \hat{Y}$ and $\hat{Y} \subseteq Y$ hold, respectively, and the theorem follows (the first conjunct is true under the assumption that Y are imputations). The second conjunct is true exactly when for every member of Y there is no C-objection to ω in Y for any C, which is exactly when $Y \subseteq \hat{Y}$ holds. The third conjunct is true iff every imputation which is not in Y has an objection in Y or, contrapositively, that every imputation which does not have an objection in Y is included in Y which is the same as $\hat{Y} \subseteq Y$. $\square$

Existence of a stable set can then be expressed as:

$$ES \equiv \bigvee_{Y \subseteq \Omega} STABLE(Y)$$

COROLLARY 1. *Γ has a stable set iff $\Gamma \models ES$.*

Finally, we focus on the notion of a bargaining set of a coalitional game which is, like a stable set, a set of imputations, but, unlike a stable set, is unique and always exists. The bargaining set of a game can be defined in terms of *objections* and *counterobjections*, but the former concept is not the same as in the definition of stable sets. Let ω be an imputation:

Objection: A pair consisting of a coalition C and a C-feasible

outcome ω' is an objection of an agent $i \in C$ against an agent $j \notin C$ to ω if every agent in C prefers ω' over ω.

Counterobjection: A pair consisting of a coalition D and a D-feasible outcome v is a counterobjection to an objection (ω', C) of i against j to ω, if D includes j but not i, every agent in $D \setminus C$ thinks v is as least as good as ω and every agent in $D \cap C$ thinks v is as least as good as ω'.

The CGL formula $OBJB(\omega', C, \omega)$ means that (ω', C) is an objection of any $i \in C$ against any $j \notin C$ to ω.

$$OBJB(\omega', C, \omega) \equiv \langle C \rangle \omega' \wedge \bigwedge_{k \in C} \omega' \succ_k \omega$$

$ECO(\omega', C, i, j, \omega)$ means that there exists a counterobjection to the objection (ω', C) of i against j to ω.

$$ECO(\omega', C, i, j, \omega) \equiv \bigvee_{v \in \Omega} \bigvee_{D' \subseteq N \setminus \{i\}} (\langle D' \cup \{j\} \rangle v \wedge (\Big(\bigwedge_{k \in (D' \cup \{j\}) \setminus C} v \succeq_k \omega\Big) \wedge \Big(\bigwedge_{k \in (D' \cup \{j\}) \cap C} v \succeq_k \omega'\Big)))$$

DEFINITION 4 (BARGAINING SET). *The bargaining set of a coalitional game is the set of all imputations ω such that there exists a counterobjection to every objection of any player i against any player j to ω.*

$INBARG(\omega)$ means that outcome $\omega \in \Omega$ is in the bargaining set:

$$INBARG(\omega) \equiv IMP(\omega) \wedge \bigwedge_{C \subseteq N} \bigwedge_{i \in C} \bigwedge_{j \in N \setminus C} \bigwedge_{\omega' \in \Omega} [OBJB(\omega', C, \omega) \rightarrow ECO(\omega', C, i, j, \omega)]$$

THEOREM 7. *ω is a member of the bargaining set of Γ iff $\Gamma \models INBARG(\omega)$.*

PROOF. It is easy to see that when ω is an imputation, C is a coalition, $i \in C, j \notin C$ and ω' an outcome, $\Gamma \models OBJB(\omega', C, \omega)$ iff (ω', C) is an objection of i against j to ω. To see that there exist a counterobjection to the objection (ω', C) of i against j to ω iff $\Gamma \models ECO(\omega', C, i, j, \omega)$, observe that (v, D) is a counterobjection iff the disjunct given by v and $D' = D \setminus \{j\}$ is true. The theorem follows immediately. □

We can now define $BS(Y)$, $Y \subseteq \Omega$, to express the fact that Y is the bargaining set.

$$BS(Y) = \bigwedge_{\omega \in Y} INBARG(\omega) \wedge \bigwedge_{\omega \in \Omega \setminus Y} \neg INBARG(\omega)$$

COROLLARY 2. *Y is the bargaining set of Γ iff $\Gamma \models BS(Y)$*

COROLLARY 3. *$\neg BS(\emptyset)$ is a theorem of* CGL.

PROOF. For any coalitional game without transferable payoff Γ, the bargaining set is non-empty [6, 15]. By Corollary 2, $\Gamma \models \neg BS(\emptyset)$ for any Γ, and by Theorem 3 $\vdash \neg BS(\emptyset)$. □

6. RELATION TO COALITION LOGIC

As we noted in section 2, it is rather tempting to believe that the outcomes of coalitional games can be interpreted as states, and that the characteristic function can be interpreted as an effectivity function, and that as a consequence Coalition Logic (CL) [14] could be interpreted directly in coalitional games. In this section, we compare the semantics of CL and CGL, and show that in fact there is a fundamental difference between the two approaches.

We first give a very brief review of some of the concepts of CL. A *coalition model* for agents N over a set of atomic propositions Φ_0 is a triple $M = (S, E, \pi)$, where S is a nonempty set of states, $\pi : \Phi_0 \rightarrow 2^S$ an assignment and E gives a function of type $2^N \rightarrow 2^{2^S}$ for each state $s \in S$. It is required that each $E(s)$ is a *playable effectivity function*, satisfying the following conditions: i) $\forall_{C \subseteq N} \emptyset \notin E(s)(C)$, ii) $\forall_{C \subseteq N} S \in E(s)(C)$, iii) for any X, if $S \setminus X \notin E(s)(N \setminus C)$ then $X \in E(s)(C)$ (*N-maximality*), iv) for all $X \subseteq X' \subseteq S$ and all C, if $X \in E(s)(C)$ then $X' \in E(s)(C)$ (*outcome monotonicity*) and v) if $C_1 \cap C_2 = \emptyset$, $X_1 \in E(s)(C_1)$ and $X_2 \in E(s)(C_2)$, then $X_1 \cap X_2 \in E(s)(C_1 \cup C_2)$ (*superadditivity*). Formulae of coalition logic, and their satisfaction in states s of coalition models M, are defined as follows[3]:

$$M, s \models \langle C \rangle \psi \quad \text{iff } \psi^M \in E(s)(C)$$

where $\psi^M = \{s \in S : M, s \models \psi\}$. If we take the set of atomic propositions to be $\Phi_0 = \Omega \cup \{\omega \succeq_i \omega' : \omega, \omega' \in \Omega, i \in N\}$, then we can read every formula in $\mathcal{L}_o \cup \mathcal{L}_c$ as a formula of coalition logic. Thus we can interpret $\mathcal{L}_c$ formulae in both a game Γ and in a pointed coalition model (M, s), and a $\mathcal{L}_o$ formula in both a pointed game (Γ, ω) and in a pointed model (M, s). Coalitional games and coalition models have many similarities. The former have "outcomes" while the latter have "states". An interesting question is: given a coalitional game Γ, does there exist an equivalent coalition model M with states corresponding to the outcomes of Γ, maybe in addition to a designated "initial" state t? Equivalence here means that Γ and the pointed coalition model (M, t) agree on $\mathcal{L}_c$ formulae and (Γ, ω) and (M, ω) agree on $\mathcal{L}_o$ formulae for any outcome ω. We can say that Γ and M then are *outcome-equivalent*.

In other words, a coalitional game Γ and a coalition model M, defined over atomic propositions Φ_0 above and having states $\Omega \cup \{t\}$, are outcome-equivalent iff for any $\varphi_1 \in \mathcal{L}_c$, any $\varphi_0 \in \mathcal{L}_o$ and any $\omega \in \Omega$: we have both (a) $\Gamma \models \varphi_1$ iff $M, t \models \varphi_1$, and (b) $\Gamma, \omega \models \varphi_0$ iff $M, \omega \models \varphi_0$.

A natural question then is: given a game, does there exist an outcome-equivalent coalition model?

The answer, given by the following theorem, is "no", except for for certain special cases of games. The latter is the class of games where $V(C) = \{\omega\}$ for all coalitions $C \neq N$, for some fixed outcome $\omega \in \Omega$. To give them a name, we will call such games *limited games*, since, first, most games are not of this kind and, second, they are not very interesting. The only coalition in a limited game which possibly can select an outcome different from the fixed outcome ω is the grand coalition.

THEOREM 8. *No non-limited coalitional game with more than one player has an outcome-equivalent coalition model.*

PROOF. Let $\Gamma = \langle N, \Omega, V, \sqsupseteq_1, \ldots, \sqsupseteq_m \rangle$ be a coalitional game, and assume that $M = (S, E, \pi)$ with $S = \Omega \cup \{t\}$ is a coalition model outcome-equivalent to Γ. We argue, by using the properties i) – v) of a playable effectivity function given above, that Γ must be limited. First, observe that for any $\mathcal{L}_o$ formula φ and coalition $C \neq \emptyset$, $\Gamma \models \langle C \rangle \varphi$ iff, by (a), $M, t \models \langle C \rangle \varphi$, i.e.

$$\varphi^M \in E(t)(C) \Leftrightarrow \exists_{\omega \in V(C)} \Gamma, \omega \models \varphi \tag{1}$$

for any $\varphi \in \mathcal{L}_0$, $C \subseteq N$, $C \neq \emptyset$.

Observe that $V(C) \neq \emptyset$ for any coalition $C \neq \emptyset$. This follows from ii) and (1): $S = \top^M \in E(t)(C)$, where $\top$ is some tautology in the $\mathcal{L}_0$ language (e.g., $\omega' \vee \neg\omega'$), so $\exists_{\omega \in V(C)} \Gamma, \omega \models \top$, which ensures that $V(C)$ is non-empty.

We show that for any coalition $C \neq \emptyset$ and any $\omega \in \Omega$

$$\omega \in V(C) \Leftrightarrow \{\omega\} \in E(t)(C) \tag{2}$$

[3]We only give the coalitional clause. Pauly [14] uses $[C]$ where we use $\langle C \rangle$; here we use the latter notation for easier comparison.

For the direction to the right, assume that $\omega \in V(C)$. $\Gamma, \omega \models \omega$ (note the dual role of ω as both an outcome and a formula), so $\omega^M \in E(t)(C)$ by (1). By (b), $M, \omega \models \omega$, so $\omega \in \omega^M$. If $\omega' \in \omega^M$, then $M, \omega' \models \omega$, $\Gamma, \omega' \models \omega$ by (b) and $\omega' = \omega$. Thus, $\{\omega\} = \omega^M \in E(t)(C)$. For the direction to the left, let $\{\omega\} \in E(t)(C)$. Since, again, $\omega^M = \{\omega\}$, by (1) there is a $\omega' \in V(C)$ such that $\Gamma, \omega' \models \omega$. This is only the case when $\omega = \omega' \in V(C)$.

For any non-empty disjoint coalitions C_1 and C_2:

$$(\omega_1 \in V(C_1) \text{ and } \omega_2 \in V(C_2)) \Rightarrow \omega_1 = \omega_2 \quad (3)$$

$$V(C_1) = V(C_2) \quad (4)$$

$$|V(C_1)| = 1 \quad (5)$$

We prove (3)–(5):

(3) Assume otherwise, that $\omega_1 \in V(C_1)$ and $\omega_2 \in V(C_2)$ and $\omega_1 \neq \omega_2$. By (2), $\{\omega_1\} \in E(t)(C_1)$ and $\{\omega_2\} \in E(t)(C_2)$, and by superadditivity it must be the case that $\emptyset = \{\omega_1\} \cap \{\omega_2\} \in E(t)(C_1 \cup C_2)$, but this contradicts i). Thus, (3) must hold.

(4) Assume that $\omega \in V(C_1)$; we show that $\omega \in V(C_2)$. Since $V(C_2)$ is non-empty, let $\omega' \in V(C_2)$. By (3), $\omega' = \omega$. Thus $\omega \in V(C_2)$. By a symmetric argument, $\omega \in V(C_2)$ implies that $\omega \in V(C_2)$.

(5) Since $V(C_1)$ is non-empty, there is an $\omega_1 \in V(C_1)$. If $\omega_2 \in V(C_1)$, then $\omega_2 \in V(C_2)$ by (4) and $\omega_1 = \omega_2$ by (3). Thus, $V(C_1) = \{\omega_1\}$.

Let $a, b \in N$ such that $a \neq b$ (existence is ensured by the assumption of more than one player). By (4) and (5) there is an ω_1 such that $V(\{a\}) = V(\{b\}) = \{\omega_1\}$. For any $d \in N$ such that $d \neq a$ and $d \neq b$, $\{a\}$ and $\{d\}$ are disjoint and we again get that $V(\{d\}) = V(\{a\}) = \{\omega_1\}$. Thus, $V(\{d\}) = \{\omega_1\}$ for any $d \in N$. Let $C \subset N$ be a coalition different from the grand coalition. There is a $d \in N$ such that C and $\{d\}$ are disjoint, so by (4) $V(C) = V(\{d\}) = \{\omega_1\}$, which shows that Γ is limited. □

Thus, in general, a coalitional game is *not* simply a coalition model with outcomes as states. Even though the language of Coalition Logic is similar to the language of our logic, it follows from Theorem 8 that we cannot use the semantic rules of Coalition Logic "directly" to say whether a formula is true or not in a coalitional game. The main reason is that a difference between outcomes in coalitional games and states in coalition models is that an outcome is *local* to the coalition which chooses it, while states are *global*. As a consequence, while it is perfectly possible in a coalitional game that both a coalition C can choose outcome ω ($\omega \in V(C)$) *and* a coalition C', C' and C disjoint, can choose outcome ω' ($\omega' \in V(C')$) when $\omega' \neq \omega$, it is not possible in a coalition model that both C is effective for $\{\omega\}$ and C' is effective for $\{\omega'\}$. The proof of Theorem 8 shows that in general there is no playable effectivity function corresponding, in the sense of (2), to a characteristic function.

7. CONCLUSIONS AND FUTURE WORK

We introduced a knowledge representation language for coalitional games without transferable payoffs, and a logic specifically intended for reasoning about such games. We presented the logic, gave a complete axiomatization for it, showed it was expressively complete with respect to coalitional games without transferable payoff, showed that the satisfiability problem was NP-complete, showed how the logic could be used to capture a range of solution concepts for coalitional games, and finally, showed formally why the logic was fundamentally different to existing cooperation logics. Other solution concepts for coalitional games [11], for which the definitions in terms of payoffs cannot be trivially extended to the more general case of preferences and non-transferable utility, are the *the kernel*, *the nucleoulus* and *the Shapley value*. Logical characterisation of these concepts, in addition to further comparison with Coalition logic, could be interesting future work.

ABSTRACT

We present an OBDD-based methodology for verifying time, knowledge, and strategies in multi-agent systems specified by the formalism of interpreted systems. To this end, we investigate the interpretation of ATL and epistemic formulae in various classes of interpreted systems, we present model checking algorithms and their implementation, and report experimental results.

Keywords

Model checking multi-agent systems; ATL

1. INTRODUCTION

Model checking was traditionally put forward to verify specifications given in *temporal* logics [6]. Recently, however, researchers have extended model checking techniques to other modal logics, including some typical multi-agent systems (MAS) logics, thereby making it possible to verify formally a range of multi-agent systems against temporal, epistemic, and other modalities. Examples of efforts on this line include [25, 4, 8, 19, 22]. These works share the model checking approach but differ in the choice of the logic-based specification language, and in the specific model checking technique employed.

In parallel developments, Alur et al. introduced Alternating-time Temporal Logic (ATL), a logic to reason about *strategies* in multi-player games [3]. Model checking approaches for this logic have been developed [2, 16]. More recently, van der Hoek and Wooldridge proposed the logic ATEL [11]. ATEL extends ATL with epistemic operators whose semantics is defined over runs of a multi-agent system. However, it has been argued [12, 15, 13, 14] that the interpretation of ATL operators in ATEL might not correspond entirely to the original spirit of ATL [3]. Following [11], various solutions have been put forward [15, 13, 14, 1, 10] to express ATL operators in a semantics based on MAS. Some of these issues relate back to the seminal work by Moore [18].

Against this background, and in parallel with this discussion, [11, 9, 20] suggested different techniques to reduce the problem of ATEL model checking to standard ATL model checking, with the idea of using MOCHA, the only existing model checker for ATL, for model checking MAS. In addition, the algorithms proposed in [16] are based on a reduction of the problem of model checking ATEL to a boolean satisfiability problem; however, no implementation is available yet.

In this paper we try to make further progress in this line by investigating interpretations of epistemic and ATL operators on interpreted systems, a mainstream semantics for MAS, and by presenting a verification methodology for it. In particular:

- we consider various classes of interpreted systems and we explore in detail the interpretation of ATL operators on these classes;
- we present model checking algorithms for ATL operators on various classes of interpreted systems;
- we present an extension for MCMAS [21] (a tool for the automatic verification of temporal and epistemic operators in interpreted systems) supporting ATL operators.

In contrast to previous approaches, our tool does not involve the translation or the reduction of the problem of model checking to plain ATL, and it permits the automatic verification of ATL operators on different classes of interpreted systems, thereby making it possible to express what agents may bring about, and what they may enforce. To our knowledge, this is not supported by any implementation. The tool is available for download from [21] under the terms of the GPL license.

The rest of the paper is organised as follows. In Section 2 we review theoretical preliminaries, and we compare briefly semantics for ATL and for interpreted systems. In Section 3 we discuss different classes of interpreted systems for the evaluation of ATL operators. In Section 4 we introduce the algorithms for model checking and we present the tool MCMAS. In Section 5 we evaluate the effectiveness of our approach by verifying three examples and we report experimental results. We conclude in Section 6.

2. PRELIMINARIES

In this section we review the main formalisms that we shall use in the remainder of this paper. We first introduce the logic ATL, then we describe the formalism of interpreted systems to model multi-agent systems, and we compare the semantics of interpreted systems with ATL semantics.

2.1 ATL

The syntax of the temporal logic ATL (Alternating-time Temporal Logic) [3] is defined as follows. Let AP be a finite set of atomic propositions, let $\Sigma = \{1, \ldots, n\}$ be a set of players, and let $\Gamma \subseteq \Sigma$ be a subset of the set of players. Let $p \in AP$ be an atomic proposition; well-formed ATL formulae are defined by the following grammar:

$$\varphi ::= p \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle\langle\Gamma\rangle\rangle X\varphi \mid \langle\langle\Gamma\rangle\rangle G\varphi \mid \langle\langle\Gamma\rangle\rangle[\varphi U \psi]$$

In [3], the formula $\langle\langle\Gamma\rangle\rangle \cdot \varphi$ is read as "the set of players Γ can enforce $\cdot\varphi$" (where $\cdot$ denotes a temporal modality). ATL can be seen as an extension of the temporal logic CTL [6] where the path quantifiers E and A are replaced with quantification over sets of computations which players can "enforce". Indeed, quantification over all the possible computations is read as the existential quantifier of CTL, while quantification over the empty set is read as the universal quantifier of CTL.

Traditionally, the semantics of ATL formulae is given in terms of *concurrent game structures* (CGS). A CGS is a tuple

$$< \Sigma, S, AP, h, d, \delta >$$

where Σ is a set of players, S is a finite set of states, AP is a set of atomic propositions, $h : AP \rightarrow 2^S$ is an evaluation function, $d : \Sigma \times S \rightarrow I\!N$ is the number of moves available to a player i in a state (moves are labelled with natural numbers), and δ is an evolution function that determines the evolution of the system. Various definitions of δ are possible, we refer to [3] for more details. A *strategy for player* i is a function f_i that maps sequences of states to a natural number, corresponding to a move available to player i at the end of the sequence, i.e., $f_i : S^+ \rightarrow I\!N$, with $f_i(s) < d(i, s)$ for all states in the sequence. Given a state $s \in S$, a set of players Γ, and a set of strategies $F_\Gamma = \{f_i | i \in \Gamma\}$, the set $out(s, F_\Gamma) \subseteq S^+$ is the set of sequences that the group Γ can *enforce* in s, as defined in [3], p. 685. A sequence of states $s_0, s_1, \ldots$ such that each $s_i, i \geq 0$ is related to s_{i+1} via the evolution function δ is denoted with π, and $\pi(i) = s_i$ denotes the i-th state in the sequence. Sequences of states are usually called *computations*. Satisfaction of an ATL formula in a state $s \in S$ of a given CGS is defined as follows:

$s \models p$	iff	$s \in h(p)$,
$s \models \neg\varphi$	iff	$s \not\models \varphi$,
$s \models \varphi_1 \vee \varphi_2$	iff	$s \models \varphi_1$ or $s \models \varphi_2$,
$s \models \langle\langle\Gamma\rangle\rangle X\varphi$	iff	there exists a set of strategies F_Γ s.t. for all computations $\pi \in out(s, F_\Gamma)$, $\pi(1) \models \varphi$.
$s \models \langle\langle\Gamma\rangle\rangle G\varphi$	iff	there exists a set of strategies F_Γ s.t. for all computations $\pi \in out(s, F_\Gamma)$ and $\forall i \geq 0$, $\pi(i) \models \varphi$.
$s \models \langle\langle\Gamma\rangle\rangle[\varphi U \psi]$	iff	there exists a set of strategies F_Γ s.t. for all computations $\pi \in out(s, F_\Gamma)$, $\exists i \geq 0$ s.t. $\pi(i) \models \psi$ and $\forall 0 \leq j < i, \pi(j) \models \varphi$

It is worth noticing here that the definitions above are given with the intuition that *every player has complete information about the system and perfect recall* (see Section 2.3 for further details).

2.2 Interpreted systems

An interpreted system [7] is a formal description of the computations carried out by a set of agents $\Sigma = \{1, \ldots, n\}$. Each agent $i \in \Sigma$ is characterised by a finite set of *private local states* L_i and by a finite set of actions Act_i that may be performed. Actions are performed in compliance with a protocol $P_i : L_i \rightarrow 2^{Act_i}$. Notice that this definition of protocols allows for *non-determinism* in the system. The environment in which agents "live" may be modelled by means of a special agent E, modelled by a set of local states L_E, a set of actions Act_E, and protocol P_E. A tuple $g = (l_1, \ldots, l_n, l_e) \in L_1 \times \cdots \times L_n \times L_E$ is called a *global state* and gives a description of the system at a particular instant of time. The evolution of the agents' local states is described by a function $t_i : L_i \times L_E \times Act_1 \times \cdots \times Act_n \times Act_E \rightarrow L_i$ which gives the "next" local state as a function of the current local state of the agent, the environment, and all the other agents' actions (the evolution function for the environment is defined as $t_E : L_E \times Act_1 \times \cdots \times Act_n \times Act_E \rightarrow L_E$). It is assumed that, in every state, agents evolve simultaneously (this assumption corresponds to the definition of *Moore synchronous* CGS, in which the evolution function δ prescribes a simultaneous evolution of players). The evolution of the (global states of the) system may be described by a function $t : G \times Act \rightarrow G$, where $G \subseteq (L_1 \times \cdots \times L_n \times L_E)$ denotes the set of *reachable* global states, and $Act = Act_1 \times \cdots \times Act_n \times Act_E$ denotes the set of "joint" actions (similarly, one can reason about the joint actions of a group of agents $\Gamma \subseteq \Sigma$). The function t is the composition of all the functions t_i, and it is defined by $t(g, a) = g'$ iff $\forall i, t_i(l_i(g), l_E(g), a) = l_i(g')$, where $l_i(g)$ denotes the local state of agent i in global state g and $a \in Act$. The set G of reachable global states is obtained by considering all the possible evolutions of the system from a set of *initial* global states, denoted with I. Finally, to complete the description of an interpreted system, a set of atomic propositions AP is introduced, together with a valuation function $h : AP \rightarrow 2^G$.

Formally, an interpreted systems IS is a tuple $IS = \left\langle (L_i, Act_i, P_i, t_i)_{i \in \Sigma \cup \{E\}}, I, h \right\rangle$. Interpreted systems have been proven a suitable formalism for reasoning about temporal and epistemic properties of agents [7, 17]. The standard semantics of interpreted systems is given Section 3.

2.3 On the relationship between interpreted systems and concurrent game structures

Interpreted systems and concurrent game structures are closely related. Consider an interpreted system

$$IS = \left\langle (L_i, Act_i, P_i, t_i)_{i \in \Sigma \cup \{E\}}, I, h \right\rangle$$

and a concurrent game structure

$$CGS =< \Sigma, S, AP, h, d, \delta >:$$

- both structures comprise a set of agents (or players) Σ, and both structures comprise a set of states, called *global* states in IS;
- the function d, which returns the number of moves available to a player in a state of a CGS, intuitively corresponds to the protocols P_i in IS;
- the evolution function δ of CGS is an "accessibility" relation between states, as the evolution function t of IS, defined in terms of the evolution functions t_i;
- the valuation functions h of CGS and IS both label (global) states with propositions.

Differently from CGS, however, global states of interpreted systems have a structure, being tuples of *private local states*. This subtle difference is key in understanding the difference in the semantics for ATL operator in CGS and in interpreted systems presented in the next section. Indeed, CGS assume that every player

has *perfect information*, i.e., every player is fully aware of the state $s \in S$ at every time instant. Conversely, in interpreted systems an agent is aware of its private local state only.

A further difference between interpreted systems and CGS is the definition of strategies. In [3], a strategy is defined as a function from *sequences* of states to an action. In the case of interpreted systems, instead, we define below a strategy for agent i to be a function from a (single) local state to an action of agent i (see the next Section for a discussion about this). In this sense, strategies and protocols in interpreted systems are closely related because they associate actions to states and, in the case of *deterministic* interpreted systems (see Section 3.2), strategies and protocols are the same mathematical object. In the remainder of the paper we will refer to protocols when describing interpreted systems, and to strategies when reasoning about ATL formulae in interpreted systems.

Explanations of other technical similarities and differences between the two semantics is not the aim of the present paper.

3. ATL OPERATORS IN INTERPRETED SYSTEMS

In this section we discuss how interpreted systems can provide a semantics for a language that includes operators to reason about time, knowledge, and strategies. Formally, let AP be a set of atomic propositions and let $p \in AP$ be an atomic proposition; the syntax of the language we consider is defined by the following grammar:

$$\begin{aligned}\varphi \quad ::= \quad & p \mid \neg\varphi \mid \varphi \vee \varphi \mid EX\varphi \mid EG\varphi \mid E[\varphi U \psi] \mid \\ & K_i\varphi \mid E_\Gamma\varphi \mid C_\Gamma\varphi \mid D_\Gamma\varphi \mid \\ & \langle\langle\Gamma\rangle\rangle X(\varphi) \mid \langle\langle\Gamma\rangle\rangle G(\varphi) \mid \langle\langle\Gamma\rangle\rangle[\varphi U \psi]\end{aligned}$$

In the grammar above, $\Gamma \subseteq \Sigma$ denotes a set of agents, $K_i\varphi$ is read as "agent i knows φ", $E_\Gamma\varphi$ is read as "everybody in group Γ knows φ", $C_\Gamma\varphi$ is read as "it is common knowledge in Γ that φ" [7], $D_\Gamma\varphi$ is read as "it is distributed knowledge in Γ that φ, and $\langle\langle\Gamma\rangle\rangle \cdot \varphi$ (where $\cdot$ is one of the temporal operators X, G, or U) is read as "group Γ can enforce $\cdot\varphi$". Other temporal and ATL operators expressing eventuality (F), and the universal quantifier (A) for paths, can be derived in a standard way. Notice that, although the temporal operators can be derived from the ATL operators, we treat them separately to stress the difference between temporal reasoning and strategic reasoning; we refer to [3, 6] for details.

To provide a semantics for well-formed formulae we proceed as follows. Given an interpreted system IS, we associate a Kripke model M_{IS} to IS. The *associated model* $M_{IS} = (G, t, (\sim_i)_{i\in\Sigma}, L)$ for a given interpreted system $IS = \left\langle (L_i, Act_i, P_i, t_i)_{i\in\Sigma\cup\{E\}}, I, h \right\rangle$ is defined as follows:

- The set of possible worlds G is the set of reachable states of IS. The set G can be obtained from the set of initial states I by iterating the evolution function t defined by the protocols and the evolution functions of each agent in Section 2.2.
- The temporal relation $t \subseteq G \times Act \times G$ relating two worlds by means of a joint action is the relation defined in Section 2.2.
- Each epistemic accessibility relations $\sim_i$ is defined by the equality of the local components of the global states: $g \sim_i g'$ iff $l_i(g) = l_i(g')$, i.e. iff the local states of agent i in global states g and g' are the same [7].
- The labelling function $L : AP \to 2^G$ is equivalent to the evaluation function h.

Temporal and epistemic formulae are interpreted on M_{IS} in a standard way; we refer to [7, 6, 3] for details. Similarly to Section 2.1, we define a strategy to be a function $f_i : L_i \to Act_i$ from (local) states to actions for agent i, with the requirement that $f_i(l_i(g)) \in P_i(l_i(g))$, i.e. $f_i(l_i(g))$ is one of the actions enabled by the protocol P_i for agent i when its local state is $l_i(g)$. Notice that this definition corresponds to the memoryless, imperfect information semantics of ATL [23]. Different partial recall semantics could be defined by using vectors of local states. Given a group of agents Γ and a state $g \in G$, let $F_\Gamma = \{f_i | i \in \Gamma\}$ be a set of strategies; as in Section 2.1, we denote with $out(g, F_\Gamma)$ the set of computations that group Γ can enforce at state g (computations are defined as in Section 2.1). For convenience, we report here the semantics for ATL and epistemic formulae.

- $M_{IS}, g \models K_i\varphi$ iff for all $g' \in G$, $g \sim_i g'$ implies $M_{IS}, g' \models \varphi$.
- $M_{IS}, g \models \langle\langle\Gamma\rangle\rangle X\varphi$ iff there exists a set of strategies F_Γ such that, for all computations $\pi \in out(g, F_\Gamma)$, $\pi(1) \models \varphi$.
- $M_{IS}, g \models \langle\langle\Gamma\rangle\rangle G\varphi$ iff there exists a set of strategies F_Γ such that, for all computations $\pi \in out(g, F_\Gamma)$ and for all $i \geq 0$, $\pi(i) \models \varphi$.
- $M_{IS}, g \models \langle\langle\Gamma\rangle\rangle[\varphi U \psi]$ iff there exists a set of strategies F_Γ such that for all computations $\pi \in out(g, F_\Gamma)$, there exists $i \geq 0$ such that $\pi(i) \models \psi$, and for all $0 \geq j < i$ $\pi(j) \models \varphi$.

Following [7] (p.118), we write $IS \models \varphi$ if $M_{IS} \models \varphi$.

It is known that non-intuitive results may arise when evaluating ATL operators in MAS logics [15, 13, 14, 1]. We investigate this issue for the semantics of interpreted systems in the next subsections, by considering various classes of interpreted systems.

3.1 Non-deterministic interpreted systems

The most general class of interpreted systems is the one defined in Section 2.2. Consider the following simple example of an interpreted system IS[1] composed by two agents Ag_1 and E (the environment); the agent Ag_1 is modelled by means of three local states $L_1 = \{l_1^1, l_1^2, l_1^3\}$ and two possible actions $Act_1 = \{a_1^1, a_1^2\}$. The protocol for Ag_1 prescribes that every action is allowed in every state. The second agent E is modelled by means of two local states $L_E = \{l_E^1, l_E^2\}$, and we assume that no action is performed by E (and thus no protocol is required). In the initial state the system can be either in global state (l_1^1, l_E^1) or in global state (l_1^1, l_E^2). The evolution function for Ag_1 is defined below:

Loc. st. Ag_1	Loc. st. E	Act. Ag_1	Next state
l_1^1	l_E^1	a_1^1	l_1^2
l_1^1	l_E^1	a_1^2	l_1^3
l_1^1	l_E^2	a_1^1	l_1^3
l_1^1	l_E^2	a_1^2	l_1^2

We assume that in every other state there is no change in local state for Ag_1, and we assume that the local state of E never changes. We introduce an evaluation function h assigning the proposition **WIN** to the global states (l_1^2, l_E^1) and (l_1^2, l_E^2). The model associated to IS is depicted in Figure 1.

In this simple example the formula $\langle\langle Ag_1\rangle\rangle X(\mathbf{WIN})$ is true in the initial states of IS; however, it is not the case that Ag_1 is capable of *enforcing* a state in which the proposition **WIN** holds. Indeed, Ag_1 cannot distinguish between the global states (l_1^1, l_E^1) and (l_1^1, l_E^2),

[1]This is a reduced version of the card game presented in [15, 13].

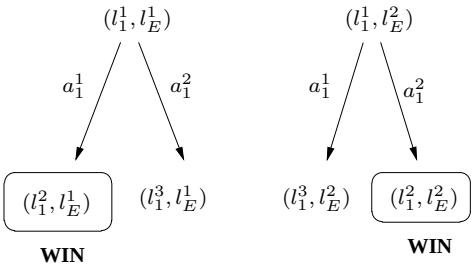

Figure 1: A simple example.

because its local state is the same in the two global states. We conclude that, similarly to what happens in the case of ATEL, ATL operators in non-deterministic interpreted systems do not express what agents may enforce, but what agents may *bring about*. In our example, the formula $\langle\langle Ag_1 \rangle\rangle X(\textbf{WIN})$ has to be read "Ag_1 may bring about a state in which the proposition **WIN** holds, maybe by *guessing* moves".

3.2 Deterministic interpreted systems

The reason the meaning of the ATL operators is subtly different in interpreted systems is that these allow for agents to run non-deterministic protocols, i.e., the same agent may perform different actions in a given local state. To follow the spirit of the original CGS more closely, we can focus on the subclass of interpreted systems, whose protocols are deterministic, i.e., protocols in which only one action is associated to a given local state: $P_i : L_i \rightarrow Act_i$.

We define an interpreted system to be *deterministic* iff the protocol of each agent is *deterministic* (a deterministic protocol associates a unique action to each local state). Notice that, since we assume the transition function to be deterministic, the models associated to deterministic interpreted systems are not branching but linear.

Since in deterministic interpreted systems agents are not allowed to "guess" actions, the evaluation of ATL operators in their associated expresses the original "enforcement" meaning of ATL operators in CGS [3].

3.3 Γ-uniform interpreted systems

Deterministic interpreted systems are close in spirit to the original interpretation of ATL in CGS, but, as exemplified later in Section 5, in many circumstances the class of deterministic interpreted systems is too restrictive to be used in the specification of MAS scenarios. In these circumstances it is useful to reason about non-deterministic interpreted systems that at least are consistent in their selection of actions in a given local state.

By extending the concepts of [15, 14], we define an agent to be *uniform* if throughout a run the agent performs always the same action when in a particular local state. A group of agents $\Gamma \subseteq \Sigma$ is *uniform* if every agent in the group is uniform. We say that an interpreted system is Γ-*uniform* if all agents in Γ are uniform. We define a Γ-uniform interpreted system IS_Γ to be *compatible* with an interpreted system IS if (i) it contains the same agents, with the same set of local states, actions, and evolution function, and (ii) the protocols P_i^Γ for the Γ agents in IS_Γ are a *restriction* of the protocols P_i of IS, in the sense that for all local states $l_i \in L_i$, $P_i^\Gamma(l_i) \in P_i(l_i)$ (i.e. only one action is selected in P_i^Γ, and the action is one of the actions specified in P_i).

Notice that, for a given interpreted system IS and a group of agents Γ, there may be several Γ-uniform interpreted systems compatible with IS (but at most $\prod_{i \in \Gamma} |Act_i|^{|L_i|}$). We denote with $\{IS\}_\Gamma$ the set of Γ-uniform interpreted systems that are compatible with a given interpreted system IS.

Similarly to the general case, we associate a Kripke model to each Γ-uniform interpreted system in $\{IS\}_\Gamma$. We say that a formula φ is true in a class of Γ-uniform interpreted systems, and write $IS \models_\Gamma \varphi$, if φ is true in at least one of the models associated with the Γ-uniform interpreted system in $\{IS\}_\Gamma$.

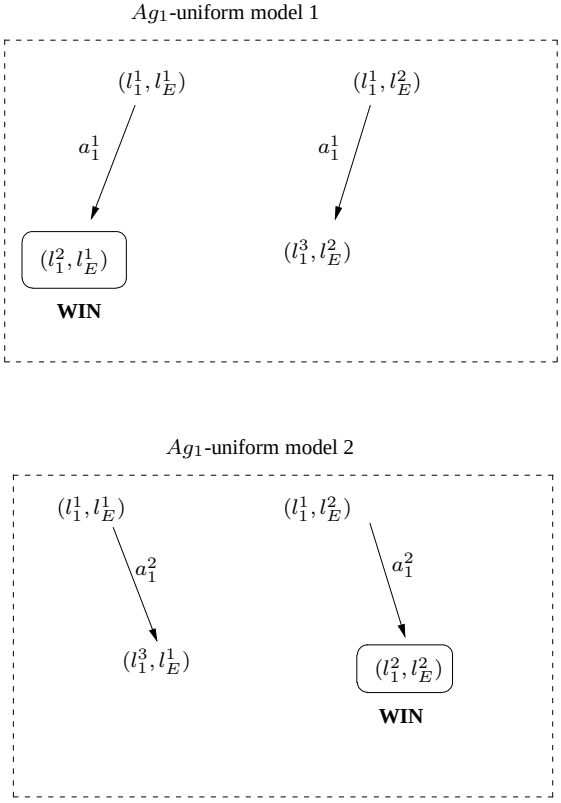

Figure 2: Ag_1-uniform interpreted systems for the interpreted system of Figure 1.

As an example, the uniform interpreted systems for the example of Figure 1 are presented in Figure 2. In this example, in the initial states we have $IS \models \langle\langle Ag_1 \rangle\rangle X(win)$, but $IS \not\models_{Ag_1} \langle\langle Ag_1 \rangle\rangle X(win)$, because there is no Ag_1-uniform interpreted system compatible with the original interpreted system in which the formula is true. Intuitively, a uniform agent chooses one of the actions allowed by the protocols, and it behaves consistently with its choice, i.e., the agent will always choose the same action in epistemically equivalent states.

4. OBDD-BASED MODEL CHECKING FOR INTERPRETED SYSTEMS

In this section we present the algorithms for the verification of temporal, epistemic, and ATL operators in the various classes of interpreted systems presented above. Our approach is similar, in spirit, to the traditional model checking techniques for the temporal logic CTL [6], and to the approach presented in [22].

4.1 Model checking algorithm

To evaluate epistemic, temporal, and ATL operators in models associated to non-deterministic interpreted systems we proceed as follows. Given an interpreted system $IS = \left\langle (L_i, Act_i, P_i, t_i)_{i \in \Sigma \cup \{E\}}, I, h \right\rangle$, note that the number of boolean variables $v_i (i \in I\!N)$ required to encode the local states of an agent is $nv(i) = \lceil log_2 |L_i| \rceil$. Similarly, to encode an agent's action, the number of boolean variables $w_i (i \in I\!N)$ required is $na(i) = \lceil log_2 |Act_i| \rceil$. A global state g can be encoded as a boolean vector $\overline{v} = (v_1, \ldots, v_N)$, where $N = \sum_i nv(i)$. Similarly, a joint action a can be encoded as a boolean vector $\overline{w} = (w_1, \ldots, w_M)$, where $M = \sum_i na(i)$. In turn, a boolean vector can be identified with a boolean formula, represented by a conjunction of literals, i.e. a conjunction of variables or their negation. In this way, a set of global states (and similarly a set of joint actions) can be expressed as the disjunction of the boolean formulae encoding each global state in the set. Given this, protocols can be encoded by implications between boolean formulae representing local states and actions (see [22] for more details). Let $P(\overline{v}, \overline{w})$ be the boolean formula obtained by taking the conjunction of the boolean formulae encoding the protocols for all the agents. The evolution function t_i for a single agent can also be expressed as a boolean formula; we denote with $t(\overline{v}, \overline{w}, \overline{v'})$ the boolean function obtained by taking the conjunction of all the boolean formulae encoding the evolution functions for the agents. Notice that evolution functions require two sets of boolean variables for encoding states; in the above $\overline{v'} = (v'_1, \ldots, v'_N)$ denotes the additional set of boolean variables required. The set of initial states can be encoded by means of a boolean formula $I(\overline{v})$, as well as the evaluation function h.

In addition to the parameters presented above, the algorithm for model checking presented below requires the definition of n boolean functions $R_i^K(\overline{v}, \overline{v'})$ (one for each agent) representing the epistemic accessibility relation, and the definition of a boolean function $R_t(\overline{v}, \overline{v'})$, representing a temporal transition between the global states g and g' encoded by means of the boolean vectors $(v_1, \ldots, v_N)$ and $(v'_1, \ldots, v'_N)$. $R_t(\overline{v}, \overline{v})$ can be obtained from the boolean function t by quantifying over actions. This quantification can be translated into a propositional formula using a disjunction (see [6] for a similar approach to boolean quantification):

$$R_t(\overline{v}, \overline{v'}) = \bigvee_{\overline{w} \in Act} [(t(\overline{v}, \overline{w}, \overline{v'}) \wedge P(\overline{v}, \overline{w})]$$

The formula above provides a boolean relation between global states that can be used in the evaluation of temporal operators. Also, the set of *reachable* states is needed by the algorithm: the set G of reachable global states can be expressed *symbolically* by a boolean formula, and it can be computed as the fix-point of the operator $\tau(Q) = (I(\overline{v}) \vee (\exists(\overline{v'})).(R_t(\overline{v'}, \overline{v}) \wedge Q(\overline{v'}))$. Intuitively, $\tau(Q)$ computes the sets of states that are reachable from Q in a single temporal step. The fix-point of τ can be computed by iterating $\tau(\emptyset)$ as standard (see [6]).

Figure 3 presents the algorithm for model checking, based on the parameters presented above. In the following, Act_Γ denotes a joint action performed by group Γ. Let $a \in Act_\Gamma$ and $b \in Act_{\Sigma \setminus \Gamma}$: we denote with (a, b) the joint action defined by the concatenation of a and b, with the appropriate reordering of elements, if needed. $SAT(\varphi)$ computes the set of global states (expressed as a boolean formula) in which φ holds. The support procedures SAT_K and SAT_X are presented in Figure 4, while SAT_G, SAT_U, SAT_E, SAT_C, and SAT_D are defined using the ideas of [3, 11, 22]. The

$SAT(\varphi)$ {
 φ is an atomic formula: return $h(\varphi)$;
 φ is $\neg\varphi_1$: return $G \setminus SAT(\varphi_1)$;
 φ is $\varphi_1 \wedge \varphi_2$: return $SAT(\varphi_1) \cap SAT(\varphi_2)$;
 φ is $\langle\langle\Gamma\rangle\rangle X\varphi_1$: return $SAT_X(\varphi_1, \Gamma)$;
 φ is $\langle\langle\Gamma\rangle\rangle[\varphi_1 U \varphi_2]$: return $SAT_U(\varphi_1, \varphi_2, \Gamma)$;
 φ is $\langle\langle\Gamma\rangle\rangle G\varphi_1$: return $SAT_G(\varphi_1, \Gamma)$;
 φ is $K_i(\varphi)$: return $SAT_K(\varphi, i)$;
 φ is $E_\Gamma(\varphi)$: return $SAT_E(\varphi, \Gamma)$;
 φ is $C_\Gamma(\varphi)$: return $SAT_C(\varphi, \Gamma)$;
 φ is $D_\Gamma(\varphi)$: return $SAT_D(\varphi, \Gamma)$;
}

Figure 3: Model checking algorithm

$SAT_X(\varphi, \Gamma)$ {
 Y = $\{g | (\exists a \in Act_\Gamma, g' \in G)$ s.t. $(\forall b \in Act_{\Sigma \setminus \Gamma}).[R_t(g, g')$ and $t(g, (a, b), g')$ and $g' \in SAT(\varphi)$ and (a, b) is consistent with the protocols in $g']\}$
 return Y;
}

$SAT_K(\varphi, i)$ {
 X = $SAT(\neg\varphi)$;
 Y = $\{g \in G$ s.t. $R_i^K(g, g')$ and $g' \in X\}$
 return $\neg$Y;
}

Figure 4: Support procedure for SAT_X and SAT_K

key difference in our work is the definition of temporal transitions by means of interpreted systems' parameters (i.e. actions, protocols, evolution functions, etc.) as presented above. The procedure $SAT_X(\varphi, \Gamma)$ uses a double quantification on actions and returns the set of states from which there exists an action for the agents in Γ such that, for all actions of the agents in $\Sigma \setminus \Gamma$, a transition is enabled such that in the next state φ holds. In the support procedures, by slight abuse of notation, we use a compact notation for global states and actions instead of boolean variables and vectors; the intended meaning should be clear from the context.

The algorithm presented above is designed to be compatible with the representation of boolean formulae by means of Ordered Binary Decision Diagrams (OBDDs, [5]): OBDDs are an efficient technique for the representation and manipulation of boolean formulae. Due to space limitation, we refer to [5] for more details about this technique.

The model checking algorithm above terminates by comparing the OBDD representing the set of states in which a formula φ holds with the OBDD for the set of reachable states. Notice that if the two OBDDs are equal, then the Boolean formulae generating them are propositionally equivalent, therefore $IS \models \varphi$.

4.2 Model checking Γ-uniform interpreted systems

The algorithm presented in Figure 3 can also be used for the evaluation of formulae in Γ-uniform interpreted systems. Indeed, the algorithm can be applied to the symbolic encoding of each model associated to each interpreted system in $\{IS\}_\Gamma$.

To evaluate epistemic, temporal, and ATL operators in Γ-uniform interpreted systems, the set $\{IS\}_\Gamma$ is built as follows:

- The set of deterministic joint protocols[2] P_Γ is computed by imposing that all the agents in Γ adhere to a deterministic

[2]A joint protocol extends the definition of protocol to a set of agents. Formally, given a set of agents Γ, a joint protocol is de-

protocol, and by imposing that elements of P_Γ are *restrictions* (in the sense of Section 3.3) of the protocols of IS. An element of P_Γ can be seen as a tuple of deterministic protocols, one for each agent in Γ. Notice that there are at most $\prod_{i\in\Gamma} |A_i|^{|L_i|}$ different elements in P_Γ, where A_i is the maximum number of non-deterministic choices available to an agent.

- For each element $p \in P_\Gamma$, an interpreted system IS_p is defined as:
  - The set of agents, their local states, actions, and evolution functions for IS_p are equal to the corresponding elements of IS.
  - The protocols for the agents in Γ in IS_p are defined by p, while the protocols for agents in $\Sigma\backslash\Gamma$ are equal to the protocols in IS.
- The set of Γ-uniform interpreted systems $\{IS\}_\Gamma$ is defined as $\{IS\}_\Gamma = \{IS_p | p \in P_\Gamma\}$.

To check $IS \models_\Gamma \varphi$, we check whether $M_{IS_p} \models \varphi$ for some $p \in P_\Gamma$.

It is worth noting that the time complexity of verifying $IS \models_\Gamma \varphi$ by means of the algorithm presented above exceeds, in the worst case, the time complexity of $IS \models \varphi$ by a factor of $\prod_{i\in\Gamma} |A_i|^{|L_i|}$. The space complexity of the verification, instead, remains the same because the space employed in the verification of each model M_s associated with Γ-uniform interpreted systems in $\{IS\}_\Gamma$ can be reused.

4.3 MCMAS

In this section we present MCMAS, a tool that implements the algorithms presented in Section 4.2. In MCMAS, interpreted systems are described using the language ISPL (Interpreted Systems Programming Language). Figure 5 gives a short example of this language. We refer to the files available online [21] for the full syntax of ISPL. Formulae to be checked are provided at the end of the specification file.

The tool automatically parses the specification and builds the relevant parameters, stored as OBDDs by using the library provided in [24]. As discussed in Section 3, formulae can be evaluated either in models associated to non-deterministic interpreted systems, or in the class of Γ-*uniform* interpreted systems. MCMAS accepts a command-line parameter to select which class should be considered.

When the class of Γ-*uniform* interpreted systems is chosen, MCMAS determines the set Γ by including in Γ all the agents appearing under the scope of ATL operators in φ (notice that other implementation choices are possible without modifying the structure of MCMAS, for instance providing a separate list of uniform agents, irrespective of φ). To optimise the verification process, the set P_Γ is computed first, and then for each $p \in P_\Gamma$ a model is generated as in Section 4.2 and checked. If the formula is true in the model, the verification process ends with success; otherwise, another element $p \in P_\Gamma$ is chosen and the loop is repeated until all the elements of P_Γ have been tested, and the process terminates with failure.

MCMAS can be run from the command line, and accepts various options to modify verbosity, to inspect OBDDs statistics and memory usage, to enable variable reordering in the OBDDs (see [24]), etc. These options can be used to determine the "critical" points, and to fine tune the performance of the tool.

MCMAS is written in C/C++ and it has been successfully compiled on various platforms, including PowerPC (Mac OS X 10.2 and 10.3), Intel (various Pentium versions using Linux 2.4 and 2.6), and SPARC (SunOS 5.8 and 5.9). The source code has been compiled with gcc/g++ from version 2.95 till version 3.3.

fined as a function from the Cartesian product of the local states of the agents in Γ to the power set of the Cartesian product of the actions of the agents in Γ.

```
Agent SampleAgent
 Lstate = {s0,s1,s2,s3};
 Action = {a1,a2,a3};
 Protocol:
   s0: {a1};
   s1: {a2};
   s2: {a1,a3};
   s3: {a2,a3};
 end Protocol
 Ev:
   s2 if ((AnotherAgent.Action=a7);
   s3 if Lstate=s2;
 end Ev
end Agent
```

Figure 5: ISPL example

5. EXAMPLES AND EXPERIMENTAL RESULTS

5.1 Nim

Nim is a two player game where players in turns remove any number of objects from one of a certain number of heaps. Typically, 3 heaps are presents and the game starts with 3 objects in the first heap, 4 in the second, and 5 in the third. The player who takes the last object wins. In a variation of this game, called *Misère*, the player who takes the last object loses.

This is a game with *perfect* information. It is not difficult to encode the game in the formalism of interpreted systems, by imposing that only one agent makes a move at any given time step. The corresponding ISPL code is available for download from [21].

We considered two examples with 3-4-5 heaps, and with 5-5-5 heaps. We could confirm the known result that the first player can force a win *both* for the Nim and the Misère scenario. To this end, we checked the two formulae:

$$init \rightarrow \langle\langle player1 \rangle\rangle [\neg player2\_removelast \; U \; player1\_removelast]$$

$$init \rightarrow \langle\langle player1 \rangle\rangle [\neg player1\_removelast \; U \; player2\_removelast]$$

(where "init" is a proposition true in the initial state of the system).

We could verify these formulae in 18 seconds (for 3-4-5) and in 4 minutes and 8 seconds (for 5-5-5 heaps) using a 2.8GHz Intel Pentium IV, 1Gb of RAM, running Linux 2.6.8. The model for 3-4-5 heaps requires 51 boolean variables for the symbolic encoding, while 57 boolean variables are needed for the encoding of the 5-5-5 heaps (corresponding approximately to models of size 10^{15} and 10^{17} respectively).

5.2 A simple card game

This example is presented in [13] and in [15] to analyse the effects of incomplete information in MAS: an agent (the player) plays a simple card game against another agent, the environment. There are just three cards in the deck: Ace (A), King (K), and Queen (Q); A wins over K, K wins over Q, and Q wins over A. In the initial state no cards are distributed; in the first step, the environment gives

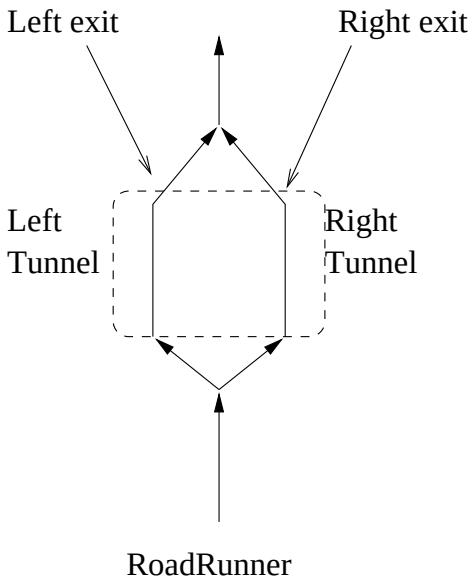

Figure 6: Diagram for RoadRunner and Coyote

a card to the player and takes a card for itself. In the second step, the player can either keep its card, or change it. A description of this scenario in terms of interpreted systems can be easily obtained, and it is available in the downloadable files from [21]. We want to verify whether or not the player has a strategy to win the game in the initial state, i.e. we want to verify the following formula:

$$init \rightarrow \langle\langle player \rangle\rangle F(player\_win)$$

Differently from the original intended meaning of ATL operators, this formula is true when evaluated with MCMAS: indeed, the player can always *guess* a move to win. However, the formula is false if it is evaluated in the class of *uniform* interpreted systems. This result confirms the intuition that the player cannot enforce a winning state.

Verification of this scenario took 0.15 seconds on a 2.8GHz Intel Pentium IV, 1Gb of RAM, running Linux 2.6.8.

5.3 RoadRunner and Coyote

This example illustrates further the different meaning of ATL operators in Γ-uniform interpreted systems and in non-deterministic interpreted systems.

RoadRunner is running in a hilly region of the desert; the main road splits in two small lanes just before the entrance of two tunnels below a mountain. RoadRunner can pick randomly either tunnel; the tunnels are identical and very narrow. Coyote knows RoadRunner has to take one of the two tunnels, and so he has bought a special tunnel-blocking device from ACME Inc. to catch RoadRunner. The device may be placed in front of either exit of the tunnel (see Figure 6).

The example can be modelled as an interpreted system IS by taking two agents, one for Coyote and one for RoadRunner. RoadRunner is described by means of two local states, "left" and "right", and by means of the single action "run"; local states for RoadRunner do not change. Coyote is modelled by means of three local states: "planning", "catch", and "fail". The initial state of Coyote is "planning" and in this local state Coyote is allowed to perform one of the two actions "place Left" or "place Right" denoting where he places the special device. The evolution function for Coyote prescribes that the next local state for Coyote is "catch" if he places the special device in front of the tunnel chosen by RoadRunner.

We introduce the proposition "catch", which is true if Coyote catches RoadRunner. The source code of the example is available from [21]. By using MCMASCoyote discovers that:

$$IS \models \text{init} \rightarrow \langle\langle Coyote \rangle\rangle X(\text{catch})$$

i.e. it is the case that in the initial state Coyote has a strategy to catch RoadRunner.

In fact, any external observer could verify that Coyote knows this very well:

$$IS \models K_{\text{Coyote}}(\text{init} \rightarrow \langle\langle Coyote \rangle\rangle X(\text{catch}))$$

Unfortunately, immediately after placing the ACME device in front of the tunnel, Coyote realises that he was assuming a *lucky* guess on where to place the device. Indeed, under the assumption Coyote is uniform $\Gamma = \{\text{Coyote}\}$, the formula turns to be false

$$IS' \not\models_{\Gamma} \text{init} \rightarrow \langle\langle Coyote \rangle\rangle X(\text{catch})$$

and, as expected, Coyote miserably fails in catching RoadRunner.

From RoadRunner's point of view, however, it is more useful and prudent to reason about what the clumsy Coyote may bring about. Thus, RoadRunner should be more interested in the verification of the non-deterministic interpreted system to discover that it is possible that Coyote catches him. In other words, to analyse the scenario from RoadRunner's point of view, we can check:

$$IS \models K_{\text{RoadRunner}}(\text{init} \rightarrow \langle\langle Coyote \rangle\rangle X(\text{catch}))$$

and also

$$IS \models K_{\text{RoadRunner}}(\text{init} \rightarrow EX(\text{catch})).$$

Given this Coyote should perhaps not be laughing so much.

Verification of all the formulae above took 0.19 seconds on a 2.8GHz Intel Pentium IV, 1Gb of RAM, running Linux 2.6.8.

6. CONCLUSIONS

In this paper we have identified three classes of interpreted systems to evaluate temporal, epistemic, and ATL operators. In the first class agents may guess moves; here, ATL operators express what agents may *bring about*. The second class is constituted by deterministic agents; therefore, ATL operators express what agents may *enforce*. The third class comprises Γ-uniform interpreted systems, non-deterministic systems in which a group of agents Γ chooses consistently to perform certain actions. We introduced model checking algorithms for these classes together with an implementation. Examples have also been presented to motivate the use of the various classes.

ABSTRACT

We present a multivalued μK-calculus, an expressive logic to specify knowledge and time in multi-agent systems. We show that the general method of translation [22] from multivalued to two-valued De Morgan algebras can be extended to mv μK-calculus model checking. This way can we reduce the model checking problem for mv μK-calculus to several instances of the model checking problem for two-valued μK-calculus. As a result, properties involving mv μK-calculus or its subsets, like mv CTLK or mv CTL*K, can be verified using any of the available model checking algorithms. Three simple examples are shown to exemplify possible applications of multivalued logics of knowledge and time.

Keywords

Model checking, interpreted systems, epistemic logic, multivalued modal logic.

1. INTRODUCTION

The field of multi-agent systems (MAS) theories is traditionally concerned with formal representation of mental attitudes of autonomous entities, known as *agents*, in a distributed system. Over the past 20 years, several modal logics, involving operators referring to time, knowledge, beliefs, desires, goals, and intentions, have been developed with this motivation in mind. These logics are perceived as *specifications* of particular classes of MAS systems. Their aim is to offer a description of the *macroscopic* mental properties (such as knowledge, beliefs, etc.) that a MAS should exhibit in a specific class of scenarios. Model checking is a widespread, basic method used in automated verification of concurrent systems, like hardware circuits, communication protocols, and distributed programs [4]. It amounts to verifying that a finite state program P satisfies a property φ (denoted $P \models \varphi$). When P is represented by its model M_P and the property φ is given by a temporal logic formula, one checks whether $M_P \models \varphi$, whereby the process of generating M_P for P and checking that $M_P \models \varphi$ is automated.

Recently, the field of model checking has been extended to cover verification of multi-agent systems [30], which has become a topic of very active research. In particular, recent contributions [12, 13, 24] have focused on extending to such systems the model checking tools and techniques usually employed for verification of reactive systems. Essentially, these study the validity of a formula representing a property of interest in the model representing all the computations of the multiagent system (MAS) under consideration. Iterative approaches to model checking (i.e., those based on explicit enumeration of all the possible states of computation) are known to suffer from the state explosion problem. For this reason, methods based on symbolic representation are currently seen as the most promising ones. In particular, methods based on variants of the Binary Decision Diagrams (BDD's) [26], and satisfiability (SAT) checkers [25, 18] are a continuing focus of research. Verification via the BDD's involves translating the model checking problem into operations on boolean functions represented in a concise and canonical way, whereas SAT-checkers are used for testing satisfiability of the formulas which encode the model checking problems.

In addition to "classic", two-valued model checking within the framework of two-valued modal logics, increasing attention has recently been devoted to multi-valued model checking, based on various variants of multi-valued (mv) modal logics. This paradigm turns out to be very useful in a number of problems for which we need to reason under uncertainty or to employ models containing inconsistency. Uncertainty can occur either when complete information is not known or cannot be obtained , or when this information has been abstracted away [9]. On the other hand, models can be inconsistent as they combine conflicting points of view or

involve components developed by many designers [5].

The aim of this paper is to report on recent progress in applying multi-valued logic to verification of not only temporal, but also epistemic properties of a MAS. Our approach is novel in offering a model checking method for a newly defined, multi-valued μ-calculus combined with knowledge modalities (named mv μK-calculus). We continue here the line of research initiated in our former papers [22, 21], showing that the general method of translating the model checking problem for mv CTL* to the two-valued model checking problem for CTL* considered in those papers can be extended to modal mv μK-calculus.

First, we show that an injection f of a De Morgan algebra $\mathcal{L} = (L, \leq, -\!\!-)$ underlying the mv-logic in question into itself which preserves the bounds in the lattice and complement allows us to translate the model-checking problem for the mv μK-calculus over $\mathcal{L}$ into the model-checking problem for the mv μK-calculus over a simpler algebra $\mathcal{L}' = (L', \leq \cap (L' \times L'), -\!\!- \cap L')$, where $L' = f(L)$. As before, a repeated application of this method reduces an mv model checking problem for the mv μK-calculus to a set of problems we can already solve.

Second, we treat the case when the translation f mentioned above does not preserve complement. Then in order to compute the value of a formula in the target, $\mathcal{L}'$-based model M$'$ for the mv μK-calculus, we need both the values of $f(x)$ and $f(\overline{x})$ for $x \in L$. For this purpose, we use negated propositions and a two-component transition relation, with the second component storing negation of the first.

The rest of the paper is organized as follows. In the next section we discuss the related work. The mv μK-calculus is introduced in Section 3. An example of a coffee machine is presented in Section 4. Then, in Section 5 the general translation method is given. In the last section we give some final remarks.

2. RELATED WORK

Translations from multi-valued temporal logics to the standard model checking problem were defined by several authors. The main idea behind the reduction techniques appears in Fitting's work [7, 8] on the connection between 'multi-expert' and 'multi-valued' semantics for a propositional modal logic. Reduction methods for the special case of **3**-valued logics were discussed in many papers [10, 14, 15]. In our former paper [22], we showed a translation from negation-free mv-CTL* model checking to CTL* model checking for models over finite quasi-boolean lattices. The above translation was generalized to the full multi-valued modal μ-calculus in [11, 2].

On the other hand, there have been recently several new approaches to model checking of temporal logics of knowledge: CTLK [12, 23, 25, 17], CTLKD [31, 28, 27], TCTLKD [32],and an epistemic extension of ATL [19, 20, 16].

3. LOGIC OF KNOWLEDGE AND TIME

In this section we define syntax and semantics of a multi-valued modal logic of knowledge, called mv μK-calculus.

Syntax of mv μK-calculus

Let PV be a set of propositional variables, and Var — a set of fixed point variables.

We consider a positive normal form of mv μK-calculus (called mv μK$^+$), where negation is only applied to propositional variables. It is important that mv μK$^+$ has the same expressive power as mv μK. The language of mv μK$^+$ is defined by:

$$\varphi :: = p \mid \neg p \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \mathrm{EX}\varphi \mid \mathrm{AX}\varphi \mid \mathrm{Z} \mid \mu Z.\varphi(Z) \mid \nu Z.\varphi(Z) \mid \mathrm{K}_i\varphi \mid \mathrm{D}_\Gamma\varphi \mid \mathrm{E}_\Gamma\varphi \mid \overline{\mathrm{K}}_i\varphi \mid \overline{\mathrm{D}}_\Gamma\varphi \mid \overline{\mathrm{E}}_\Gamma\varphi,$$

where p ranges over PV, Z — over Var, $i \in A$, and $\Gamma \subseteq A$, with A being a finite set of agents defined below. Here AX and EX represent the familiar temporal modalities "at the next step for all paths" and "at the next step for some path", while ν and μ are the greatest and the least fixed point modalities, respectively. When formulating properties in mv μK$^+$ we also use the following derived operators:

$$\mathrm{AG}\varphi = \nu Z.(\varphi \wedge \mathrm{AX}(Z)), \qquad \mathrm{EF}\varphi = \mu Z.(\varphi \vee \mathrm{EX}(Z)).$$

In turn, $\mathrm{K}_i, \mathrm{E}_\Gamma$ and D_Γ represent the well-known modalities of the logic of knowledge: K_i means "agent i knows", E_Γ — "everybody in group Γ knows" (everyone knows), and D_Γ — "somebody in group Γ knows" (distributed knowledge), with $\overline{\mathrm{K}}_i, \overline{\mathrm{E}}_\Gamma$ and $\overline{\mathrm{D}}_\Gamma$ being their duals. What is more, with help of ν and μ we can also define the more sophisticated group knowledge modality C_Γ (common knowledge), together with its dual $\overline{\mathrm{C}}_\Gamma$, as derived operators[1]

$$\mathrm{C}_\Gamma\varphi = \nu Z.(\mathrm{E}_\Gamma\varphi \wedge \mathrm{E}_\Gamma(Z)), \qquad \overline{\mathrm{C}}_\Gamma\varphi = \mu Z.(\overline{\mathrm{E}}_\Gamma\varphi \vee \overline{\mathrm{E}}_\Gamma(Z)).$$

Semantics for mv μK-calculus

We start with defining quasi-boolean lattices, which are used as logical domains of interpretation for the formulas of our multi-valued logics.

DEFINITION 1. *A* lattice *is a partial order $\mathcal{L} = (L, \leq)$, where, for any two elements $x, y \in L$, there exist their greatest lower bound (called* meet *and denoted by $x \cap y$) and their least upper bound (called* join *and denoted by $x \cup y$) with respect to the lattice order $\leq$.*[2]

In what follows, we consider **finite** lattices only, for which **F** (**T**) denotes the least (greatest, resp.) element.

DEFINITION 2. *A tuple $\mathcal{L} = (L, \leq, -\!\!-)$ is a* quasi-boolean algebra *if $(L, \leq)$ is a lattice and $-\!\!-$ is a unary operator (complement) having the following properties for any $x, y \in L$:*

- $\overline{x \cap y} = \overline{x} \cup \overline{y}$,
- $\overline{x \cup y} = \overline{x} \cap \overline{y}$,
- $x \leq y$ *iff* $\overline{y} \leq \overline{x}$,
- $\overline{\overline{x}} = x$.

$\mathcal{L}$ is distributive if the following two conditions hold for any $x, y, z \in L$:

- $z \cup (x \cap y) = (z \cup x) \cap (z \cup y)$,
- $z \cap (x \cup y) = (z \cap x) \cup (z \cap y)$.

[1] In the logic of knowledge, the usual practice is to introduce C_Γ as a primary operator, but the presence of the fixpoint operators in our logic allows us to derive it from the simpler knowledge modalities.

[2] Clearly, from antisymmetry of a partial order it follows that both the greatest lower bound and the least upper bound of x, y are uniquely determined elements of L.

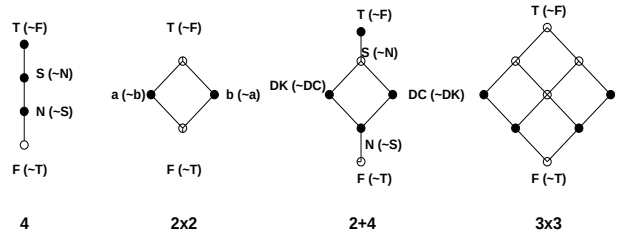

Figure 1: Examples of De Morgan algebras

A distributive, quasi-boolean algebra is called a De Morgan *algebra.*

EXAMPLE 1. *In Figure 3 we show a finite total order* **4** *representing uncertainty, and three well-known finite lattices, the use of which is motivated by clear practical intuitions: the lattices* $\mathbf{2} \times \mathbf{2}$ *and* $\mathbf{3} \times \mathbf{3}$ *representing disagreement, and the lattice* $\mathbf{2} + \mathbf{4}$ *representing both uncertainty and disagreement.*

The semantics of mv $\mu\mathrm{K}^+$ is based on the well-known notion of interpreted systems semantics [6], which can be shortly defined as follows. Assume a set $A = \{1, \ldots, n\}$ of agents, together with sets Loc_i and Act_i of local states and possible actions, respectively, for each agent $i \in A$, and sets Loc_e and Act_e of local states and actions for the environment. The set of global system states is defined as $S \subseteq Loc_1 \times \cdots \times Loc_n \times Loc_e$, where each $(l_1, \ldots, l_n, l_e) \in S$ represents a computational state of the whole system. Further assume a set of protocols $P_i : Loc_i \rightarrow 2^{Act_i}$, for $i = 1, \ldots, n$, representing the functional behaviour of every agent, and a function $P_e : Loc_e \rightarrow 2^{Act_e}$ for the environment. We can model the computation taking place in the system by means of a transition function $t : S \times Act \times S \longrightarrow L$, where $Act \subseteq Act_1 \times \cdots \times Act_n \times Act_E$ is the set of joint actions. We assume[3] $t(s, a, s') = t(s, a', s')$ for each $s, s' \in S$ and $a, a' \in Act$. Based on the above framework, we define the notion of a model underlying the semantics of mv $\mu\mathrm{K}^+$:

DEFINITION 3. *Given a set of agents* $A = \{1, \ldots, n\}$*, an mv modal epistemic* model *(or simply an mv model) is a tuple* $\mathrm{M} = (S, \mathcal{R}, \sim_1, \ldots, \sim_n, V, \mathcal{L})$*, where*

- S *is a finite set of global states of the system,*
- $\mathcal{R} : S \times S \rightarrow L \times L$ *is an mv transition relation on* S*,*
- $\sim_i \subseteq S \times S$ *(*$i \in A$*) is an* epistemic accessibility relation *for each agent* $i \in A$ *defined by* $s \sim_i s'$ *iff* $l_i(s') = l_i(s)$*, where* $l_i : S \longrightarrow Loc_i$ *extracts the local state of agent* i *from a global state* s*. Obviously,* $\sim_i$ *is an equivalence relation,*
- $V : S \times PV \rightarrow L$ *is a valuation function, for propositional variables* PV*,*
- $\mathcal{L} = (L, \leq, \overline{})$ *is a De Morgan algebra.*

Our definition of $\mathcal{R}$ is a bit more general than that of [11] as we assign two values to each transition. In what follows, by $\mathcal{R}_j(s,t)$, for $j = 1, 2$, we mean the j-th component of $\mathcal{R}(s,t)$. In the model corresponding to an interpreted system (defined above), we take $\mathcal{R}_1(s,s') = t(s,a,s')$ for some $a \in Act$. $\mathcal{R}_2$ [4] is used for storing the complement of $\mathcal{R}_1$. Next, we show a simple example of an mv model, which results from the standard two-valued model by using abstraction that collapses concrete states into a single abstract one. Typically, abstraction is used to overcome the state-explosion problem in classical model-checking

[3]This restriction allows to simplify the definition of $\mathcal{R}$ in a model.

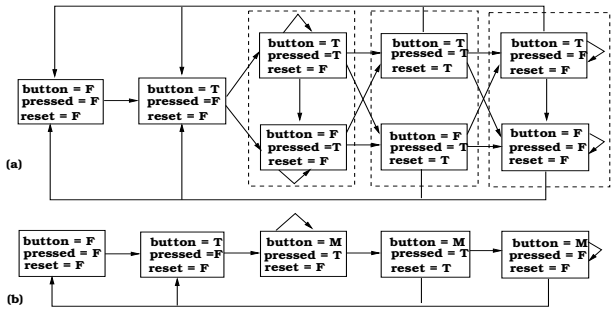

Figure 2: A model of the Button and the abstracted Button over the lattice 3

EXAMPLE 2. *The elevator model of Plath & Ryan consists of a single elevator which accepts requests made by agents (not shown in the figure) pressing buttons on the floor landings and from inside the elevator. The elevator moves up and down between floors and opens and closes its doors in response to these requests. The main module of the elevator is composed of several instances of the module Button (one per floor), which is shown in Figure 2 (a). Each of the states assigns values to the three propositional variables:* **button**, **pressed**, *and* **reset** *with the following meaning:* **button** $= T$ *- button available for pressing,* **pressed** $= F$*- button not latched, and* **reset** $= F$ *- request not fulfilled yet The arrows denote transitions between states. The transition relation is two-valued (so the transitions are not labeled) and corresponds to the possible changes between the states. The states indicated by the dashed lines (having symmetric transition relations) can be abstracted. This requires the use of a three-valued abstracted model (see Figure 2 (b)) in order to assign the value M (see Figure 5 (***3***)) to the variable* **button** *in the abstracted states.*

The semantics of mv $\mu\mathrm{K}^+$ is given by the function $[\cdot]^{\mathrm{M}}_{\rho}(s)$, which, for each formula φ of mv $\mu\mathrm{K}^+$, a model M, a state s in M, and a valuation of the fixed point variables $\rho : Var \longrightarrow L^S$, returns the value of φ at the state s of the model M for the valuation ρ, defined as follows:

- $[p]^M_\rho(s) = V(s,p)$ for $p \in PV$,
- $[Z]^M_\rho(s) = \rho(Z)(s)$ for $Z \in Var$,
- $[\neg p]^M_\rho(s) = \overline{[p]^M_\rho(s)}$,
- $[\varphi \vee \psi]^M_\rho(s) = [\varphi]^M_\rho(s) \cup [\psi]^M_\rho(s)$,
- $[\varphi \wedge \psi]^M_\rho(s) = [\varphi]^M_\rho(s) \cap [\psi]^M_\rho(s)$,
- $[\mathrm{EX}\varphi]^M_\rho(s) = \bigcup_{t \in S}(\mathcal{R}_1(s,t) \cap [\varphi]^M_\rho(t))$,

[4]We do not show $\mathcal{R}_2$ in the figures.

- $[\mathrm{AX}\varphi]^M_\rho(s) = \bigcap_{t\in S}(\overline{\mathcal{R}_1(s,t)} \cup [\varphi]^M_\rho(t))$,
- $[\nu Z.\varphi(Z)]^M_\rho(s) = \bigcup\{\mathcal{O} \in L^S \mid \mathcal{O} \leq' [\varphi]^M_{\rho[Z\to\mathcal{O}]}\}(s)$,
- $[\mu Z.\varphi(Z)]^M_\rho(s) = \bigcap\{\mathcal{O} \in L^S \mid [\varphi]^M_{\rho[Z\to\mathcal{O}]} \leq' \mathcal{O}\}(s)$, where $\rho[Z \to \mathcal{O}]$ coincides with ρ except for mapping Z to $\mathcal{O}$, and $\leq'$ is a pointwise extension of the corresponding operator of $\mathcal{L}$.
- $[\mathrm{K}_i\varphi]^M_\rho(s) = \bigcap_{\{s\in S|s\sim_i s'\}}[\varphi]^M_\rho(s')$,
- $[\mathrm{E}_\Gamma\varphi]^M_\rho(s) = \bigcap_{i\in\Gamma}[\mathrm{K}_i\varphi]^M_\rho(s)$
- $[\mathrm{D}_\Gamma\varphi]^M_\rho(s) = \bigcup_{i\in\Gamma}[\mathrm{K}_i\varphi]^M_\rho(s)$,
- $[\overline{\mathrm{K}}_i\varphi]^M_\rho(s) = \bigcup_{\{s\in S|s\sim_i s'\}}[\varphi]^M_\rho(s')$,
- $[\overline{\mathrm{E}}_\Gamma\varphi]^M_\rho(s) = \bigcup_{i\in\Gamma}[\overline{\mathrm{K}}_i\varphi]^M_\rho(s)$
- $[\overline{\mathrm{D}}_\Gamma\varphi]^M_\rho(s) = \bigcap_{i\in\Gamma}[\overline{\mathrm{K}}_i\varphi]^M_\rho(s)$,

where φ, ψ are formulas of mv $\mu\mathrm{K}^+$, $i \in A$ and $\Gamma \subseteq A$. Note that in fact we can get rid of negation (complement) completely. Indeed, negated propositions can be replaced by fresh propositions, following e.g. [1]. That is, for $p \in PV$ we can define $\overline{p}$ such that $V(s,\overline{p}) = \overline{V(s,p)}$[5]; the complements of the values of $\mathcal{R}_1$ can be represented by the second component of $\mathcal{R}$, set at $\mathcal{R}_2(s,t) = \overline{\mathcal{R}_1(s,t)}$; and $\overline{\mathcal{R}_1(s,t)}$ can be replaced by $\mathcal{R}_2(s,t)$ in the semantics of $\mathrm{AX}\varphi$. This way we can 'forget' about negation at the price of having to use two values for the transition relation. We show that the above 'trick' is superfluous not only when we do not translate formulas containing both universal and existential subformulas [11], but also when the translation preserves complement.

4. MOTIVATING EXAMPLES

Next, we show two examples. The first of them justifies the use of multiple logical values for expressing the knowledge possesed by agents, whereas the second one shows an mv model where the transition relation is also multivalued.

EXAMPLE 3. *Consider an agent B representing the bank, whose task is to decide if a customer C applying for a loan is to be granted that loan to not. For this purpose, the agent sends a query regarding the reliability of customer to a number of databases which contain information about bad debtors. From each database, B may obtain the following information:* **Yes**, *customer C is a bad debtor;* **No**, *customer C is not a bad debtor;* **Error** *- access denied or impossible. What is more, different databases can surely provide different responses — depending on whether customer C occurs in them or not. Clearly, in such a situation the two classical logical values are not enough, and the agent has to take into consideration all basic combinations of responses from the databases:* **F** *— no information on the customer;* **a** *— unanimous "***No***",* **b** *— unanimous "***Yes***", and* **T** *— inconsistent information from different databases (both "***No***" and "***Yes***" occur) Thus the natural logic for the agent would be a four-valued one, featuring the above values ordered into the lattice* $\mathbf{2}\times\mathbf{2}$ *shown in Figure 4. Let p_C represent the proposition "C is a bad debtor", and s — the agent's decision state. Then, given suitable formal details about the model* M[6]*, a resonable policy to be followed by the agent B is: Refuse the loan irrevocably if* $[K_B p_C]^{\mathrm{M}}(s) = \mathbf{b}$*, and grant it unconditionally if* $[K_B p_C]^{\mathrm{M}}(s) = \mathbf{a}$*. In turn, if* $[\overline{K}_B p_C]^{\mathrm{M}}(s) = \mathbf{F}$*, the agent could delay decision until getting some information from the databases, and if* $[\overline{K}_B p_C]^{\mathrm{M}}(s) = \mathbf{T}$ *(conflicting information about C's reliability) — demand a security for the credit from the customer.*

EXAMPLE 4. *In Figure 3 we show an example of a standard multi-valued model representing our requirements for a simple coffee machine (a modified example from [3]). The coffee machine can be operated by several agents. However, here we show one agent only, for simplicity and clarity sake. The model uses multiple truth values to distinguish between transitions and propositions that* **must**, **should**, **should not**, *or* **must not** *be true. Two types of unknown values are used:* **do not know** *for values controlled by the system, but not yet decided, and* **do not care** *for values controlled by the environment. Labelling a state s with $p = x$ means that $V(s,p) = x$, where p is a proposition and x is a truth value. Labelling a transition with x means that its truth value is x. In the figure we omit all the transitions labelled* **F**, *i.e., "prohibited". The coffee machine starts in the state* **OFF**, *where it is irrelevant whether a cup is provided or not, which is modeled by cup =* **DC**. *Since it has not been decided yet whether the machine should be able to go directly to* **IDLE**, *the corresponding transition is labelled* **DK**. *On the other hand, all the transitions labelled* **T** *represent the required changes of states. Note that the transitions from the states* **Delivers ...** *to* **OFF** *are labelled* **N**. *As they are dependent on the environment they cannot be prohibited, i.e., labelled with* **F**. *The value* **DK** *of the proposition power in the state* **IDLE** *represents the fact that it has not yet been decided whether the power should be ON or OFF on idle. Notice that the model abstracts away from the payments required from clients for simplicity sake.*

The transitions labelled with actions $BC, C + S, WC, WC + S, Ret$ are shared between the coffee machine and the agent. More precisely, a transition labelled with an action of the coffee machine can be only executed synchronously with a transition labelled with the same action of the drinking agent. Namely, the agent can select a type of coffee to be delivered by the machine and the machine returns to **READY** *only after the agent has finished drinking and moved back to the state* **HAPPY**.

There are several properties that can be specified and then checked in the model:

1. *The machine must eventually be able to deliver coffee,*
2. *Coffee is always delivered in a cup,*
3. *After coffee has been delivered, coffee cannot be immediately delivered again.*
4. *Always when coffee is delivered the agent knows that he is drinking,*
5. *Always when the agent is thirsty, he will eventually drink coffee,*
6. *Always when there is no coffee, the agent knows that he is not drinking.*

The properties of the coffee machine model can be specified by the following formulas:

[5]We consider only propositions that are used by the formula to be verified.

[6]We disregard ρ here for simplicity.

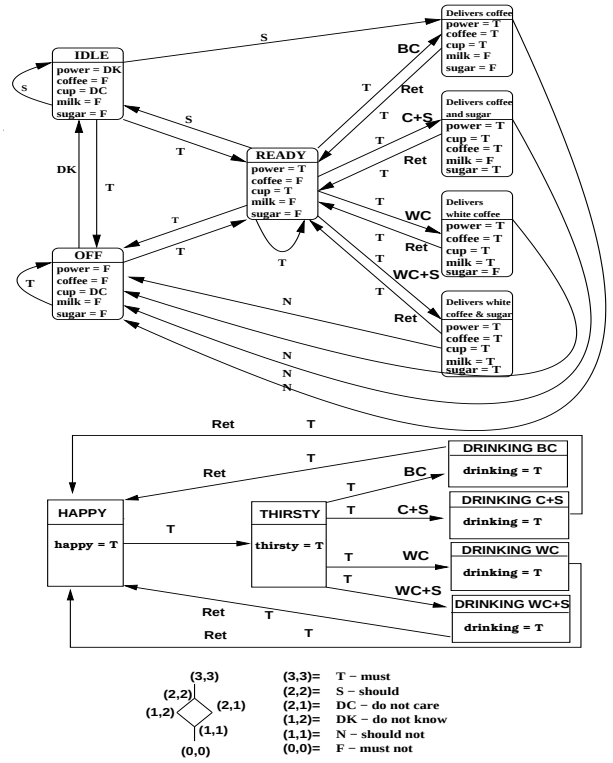

Figure 3: A coffee machine model with one drinking agent over the lattice $\mathbf{2 \times 2 + 2}$

1. EF*coffee*,
2. AG($\neg$*coffee* $\vee$ *cup*),
3. AG($\neg$*coffee* $\vee$ AX($\neg$*coffee*)).

The properties of the drinking agent model can be specified by the following formulas:

4. AG(*coffee* $\Rightarrow$ K$_1$*drinking*),
5. AG(*thirsty* $\Rightarrow$ EF *drinking*),
6. AG($\neg$ *coffee* $\Rightarrow$ K$_1\neg$*drinking*).

5. MODEL CHECKING FOR mv μK$^+$

Now we proceed with the basic results which will underlie all of the translations for the mv logic of knowledge and time with more than two logical values.

5.1 Translations preserving complement

THEOREM 1. *Let $\mathcal{L} = (L, \leq, \overline{})$ be an arbitrary quasi-boolean lattice* [7] *and let $f : L \to L$ be a function with $f(\mathbf{F}) = \mathbf{F}$ preserving complement and arbitrary bounds in $\mathcal{L}$, i.e.,*

$$f(\overline{x}) = \overline{f(x)}.$$
$$f(\bigcap_{i\in I} x_i) = \bigcap_{i\in I} f(x_i), \quad f(\bigcup_{i\in I} x_i) = \bigcup_{i\in I} f(x_i). \tag{1}$$

[7]Actually, the theorem holds for any lattice, but if $\mathcal{L}$ does not satisfy De Morgan laws, then the positive normal form mv μK$^+$ of mv μK we consider here is not equivalent to the full language mv μK allowing abritrary placement of negation.

where I is an arbitrary set of indices. Further, let $M = (S, \mathcal{R}, \sim_1, \ldots, \sim_n, V, \mathcal{L})$ be an L-valued model of mv μK^+, and let $M' = (S, \mathcal{R}', \sim_1, \ldots, \sim_n, V', f(\mathcal{L}))$ be a model[8] *with values in $f(L)$, obtained out of* M *by replacing each value $x \in L$ returned by V and $\mathcal{R}_1$ in* M *with $f(x)$, i.e., $\mathcal{R}'_1(s, s') = f(\mathcal{R}_1(s, s'))$ and $V'(s, p) = f(V(s, p))$, for $s, s' \in S$ and $p \in PV$. Then, for any formula φ of mv μK^+ over $\mathcal{L}$, any valuation ρ, any state s, and any $x \in f(L)$, we have*[9]

$$[\varphi]^{M'}_{f\rho}(s) = x \text{ iff } [\varphi]^M_\rho(s) \in f^{-1}(x) \tag{2}$$

The proof of the theorem is based on a key result for the extended language which we will define now. Assume the set of atomic formulas of our language mv μK$^+$ is extended by adding expressions of the form $\underline{\mathcal{R}_1}(\underline{s}, \underline{t})$ for $s, t \in S$, where, for any s, $\underline{s}$ is a constant representing the state s, and $\underline{\mathcal{R}_1}$ is a constant representing the first component of the mv-transition relation $\mathcal{R}$. Denote the resulting language by mv μK$_e$, and assume that the interpretation of mv μK$^+$ is accordingly extended to mv μK$_e$.

LEMMA 1. *Let a formula φ be such that $[\varphi]^M_\rho(s) = \bigcup_{i\in I}[\varphi_i]^M_\rho(g_i(s))$ or $[\varphi]^M_\rho(s) = \bigcap_{i\in I}[\varphi_i]^M_\rho(g_i(s))$ for any model M, any valuation ρ and any state s of M, where I is an arbitrary set, $\varphi_i \in$ mv μK_e, $g_i : S \to S$ for $i \in I$, and (2) holds for each φ_i. Then (2) holds for φ too.*

PROOF. We consider the case when $[\varphi]^M_\rho(s) = \bigcap_{i\in I}[\varphi_i]^M_\rho(g_i(s))$; proof of the other case is similar. As f preserves the bounds, by the assumption on φ we have $f([\varphi]^M_\rho(s)) = \bigcap_{i\in I} f([\varphi_i]^M_\rho((g_i(s)))$. Since each φ_i satisfies (2), this yields $f([\varphi]^M_\rho(s)) = \bigcap_{i\in I}[\varphi_i]^{M'}_{f\rho}(g_i(s)) = [\varphi]^{M'}_{f\rho}(s)$, whence $[\varphi]^{M'}_{f\rho}(s) = x$ iff $[\varphi]^M_\rho(s) \in f^{-1}(x)$, and (2) holds for φ. □

Now we can prove the theorem itself. To simplify notation, we drop the brackets in expressions denoting application of functions wherever possible. We use induction on the length of the formula. The hypothesis (2) clearly holds for propositional variables and their negations, as well as for $\underline{\mathcal{R}_1}(\underline{s}, \underline{t})$ and $\neg\underline{\mathcal{R}_1}(\underline{s}, \underline{t})$. It also holds for fixed point variables, since $f([Z]^M_\rho(s)) = f((\rho Z)(s)) = ((f\rho)(Z))(s) = [Z]^{M'}_{f\rho}(s)$. Next, we assume (2) holds for the formulas of length at most k, and prove it holds for any formula φ of length $k + 1$.

If $\psi = \varphi_1 \vee \varphi_2, \psi = \varphi_1 \wedge \varphi_2, \psi = \mathrm{EX}\varphi$, $\psi = \mathrm{AX}\varphi$, $\psi = \mathrm{K}_i\varphi$ for $i \in A$, where $\varphi, \varphi_1, \varphi_2$ are formulas of length at most k, then by the definition of semantics for $\vee, \wedge, \mathrm{EX}, \mathrm{AX}, \mathrm{K}_i, \overline{\mathrm{K}_i}$ the formula ψ satisfies the assumptions of Lemma 1, whence (2) holds for ψ by that lemma. Further, if $\psi \in \{\mathrm{D}_\Gamma\varphi, \mathrm{E}_\Gamma\varphi, \overline{\mathrm{D}_\Gamma}\varphi, \overline{\mathrm{E}_\Gamma}\varphi\}$, then by the definition of semantics for $\mathrm{D}_\Gamma, \mathrm{E}_\Gamma, \overline{\mathrm{D}_\Gamma}, \overline{\mathrm{E}_\Gamma}$ and the result obtained above for $\mathrm{K}_i\varphi, \overline{\mathrm{K}_i}\varphi$ the formula ψ satisfies the assumptions of the lemma too.

It remains to consider the case when $\psi \in \{\mu Z.\varphi(Z), \nu Z.\varphi(Z)\}$, where φ is of length at most k. We shall only give the proof for the operator μ, since the case of ν is just dual, and the case of $\mathrm{C}_\Gamma\varphi$ reduces to the latter. Let $[\varphi]^M_\rho$ denote the function which maps each $s \in S$ to $[\varphi]^M_\rho(s)$. First, note that (2) is equivalent to

$$f([\varphi]^M_\rho) = [\varphi]^{M'}_{f\rho} \tag{3}$$

[8]By $f(\mathcal{L})$ we denote the structure $(f(L), \leq \cap (f(L) \times f(L)), \overline{} \cap f(L))$.

[9]The composition of the functions f and ρ is denoted by $f\rho$ or by $f(\rho)$.

We shall assume the above holds for φ, and prove it also holds for $\psi = \mu Z.\varphi(Z)$.

By the fixed point properties of μ [29], we have

$$[\psi]^M_\rho = \bigcup_{i=0}^{\infty} [\varphi]^M_{\rho_i} \tag{4}$$

where $\rho_0 = \rho[Z \to \mathbf{FF}]$[10], $\rho_{i+1} = \rho_i[Z \to [\varphi]^M_{\rho_i}]$ for $i \geq 0$. Likewise,

$$[\psi]^{M'}_{f\rho} = \bigcup_{i=0}^{\infty} [\varphi]^{M'}_{\rho'_i} \tag{5}$$

where $\rho'_0 = (f\rho)[Z \to \mathbf{FF}], \rho'_{i+1} = \rho'_i[Z \to [\varphi]^{M'}_{\rho'_i}]$ for $i \geq 0$. We shall now prove by induction on i that

$$f\rho_i = \rho'_i,\ i \geq 0 \tag{6}$$

For $i = 0$, we have $f\rho_0 = f(\rho[Z \to \mathbf{FF}]) = (f\rho)[Z \to \mathbf{FF}] = \rho'_0$, since $f(\mathbf{F}) = \mathbf{F}$. Now assume the thesis holds for some $i \geq 0$. Then, $f\rho_{i+1} = f(\rho_i[Z \to [\varphi]^M_{\rho_i}]) = f\rho_i([Z \to [\varphi]^{M'}_{f\rho_i}]) = \rho'_i[Z \to [\varphi]^{M'}_{\rho'_i}] = \rho'_{i+1}$, where the second equality follows from the inductive assumption on φ, and the third - from the inductive assumption on ρ_i. This ends the proof of (6). As f preserves arbitrary bounds, from (4), the inductive assumption on φ, and finally (5) we get that $f([\psi]^M_\rho) =$

$$f(\bigcup_{i=0}^{\infty}([\varphi]^M_{\rho_i})) = \bigcup_{i=0}^{\infty} f([\varphi]^M_{\rho_i}) = \bigcup_{i=0}^{\infty}[\varphi]^{M'}_{f\rho_i} = \bigcup_{i=1}^{\infty}[\varphi]^{M'}_{\rho'_i} = [\psi]^{M'}_{f\rho}$$

Thus (3) holds for ψ too, which ends the proof.

First and foremost, the bounds and complement preservation conditions (1) imply clearly that $f(\mathcal{L}) = (f(L), \leq \cap\ (f(L) \times f(L)), \overline{} \cap f(L))$ is a De Morgan subalgebra of $\mathcal{L}$ - hence we can indeed consider a model M' taking values in $f(L)$. This theorem provides the basis for reducing the model-checking problem over an algebra $\mathcal{L}$ to the model-checking problems over its proper subalgebras of the form $f(\mathcal{L})$, where f is the mapping referred to in Theorem 1.

The general method defines k mappings (translations) $f_1, \ldots, f_k$ such that:

- $f_1(\mathcal{L}), \ldots, f_k(\mathcal{L})$ are algebras for which we already have model-checking algorithms,
- for any $x \in L$, there exist some $x_i \in f_i(L), i = 1, \ldots, k$, such that $\bigcap_{i=1}^{k} f_i^{-1}(x_i) = \{x\}$[11].

Indeed: in such a case, Theorem 1 implies that, for any formula φ of mv $\mu\mathrm{K}^+$, any model M over $\mathcal{L}$, any valuation ρ, and any state $s \in S$, $[\varphi]^M_\rho(s) = x$ iff $[\varphi]^{M_i}_{f_i\rho}(s) = x_i$ for all $i = 1, \ldots, k$, where each M_i is the model over $f_i(L)$ obtained out of M using the mapping (translation) f_i. Hence the model-checking problem for $\mathcal{L}$ reduces to the model-checking problems over $f_1(\mathcal{L}), \ldots, f_k(\mathcal{L})$.

Notice that so far we have not used the second component of $\mathcal{R}$, i.e., $\mathcal{R}_2$, which is not needed in the case where the translation preserves complement.

[10] $\mathbf{FF}$ denotes the function $S \longrightarrow \{\mathbf{F}\}$.

[11] Note that the condition imposed on the x_i's is satisfied by join-irreducible elements (see Definition 4). In that case, the condition is equivalent to Birkhoff's representation theorem for finite distributive lattices. To the authors' best knowledge, the above formulation is new.

5.2 Translations not preserving complement

When complement is not preserved by our translation f, we cannot directly reduce the validity over M to the validity over M' using single values for V and $\mathcal{R}$ only. The problem is that in order to compute $[\varphi]^{M'}_{f\rho}$ we need both the values $f(x)$ and $f(\overline{x})$ for $x = V(s,p)$ or $x = \mathcal{R}_1(s,s')$. Unfortunately, now $f(\overline{x})$ cannot be computed from $f(x)$. Therefore, to keep this information we need new names not only for the negated propositions, but also for the complement of the first component of the transition relation. The situation with the propositions is much easier to deal with as we can simply assign fresh propositions to the states. As far as the transition relation is concerned, there are several possibilities to deal with $\mathcal{R}_1(s,s')$. When translating to **2**, one could obviously get a standard 2-valued model by duplicating states (see [2] or [11] p. 275) of M, so that the values of $f(\mathcal{R}_1(s,s'))$ and $f(\overline{\mathcal{R}_1(s,s')})$ were available as corresponding to the transition between either the original states or their copies.

Here we suggest also another solution, which would not give us a standard model, but does not require duplicating states, and can be directly used by some model checkers which encode transition relation w.r.t. the formula to be verified. As we have already mentioned in the former section, the idea is to use the second component of $\mathcal{R}$ to store the complement of the first one in the model M, i.e., to have $\mathcal{R}_2(s,s') = \overline{\mathcal{R}_1(s,s')}$, and to replace $\overline{\mathcal{R}_1(s,s')}$ with $\mathcal{R}_2(s,s')$ in the semantics of $\mathrm{AX}\varphi$. Then the function f is applied to both the values, returning $\mathcal{R}'_1(s,s') = f(\mathcal{R}_1(s,s'))$ and $\mathcal{R}'_2(s,s') = f(\mathcal{R}_2(s,s'))$ in M'. In other words, we translate the complement of $\mathcal{R}_1(s,s')$ directly. In case of two-valued models, the transitions would be labelled by pairs $(\mathbf{F},\mathbf{F}), (\mathbf{F},\mathbf{T}), (\mathbf{T},\mathbf{F})$, and $(\mathbf{T},\mathbf{T})$, and depending on whether the value of an existential or an universal formula is computed, either the first or the second element of the pair would be used.

5.3 Translation to 2-valued algebra

In this section we show that the translation method based on join irreducible elements [11, 2] can be seen as a special instance of our general translation.

Definition 4. *An element $l \in L$ is called* join-irreducible *iff $l \neq \mathbf{F}$ and, for any $x, y \in L$, $l = x \cup y$ implies that either $l = x$ or $l = y$.*
The set of all the join-irreducible elements of a lattice $\mathcal{L}$ is denoted by $\mathcal{JI}(\mathcal{L})$.

In Figure 3, the join-irreducible elements in the lattices are marked with black dots.

It is well known that every element of a finite distributive lattice can be uniquely decomposed into the join of all the join-irreducible elements in its downard closure $\downarrow x = \{y \in L \mid y \leq x\}$ of x, i.e.,

$$x = \bigcup(\mathcal{JI}(\mathcal{L}) \cap \downarrow x) \tag{7}$$

Let S be a set and $\mathcal{L} = (L, \leq, \overline{})$ a De Morgan algebra. Denote by L^S the set of all the functions from S to L. Then, $(L^S, \leq', \overline{}')$ is a De Morgan algebra, where $\leq'$ and $\overline{}'$ are pointwise extensions of the corresponding operators of $\mathcal{L}$.

For $x \in L$ let $\uparrow x = \{y \in L \mid x \leq y\}$ denote the upward closure of x.

THEOREM 2. *Let $\mathcal{L}$ be a finite De Morgan algebra, and let $l \in \mathcal{JI}(\mathcal{L})$. Then, the function $f_l : L \longrightarrow \{\mathbf{T}, \mathbf{F}\}$ defined by $f_l(\uparrow l) = \mathbf{T}$ and $f_l(L \setminus \uparrow l) = \mathbf{F}$ preserves arbitrary bounds.*

PROOF. This proof uses two facts, namely that $l \in \mathcal{JI}(\mathcal{L})$ and that $\mathcal{L}$ is distributive. We should prove that

$$\text{(a) } f_l(\bigcup_{i\in I} x_i) = \bigcup_{i\in I} f_l(x_i), \qquad \text{(b) } f_l(\bigcap_{i\in I} x_i) = \bigcap_{i\in I} f_l(x_i)$$

(a): Obviously, $f_l(\bigcup_{i\in I} x_i) = \mathbf{T}$ implies $(\bigcup_{i\in I} x_i) \in \uparrow l$, whence $l = l \cap \bigcup_{i\in I} x_i$. As $\mathcal{L}$ is distributive, the latter implies $l = \bigcup_{i\in I}(l \cap x_i)$. Since $l \in \mathcal{JI}(\mathcal{L})$, one can easily see that this in turn yields $l \cap x_i = l$, i.e., $x_i \in \uparrow l$, for some $i \in I$, whence $f_l(x_i) = \mathbf{T}$, and in consequence $\bigcup_{i\in I} f_l(x_i) = \mathbf{T}$.

Conversely, if $\bigcup_{i\in I} f_l(x_i) = \mathbf{T}$, then $f_l(x_i) = \mathbf{T}$ for some $i \in I$. Thus $x_i \in \uparrow l$ for some $i \in I$, whence $\bigcup_{i\in I} x_i \in \uparrow l$ by the monotonicity of join and $f_l(\bigcup_{i\in I} x_i) = \mathbf{T}$, which proves (a).

(b): Clearly, $f_l(\bigcap_{i\in I} x_i) = \mathbf{T}$ iff $\bigcap_{i\in I} x_i \in \uparrow l$ iff $x_i \in \uparrow l$ for each $i \in I$ by the anti-monotonicity of join. This in turn holds iff $f_l(x_i) = \mathbf{T}$ for each $i \in I$ iff $\bigcap_{i\in I} f_l(x_i) = \mathbf{T}$. Thus (b) holds too. □

By (7), for each $x \in L$ we have $x = \bigcup(\mathcal{JI}(\mathcal{L}) \cap \downarrow x)$. Let M^l be the model obtained using the translation f_l. Therefore, according to Theorem 1 (provided f_l preserves complement)

$$[\varphi]^{M_l}_{f_l(\rho)}(s) = x \text{ iff } [\varphi]^M_\rho(s) \in f_l^{-1}(x)$$

whence

$$[\varphi]^{M_l}_{f_l(\rho)}(s) = \mathbf{T} \text{ iff } [\varphi]^M_\rho(s) \in \uparrow l$$

Thus,

$$[\varphi]^M_\rho(s) = \bigcup\{l \in \mathcal{JI}(\mathcal{L}) \mid [\varphi]^{M_l}_{f_l(\rho)}(s) = \mathbf{T}\} \qquad (8)$$

Now, we give a sufficient condition for f_l to preserve complement.

THEOREM 3. *Let f_l be the translation function defined as in Theorem 2 for $l \in \mathcal{JI}(\mathcal{L})$ satisfying the following condition: for each $x \in L$, $x \in \uparrow l$ iff $\overline{x} \in L \setminus \uparrow l$. Then, f_l preserves complement, i.e., $f_l(\overline{x}) = \overline{f_l(x)}$ for each $x \in L$.*

PROOF. By the definition of f_l, we have $f_l(\overline{x}) = \mathbf{T}$ iff $\overline{x} \in \uparrow l$. By the condition assumed, the latter holds iff $\overline{\overline{x}} \in L \setminus \uparrow l$. As $\overline{\overline{x}} = x$, this is true iff $f_l(x) = \mathbf{F}$, whence indeed $f_l(\overline{x}) = \overline{f_l(x)}$. □

EXAMPLE 5. *For three lattices and their join-irreducible elements l, we show which of the corresponding functions f_l preserve (Figure 4) and which do not preserve (Figure 5) complement. Notice that no translation from* **3** *preserves complement. This explains why all the existing translations require duplication of states in the translated models. For the lattice* **4** *only f_S preserves complement, for* $\mathbf{2} \times \mathbf{2}$ *both the functions f_a and f_b preserve complement, whereas for* $\mathbf{2} + \mathbf{4}$ *only f_{DK} and f_{DC} do so. The functions f_l for the remaining join-irreducible elements l of the above lattices do not preserve complement. To mark a translation graphically, we adopt the convention that the lattice elements lying above the extra line are superimposed on the lattice structure mapped to* **T**, *whereas the elements below the line are mapped to* **F**. *Notice that for the lattice* $\mathbf{2} + \mathbf{4}$ *two translations are shown in Figure 4.*

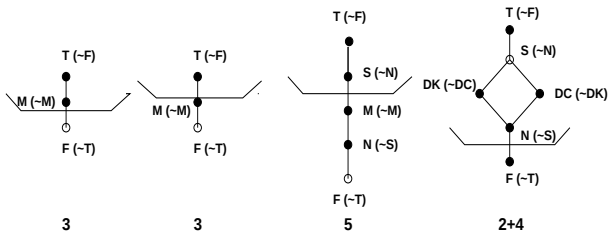

Figure 5: Translations not preserving complement

6. FINAL REMARKS

We have combined here three different logical frameworks: the logic of knowledge with interpreted system semantics, temporal logic and modal μ-calculus. Motivated by the cases of incomplete or inconsistent information occurring in real life applications, we have equipped the resulting cross-framework language in a logical domain being an arbitrary De Morgan lattice. We have obtained a new, unified mv logic of knowledge and time with a great expressive power, providing a universal framework for reasoning simultaneously about the phenomena related to knowledge and properties of concurrent systems in a multi-valued environment, and featuring additionally the fixpoint operators of μ-calculus. We have shown that the general method of model checking for mv temporal logic and mv μ-calculus via a translation to standard, two-valued models which preserves the lattice bounds, developed in our earlier papers, can be extended to the above unified logic, and is characterized by greater efficiency if the translation preserves complement in addition to the bounds. We have also given several examples illustrating the motivation for this type of framework and supporting practical applicability of our improvement.

ABSTRACT

Qualitative Coalitional Games (QCGs) are a version of coalitional games in which an agent's desires are represented as goals which are either satisfied or unsatisfied, and each choice available to a coalition is a set of goals, which would be jointly satisfied if the coalition made that choice. A coalition in a QCG will typically form in order to bring about a set of goals that will satisfy all members of the coalition. In this paper, we introduce and study *Temporal QCGs* (TQCGs), i.e., games in which a sequence of QCGs is played. In order to represent and reason about such games, we introduce a linear time temporal logic of QCGs, known as $\mathcal{L}(TQCG)$. We give a complete axiomatization of $\mathcal{L}(TQCG)$, use it to investigate the properties of TQCGs in a small example, identify its expressive power, establish its complexity, characterise classes of TQGCs with formulas from our logical language, and formulate several (temporal) solution concepts for TQCGs.

1. INTRODUCTION

The study of repeated games now forms a major component of the game theory literature [9, pp.133–161]. Perhaps the best-known example of such a repeated game is the iterated prisoner's dilemma, which has for example been studied both analytically [3, pp.353-358] and by means of competitions [2].

Given the role of game theory as a theoretical underpinning to the multi-agent systems field [11], it seems that repeated games are of particular importance to the field. By-and-large, we are not interested in building multi-agent systems that will operate in a "one-shot" fashion: we typically want them to operate over time, often without a pre-defined termination time. Moreover, given the important role that *coalitional games* play in multi-agent systems [12, 13], it seems that repeated coalitional games are also likely to be of significance. However, comparatively little research has considered repeated coalitional games, or coalitional games played over time [7].

Our aim in this paper is to study an iterated version of *Qualitative Coalitional Games* (QCGs) [15], a variation of coalitional games in which agent's desires are represented as goals which are either satisfied or unsatisfied, and each choice available to a coalition is a set of goals, which would be jointly satisfied if the coalition made that choice. A coalition in a QCG will typically form in order to bring about a set of goals that will satisfy all members of the coalition. In this paper, we introduce and study *Temporal QCGs* (TQCGs): games in which QCGs are played repeatedly. In order to represent and reason about such games, we introduce $\mathcal{L}(TQCG)$, a linear time temporal logic of QCGs. We give a complete axiomatization of $\mathcal{L}(TQCG)$, demonstrate its expressive power with respect to a type of simulation between TQCGs, establish the computational complexity of satisfiability for TQCGs, investigate the properties of TQCGs by characterising them as formulae in $\mathcal{L}(TQCG)$ and finally characterise some solution concepts of TQCGs in $\mathcal{L}(TQCG)$.

We begin, in the following section, with a short introduction to QCGs. As part of this introduction, in section 2.1 we define a logic for expressing properties of individual QCGs: this logic will serve as the "state language" or "assertion language" for the temporal QCG logic. In section 3, we introduce TQCGs. We begin with a short informal motivation, then give the temporal language for expressing properties of TQCGs, present an example to illustrate the idea of TQCGs and the role of the temporal language, investigate the expressive power of the language by means of a simulation relation between TQCG structures, give a complete axiomatization of the temporal language, and then investigate the axiomatic characterisation of various classes of TQCGs.

2. QUALITATIVE COALITIONAL GAMES

We give a brief introduction to Qualitative Coalitional Games (QCGs): details may be found in [15]. A QCG contains a (non-empty, finite) set $\mathcal{A} = \{1, \ldots, m\}$ of *agents*. Each agent $i \in \mathcal{A}$ is assumed to have associated with it a (finite) set $\mathcal{G}_i$ of *goals*, drawn from a set of overall possible goals $\mathcal{G}$. The intended interpretation is that the members of $\mathcal{G}_i$ represent all the individual rational outcomes for i – intuitively, the outcomes that give it "better than zero utility". That is, agent i would be happy if *any* member of $\mathcal{G}_i$ were

achieved – then it has "gained something". But, in QCGs, we are not concerned with preferences over individual goals. Thus, at this level of modelling, i is *indifferent* among the members of $\mathcal{G}_i$: it will be *satisfied* if *at least one* member of $\mathcal{G}_i$ is achieved, and *unsatisfied* otherwise. Note that cases where more than one of an agent's goals are satisfied are not an issue – an agent's aim will simply be to ensure that at least one of its goals is achieved, and there is no sense of an agent i attempting to satisfy as many members of $\mathcal{G}_i$ as possible.

A *coalition*, typically denoted by C, is simply a set of agents, i.e., a subset of $\mathcal{A}$. The *grand coalition* is the set of all agents, $\mathcal{A}$. We assume that each possible coalition has available to it a set of possible *choices*, where each choice intuitively characterises the outcome of one way that the coalition could cooperate. We model the choices available to coalitions via a *characteristic function* with the signature $\mathcal{V} : 2^{\mathcal{A}} \rightarrow 2^{2^{\mathcal{G}}}$. Thus, in saying that $G \in \mathcal{V}(C)$ for some coalition $C \subseteq \mathcal{A}$, we are saying that one choice available to the coalition C is to bring about *exactly* the goals in G. At this point, the reader might expect to see some constraints placed on characteristic functions. For example, at first sight the following *monotonicity* constraint might seem natural: $C \subseteq C'$ implies $\mathcal{V}(C) \subseteq \mathcal{V}(C')$. Although such a constraint is entirely appropriate for many scenarios, there are cases where such a constraint is not appropriate[1].

Bringing these components together, a qualitative coalitional game (QCG) is a tuple:

$$\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V} \rangle \text{ where}$$

- $\mathcal{A}$ is a finite, non-empty set of *agents*;
- $\mathcal{G}$ is a finite, non-empty set of possible *goals*;
- $\mathcal{G}_i \subseteq \mathcal{G}$ is the set of goals for agent $i \in \mathcal{A}$; and
- $\mathcal{V} : 2^{\mathcal{A}} \rightarrow 2^{2^{\mathcal{G}}}$ is the characteristic function of the game.

EXAMPLE 1. *Let Γ_1 be the following QCG for a collection of agents and a collection of goals $\{g_1, \ldots\}$. Agent 1 is satisfied with g_1 and g_4, and agent 2 is satisfied with g_2 and g_3. The characteristic function, where C_1, C_2, C_3, C_4 are different coalitions:*
$\mathcal{V}(C_1) = \{ \{g_1, g_2\} \}$ $\mathcal{V}(C_2) = \{ \{g_2, g_3\}, \{g_1\} \}$
$\mathcal{V}(C_3) = \{ \{g_5, g_6\} \}$ $\mathcal{V}(C_4) = \{ \{g_2, g_3\}, \{g_1\}, \{g_4\} \}$
We will make use of Γ_1 in later examples.

2.1 A Logic for QCGs

A logic for expressing properties of individual QCGs has not been formalised before. We now introduce such a logic. This logic will later be used as the assertion language, or state language, for the temporal logic we develop in section 3. The language is defined in two parts: $\mathcal{L}_c$ is the *satisfaction language*, and is used to express properties of choices made by agents. The basic constructs in this language are of the form sat_i, meaning "agent i is satisfied". The overall language $\mathcal{L}(QCG)$ is used for expressing properties of QCGs themselves. The main construct in this language is of the form $\langle C \rangle \varphi$, where φ is a formula of the satisfaction language, and means that C have a choice such that this choice makes φ true. For example, $\langle 3 \rangle (sat_1 \wedge sat_4)$ will mean that 3 has a choice that simultaneously satisfies agents 1 and 4.

Formally, the grammar φ_c defines the *satisfaction language* $\mathcal{L}_c$, while φ_q defines the *QCG language* $\mathcal{L}(QCG)$.

$$\begin{array}{lcl} \varphi_c & ::= & sat_i \mid \neg\varphi_c \mid \varphi_c \vee \varphi_c \\ \varphi_q & ::= & \langle C \rangle \varphi_c \mid \neg\varphi_q \mid \varphi_q \vee \varphi_q \end{array}$$

[1]For example, consider a legal scenario in which certain coalitions are forbidden by monopoly or anti-trust laws.

where $i \in \mathcal{A}$ and $C \subseteq \mathcal{A}$. (We note some similarities between our logical language $\mathcal{L}(QCG)$ and Pauly's language for axiomatizing judgement aggregation procedures [10], although the motivation and use of the languages are quite different.)

We use the usual derived propositional connectives ($\wedge$, $\rightarrow$, $\leftrightarrow$) for both languages $\mathcal{L}_c$ and $\mathcal{L}(QCG)$, and in addition write $[C]\varphi$ to abbreviate $\neg\langle C \rangle \neg\varphi$. The formula $[C]\varphi$ will be defined to be true exactly when φ is a *necessary* consequence of the coalition C making a choice; φ will be true no matter *which* choice the coalition makes. When $C = \{a\}$ is a singleton, we sometimes write $\langle a \rangle$ and $[a]$ for $\langle C \rangle$ and $[C]$.

When $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V} \rangle$ is a QCG, $G \subseteq \mathcal{G}$ and $\varphi \in \mathcal{L}_c$, $\Gamma, G \models_Q \varphi$ is defined as follows:

$\Gamma, G \models_Q sat_i$ iff $\mathcal{G}_i \cap G \neq \emptyset$
$\Gamma, G \models_Q \neg\psi$ iff not $\Gamma, G \models_Q \psi$
$\Gamma, G \models_Q \psi_1 \vee \psi_2$ iff $\Gamma, G \models_Q \psi_1$ or $\Gamma, G \models_Q \psi_2$

When $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V} \rangle$ is a QCG and φ is a $\mathcal{L}(QCG)$ formula, $\Gamma \models_Q \varphi$ is defined as follows:

$\Gamma \models_Q \langle C \rangle \psi$ iff there is a $G \in \mathcal{V}(C)$ such that $\Gamma, G \models_Q \psi$
$\Gamma \models_Q \neg\psi$ iff not $\Gamma \models_Q \psi$
$\Gamma \models_Q \psi_1 \vee \psi_2$ iff $\Gamma \models_Q \psi_1$ or $\Gamma \models_Q \psi_2$

EXAMPLE 2. *Let Γ_1 be as in Example 1. Then:*

$\Gamma_1 \models_Q \langle C_1 \rangle (sat_1 \wedge sat_2)$
$\Gamma_1 \models_Q (\langle C_2 \rangle sat_1 \wedge \langle C_2 \rangle sat_2) \wedge \neg(\langle C_2 \rangle (sat_1 \wedge sat_2))$
$\Gamma_1 \models_Q \neg(\langle C_3 \rangle sat_1 \vee \langle C_3 \rangle sat_2)$

Summarising, the satisfaction of agents is evaluated against a set of goals, while Boolean combinations of expressions referring to choices of coalitions are evaluated on a QCG Game Γ. The latter combinations will be the atomic assertions in our temporal framework of Section 3.

2.2 Expressive Power of L(QCG)

We look at the properties of QCGs which are definable in our language. It is clear from our language definition that what $\mathcal{L}(QCG)$ can express is which coalition can satisfy which set of agents concurrently. Note that we are not interested in *how* the coalitions make certain sets of agents satisfied, nor *why* an agent is satisfied (i.e., which goal satisfied him). We will now demonstrate that the properties of QCGs we can express in the language $\mathcal{L}(QCG)$ are exactly the properties closed under a notion of *QCG-simulation*. In other words, the language can not differentiate two games Γ and Γ' iff they *QCG-simulate* each other.

Obviously, equivalence of models transcends mere isomorphism. In particular, the semantics of performing a *choice* seem to depend only on which agents are satisfied by the choice. For example, one could imagine a mapping between "equivalent" goals of two models, maybe collapsing two goals of one model into one goal of the other. However, such a relation between models does not capture all instances of equivalent models. What is needed is a relation between *sets* of goals. This motivates the following definition of a QCG-simulation as a *relation* between two models. It is only necessary to relate goals which can actually be chosen by some coalition. Furthermore, it only makes sense to relate models which are defined over the same set of agents.

A relation

$$Z \subseteq \bigcup_{C \subseteq \mathcal{A}} (\mathcal{V}(C) \times \mathcal{V}'(C))$$

is a *QCG-simulation* between two QCGs $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V} \rangle$ and $\Gamma' = \langle \mathcal{A}, \mathcal{G}', \mathcal{G}'_1, \ldots, \mathcal{G}'_n, \mathcal{V}' \rangle$ iff the following conditions hold for all coalitions C.

1. If GZG' then $G \cap \mathcal{G}_i = \emptyset$ iff $G' \cap \mathcal{G}'_i = \emptyset$, for all i (the *satisfaction condition*)
2. For every $G \in \mathcal{V}(C)$ there is a $G' \in \mathcal{V}'(C)$ such that GZG' (Z is *total*)
3. For every $G' \in \mathcal{V}'$ there is a $G \in V(C)$ such that GZG' (Z is *surjective*)

If there exist a QCG-simulation between two games Γ and Γ', we write $\Gamma \rightleftharpoons \Gamma'$. If $\Gamma \rightleftharpoons \Gamma'$, we can simulate any choice in one model with a choice in the other, and vice versa. This notion of simulation is somewhat similar to the notion of "alternating simulation" between alternating transition systems in [1].

EXAMPLE 3. *Let Γ_2 be the QCG with the same agents as in Γ_1 (Example 1), goals $f_1, f_2, \ldots$ such that agent 1 is satisfied in f_1 and f_3 and agent 2 is satisfied in f_2, f_3 and f_4, and the following characteristic function:*

$$\mathcal{V}(C_1) = \{\ \{f_3\}\ \} \quad \mathcal{V}(C_2) = \{\ \{f_2\}, \{f_1\}\ \}$$
$$\mathcal{V}(C_3) = \{\ \{f_5\}\ \} \quad \mathcal{V}(C_4) = \{\ \{f_1\}, \{f_2\}, \{f_4\}\ \}$$

Then $\Gamma_1 \rightleftharpoons \Gamma_2$. The relation Z consisting of the following pairs is a QCG-simulation between Γ_1 and Γ_2.

$$\begin{array}{ccc} \langle\{g_1, g_2\}, \{f_3\}\rangle & \langle\{g_2, g_3\}, \{f_2\}\rangle & \langle\{g_1\}, \{f_1\}\rangle \\ \langle\{g_5, g_6\}, \{f_5\}\rangle & \langle\{g_2, g_3\}, \{f_2\}\rangle & \langle\{g_2, g_3\}, \{f_4\}\rangle \\ \langle\{g_1\}, \{f_1\}\rangle & \langle\{g_4\}, \{f_1\}\rangle & \end{array}$$

Note that Z is not a function, nor the inverse of a function.

We write $\Gamma \equiv \Gamma'$ iff $\forall_{\varphi \in \mathcal{L}(QCG)}[\Gamma \models_Q \varphi \Leftrightarrow \Gamma' \models_Q \varphi]$.

THEOREM 1. *Satisfaction is invariant under QCG-simulation:*

$$\Gamma \rightleftharpoons \Gamma' \quad \Rightarrow \quad \Gamma \equiv \Gamma'$$

PROOF. Let $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V}\rangle$ and $\Gamma' = \langle \mathcal{A}, \mathcal{G}', \mathcal{G}'_1, \ldots, \mathcal{G}'_n, \mathcal{V}'\rangle$ with $\Gamma \rightleftharpoons \Gamma'$. First, we show that

$$GZG' \Rightarrow (\Gamma, G \models_Q \psi \Leftrightarrow \Gamma', G' \models_Q \psi) \qquad (1)$$

for any ψ by induction over ψ. For the base case, let $\psi = sat_i$. $\Gamma, G \models_Q \psi$ iff $\mathcal{G}_i \cap G \neq \emptyset$ iff, by the satisfaction condition, $\mathcal{G}'_i \cap G' \neq \emptyset$ iff $\Gamma', G' \models_Q \psi$. The inductive step (negation and disjunction) is straightforward. We now show that

$$\Gamma \models_Q \varphi \Leftrightarrow \Gamma' \models_Q \varphi$$

for any φ by induction on φ. For the base case, let $\varphi = \langle C\rangle\psi$. For the direction to the right, if $\Gamma \models_Q \varphi$ then there is a $G \in \mathcal{V}(C)$ such that $\Gamma, G \models_Q \psi$. By totality of Z, there is a $G' \in \mathcal{V}'(C)$ such that GZG'. By (1), $\Gamma', G' \models_Q \psi$, and thus $\Gamma' \models_Q \varphi$. The direction to the left is symmetric: if $\Gamma' \models_Q \varphi$ there is a $G' \in \mathcal{V}'(C)$ such that $\Gamma', G' \models_Q \psi$; by surjectivity of Z there is a $G \in \mathcal{V}(C)$ such that GZG'; and by (1) $\Gamma, G \models_Q \psi$ and thus $\Gamma \models_Q \varphi$. The inductive step (negation and disjunction) is straightforward. □

The obvious question now is whether every pair of equivalent models are connected by a QCG-simulation. The answer is "yes".

THEOREM 2. *Let Γ, Γ' be defined over the same set of agents:*

$$\Gamma \rightleftharpoons \Gamma' \quad \Leftarrow \quad \Gamma \equiv \Gamma'$$

PROOF. Let $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V}\rangle$ and $\Gamma' = \langle \mathcal{A}, \mathcal{G}', \mathcal{G}'_1, \ldots, \mathcal{G}'_n, \mathcal{V}'\rangle$ with $\Gamma \equiv \Gamma'$. With any coalition C and any choice $G \in \mathcal{V}(C)$, associate the set $S^C_G = \{i : G \cap \mathcal{G}_i \neq \emptyset\}$ of agents satisfied if C chooses G. Similarly for Γ': $T^C_{G'} = \{i : G' \cap \mathcal{G}'_i \neq \emptyset\}$ for any $G' \in \mathcal{V}'(C)$.

We define a QCG-simulation $Z : \Gamma \rightleftharpoons \Gamma'$ as follows: for every coalition C and pair of choices $G \in \mathcal{V}(C)$, $H \in \mathcal{V}'(C)$,

$$GZH \Leftrightarrow S^C_G = T^C_H$$

We must show that Z is total, i.e., that if $G \in \mathcal{V}(C)$, then there is a $H \in \mathcal{V}'(C)$ such that $S^C_G = T^C_H$. Suppose not: assume that $i \in S^C_G$ and $i \notin T^C_H$ for all $H \in \mathcal{V}'(C)$ (the argument is similar when $i \notin S^C_G$ and $i \in T^C_H$ for some $H \in \mathcal{V}'(C)$). Then $\Gamma \models_Q \langle C\rangle sat_i$ and $\Gamma' \models_Q \neg\langle C\rangle sat_i$, which contradicts the fact that $\Gamma \equiv \Gamma'$.

Similarly, we must show that Z is surjective, i.e., that if $H \in \mathcal{V}'(C)$, then there is a $G \in \mathcal{V}(C)$ such that $S^C_G = T^C_H$. Suppose not: assume that $i \in T^C_H$ and $i \notin S^C_G$ for all $G \in \mathcal{V}(C)$ (the argument is similar when $i \notin T^C_H$ and $i \in S^C_G$ for some $G \in \mathcal{V}(C)$). Then $\Gamma' \models_Q \langle C\rangle sat_i$ and $\Gamma \models_Q \neg\langle C\rangle sat_i$, which contradicts the fact that $\Gamma \equiv \Gamma'$.

Finally, we show that the satisfaction condition holds. If GZH, then $G \cap \mathcal{G}_i \neq \emptyset$ iff $i \in S^C_G$ iff, by the definition of Z, $i \in T^C_H$ iff $H \cap \mathcal{G}'_i \neq \emptyset$. □

2.3 Axiomatisation for QCGs

We define a Hilbert style axiomatisation of qualitative coalitional games, and prove its soundness and completeness. We name our axiomatisation for QCGs $\mathbf{K}(QCG)$. This name emphasises the close resemblance to the modal system $\mathbf{K}$, which also indicates that our logic, is in a sense, a weakest basic system for QCGs, to which more sophisticated constraints can easily be added — such extensions are the topic of Section 4. The system $\mathbf{K}(QCG)$ over the language $\mathcal{L}(QCG)$ is defined as follows, where φ, ψ are arbitrary $\mathcal{L}(QCG)$ formulae, α, β are arbitrary $\mathcal{L}_c$ formulae and C an arbitrary coalition:

$Prop^-$	If φ is an $\mathcal{L}(QCG)$-instance of a propositional tautology, then φ is provable
K^-	$[C](\alpha \to \beta) \to ([C]\alpha \to [C]\beta)$ is provable
MP^-	If $\varphi, \varphi \to \psi$ are provable, then ψ is provable
Nec^-	If α is an ($\mathcal{L}_c$) instance of a propositional tautology, then $[C]\alpha$ is provable

It is easy to see that the deduction theorem holds for $\mathbf{K}(QCG)$.

We will need the following properties of $\mathbf{K}(QCG)$. The proofs are straightforward for readers familiar with modal logic.

LEMMA 1. *Let $\alpha, \beta \in \mathcal{L}_c$:*

1. $\vdash_{\mathbf{K}(QCG)} \langle C\rangle(\alpha \wedge \beta) \to \langle C\rangle\alpha$
2. $\vdash_{\mathbf{K}(QCG)} \langle C\rangle(\alpha \vee \beta) \to (\langle C\rangle\alpha \vee \langle C\rangle\beta)$
3. $\vdash_{\mathbf{K}(QCG)} (\langle C\rangle\alpha \wedge [C](\alpha \to \beta)) \to \langle C\rangle\beta$

THEOREM 3 (SOUNDNESS & COMPLETENESS). *For any $\Phi \subseteq \mathcal{L}(QCG)$, $\varphi \in \mathcal{L}(QCG)$: $\Phi \models_Q \varphi \Leftrightarrow \Phi \vdash_{\mathbf{K}(QCG)} \varphi$*

PROOF. For soundness (the direction to the left), it is easy to see that the axioms are valid, and that the rules preserve logical consequence.

For completeness, let $\Psi \subseteq \mathcal{L}(QCG)$ be $\mathbf{K}(QCG)$ consistent. We show that Ψ is satisfied by some QCG. Let $\mathcal{A}$ be the set of agents and let $n = |\mathcal{A}|$. Let Δ be a $\mathcal{L}(QCG)$ maximal and $\mathbf{K}(QCG)$ consistent set containing Ψ (the proof of existence of such a set is the standard proof of Lindenbaum's lemma). We now construct $\Gamma = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1, \ldots, \mathcal{G}_n, \mathcal{V}\rangle$, intended to satisfy Ψ, as follows:

- $\mathcal{G} = \{sat_1, \ldots, sat_n\}$
- $\mathcal{G}_i = \{sat_i\}$, for each i

- $X \in \mathcal{V}(C) \Leftrightarrow \langle C\rangle\xi_X \in \Delta$, for any $X \subseteq \mathcal{G}$, where

$$\xi_X \equiv \bigwedge_{sat_i \in X} sat_i \wedge \bigwedge_{i \in \mathcal{A}, sat_i \notin X} \neg sat_i$$

We show that

$$Gamma \models_Q \gamma \Leftrightarrow \gamma \in \Delta$$

for any γ by structural induction over γ. For the base case, $\gamma = \langle C\rangle\alpha$ for some $\alpha \in \mathcal{L}_c$. Again, we use induction on the structure of α. For the (nested) base case, let $\alpha = sat_i$. For the direction to the right, if $\Gamma \models_Q \gamma$ then there is an $X \in \mathcal{V}(C)$ such that $\Gamma, X \models_Q \alpha$, i.e., there is an $X \subseteq \mathcal{G}$ such that $\langle C\rangle\xi_X \in \Delta$ and $X \cap \{sat_i\} \neq \emptyset$. Thus, $sat_i \in X$, and by Lemma 1.1, $\gamma = \langle C\rangle sat_i \in \Delta$. For the direction to the left, let $\langle C\rangle sat_i \in \Delta$. Let

$$\chi_i = \bigvee_{S \subseteq \mathcal{A}} \xi_{(S \cup \{sat_i\})}$$

$sat_i \rightarrow \chi_i$ is a $\mathcal{L}_c$ instance of a propositional tautology, so $[C](sat_i \rightarrow \chi_i) \in \Delta$ by *Nec*. By Lemma 1.3, $\langle C\rangle\chi_i \in \Delta$. By Lemma 1.2,

$$\bigvee_{S \subseteq \mathcal{A}} \langle C\rangle\xi_{(S \cup \{sat_i\})} \in \Delta$$

and thus $\langle C\rangle\xi_{S \cup \{sat_i\}} \in \Delta$ for some $S \subseteq \mathcal{A}$. It follows that $S \cup \{sat_i\} \in V(C)$, and since $\Gamma, (S \cup \{sat_i\}) \models_Q sat_i$ we get that $\Gamma \models_Q \langle C\rangle sat_i$ which concludes the proof of the direction to the left in the innermost induction proof. Both the inner and the outer induction steps (negation and disjunction) are straightforward. □

Note that the completeness proofs demonstrates that we do not need to deal with multiple satisfaction of an agent's goal: in fact, one (symbol for a) goal for each agent is enough to reason about abilities for satisfaction!

3. TEMPORAL QCGS

In principle there are many ways to temporalise QCGs. As a first investigation, we assume a linear time model, in which, at each time point, a (possibly different) QCG Γ is played. A *temporal qualitative coalitional game* (TQCG) is then a triple

$$M = \langle S, \sigma, Q\rangle \text{ where:}$$

- S is a set of *states*;
- $\sigma : \mathbb{N} \rightarrow S$ associates a state $\sigma(u)$ with every natural number time point $u \in \mathbb{N}$; and
- $Q : S \rightarrow \mathbf{Q}$, where $\mathbf{Q}$ is the class of all QCGS, is a function associating a qualitative coalitional game $Q(s) = \langle \mathcal{A}^s, \mathcal{G}^s, \mathcal{G}^s_1, \ldots, \mathcal{G}^s_n, \mathcal{V}^s\rangle$ with every state s.

We will make just one requirement of TQCGs: that the set of agents and overall goals remains the same in all states. Formally, $\forall s, t \in S$: $\mathcal{A}^s = \mathcal{A}^t$ and $\mathcal{G}^s = \mathcal{G}^t$. This does not mean that an agent's goals must remain fixed, however: we allow for the possibility that an agent has different goals in different states. We also admit the possibility of a coalition having different choices in different states. Since the sets of agents and overall goals are fixed across all states, we will simply denote these by $\mathcal{A}$ and $\mathcal{G}$ respectively, omitting the state index.

3.1 A Logic for TQCGs

To express properties of TQCGs, we extend the QCG language $\mathcal{L}(QCG)$ with the standard temporal operators of linear-time temporal logic: $\bigcirc$ – "next", $\Diamond$ – "eventually", $\Box$ – "always in the future", and $\mathcal{U}$ – "until" [8]. Formally, the language $\mathcal{L}(TQCG)$ is defined by the grammar φ_t.

$$\varphi_t \quad ::= \quad \langle C\rangle\varphi_c \mid \neg\varphi_t \mid \varphi_t \vee \varphi_t \mid \varphi_t \,\mathcal{U}\, \varphi_t \mid \bigcirc\varphi_t$$

We again assume the usual derived propositional connectives, in addition to $\Diamond\varphi$ for $\top\,\mathcal{U}\,\varphi$ and $\Box\varphi$ for $\neg\Diamond\neg\varphi$. Moroever, we define $\Box^*\varphi$ as $(\varphi \wedge \Box\varphi)$ (φ is true now and always in the future), and $\Diamond^*\varphi = \neg\Box^*\neg\varphi$ (φ is true now or sometime in the future).

When $M = (S, \sigma, Q)$ is a TQCG, $u \in \mathbb{N}$, and φ is a $\mathcal{L}(TQCG)$ formula, the satisfaction relation $M, u \models_T \varphi$ is defined as follows (the cases for negation and disjunction are defined as usual):

$M, u \models_T \varphi$ iff $Q(\sigma(u)) \models_Q \varphi$, when $\varphi \in \mathcal{L}(QCG)$

$M, u \models_T \bigcirc\psi$ iff $M, u+1 \models_T \psi$

$M, u \models_T \psi_1 \,\mathcal{U}\, \psi_2$ iff there is some i such that $M, u+i \models_T \psi_2$ and for all $0 < j < i$ $M, u+j \models_T \psi_1$

For instance, the following formula of $\mathcal{L}(TQCG)$ means that eventually, agent 3 can always choose to satisfy agents 1 and 4 simultaneously: $\Diamond\Box\langle 3\rangle(sat_1 \wedge sat_4)$.

We will henceforth use $\mathcal{L}(TQCG)$ to refer to both the language, and the logic we have defined over this language.

3.2 An Example

We illustrate the logic by a small example. We focus here on temporal properties of goal satisfaction, rather than on contrasting the power of different coalitions (i.e., on which coalitions are likely to form). The latter is discussed in detail in Section 4.

We model the following situation by a temporal qualitative coalitional game. Two agents 1 and 2 both need to use the same resource, say a web service, from time to time. Sometimes an agent needs *read* access, and sometimes it needs *write* access. The integrity of the web service is violated if at the same time either i) both read and write access are granted (inconsistent reads), ii) two write accesses are granted (inconsistent writes) or iii) no read access and no write access are granted (inefficiency).

Let $M = (S, \sigma, Q)$ be a TQCG where S is some infinite set of states, and σ and Q are such that the following holds for $Q(\sigma(k)) = \langle \mathcal{A}, \mathcal{G}, \mathcal{G}_1^{\sigma(k)}, \mathcal{G}_2^{\sigma(k)}, \mathcal{G}_{sys}^{\sigma(k)}, \mathcal{V}^{\sigma(k)}\rangle$ for any $k \geq 0$:

- $\mathcal{A} = \{1, 2, sys\}$. We model the agents as players 1 and 2, and the web service as player sys ("the system").
- $\mathcal{G} = \{r, w_1, w_2, ok\}$. That each of these goals are achieved means that right now:

  r : every client is granted read access
  w_i : agent i is granted write access
  ok : the integrity of the system is not violated

- $\mathcal{G}_1^{\sigma(k)} = \begin{cases} \{w_1\} & \text{if } k \mod 5 = 0 \\ \{r, w_1\} & \text{otherwise} \end{cases}$
  Agent 1 needs to have write access at every fifth point in time. At any other point in time, it is happy as long as it is not left idle, i.e., if it has either read or write access.
- $\mathcal{G}_2^{\sigma(k)} = \begin{cases} \{w_2\} & \text{if } k \mod 3 = 0 \\ \{r, w_2\} & \text{otherwise} \end{cases}$
  Agent 2's goals are similar to agent 1's, except that it needs write access at every third instead of fifth time point.
- $\mathcal{G}_{sys}^{\sigma(k)} = \{ok\}$. The system is satisfied if the integrity is not violated. Note that $\mathcal{G}_{sys}^{\sigma(k)}$ does not depend on k; the system's goal does not vary over time.

- $\mathcal{V}^{\sigma(k)}(sys) = \left\{ \begin{array}{c} \emptyset, \{w_1, ok\}, \{w_2, ok\}, \{r, ok\}, \\ \{w_1, w_2\}, \{w_1, r\}, \{w_2, r\}, \{w_1, w_2, r\} \end{array} \right\}$. The web service can satisfy certain sets of goals. These sets does not necessarily include the goal that the integrity is not violated. We have implicitly defined what is the desired behaviour of the system: each choice involving ok implements a choice in which the integrity invariant is not violated. Note that the choices available to the system do not vary over time. For reasons of space, in this example we are not bothered about $\mathcal{V}^s(C)$ when C is a coalition different from $\{sys\}$.

The following properties hold in $M, 1$.

1. $\Box\langle sys\rangle sat_{sys}$. The system can maintain integrity.
2. $\Box(\langle sys\rangle sat_1 \wedge \langle sys\rangle sat_2)$. Agent 1 can always be satisfied by the system, and the same for agent 2.
3. $\Box\langle sys\rangle(sat_1 \wedge sat_2)$. Agents 1 and 2 can always be simultaneously satisfied by the system.
4. $\Diamond\!\!\!\!\Box\neg\langle sys\rangle(sat_1 \wedge sat_2 \wedge sat_{sys})$. The system cannot always satisfy agents 1 and 2 simultaneously without violating the integrity of the system.
5. $\Box\langle sys\rangle\neg sat_1$. The system can keep agent 1 unsatisfied forever.
6. $\Box\Diamond\!\!\!\!\Box\langle sys\rangle(\neg sat_1 \wedge \neg sat_2 \wedge sat_{sys})$. It is infinitely often the case that the system can make agents 1 and 2 unsatisfied at the same time without violating integrity (this happens at multiples of fifteen).
7. $\langle sys\rangle(\neg sat_1 \wedge \neg sat_2 \wedge sat_{sys})\,\mathcal{U}\,\neg\langle sys\rangle(sat_1 \wedge sat_2 \wedge sat_{sys})$. At some point in the future (i.e., $u = 15$), the system is unable to jointly satisfy agents 1 and 2 without violating integrity. Up until that time, *sys* is always able to make agents 1 and 2 jointly *un*satisfied (note that we evaluate the formula in $M, 1$).
8. $\psi \wedge \Box(\psi \rightarrow \overbrace{\bigcirc(\neg\psi \wedge \cdots \bigcirc(\neg\psi \wedge \bigcirc\psi)\cdots)}^{\text{“}\bigcirc(\neg\psi\wedge\text{” 14 times}})$ where $\psi = \langle sys\rangle(\neg sat_1 \wedge \neg sat_2 \wedge sat_{sys})$. The system can make agents 1 and 2 jointly unsatisfied without violating integrity at time points which are multiples of fifteen, and at no other time points.

As a final point, observe that from a logical point of view, the situations at time points 3 and 5 are indistinguishable:

$$Q(\sigma(3)) \rightleftharpoons Q(\sigma(5))$$

This once again demonstrates that our logic abstracts away from *how* a coalition satisfies individuals: obviously, to satisfy agent 1 for instance, *sys* has to make different choices in $\sigma(3)$ from those in $\sigma(5)$.

3.3 Expressive Power of TQCGs

The notion of simulation for QCGs (Section 2.2) can be naturally lifted to the temporal case. When $M = (S, \sigma, Q)$ and $M' = (S', \sigma', Q')$ are TQCGS and $k \geq 0$, we define

$$\begin{array}{lcl} M, k \rightleftharpoons_T M', k & \Leftrightarrow & Q(\sigma(k)) \rightleftharpoons Q'(\sigma'(k)) \\ M \rightleftharpoons_T M' & \Leftrightarrow & \forall_{n\geq 0} M, n \rightleftharpoons_T M', n \end{array}$$

The notion of elementary equivalence for TQCGS over the language $\mathcal{L}(TQCG)$ can be defined as follows. $M, k \equiv M', k$ iff, for every $\varphi \in \mathcal{L}(TQCG)$, $M, k \models_T \varphi$ iff $M', k \models_T \varphi$. $M \equiv M'$ iff $M, k \equiv M', k$ for every $k \geq 0$.

THEOREM 4. *For all TQCGs M, M': $M \rightleftharpoons_T M' \Leftrightarrow M \equiv M'$*

Note that in the temporal case, the fact that $M, k \rightleftharpoons_T M', k$ is not sufficient for $M, k \equiv M', k$ to hold.

3.4 Satisfiability

The *satisfiability* problem for $\mathcal{L}$(TQCG) is as follows: given a formula $\varphi \in \mathcal{L}$(TQCG), does there exist a TQCG M and $u \in \mathbb{N}$ such that $M, u \models \varphi$?

THEOREM 5. *The sat. probl. for $\mathcal{L}(TQCG)$ is* PSPACE*-complete.*

PROOF. Membership of PSPACE follows from the fact that satisfiability for LTL+K_n (the fusion of LTL and multi-modal K) is PSPACE-complete [5]. Any $\mathcal{L}$(TQCG) formula is also a formula of LTL+K_n, interpreting sat_i as Boolean variable. (The reverse is not the case, of course.) But the relationship is more than merely syntactic: for all $\varphi \in \mathcal{L}$(TQCG):

$$\varphi \text{ is } \mathcal{L}\text{(TQCG)-satisfiable iff } \varphi \text{ is LTL+}K_n \text{ satisfiable}$$

(Notice that we are here quantifying over $\mathcal{L}$(TQCG), formulae, not LTL+K_n formulae.) Given an LTL+K_n interpretation that satisfies $\varphi \in \mathcal{L}$(TQCG), it is straightforward to extract from this a TQCG that satisfies φ.

For PSPACE-hardness, we reduce LTL satisfiability [14]. First, let $\varphi^\dagger$ denote the result of systematically replacing each Boolean variable p that occurs in LTL formula φ with a symbol sat_p. Next, we define a transformation τ, from LTL formulae to $\mathcal{L}$(TQCG), as follows:

$$\tau(\varphi) = \left\{ \begin{array}{ll} [1](\varphi^\dagger) & \text{where } \varphi \text{ is propositional} \\ \#\tau(\psi) & \text{where } \varphi = \#\psi \text{ and } \# \in \{\neg, \bigcirc\} \\ \tau(\psi)\#\tau(\chi) & \text{where } \varphi = \psi\#\chi \text{ and } \# \in \{\vee, \mathcal{U}\} \end{array} \right.$$

Finally, given an LTL formula φ, the $\mathcal{L}$(TQCG) instance φ^τ we create is:

$$\varphi^\tau = (\langle 1\rangle\top) \wedge (\Box\langle 1\rangle\top) \wedge \tau(\varphi)$$

We claim that φ is LTL satisfiable iff φ^τ is $\mathcal{L}$(TQCG) satisfiable; the proof is an easy induction. The key point is that the choice sets of agent 1 in any TQCG satisfying φ^τ define an appropriate valuation for propositional variables in a corresponding LTL interpretation satisfying φ, and *vice versa* (remember that $[1]\varphi$ iff φ holds for all of 1's choices). The first two conjuncts in the definition of φ^τ ensure that such a choice set always exists. □

3.5 Axiomatisation for TQGCs

The system $\mathbf{K}(TQCG)$ over the language $\mathcal{L}(TQCG)$ is defined as follows, where φ, ψ are arbitrary $\mathcal{L}(TQCG)$ formulae, A, B are arbitrary $\mathcal{L}(QCG)$ formulae, α, β are arbitrary $\mathcal{L}_c$ formulae and C an arbitrary coalition. For simplicity, we write $\vdash_{\mathbf{T}}$ instead of $\vdash_{\mathbf{K}(TQCG)}$ for derivability in $\mathbf{K}(TQCG)$.

$Prop^-$	If A is an ($\mathcal{L}(QCG)$) instance of a propositional tautology, then $\vdash_{\mathbf{T}} A$
K^-	$\vdash_{\mathbf{T}} [C](\alpha \rightarrow \beta) \rightarrow ([C]\alpha \rightarrow [C]\beta)$
MP^-	If $\vdash_{\mathbf{K}(QCG)} A$ and $\vdash_{\mathbf{K}(QCG)} A \rightarrow B$, then $\vdash_{\mathbf{T}} B$
Nec^-	If α is an ($\mathcal{L}_c$) instance of a propositional tautology, then $\vdash_{\mathbf{T}} [C]\alpha$
$A1$	$\vdash_{\mathbf{T}} \Box(\varphi \rightarrow \psi) \rightarrow (\Box\varphi \rightarrow \Box\psi)$
$A2$	$\vdash_{\mathbf{T}} \bigcirc\neg\varphi \leftrightarrow \neg\bigcirc\varphi$
$A3$	$\vdash_{\mathbf{T}} \bigcirc(\varphi \rightarrow \psi) \rightarrow (\bigcirc\varphi \rightarrow \bigcirc\psi)$
$A4$	$\vdash_{\mathbf{T}} \Box\varphi \rightarrow (\bigcirc\varphi \wedge \bigcirc\Box\varphi)$
$A5$	$\vdash_{\mathbf{T}} \Box(\varphi \rightarrow \bigcirc\varphi) \rightarrow (\bigcirc\varphi \rightarrow \Box\varphi)$
$U1$	$\vdash_{\mathbf{T}} \varphi\,\mathcal{U}\,\psi \rightarrow \Diamond\!\!\!\!\Box\psi$
$U2$	$\vdash_{\mathbf{T}} \varphi\,\mathcal{U}\,\psi \leftrightarrow \bigcirc\psi \vee (\bigcirc\varphi \wedge \bigcirc(\varphi\,\mathcal{U}\,\psi))$
$Prop$	If φ is an ($\mathcal{L}(TQCG)$) instance of a propositional tautology, then $\vdash_{\mathbf{T}} \varphi$
MP	If $\vdash_{\mathbf{T}} \varphi$ and $\vdash_{\mathbf{T}} \varphi \rightarrow \psi$, then $\vdash_{\mathbf{T}} \psi$
Nec	If $\vdash_{\mathbf{T}} \varphi$ then $\vdash_{\mathbf{T}} \Box\varphi$

Axioms $Prop^-$ and K^- and rules MP^- and Nec^- say that every $\mathbf{K}(QCG)$-theorem is also a $\mathbf{K}(TQCG)$-theorem. The subsystem consisting of axioms $A1$–$U2$ and rules *Prop–Nec* is a version (with $\mathcal{L}(QCG)$ formulae in place of atomic propositions) of an axiomatisation of linear time logic proved to be be sound and complete in [6].

THEOREM 6 (SOUNDNESS & COMPLETENESS). *For any* $\varphi \in \mathcal{L}(TQCG)$: $\vdash_{\mathbf{T}} \varphi \quad \Leftrightarrow \quad \models_T \varphi$

PROOF. The logic $\mathbf{K}(TQCG)$ is what Finger and Gabbay [4] calls a *temporalisation* of $\mathbf{K}(QCG)$: the language of $\mathbf{K}(TQCG)$ has atomic $\mathbf{K}(QCG)$ formulae in place of atomic propositions; the semantic structures of $\mathbf{K}(TQCG)$ identifies a semantic structure for $\mathbf{K}(QCG)$ at each time point used to interpret $\mathbf{K}(QCG)$ formulae; and the axioms/rules of $\mathbf{K}(TQCG)$ are the axioms/rules of the temporal logic for temporal formulae in addition to axioms/rules of $\mathbf{K}(QCG)$ for $\mathbf{K}(QCG)$ formulae.

Finger and Gabbay show that the temporalisation of a sound and complete system is sound and complete. It should be noted that our definition of $\mathbf{K}(TQCG)$ differs from the definition of a temporalisation in [4] by the following. First, we do not have past-time operators in our language. The expressive power is nevertheless the same [6]. Second, we use a slightly different temporal axiomatisation. Neither of these differences change the soundness and completeness proof in [4] in any significant degree. The theorem thus follows immediately from Theorem 3. □

4. CHARACTERIZING TQCGS

In this section, we investigate the axiomatic characterisation of various classes of TQCG. As usual, in saying that a formula scheme φ characterises a property P of models, we mean that φ is valid in a model M iff M has property P; if only the right-to-left part of this biconditional holds, then we say property P implies φ. Also note that for an $\mathcal{L}(TQCG)$ formula φ, to say that φ is valid in a class of models, is the same as saying that $\Box^*\varphi$ is valid in that class.

Basic Correspondences

Let $h^s(C)$ denote the set of all agents that could possibly be satisfied (not necessarily jointly) by coalition C in state s:

$$h^s(C) = \{i : i \in \mathcal{A} \,\&\, \exists G \in \mathcal{V}^s(C), \mathcal{G}_i^s \cap G \neq \emptyset\}$$

The "h" here is for "happpiness": we think of $h^s(C)$ as all the agents that C could possibly make happy in s. Thus the semantic property $i \in h^s(C)$ is a counterpart to the syntactic expression $\langle C\rangle sat_i$.

The first property on models that we consider is the *persistence of happiness* (PH): if coalition C can make i happy in a state s, they can make i happy in the state immediately following s.

$$\forall u \in \mathbb{N}, (i \in h^{\sigma(u)}(C)) \rightarrow (i \in h^{\sigma(u+1)}(C)) \qquad (PH)$$

We have the following characterisation.

LEMMA 2. $\langle C\rangle sat_i \rightarrow \bigcirc\langle C\rangle sat_i$ *characterises* PH.

In the same way, we can characterise the persistence of *un*happiness: property PU says that if C cannot make i happy in a state s, then they cannot make i happy in the state t that immediately follows s.

$$\forall u \in \mathbb{N}, (i \notin h^{\sigma(u)}(C)) \rightarrow (i \notin h^{\sigma(u+1)}(C)) \qquad (PU)$$

LEMMA 3. $\neg\langle C\rangle sat_i \rightarrow \bigcirc\neg\langle C\rangle sat_i$ *characterises* PU.

Now consider the following two constraints. The first, EH, says that eventually, C will be able to make i happy.

$$\exists u \in \mathbb{N}, (i \in h^{\sigma(u)}(C)) \qquad (EH)$$

Notice that in the terminology of reactive systems, this is a *fairness* or *response* property [8, p.288]: it implies that something (i being made happy) can happen infinitely often. (Of course, the fact that C *can* make i happy infinitely often does not mean they will do so.)

LEMMA 4. $\diamondsuit^*\langle C\rangle sat_i$ *characterises* EH.

The obvious counterpart to EH is of course the property EU, which states that, eventually, C will be unable to satisfy i.

$$\exists u \in \mathbb{N}, (i \notin h^{\sigma(u)}(C)) \qquad (EU)$$

LEMMA 5. $\diamondsuit^*\neg\langle C\rangle sat_i$ *characterises* EU.

Combining these properties, we get the following.

LEMMA 6. *PH and EH together imply $\diamondsuit^*\Box^*\langle C\rangle sat_i$, while properties PU and EU together imply $\diamondsuit^*\Box^*\neg\langle C\rangle sat_i$.*

Finally, we consider *safety* properties. The constraint AH says that C can always make i happy, while the constraint AU says that C can never make i happy.

$$\forall s \in S, (i \in h^s(C)) \;\; (AH) \quad \forall s \in S, (i \notin h^s(C)) \;\; (AU)$$

The characterizations are as follows. (Note that there are some obvious implications between these and other properties that we do not list explicitly – e.g., AH implies both EH and PH.)

LEMMA 7. *$\langle C\rangle sat_i$ characterises AH, and $\neg\langle C\rangle sat_i$ char. AU.*

Basic Properties of Choice Sets

Three obvious constraints that we might consider relate to whether or not a particular coalition C has any "real" choices. The first, ECS, says that C never has any choices.

$$\forall s \in S, \mathcal{V}^s(C) = \emptyset \qquad (ECS)$$

The second says that C always has a meaningful choice.

$$\forall s \in S, \exists G \in \mathcal{V}^s(C), G \neq \emptyset \qquad (NECS)$$

The third says that C can choose everything .

$$\forall s \in S, \mathcal{G} \in \mathcal{V}^s(C) \qquad (CCS)$$

LEMMA 8. *Any model that satisfies ECS also satisfies AU, and so ECS implies $\neg\langle C\rangle sat_i$, while any model that satisfies CCS also satisfies AH, and so CCS implies $\langle C\rangle sat_i$.*

Note that $NECS$ alone does not have any characterization: however, when combined with other properties, below, we will see that it has a role.

Static Goal Sets and Choices

Another two simple properties are that the goal sets for each agent and the choice sets for each coalition are guaranteed to remain unchanged. We get the following two constraints, stating that agent i's goal sets are static (constraint SGS) and that coalition C's choices remain static (SC).

$$\forall s, s' \in S, (\mathcal{G}_i^s = \mathcal{G}_i^{s'}) \qquad \text{(SGS)}$$

$$\forall s, s' \in S, (\mathcal{V}^s(C) = \mathcal{V}^{s'}(C)) \qquad \text{(SC)}$$

Taken separately, there does not seem too much we can say about static goal sets and static choice sets. However, taken together, we get the following.

LEMMA 9. *Any model satisfying both SGS and SC also satisfies PH and PU, and as a consequence, SGS and SC together imply* $\langle C\rangle sat_i \leftrightarrow \bigcirc\langle C\rangle sat_i$.

Note that we do not immediately derive a characterisation here. It is perfectly well possible that $\langle C\rangle sat_i \leftrightarrow \bigcirc\langle C\rangle sat_i$ is true in a model M not just because all agents' goals and all coalitions' choices stay fixed, but because there is an intricate interplay going on between for instance an agent changing some of his goals, while at the same time, the coalition C 'synchronously' changing its options. Note that in our example of Section 3.2 for instance, both (SGS) and (SC) are true for $C = \{sys\}$ and $i = sys$, so that, indeed, $\langle\{sys\}\rangle sat_{sys} \leftrightarrow \bigcirc\langle\{sys\}\rangle sat_{sys}$. On the other hand, taking $C = \{sys\}$ and $i = 1$, we don't have (SGS) and (SC), although we still have $\langle\{sys\}\rangle sat_1 \leftrightarrow \bigcirc\langle\{sys\}\rangle sat_1$.

Dynamic Goal Sets

There are several properties we can investigate with respect to goal sets. First, suppose that agent i's goal set is guaranteed to *monotonically decrease* over time. Roughly, this condition means that every agent is guaranteed to get *no easier* to satisfy over time. Formally, this condition on a model M is defined by the following property.

$$\forall u \in \mathbb{N}\,(\mathcal{G}_i^{\sigma(u+1)} \subseteq \mathcal{G}_i^{\sigma(u)}) \qquad (MDGS)$$

LEMMA 10. *Any model satisfying SC and MDGS will satisfy PU, and hence SC and MDGS together imply* $\neg\langle C\rangle sat_i \rightarrow \bigcirc\neg\langle C\rangle sat_i$.

Suppose we this condition is *strict*, so that an agent i is guaranteed to get strictly harder to satisfy over time. This condition is defined by the following further constraint, in addition to $MDGS$.

$$\forall u \in \mathbb{N} \quad \begin{array}{l}(\mathcal{G}_i^{\sigma(u)} = \emptyset) \vee \\ (\exists v \in \mathbb{N} : (v > u) \wedge (\mathcal{G}_i^{\sigma(v)} \subset \mathcal{G}_i^{\sigma(u)}))\end{array} \qquad (SMDGS)$$

We get the following.

LEMMA 11. *Any model satisfying SC, MDGS, and SMDGS will also satisfy PU and EU, and so SC, MDGS, and SMDGS together imply* $\Diamond^*\Box^*\neg\langle C\rangle sat_i$.

Now suppose agent i has monotonically *increasing* goal sets: that is, agent i gets *no harder* to satisfy over time.

$$\forall u \in \mathbb{N}, (\mathcal{G}_i^{\sigma(u)} \subseteq \mathcal{G}_i^{\sigma(u+1)}) \qquad (MIGS)$$

LEMMA 12. *Any model satisfying both SC and MIGS will satisfy constraint PH, and hence SC and MIGS together imply* $\langle C\rangle sat_i \rightarrow \bigcirc\langle C\rangle sat_i$.

The associated strictness constraint is as follows.

$$\forall u \in \mathbb{N} \quad \begin{array}{l}(\mathcal{G}_i^{\sigma(u)} = \mathcal{G}) \vee \\ (\exists v \in \mathbb{N} : (v > u) \wedge (\mathcal{G}_i^{\sigma(u)} \subset \mathcal{G}_i^{\sigma(v)}))\end{array} \qquad (SMIGS)$$

We might expect that SC, $MIGS$, and $SMIGS$ together imply the validity of the formula scheme $\Diamond^*\Box^*\langle C\rangle sat_i$, but this is not the case. A counter example is given by a model that satisfies the empty choice set property (ECS) for coalition C, as described above. If we add the constraint that the choices for C are non-empty $(NECS)$, however, then we get the following.

LEMMA 13. *Any model that satisfies NECS, SC, MIGS, and SMIGS also satisfies PH and EH, and hence the following formula scheme will be valid in any model satisfying NECS, SC, MIGS, and SMIGS:* $\Diamond^*\Box^*\langle C\rangle sat_i$.

Dynamic Choices

We can also consider the ways in which the choices available to coalitions may change over time. Analogously to $MIGS$ and $MDGS$, we can define properties $MICS$ and $MDCS$, which say that the sets of choices available to coalition C monotonically increase and decrease respectively.

$$\forall u \in \mathbb{N}, (\mathcal{V}^{\sigma(u)}(C) \subseteq \mathcal{V}^{\sigma(u+1)}(C)) \qquad \text{(MICS)}$$

$$\forall u \in \mathbb{N}, (\mathcal{V}^{\sigma(u+1)}(C) \subseteq \mathcal{V}^{\sigma(u)}(C)) \qquad \text{(MDCS)}$$

Notice that taken together, these two conditions imply static choice sets (SC). Alone, the properties do not have any characterisation, but axioms emerge when we make assumptions about goal sets.

LEMMA 14. *(1) Any model satisfying MICS and SGS will satisfy constraint PH, and hence MICS and SGS together imply* $\langle C\rangle sat_i \rightarrow \bigcirc\langle C\rangle sat_i$.
(2) Any model satisfying MDCS and SGS will satisfy constraint PU, and hence MICS and SGS together imply $\neg\langle C\rangle sat_i \rightarrow \bigcirc\neg\langle C\rangle sat_i$.

The associated strictness condition for increasing choice sets is:

$$\begin{array}{l}\forall u \in \mathbb{N}, \forall G_1 \in \mathcal{V}^{\sigma(u)}(C)(G_1 = \mathcal{G}) \vee \\ \quad (\exists v \in \mathbb{N}, \exists G_2 \in \mathcal{V}^{\sigma(v)}(C), (v > u) \wedge (G_1 \subset G_2))\end{array} \qquad (SMICS)$$

LEMMA 15. *Any model satisfying MICS, SGS, and SMICS or MICS, MIGS, and SMICS will also satisfy constraints PH and EH, and hence MICS, SGS, and SMICS together imply* $\Diamond^*\Box^*\langle C\rangle sat_i$.

We omit here the analysis for the case of monotonically *de*creasing choice sets.

Solution Concepts

In [15], a range of different solution concepts were defined for QCGs. It should be clear that many of the solution concepts of [15] can be characterised via formulae of $\mathcal{L}(QCG)$. For example, a basic solution concept is that of a *successful* coalition – one that has a choice available such that this choice satisfies all its members [15, p.47]. We can characterise this via a predicate $succ(C)$, as follows.

$$succ(C) \equiv \langle C\rangle(\bigwedge_{i\in C} sat_i)$$

Similarly, the notion of a minimal coalition (one such that no subset of the coalition is successful [15, p.51]) may be captured as follows.

$$min(C) \equiv \bigwedge_{C'\subseteq C} \neg succ(C')$$

Thus the core of a coalition being non-empty [15, p.54] may be captured as follows:

$$cne(C) \equiv (succ(C) \wedge min(C))$$

The idea of agent i being a veto player for agent j [15, p.57] is defined by:

$$veto(i,j) \equiv \bigwedge_{C\subseteq\mathcal{A}} (\langle C\rangle sat_j \rightarrow \neg\langle C \setminus \{i\}\rangle sat_j)$$

And finally, the idea of a coalition being mutually dependent [15, p.58] is captured as follows:

$$md(C) \equiv \bigwedge_{i\neq j\in C} veto(i,j)$$

How might these concepts be extended into the temporal dimension of TQCGs and $\mathcal{L}(TQCG)$? It should first be clear that each concept has four different temporal versions, corresponding to prefixing the formula characterising it with one of the following four, increasingly powerful temporal operators:

$$\Diamond \qquad \Box\Diamond \qquad \Diamond\Box \qquad \Box$$

Thus, for example, $\Box\Diamond succ(C)$ means that coalition C are successful *infinitely often* – no matter which time point we pick, there will be a subsequent time point at which C are successful. (Using the terminology of reactive systems [8], we might then say that C are hence *fairly successful*.) Similarly, a *temporally strong* form of coalitional stability is captured by the formula $\Box cne(\mathcal{A})$: if this formula is satisfied in a TQCG, then, it can be argued, the only coalition that will ever form is the grand coalition.

It is potentially more interesting, however, to study a richer interplay between temporal and QCG dimensions. For example, from agent is point of view, perhaps the only really interesting issue is whether at every time point there is some stable coalition, containing this agent.

$$tstable(i) \equiv \Box \bigvee_{C \subseteq \mathcal{A}: i \in C} cne(C)$$

From the point of view of a coalition C, which seeks to form, the notion of a *stable government* seems relevant: a stable government is a coalition that can always satisfy its "electorate".

$$sg(C) \equiv \Box\langle C\rangle(\bigwedge_{i \in \mathcal{A}} sat_i)$$

This can of course be strengthened, requiring C to in addition be an internally stable coalition.

$$sg'(C) \equiv \Box(cne(C) \wedge \langle C\rangle(\bigwedge_{i \in \mathcal{A}} sat_i))$$

With respect to mutual dependence, one possibility, captured by the formula $\Box md(C)$, is that a coalition is *always* mutually dependent. However, we can capture a weaker type of mutual dependence as follows:

$$wmd(C) \equiv \bigwedge_{i \neq j \in C} \Diamond veto(i,j)$$

We draw two conclusions. The first is that the language $\mathcal{L}(TQCG)$ is well suited to capturing such solution concepts: it makes it possible to express elegantly concepts that would be difficult to understand were they expressed at the semantic level. The second is that extending QCGs into the temporal dimension adds an entirely new level of richness to their structure, which as these examples suggest, demands further study.

5. CONCLUSION

Qualitative Game Structures were introduced in [15] as a model to deal with one of the driving questions in cooperation: 'Which coalition should I join?'. The design of such games is motivated by a principle of economy: rather than associationg a utility to every choice, the emphasis is on *satisfaction* of agents, which is triggered or not by *choices* of coalitions.

The logical analysis of such games, as underlines the idea that we have a basic and simple notion of coalitional games with QCGs: a natural language for it gives rise to an axiomatisation almost identical to the simplest modal logic **K**. We established several technical results for this language, and were then able to lift them to the era of temporal QCGs.

The possible directions for further research are multiple. First of all, the properties of TQGCs that we characterised in Section 4 are only the most straightforward. Even in static games, there are interesting conditions to be investigated (see the *monotonicity* property mentioned in Section 2, for example). Second, our way of temporalising QCGs also only reflects a simple case. It would be interesting to add temporal structure to the games themselves, and reason about what agents can achieve over time, by applying suitable *strategies*, rather than making 'one-shot choices'. In addition, *finite horizon* versions of TQCGs might also be worth investigating: for example, if an agent is only concerned about being satisfied *once*, then it might be prepared to join a coalition that does not satisfy it throughout a game, as long as, in the final state of the game, the coalition *does* satisfy it. Such strategising is not possible or appropriate in infinite horizon games.

ABSTRACT

We present a logic for reasoning both about the ability of agents to cooperate to execute complex actions, and how this relates to their ability to reach certain states of affairs. We show how the logic can be obtained in a modularised way, by combining a model for reasoning about actions and their effects with a model that describes what actions an agent can perform. More precisely, we show how one can combine an action logic which resembles Propositional Dynamic Logic with a cooperation logic which resembles Coalition Logic. We give a sound and complete axiomatisation for the logic, illustrate its use by means of an example, and discuss possible future extensions to it.

1. INTRODUCTION

When reasoning about cooperation in multi-agent systems, at least two questions seem important: *Who* can achieve some state of affairs and *How* can they obtain it? Historically, the latter question has received far more attention than the former. In the AI planning community, for example, it is known as the means-ends reasoning problem, and indeed the AI planning project is directed at developing computer programs that can answer it efficiently [4]. In the logic community, the question has been studied largely through the medium of action and program logics, of which PDL is perhaps the best known example [7]. A basic issue in such logics is the construction of complex programs from simpler ones. Typical constructs to build complex programs include sequential composition, non-deterministic choice and tests. However, there are limits to what one can say in such logics. For example, in standard PDL, one cannot express that an action is *not* executed; nor is not straightforward to say that one complex action *subsumes*, or *implies* another. Last but not least, although there is a notion of concurrency in PDL, all processes are expected to behave as specified by the program under consideration, and there is no notion of competition or cooperation, and hence no need to express *who* can achieve something. Building on work in PDL and related formalisms, some early attempts in the multi-agent systems community to formalise the ability of agents to execute plans and bring about states of affairs include [8, 14, 9].

The question of *who* can achieve some state of affairs has received much less attention within the AI and logic community. Although Moore presented a modal analysis of ability as long ago as 1977 [11], and a number of other authors built on this work over the intervening three decades, it is only recently that the logical analysis of ability has entered the mainstream of multi-agent systems research. Two closely related formalisms have received particular attention: the Alternating-time Temporal Logic (ATL, [1]), in which one can express that a coalition can enforce a certain temporal property, and Coalition Logic ([12]), in which the basic expression states that a coalition is effective for some outcome. Another closely related formalism is the Coalition Logic for Propositional Control (CL-PC, [15]), where the propositional atoms under the control of an agent determine what he, or any coalition he is a member of, can achieve. All these approaches revolve around a model in which a set of agents, who may have conflicting interests, may or may not work together to obtain a certain state of affairs. Central is the notion of so-called α-ability: the capability of a group of agents to enforce a certain state of affairs, no matter what actions the other agents take. As in [15], we will call such logics *Cooperation Logics*.

Notice that in all of these approaches, the ability of groups of agents to obtain a state of affairs is modeled without an explicit representation of *how* these agents obtain them. In other words, these logics do not represent actions and plans in the object language, even though in some cases, actions or choices are present in the underlying semantics. However, such an *explicit* representation of action in the object language is important in many domains. For example, certain actions may be more costly than others, and the costs may be distributed among the agents helping to achieve the goal according to the actions they perform. Also, in some situa-

tions, it seems a good heuristic to formulate a plan before organising a coalition to execute it [16, 13]. Finally, using such a language for verification of a MAS would not only provide the user — or indeed, the agents themselves— with a proof *that* a desired goal of the system can be achieved, but it would also explicitly capture a *plan* of how to achieve it.

In this paper, we are interested in how the ability to obtain a state of affairs relates to the ability to execute certain, possibly complex, and possibly collective, actions. We develop a logic that combines operators from cooperation logics with an explicit representation of actions. We achieve this by dividing the problem in two parts: a logic for reasoning about actions and their effects (*à la* dynamic logic) together with a variant of coalition logic to reason about (groups of) agents and the actions that they can perform. In more detail, we study multiagent systems that consist of two separate parts: an *environment module* that describes actions and their effects, and an *agents module* describing how the agents can interact with the environment by performing certain actions.

We use the agents module to represent the ability of a coalition G to *execute* certain type of actions. Where β is a joint action (i.e., it denotes a set of actions to be executed concurrently), we write $\langle\langle G\rangle\rangle\beta$ to indicate that coalition G can execute the complex action β. In the environment, then, we can reason about the effect of actions using our environment logic, and write, for example $[\beta]\phi$ for 'every successful execution of β results in state where ϕ is true' (cf. PDL).

The cooperation modality of Coalition Logic expresses the ability of a group to obtain a certain state of affairs. This kind of expression can now be analysed using the two modules described above: a group G of agents has the ability to obtain a state of affairs ϕ just in case there exists a plan β that G is able to execute, which is guaranteed to result in ϕ.

Such an approach presumes that the effect of actions can be modeled more or less independently from the behaviour of the agents that perform these actions. This approach seems applicable to many real life scenarios. For example, an environment may be a communication channel via which agents send and receive messages. Or, the environment may be a Database Management System, defining actions and constraints in a general way, and the agents are users querying and updating the database.

Separating actions from the agents that perform them is not only practical from an operative viewpoint, but from a logical standpoint as well. It allows us to break up the problem of reasoning about planning in a multi-agent environment into two sub-problems, and to study the logic of each of these 'modules' in isolation before putting them together. This approach is also interesting, because it allows us to 'reuse' existing logics and exploit them as 'modules' in a richer system.

In Section 2 we will present the two building blocks of our framework. In section 2.1 we define a logic for the environment, in which one can reason about the effect of executing joint actions. The language can express that an action is not taken, but also, in a natural way, compares joint actions in relative 'strength': if the joint action β is stronger than α, then we also have that whatever is true as a result of α, is true when executing β. We then (in section 2.2) define our agents' module, in which the α-ability of coalitions can be expressed — but now, not with respect to states of affairs that can be reached, but for joint actions that can be guaranteed.

Section 2.3 puts these blocks together in a module called a multi-agent system. Here, we define $\langle\langle G\rangle\rangle\phi$, the α-ability of coalition G to bring about state of affairs ϕ, in terms of $\langle\langle G\rangle\rangle\alpha$ and $[\alpha]\phi$. Apart from the completeness results for the separate building blocks, which we judge to provide insight in the systems themselves, we believe that one of the interesting technical developments of our work relates to the fact that the completeness result for the *combined* logic is straightforward given the completeness of the two logics of the underlying modules. We see this as indicative of the success of the modularisation approach we adopt in this paper, and a good indication that it might be usefully applied elsewhere.

Section 3 is devoted to an example, illustrating how the logic can be used to represent properties of a multi-agent system. The example is a scenario in which agents in a coalition can collectively set variables which they are unable to change on their own. Section 4 indicates a few of the many possible extensions to our multi-agent system, and Section 5 concludes.

2. ACTION AND COOPERATION

In our setting, a multiagent system is composed of two *modules*: one module describes the *agents* in terms of the actions they can execute, another describes the *environment* that is populated by these agents, and in particular the effects of performing certain actions.

2.1 The environment module

There are many ways of modeling an environment. One very general way to model actions and their effects is by using a Labeled Transition System (LTS) [6, 2, 10]. An LTS is a directed graph in which the edges are labeled by elements from a set of atomic actions and the vertices are labeled with sets of propositional variables. Edges are called transitions, the vertices are called states. The idea is that if a state s is connected to another state s' by a transition labeled with an action a, this means that s' is a possible result of executing action a in state s. The sets of variables at each end of the transition tell us how the performance of the action changes the state of the environment, in terms of the propositions that change value.

One of the drawbacks of this basic LTS model is that it does not allow for modeling concurrency directly: there is no straightforward way to model the fact that performing certain actions together may have a very different effect than performing each of them separately.

In the present context, we are interested in the way that the choice of actions of different agents interact, so we propose to model the effect of actions being performed concurrently directly in the model. We do this by labeling the transitions not with single actions, but with *sets* of actions. Intuitively, a transition labeled with a set of actions A represents the effect of executing exactly those actions together, and no others. This approach to deal with concurrency is similar to that taken in [5].

DEFINITION 1 (ENVIRONMENT MODULE).
An environment module Env is a Set-Labeled Transition System *(SLTS) is a tuple* $\langle S, Ac, (\rightarrow)_{A\subseteq Ac}, P, \pi\rangle$ *where:*

1. S *is a set of states.*
2. Ac *is a finite set of actions.*
3. *For each* $A \subseteq Ac$, $\rightarrow_A$ *is a relation over* S.
4. P *is a set of propositional variables*
5. $\pi : (S \times P) \rightarrow \{1, 0\}$ *is an interpretation function that assigns to each state and each propositional variable a truth value.*

We require that the accessibility relations $\rightarrow_A$ *are* serial *for each set of actions* A*, i.e., that for each state* s *there is always an* s' *with* $s \rightarrow_A s'$. □

A state s is characterised by the propositional variables that are true and false in it, as given by $\pi(s)$, and by the possible effects of executing combinations of actions A concurrently, as defined by the accessibility relations $\rightarrow_A$. We will refer to a set of actions A as a *concurrent action*. Actions may be *non-deterministic*, in the sense that the outcome of performing a set of actions may not always determine a unique result.

To reason about actions and their effect in an SLTS, we use a language that is similar to that of Propositional Dynamic Logic. PDL has a language that consists of two parts: an action language to describe actions, and a 'static' language to describe properties of states. However, rather than directly incorporating the program constructs of PDL, we use *Boolean combinations* of atomic actions to reason about sets of actions.

DEFINITION 2 (ACTION EXPRESSIONS).
Given the set of atomic actions Ac, the set of action expressions *is defined by the grammar:*

$$\alpha ::= a \mid \alpha \wedge \alpha \mid \neg\alpha$$

where $a \in Ac$.

To interpret this action language, we define a relation $\models^p$ between subsets of Ac and action expressions. $A \models^p \alpha$ is to be read as 'concurrent action A is of type α', or 'α is true of A'.

DEFINITION 3 (INTERPRETATION OF ACTIONS).

1. $A \models^p a$ *iff* $a \in A$
2. $A \models^p \neg\alpha$ *iff* $A \not\models^p \alpha$
3. $A \models^p \alpha \wedge \beta$ *iff* $A \models^p \alpha$ *and* $A \models^p \beta$.

So, for example, the concurrent action $\{a, b\}$ is of type $a \wedge \neg c$, but it is not of type $\neg b$. Formally, the action language is of course simply classical Boolean propositional logic, with Boolean variables corresponding to atomic actions. We can define additional connectives, such as $\vee$ or $\rightarrow$, in the usual way.

DEFINITION 4 (LANGUAGE OF ENVIRONMENT LOGIC).
Given a set of actions Ac and a set of propositional variables P, the language of environment logic is given by:

$$\phi ::= p \mid \phi \wedge \phi \mid \neg\phi \mid [\alpha]\phi$$

where $p \in P$, and α is an expression of the action language.

In effect, the resulting language is Boolean Modal Logic [3]. The truth of sentences of environment logic is defined in the standard way, as follows.

DEFINITION 5 (SEMANTICS OF ENVIRONMENT LOGIC). *Let $Env = \langle S, Ac, (\rightarrow)_{A \subseteq Ac}, P, \pi\rangle$ be a SLTS, and s is a state in S. Truth of sentences of the language of environment logic is defined inductively as follows:*

1. $Env, s \models^e p$ *iff* $\pi(s, p) = 1$
2. $Env, s \models^e \phi_1 \wedge \phi_2$ *iff* $Env, s \models^e \phi_1$ *and* $Env, s \models^e \phi_2$.
3. $Env, s \models^e \neg\phi$ *iff* $Env, s \not\models^e \phi$
4. $Env, s \models^e [\alpha]\phi$ *iff for all* $A \subseteq Ac$ *and* $s' \in S$, *if* $A \models^p \alpha$ *and* $s \rightarrow_A s'$ *then* $Env, s' \models^e \phi$.

As usual we write $Env \models^e \phi$ when for all states $s \in S$, $Env, s \models^e \phi$. For example, if a is an atomic action, then $[a]\phi$ is true just in case executing a will always result in a state where ϕ is true, no matter what other actions are performed concurrently.

A sentence $[\neg a]\phi$ expresses that *not* doing a will always result in a state where ϕ is true – performing any concurrent action that does not involve a will results in a state where ϕ is true.

In a precise sense, the formula $[\alpha]\phi$ expresses that being of type α is a sufficient condition for a set of actions to guarantee that ϕ be true; the formula $[\neg\alpha]\neg\phi$ expresses that doing an action of type α is a *necessary* condition for reaching a state where ϕ is true – if the action is not of type α, for all the states in which the system will result ϕ is false.

The logic that results from this semantics is given by the following set of axioms and rules.

DEFINITION 6 (ENVIRONMENT LOGIC).
The environment logic *($\vdash^e$) has the following axioms*

1. *All axioms of propositional logic*
2. $[\alpha](\phi \rightarrow \psi) \rightarrow ([\alpha]\phi \rightarrow [\alpha]\psi)$ *for each α (distribution)*
3. *All axioms of the form $[\alpha]\phi \rightarrow [\beta]\phi$, if $\vdash \beta \rightarrow \alpha$ in propositional logic.*
4. $([\alpha]\phi \wedge [\beta]\phi) \rightarrow [\alpha \vee \beta]\phi$ *(additivity)*
5. $\neg[\alpha]\neg\top$ *if α is consistent in propositional logic (seriality)*
6. $[\bot]\ \bot$

Rules:

1. *from $\vdash^e \phi$ and $\vdash^e \phi \rightarrow \psi$, derive $\vdash^e \psi$ (modus ponens)*
2. *from $\vdash^e \phi$, derive $\vdash^e [\alpha]\phi$ (necessitation for each action expression α)*

We write $\Sigma \vdash^e \phi$ if ϕ can be derived from the set of sentences Σ using these rules and axioms.

Axiom 2 and the rule of necessitation state that the $[\alpha]$-operators are normal modal operators. Axiom 3 says that if β implies α in propositional logic, then, if an α-action always results in a ϕ state, then a β-action will as well (since any β-action is an α-action). Axiom 4 says that if all α-actions and all β-actions result in a state where ϕ is true, then also all $\alpha \vee \beta$-actions will. Finally, the seriality axiom reflects that any consistent combination of actions will lead to some resulting state.

This logic is sound and complete with respect to the semantics.

PROPOSITION 7 (SOUNDNESS AND COMPLETENESS).
Environment logic is sound and complete with respect to environment models.

$$\vdash^e \phi \quad \textit{iff} \quad Env \models^e \phi \textit{ for each environment model } Env.$$

proof: We give the main steps of a proof. Construct a canonical model in the usual way, by taking maximal consistent sets of the logic as states in the model. The following *truth lemma* holds for each maximal consistent Σ:

$$\phi \in \Sigma \text{ iff } \Sigma \models^e \phi \text{ in the canonical model}$$

So, suppose $[\alpha]\psi \in \Sigma$. We need to show that $\Sigma \models^e [\alpha]\psi$. If α is not consistent this holds trivially. So, assume that $\Sigma \rightarrow_A \Gamma$ for some A such that $A \models^p \alpha$. Then $\psi \in \Gamma$ by definition of the

canonical model, and by induction hypothesis, $\Gamma \models^e \psi$. Since Γ was arbitrary, it follows that $\Sigma \models^e [\alpha]\psi$.

For the other direction. Before proving the general case, we first consider the case where our action expression is of the form $\alpha_A = \bigwedge A \wedge \bigwedge\{\neg a \mid a \in Ac \text{ and } a \notin A\}$ for some set of actions A.

Suppose $[\alpha_A]\psi \notin \Sigma$ for some A. With axiom 2 and the consistency of Σ, this means that $\{\chi \mid [\alpha_A]\chi \in \Sigma\} \cup \{\neg\psi\}$ is consistent. This set can be extended to a maximal consistent Γ. We show that $\Sigma \rightarrow_A \Gamma$. To see this, take an arbitrary $[\alpha]\chi \in \Sigma$ such that $A \models^p \alpha$. Then, in propositional logic, $\vdash \alpha_A \rightarrow \alpha$, and by axiom 3, it must hold that $[\alpha_A]\chi \in \Sigma$. But then, by construction of Γ, $\chi \in \Gamma$. Putting everything together, we have that $\Sigma \rightarrow_A \Gamma$, $A \models^p \alpha_A$, and, by induction hypothesis, $\Gamma \not\models^e \psi$. We conclude that $\Sigma \not\models^e [\alpha_A]\psi$.

Now we move to the general case. Suppose that $\Sigma \models^e [\alpha]\psi$ for arbitrary α. If α is not consistent, then we can use axioms 6 and 3 to conclude that $[\alpha]\psi$ is in Σ. If α is consistent, then the sentence α is equivalent in propositional logic to the sentence $\alpha^\vee := \bigvee\{\alpha_A \mid A \models^p \alpha\}$. Clearly, we have that $\Sigma \models^e [\alpha^\vee]\psi$; and also that, for axiom 3, $\Sigma \models^e [\alpha_A]\psi$ for each A such that $A \models^p \alpha$. By the previous argument, we have that $[\alpha_A]\psi \in \Sigma$ for each A such that $A \models^p \alpha$. With axiom 4, it follows then that $[\alpha^\vee]\psi \in \Sigma$. We can now use axiom 3 and the fact that $\alpha^\vee \rightarrow \alpha$, and conclude that $[\alpha]\psi \in \Sigma$. □

So, what we have now is a dynamic logic in which we can reason about *concurrent* actions. That is, we have a way of reasoning about the effect of performing *combinations* of actions, as well as about the effect of *not* performing certain actions. This dynamic logic will serve as the environment module of our multi-agent system. We will now proceed to define the agents that will populate this environment.

2.2 Agents Module

Agents are identified with the set of actions that they can perform.

DEFINITION 8 (AGENTS MODULE).
Given a set of agents Ag and a set of actions Ac, an agents *module is a tuple $\langle Ag, Ac, \mathsf{act}\rangle$, where* act *is a function $Ag \mapsto \mathcal{P}(Ac)$ that assigns to each agent i a subset $\mathsf{act}(i)$ of actions from Ac.*
We require that $\bigcup_{i\in Ag} \mathsf{act}(i) = Ac$.

We will abuse notation somewhat, and write 'act' as a *pars pro toto* for $\langle Ag, Ac, \mathsf{act}\rangle$. We denote with $\mathsf{act}(G)$ the set $\bigcup_{i\in G} \mathsf{act}(i)$ of actions that the group G of agents can perform.

To represent the ability of agents to perform actions of a certain type, we will use some notation from cooperation logic. For an action expression α, a sentence of the form $\langle\!\langle G\rangle\!\rangle\alpha$ expresses the fact that G has the power to bring it about that a set of actions of type α will be performed; we say that G is *effective for* α, that G is able to enforce α, or simply that G is able to do α. It is important to note that α here is an action type: we are dealing with the ability to *carry out a complex action*, not the ability to *bring about some state of affairs*.

A group G is able to enforce α exactly if there is a subset from the actions under their control that, no matter what actions the other agents choose, is such that the resulting concurrent action is of type α.

The way the semantics is defined is similar to that of the Coalition Logic of Propositional Control of [15], except that we explicitly allow for different agents to 'control' the same action.

DEFINITION 9 (ABILITY FOR ACTIONS).
Let $\langle Ag, Ac, \mathsf{act}\rangle$ be an agents module, let $G \subseteq Ag$ be a set of agents.

$\langle Ag, Ac, \mathsf{act}\rangle \models^a \langle\!\langle G\rangle\!\rangle\alpha$ *iff there is an $A \subseteq \mathsf{act}(G)$ such that for all $B \subseteq \mathsf{act}(Ag \setminus G)$ it holds that $A \cup B \models^p \alpha$*

So, for example, if act is an agents module in which an agent i can execute action a, then $\mathsf{act} \models^a \langle\!\langle\{i\}\rangle\!\rangle a$: i can enforce a. However, i can only enforce $\neg a$ if he is the only one that can execute a: $\mathsf{act} \models^a \langle\!\langle\{i\}\rangle\!\rangle\neg a$ only if $a \notin \mathsf{act}(j)$ for any j other than i. Similarly, $\mathsf{act} \models^a \langle\!\langle G\rangle\!\rangle(a \wedge \neg b)$ exactly when at least one agent in G can execute a, while no agent outside of G can do b.

DEFINITION 10 (COALITION LOGIC FOR ACTIONS).
The coalition logic for actions is given by the following axioms, together with all axiom schemes of propositional logic, and modus ponens. We denote derivability in this logic with $\vdash^a$.

1. $\langle\!\langle G\rangle\!\rangle\top$, *for all* $G \subseteq Ag$
2. $\langle\!\langle G\rangle\!\rangle\alpha \rightarrow \neg\langle\!\langle Ag \setminus G\rangle\!\rangle\neg\alpha$
3. $\langle\!\langle G\rangle\!\rangle\alpha \rightarrow \langle\!\langle G\rangle\!\rangle\beta$ *if* $\vdash \alpha \rightarrow \beta$ *in propositional logic.*
4. $(\langle\!\langle G_1\rangle\!\rangle\alpha \wedge \langle\!\langle G_2\rangle\!\rangle\beta) \rightarrow \langle\!\langle G_1 \cup G_2\rangle\!\rangle(\alpha\wedge\beta)$ *for all* $G_1, G_2 \subseteq Ag$ *such that* $G_1 \cap G_2 = \emptyset$
5. $\langle\!\langle G\rangle\!\rangle a \rightarrow \bigvee_{i\in G} \langle\!\langle\{i\}\rangle\!\rangle a$, *for all* $G \subseteq Ag$ *and atomic* $a \in Ac$
6. $(\langle\!\langle G\rangle\!\rangle\alpha \wedge \langle\!\langle G\rangle\!\rangle\beta) \rightarrow \langle\!\langle G\rangle\!\rangle(\alpha\wedge\beta)$ *if* α *and* β *have no atomic actions in common.*
7. $\langle\!\langle G\rangle\!\rangle\neg a \rightarrow \langle\!\langle G\rangle\!\rangle a$ *for atomic* $a \in Ac$.
8. $\langle\!\langle G\rangle\!\rangle\alpha \rightarrow \bigvee\{\langle\!\langle G\rangle\!\rangle \bigwedge\Phi \mid \Phi$ *is a set of literals such that* $\bigwedge\Phi \rightarrow \alpha\}$

An explanation of some of the axioms is in order.

The first axiom states that any group of agents is able to enforce some trivial action. Axiom 2 is typical of cooperation logics, and states that if a group G is able to enforce an action α, then the agents outside that group cannot enforce that an action that is not of type α will happen. This follows directly from the definitions.

Axiom 3 says that if a group of agents is able to enforce an α-action, and all α-actions are also of type β, then G is also able to enforce a β-action. Note that the axioms 1 and 3 give us a kind of necessitation, even for actions: If α is a classical tautology, then we also have $\vdash^a \langle\!\langle G\rangle\!\rangle\alpha$.

Axiom 4 states that if two independent groups of agents have the ability to enforce, respectively, actions of type α and of type β, then they can combine forces to enforce an $\alpha\wedge\beta$-action. This holds only if the two groups are disjoint: if this is not the case, and the two groups have an agent in common, say agent i, then it may be that i needs to execute action a to (help) enforce α, while he needs to refrain from doing a to enforce β: there is no single choice of actions that guarantees that $\alpha \wedge \beta$ will happen.

Axiom 5 says that if a group of agents has the ability to enforce an atomic action, then at least one of them must have that ability by himself.

Axiom 6 says that if a group can enforce actions α and β, and α and β involve completely different atomic actions, then the group can also enforce $\alpha\wedge\beta$ (by choosing the actions needed to guarantee α and performing them together with those that guarantee β).

The validity of axiom 7 is a consequence of the assumption in definition 8 that any atomic action can be executed by at least one agent. It says that if a group of agents can guarantee that an *atomic*

action is *not* performed, then one of the agents in that group must be able to execute that action.

Axiom 8 says that if a group of agents can perform an α-action, then there must be a set of literals (that is, formulas of the form a or $\neg a$) that together imply α, that they can enforce – that is, there must be a 'recipe' that tells them which actions to execute and which not to execute, that guarantees that α results.

PROPOSITION 11 (SOUNDNESS AND COMPLETENESS).
Coalition logic for actions is sound and complete with respect to agent models.

proof: Soundness is relatively straightforward. To prove completeness, we define, given a maximal $\vdash^a$-consistent set of sentences Σ, a function act for which the following truth lemma holds:

$$\mathsf{act} \models^a \phi \text{ iff } \phi \in \Sigma$$

which gives us an immediate completeness result. We define act by setting $\mathsf{act}(i) = \{a \mid \langle\langle i \rangle\rangle a \in \Sigma\}$. Note that with axioms 4 and 5, we have for atomic actions a that $a \in \mathsf{act}(G)$ iff $\langle\langle G \rangle\rangle a \in \Sigma$, a fact that we will use in the proof.

Before proving the truth lemma, we define, for a group of agents G and a set of actions $A \subseteq \mathsf{act}(G)$, the set $\Phi(A, G)$ to consist of all literals $A \cup \{\neg a \mid a \in \mathsf{act}(G), a \notin A \text{ and } a \notin \mathsf{act}(Ag \setminus G)\}$. The sentence $\Phi(A, G)$ characterises exactly those possible courses of action that might result when G chooses to do A.

We prove the truth lemma by induction on ϕ, where the only interesting case is the one where ϕ is of the form $\langle\langle G \rangle\rangle \alpha$.

Suppose first that $\mathsf{act} \models^a \langle\langle G \rangle\rangle \alpha$. That means that there is an $A \subseteq \mathsf{act}(G)$ such that for all $B \subseteq \mathsf{act}(Ag \setminus G) : A \cup B \models^p \alpha$. Clearly, then, $\vdash \bigwedge \Phi(A, G) \rightarrow \alpha$ in propositional logic.

By definition of act, it holds that $\langle\langle G \rangle\rangle a \in \Sigma$ for each $a \in A$. Similarly, we have for each $a \notin \mathsf{act}(Ag \setminus G)$ that $\langle\langle Ag \setminus G \rangle\rangle a \notin \Sigma$, from which it follows with maximality and axiom 2 that $\langle\langle G \rangle\rangle \neg a \in \Sigma$. Axiom 6 allows us to conclude that $\langle\langle G \rangle\rangle \bigwedge \Phi(A, G) \in \Sigma$, and by the monotony axiom 3 it follows that $\langle\langle G \rangle\rangle \alpha \in \Sigma$.

For the other direction, assume that $\langle\langle G \rangle\rangle \alpha \in \Sigma$. Since Σ includes axiom 8, there must be a set of literals Φ such that $\bigwedge \Phi \vdash \alpha \in \Sigma$ and $\langle\langle G \rangle\rangle \bigwedge \Phi \in \Sigma$. With axiom 3, we know that for each of the literals l in Φ it holds that $\langle\langle G \rangle\rangle l \in \Sigma$.

For positive literals a, we immediately have that $\langle\langle G \rangle\rangle a$ implies that $a \in \mathsf{act}(G)$.

For negative literals $\neg a$, we have with axiom 7 that $\langle\langle G \rangle\rangle \neg a$ implies that $a \in \mathsf{act}(G)$. Moreover, for the negative literals we can use axiom 2 to conclude that $a \notin \mathsf{act}(Ag \setminus G)$.

But this means that $\mathsf{act} \models^a \langle\langle G \rangle\rangle \bigwedge \Phi$, and since $\bigwedge \Phi \rightarrow \alpha$, that $\mathsf{act} \models^a \langle\langle G \rangle\rangle \alpha$. □

2.3 A multi-agent system – agents acting in an environment

In the previous two subsections we defined a module describing an environment, and a separate module describing the actions that agents can choose to perform, either by themselves or together. These two modules can be related by identifying the set of actions in the two respective modules. Such a combination provides us with a semantics for reasoning about agents that act in an environment by way of performing certain actions.

Formally, a multi-agent system is an environment together with an agent module that shares its action repertoire.

DEFINITION 12 (MULTI-AGENT SYSTEM).
A multi-agent system MaS is a tuple

$$\langle S, Ac, (\rightarrow)_{A \subseteq Ac}, P, \pi, Ag, \mathsf{act} \rangle$$

where:

1. $\langle S, (\rightarrow_{A'})_{A \subseteq Ac}, P, \pi \rangle$ *is an environment (in the sense of definition 1).*
2. $\langle Ac, Ag, \mathsf{act} \rangle$ *is an agent module (in the sense of definition 8).*

Of course, everything that we could express with the languages we used to talk about the environment and about the capabilities of the agents remains interesting in the combined system as well, so a logic for reasoning about a multi-agent system should include both. But in the new, more complex system, there are other notions of interest that did not make sense in the separate modules.

In particular, we are interested in the more standard operators of coalition logic that reason not about ability to enforce complex *actions*, but ability to enforce certain *results*. We will overload the operators $\langle\langle G \rangle\rangle$ for this purpose, and add sentences of the form $\langle\langle G \rangle\rangle \phi$ to the language, where ϕ can be any sentence. Intuitively, $\langle\langle G \rangle\rangle \phi$ means that the agents in G have the power to obtain a state where ϕ is true.

This leads to the following definition of a language for multi-agent systems:

$$\phi ::= p \mid \phi \wedge \phi \mid \neg \phi \mid [\alpha]\phi \mid \langle\langle G \rangle\rangle \alpha \mid \langle\langle G \rangle\rangle \phi$$

where $p \in P$, and α is an expression of the action language, as in definition 2. The satisfaction of formulae of the type $\langle\langle G \rangle\rangle \phi$ is defined as follows.

DEFINITION 13 (ABILITY).
MaS, $s \models^m \langle\langle G \rangle\rangle \phi$ *iff there is a set of actions* $A \subseteq \mathsf{act}(G, s)$ *such that for all* $B \subseteq \mathsf{act}(Ag \setminus G)$ *and for all states* t, *if* $s \rightarrow_{A \cup B} t$, *then MaS*, $t \models^m \phi$.

So, $\langle\langle G \rangle\rangle \phi$ is true in a certain state just in case the agents in G are able to execute a concurrent action that guarantees, independently from what the other agents do, the truth of ϕ. As for the environment module, *MaS* $\models^m \phi$ means that for all $s \in S$, *MaS*, $s \models^m \phi$.

The following proposition provides a precise link between the ability to obtain a certain state of affairs, and the ability to execute an action that is guaranteed to result in such a state. It states that a group has the ability to enforce the truth of a sentence just in case it is able to enforce a concurrent action that is guaranteed to result in a state in which that sentence is true:

OBSERVATION 14. *Given a multi-agent system MaS and a state* s *of its environment:*
MaS, $s \models^m \langle\langle G \rangle\rangle \phi$ *iff there exists an action expression* α *with MaS*, $s \models^m \langle\langle G \rangle\rangle \alpha$ *and MaS*, $s \models^m [\alpha]\phi$

proof: Assume that *MaS*, $s \models^m \langle\langle G \rangle\rangle \phi$, and let A be a witness for this fact. The action expression $\bigwedge \Phi(A, G)$ (the set of sentences we used in the proof of proposition 11) is the witness we are looking for: it holds that *MaS*, $s \models^m \langle\langle G \rangle\rangle \bigwedge \Phi(A, G)$, and that *MaS*, $s \models^m [\bigwedge \Phi(G, A)]\phi$.

For the other direction, let α be such that *MaS*, $s \models^m \langle\langle G \rangle\rangle \alpha$ and *MaS*, $s \models^m [\alpha]\phi$. By definition it follows from *MaS*, $s \models^m \langle\langle G \rangle\rangle \alpha$ that there must be a set of actions $A \in \mathsf{act}(G, s)$ such that $A \cup B \models^m \alpha$ for each $B \subseteq \mathsf{act}(Ag \setminus G, s)$. Take this A, and take any $B \subseteq \mathsf{act}(Ag \setminus G)$ and t such that $s \rightarrow_{A \cup B} t$. Since $A \cup B \models^p \alpha$ and *MaS*, $s \models^m [\alpha]\phi$, it must hold that $t \models^m \phi$. So *MaS*, $s \models^m \langle\langle G \rangle\rangle \phi$. □

The logic for the multiagent system obviously contains all axioms we already had from the two separate models. To obtain a complete axiom system, it suffices to add just two axioms that relate the ability to obtain a state of affairs with the ability to execute concurrent actions.

DEFINITION 15 (COOPERATION LOGIC WITH ACTIONS). *The cooperation logic with actions, $\vdash^m$, is given by:*

1. *All axioms and rules from the environment logic of section 2.1*
2. *All axioms and rules from the agent logic of section 2.2*
3. $(\langle\langle G\rangle\rangle\alpha \wedge [\alpha]\phi) \rightarrow \langle\langle G\rangle\rangle\phi$ *for each* α
4. $\langle\langle G\rangle\rangle\phi \rightarrow \bigvee\{\langle\langle G\rangle\rangle\alpha \wedge [\alpha]\phi \mid \alpha$ *is the conjunction of a set of action literals* $\}$

where 'action literals' are atomic actions a or their negations $\neg a$.

The two new axioms relate the ability to execute actions with the ability to enforce the truth of propositions, in the same way as is done in observation 14.

PROPOSITION 16 (SOUNDNESS AND COMPLETENESS). *Cooperation logic with actions is sound and complete with respect to action models:*

$$\vdash^m \phi \quad \textit{iff} \quad \textit{MaS} \models^m \phi \textit{ for all models MaS}$$

proof: Soundness follows from the soundness of the two modules and the previous observation 14.

Completeness is relatively straightforward with the completeness results of sections 2.1 and 2.2. We first construct a model *MaS* combining the constructions of the previous proofs in the straightforward way.

We need to prove a truth lemma stating that $\textit{MaS}, \Sigma \models^m \phi$ iff $\phi \in \Sigma$. This is proven by induction on ϕ, leaving the proofs of propositions 11 and 7 practically unchanged. The only interesting case is the new operator. So suppose that

ϕ is of the form $\langle\langle G\rangle\rangle\psi$

Suppose $\textit{MaS}, \Sigma \models^m \langle\langle G\rangle\rangle\psi$. With observation 14, there is an action expression α such that $\Sigma \models^m \langle\langle G\rangle\rangle\alpha$ and $\Sigma \models^m [\alpha]\psi$. By induction hypothesis and the previous two cases, we have that $\langle\langle G\rangle\rangle\alpha \in \Sigma$ and $[\alpha]\phi \in \Sigma$, and therefore, with our axiom 3 and the fact that Σ is maximal, that $\langle\langle G\rangle\rangle\phi \in \Sigma$.

For the other direction, assume that $\langle\langle G\rangle\rangle\psi \in \Sigma$. Then, with the axiom 4 and maximality of Σ, there is a set of action literals Φ such that $[\bigwedge \Phi]\psi \in \Sigma$ and that $\langle\langle G\rangle\rangle \bigwedge \Phi$ in Σ. We can conclude (by induction hypothesis and the previous cases) that $\Sigma \models^m [\bigwedge \Phi]\psi$ and $\Sigma \models^m \langle\langle G\rangle\rangle \bigwedge \Phi$. We then use observation 14 again to conclude that $\Sigma \models^m \langle\langle G\rangle\rangle\psi$. □

Summarising, we have defined an environment as a Set-Labelled Transition System, and defined a PDL-like logic for representing the performance of complex actions in such an environment. We gave a sound and complete logic for this logic. We then defined agents as actors that can choose to do certain sets of actions, and defined a sound and complete logic for reasoning about the ability of groups of agents to enforce that a certain type of concurrent action is executed. We then defined a notion of cooperative ability. This *modularisation* of a multi-agent system paid off: it turned out to be relatively easy to find a sound and complete axiomatisation for the combination of these two logics.

3. AN EXAMPLE

Often in a multi-agent system, certain variables can be changed only when two or more agents cooperate, while other variables can be changed by the agents acting by themselves. For example, a database may contain crucial data that can be changed only with the consent of all operators, while data of a lesser importance can be changed by any agent. For another example, a website may accept a request for information without further ado, but for accepting a transaction with a credit card, it will need the consent of both the customer and the credit card company. Similarly, a website such as Ebay will accept advertisements that are submitted by a single agent acting alone, but will not accept a transaction if this is not confirmed by all parties involved.

All of these examples are instances of a case in which certain variables are under control of single agents, while other variables can only be changed by groups of agents acting together. We will consider an instance of this schema, in which two agents control two variables. To make the example concrete, we will talk about prison guards that control two doors (see Figure 1). A prison is composed of two interiors, a dormitory and a courtyard. One door opens to the outside, and it is important that it is not opened by accident. It can therefore only be opened if both guards act together; if it is open, each of the agents can close it at will. The other door separates the cell block from the courtyard, and each guard can open that door by himself. The fact that the inner gate is open is expressed by a proposition $\mathsf{in\_open}$; if the outer gate is open, $\mathsf{out\_open}$ is true.

The state of the gates is ruled by four buttons: a_1, b_1, a_2 and b_2. The gate $\mathsf{in\_open}$ toggles its state if and only if at least one of a_1 and a_2 is pressed. The outer gate $\mathsf{out\_open}$ toggles its state if and only if both b_1 and b_2 are pressed.

This description can be captured by an environment model *Env* with four states determined by the fact whether the gates are open or not. For example, we will write 01 for the state in which the inner door is closed and the outer door is open. Each of the buttons corresponds to an atomic action in the model, and the transitions are as described (so, for example, it will hold that $01 \rightarrow_{\{a_2,b_2\}} 11$).

With our environment language, we can express properties of the environment such that the fact that the action $a_1 \wedge b_1 \wedge b_2$ ensures, in the state 00, that in the next state both the gates will be open:

$$\textit{Env}, 00 \models^e [a_1 \wedge b_1 \wedge b_2](\mathsf{in\_open} \wedge \mathsf{out\_open})$$

Similarly, the fact that if the outer gate is closed, the action $b_1 \wedge b_2$ is both a sufficient and necessary condition to open the outer gate is captured by:

$$\textit{Env} \models^e \neg\mathsf{out\_open} \rightarrow ([b_1 \wedge b_2]\mathsf{out\_open} \wedge [\neg(b_1 \wedge b_2)]\neg\mathsf{out\_open})$$

Two guards, gd_1 and gd_2, control the buttons. The first guard gd_1 has access to the buttons a_1 and b_1, whereas gd_2 has access to a_2 and b_2. This situation can be captured by an agents model with the same set of atomic actions as the environment, and a function act such that $\mathsf{act}(gd_1) = \{a_1, b_1\}$ and $\mathsf{act}(gd_2) = \{a_2, b_2\}$.

We can express that the action b_1 can be executed only by the guard gd_1 as $\langle\langle gd_1\rangle\rangle b_1 \wedge \neg\langle\langle gd_2\rangle\rangle b_1$ (strictly speaking, we should have written $\langle\langle gd_1\rangle\rangle$ instead of $\langle\langle\{gd_1\}\rangle\rangle$, but we are omitting the curly brackets for readability).

Together, the agents can push both b_1 and b_2, that is, $\mathsf{act} \models^a \langle\langle gd_1, gd_2\rangle\rangle(b_1 \wedge b_2)$. Analogously, both of them can, individually, execute the disjunction of a_1 and a_2: $\mathsf{act} \models^a \langle\langle gd_1\rangle\rangle(a_1 \vee a_2) \wedge \langle\langle gd_2\rangle\rangle(a_1 \vee a_2)$.

Combining the environment and the agents modules in multiagent system *MaS*, we obtain a model of the guards controlling the prison.

For example, since $b_1 \wedge b_2$ is a necessary condition to open the outer gate, and each guard gd_i can prevent the execution of b_i, it follows that both guards are needed to open the outer gate. Indeed, it holds that $\textit{MaS} \models^m \neg\mathsf{out\_open} \rightarrow (\neg\langle\langle gd_1\rangle\rangle\mathsf{out\_open} \wedge$

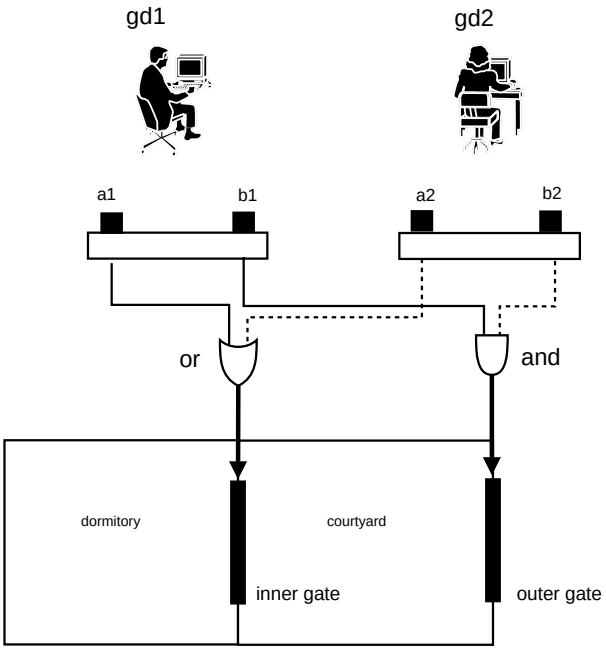

Figure 1: ***The prison example.***

$\neg\langle\langle gd_2\rangle\rangle$out_open)). Together, they can, indeed, open the door: *MaS* $\models^m \langle\langle gd_1, gd_2\rangle\rangle$out_open. To escape, the prisoner will need to take both of the guards hostage to open the outer door.

On the other hand, we want to be sure that when either one of the guards notes that there's a fire in the dormitory, he can open the inner gate to let the prisoners into the courtyard. Since both the guards are able to execute at least one of the actions a_1 and a_2, act $\models^a \langle\langle gd_1\rangle\rangle(a_1 \vee a_2) \wedge \langle\langle gd_2\rangle\rangle(a_1 \vee a_2)$, and an action of type $a_1 \vee a_2$ opens the inner gate, *Env* $\models^e \neg$in_open $\rightarrow [a_1 \vee a_2]$in_open, each of the guards has the power to open the inner gate if required:

$$\textit{MaS} \models^m \neg\mathsf{in\_open} \rightarrow (\langle\langle gd_1\rangle\rangle\mathsf{in\_open} \wedge \langle\langle gd_1\rangle\rangle\mathsf{in\_open}).$$

4. RICHER SYSTEMS

We have studied a system in which 'plans' of agents to obtain certain goals (i.e., complex action expressions) never look more than one transition ahead. There are different ways of enriching the system. First of all, one may enrich the model itself, and, for example, take a more sophisticated view of agents, taking the information they have and/or their goals into account as well. But also if we leave the semantical model the way it is, there are ways to enrich the language to allow us to express other interesting properties of a system.

One obvious choice is to enrich the language on the level of the multi-agent system with other operators borrowed from ATL [1].

Let a strategy for a group of agents G be a function that assigns to each state a subset of actions from act(G). A strategy for G together with a strategy for the agents not in G defines a unique path through the model, and we can define logical operators that not only talk about those states that can be reached by performing a single action, but also about strategies that guarantee that a sentence will always remain true, or will eventually become so:

1. *MaS*, $s \models \langle\langle G\rangle\rangle\Box\phi$ iff there is a strategy for the agents in G such that, no matter what the other agents do, ϕ will be true in all the states along the resulting paths.
2. *MaS*, $s \models \langle\langle G\rangle\rangle\Diamond\phi$ iff there is a strategy for the agents in G such that, no matter what the other agents do, will eventually result in a state where ϕ is true.

What we want to do is 'decompose' these notions into independent statements about the environment and about the agent module, to obtain a theorem similar to that of observation 14. We will focus on the second construct: the ability of a coalition to *eventually* bring about some state of affairs.

To express the type of actions that guarantee that some state will obtain at some point arbitrarily far in the future, we need a richer action language. A more program-like language is suitable here, in which we can express things like 'continue doing α until ϕ is true.' One well-studied set of operators for expressing these kinds of properties are those of Propositional Dynamic Logic [7]. We obtain an action repertoire like the following:

$$\alpha, \beta ::= \gamma \mid ?\phi \mid \alpha;\beta \mid \alpha \cup \beta \mid \alpha^*$$

where γ is a simple action expression (a Boolean combination of atomic actions), as in definition 2 and ϕ is a sentence as in definition 4. These operators can be given their standard semantics, which we do not repeat here.

We will call these types of action expression 'plans', in conformance with the usage we make of them. Now, what we are looking for is the following type of 'decomposition' of the meaning of $\langle\langle G\rangle\rangle\Diamond\phi$ — which is defined in terms of strategies — into a statement about the ability to execute a certain action and a statement about the effect of this action, in a way that is similar to observation 14:

Let MaS consist of an agent module act *and an environment module Env. Then:*

MaS, $s \models \langle\langle G\rangle\rangle\Diamond\phi$ *iff there is a plan* α *such that* G *has the ability to perform* α *(in the action module* act*), and* α *is guaranteed to reach a state where* ϕ *is true (in the environment module Env).*

With action expressions to express complex plans, then, we need a way of expressing that a plan is guaranteed to result in a state where ϕ is true. Somewhat disappointingly, PDL does not provide us with a way of doing that: the expression $[\alpha]\phi$ captures that all halting executions end up in a ϕ-state. The problem is that α might not halt at all, in which case ϕ may never become true, even if $[\alpha]\phi$ is.

One way of remedying this lack of expressive power is to add a new predicate to the language to obtain sentences of the form halt(α), that are true in a state s exactly when all executions of α are guaranteed to halt.

We also need to extend the language of the agent module of the previous section with expressions that express the ability to perform these complex actions. If we assume that all agents can observe all static sentences, the following definitions are reasonable:

1. act $\models \langle\langle G\rangle\rangle?\phi$ (since agents can observe anything)
2. act $\models \langle\langle G\rangle\rangle\alpha;\beta$ iff act $\models \langle\langle G\rangle\rangle\alpha$ and act $\models \langle\langle G\rangle\rangle\beta$
3. act $\models \langle\langle G\rangle\rangle\alpha \cup \beta$ iff act $\models \langle\langle G\rangle\rangle\alpha$ and act $\models \langle\langle G\rangle\rangle\beta$
4. act $\models \langle\langle G\rangle\rangle\alpha^*$ iff act $\models \langle\langle G\rangle\rangle\alpha$

Putting all of this together, we obtain the following conjecture:

CONJECTURE 17. *MaS*, $s \models \langle\langle G\rangle\rangle F\phi$ *iff there is a plan* α *(in the language extended with PDL-operators) such that MaS*, $s \models$

$[\alpha]\phi$ *(if* α *halts, it is in a* ϕ*-state, MaS,* $s \models \langle\alpha\rangle\top$ *(*α *is executable), MaS,* $s \models \mathsf{halts}(\alpha)$ *(*α *is guaranteed to halt), and MaS,* $s \models \langle\langle G\rangle\rangle\alpha$ *(the agent in* G *are able to enforce* α*).*

5. CONCLUSIONS

Many logic-based formalisms – cooperation logics – have been developed in order to represent the power of groups of agents to achieve certain states of affairs.

Pauly [12] provides a modal logic, Coalition Logic, which axiomatises α-ability – a notion of power developed in game theory. A state of affairs is denoted as a set of states that satisfy a propositional formula ϕ and, informally, a group of agents G is α-effective for ϕ if and only if there exists a joint strategy for G which, no matter what the other agents do, ensures the satisfaction of ϕ. Another example is CL-PC, van der Hoek et al. [15]. In CL-PC each agent controls the truth value of a set of variables. In this way, the notion of α-ability can be formalised a standard multi-modal Kripke model and the usual semantics for box and diamond operators can be used. Finally another well-known logic to reason about the α-ability is ATL, in which the expressivity of the previous approaches is enriched with CTL temporal formulas [1].

All these approaches directly describe the achievement power of groups of agents without explicitly representing what they actually do in order to achieve a certain state of affairs. This fact has two drawbacks. First, it may not be easy to reason about meta-information such as the costs required to achieve a certain state of affairs or how these costs are distributed. Second, even if these logics correctly describe whether a group of agents has the power achieve a state of affairs, they do not provide, as required in cooperative problem solving or social reasoning mechanism, any clue about which group of agents has the power to achieve a desired state of affairs.

Thus, inspired by work on cooperative problem solving [16] and social reasoning mechanisms [13], we have formalised a notion of power in two modules: in the first module, the environment module, we addressed the problem to describe a causal model of an environment in which several agents act at the same time. In this module it is possible to describe the fact that a plan, intended as a set of concurrent actions, assures a certain state of affairs. In the second module, the agents module, the capabilities of the agents are modeled and in particular the possibility for a group of agents to execute a plan no matter what the other agents do. Combining these two modules provides a straightforward way to describe the achievement power a group of agents: a group of agents has the power to achieve a state of affairs ϕ if there exists a plan α assuring ϕ and the group can execute α without being obstructed by the other agents.

We have provided a complete axiomatisation for the two separated modules as well as for their combination. We noted that the axiomatisation of the combined module is straightforward, given the completeness of the two logics of the underlying modules. This is evidence that the modularisation of the notion of power is possible.

Finally we also provided an indication of how to enrich the expressiveness of our framework, maintaining the modularisation uninjured, with operators borrowed from Dynamic Logic. Our future work is devoted to provide formal results in this sense.

ABSTRACT

The 'Cooperation Logic of Propositional Control', CL-PC, of van der Hoek and Wooldridge is a logic for reasoning about the ability of agents and groups of agents to obtain a certain state of affairs in a situation in which each of the agents controls a number of propositional variables.

We present a number of generalizations of this model, to represent situations in which agents only partially control the value of a variable, or cases in which agents share the control of a variable. We discuss and axiomatize some of these logics of 'partial control.' In addition, we show how this family of logics are closely connected to a body of work in mathematical logic: Cylindric Modal Logic.

1. INTRODUCTION

Cooperation logics are logics for reasoning about what agents and groups of agents in a multi-agent system can obtain. Formal models for cooperation logics have recently gained some attention; examples are Coalition Logic [10, 9], and ATL [1]. These logics provide ways of talking about what agents, alone or in groups, can obtain with or without the cooperation of the other agents.

A cooperation logic for a specific kind of multi-agent system is the *Coalition Logic of Propositional Control* (CL-PC) from [13]. CL-PC is a logic for reasoning about a situation in which a number of binary control variables is allocated to a group of agents. Given a certain *state* – that is, given that the values of the variables are set in a certain way – agents can then change the variables allocated to them to change the state into a new one.

One of the observations we make in this paper is that the CL-PC model is naturally seen as a *game* (in the game-theoretical sense): the model concerns a set of agents that each can choose between a number of *strategies* (a strategy is for an agent is a valuation for the propositional variables allocated to it), and a choice of strategy for each of the agents determines the final result (a valuation over all variables). Seen as a game, it is quite natural to generalize the kind of model used in CL-PC, which is exactly what we will do.

The model for CL-PC proposed by [13] is about a particular case of propositional control: each variable is controlled by exactly one agent, and all variables can be controlled independently of each other. It is natural to weaken one or both of these assumptions, and consider models in which several agents share the control over the same variables, or cases in which one cannot change a certain variable without changing another as well.

The paper consists of two parts. In section 2, we introduce a general model for reasoning about situations in which propositions get allocated to a number of agents, whose choices with regard to the values of 'their' variables determine their final value. We will call such situations 'games of propositional control.' We show how the logical formalism used in CL-PC can be extended to apply to this larger class of games in a straightforward way. The result of this exercise gives us a modal logic that has been studied in mathematical logic as 'cylindric modal logic' This is a useful observation as it gives us a number of properties that are shared by all logics of propositional control.

In section 3, we discuss a number of particular types of propositional games. One of these is, of course, the model for CL-PC from [13], but we will also consider other types of games, in which agents may *share* the control over certain variables, or games in which the choices of the agents are restricted in certain ways. We will give a number of sound and complete axiomatizations for reasoning for this type of games.

2. GAMES OF PROPOSITIONAL CONTROL

There are different ways of defining a model for representing the control of agents over a given set of propositional variables. One general schema is to define such a situation

as a *game*. A specification of a game of propositional control, then, starts with an *allocation* of propositional variables to each of the agents. The agents each choose a valuation for the variables that are allocated to them; the *strategies* of an agent are valuations over the variables that he controls.

Because the valuations chosen by each of the agents may not determine the final values in an unambiguous way (because the choices may conflict), there is an *outcome function* that gives us, for each combination of choices of strategies, an *outcome*, which is a valuation for all propositional variables. Formally, we define a game of propositional control as:

DEFINITION 1. *A* game of propositional control *is a tuple*

$$\mathcal{M} = \langle \mathsf{Ag}, \mathsf{At}, \mathsf{alloc}, \mathsf{strategy}, \mathsf{outcome} \rangle$$

Where:

- $\mathsf{Ag} = \{1, 2, \ldots n\}$ *is a finite, non-empty set of agents*
- At *is a set of propositional variables (or 'atoms').*
- alloc *is an* allocation function *that assigns to each agent from* Ag *a subset of variables from* At.
- *A* strategy *for a player i is a valuation over the propositional variables in* $\mathsf{alloc}(i)$ *– that is, a function that assigns to each propositional variable in* $\mathsf{alloc}(i)$ *a truth value.*
- *The function* strategy *assigns a set of available strategies to each agent i.*
- *We say that a* state *of the game is a tuple $s = (s_1, \ldots s_n)$ consisting of a strategy s_i from* $\mathsf{strategy}(i)$ *for each agent i.*
- outcome *is an* outcome function *that assigns to each state s a valuation over all the propositional variables in* At.

As an example, consider a case with two agents, a website and a telephone operator, that together control a database with customer data of some company. Say that a variable credit_ok represents the information that the credit card rating of mr. X is fine, and another variable, webcustomer, represents the fact that mr. X has placed an order over the internet.

The variable credit_ok is controlled by both agents, in the sense that if either the telephone operator or the website get the information that there is something wrong with mr X's credit rating, they can change the value of credit_ok to 0. The credit rating can only be set to 1 if both agents agree. The variable webcustomer is completely under control of the website.

This situation can be represented as a game of propositional control. A game with two players is represented naturally as a matrix, in the following way:

website\ operator	credit_ok : 1	credit_ok : 0
credit_ok : 1 webcustomer : 1	credit_ok : 1 webcustomer : 1	credit_ok : 0 webcustomer : 1
credit_ok : 1 webcustomer : 0	credit_ok : 1 webcustomer : 0	credit_ok : 0 webcustomer : 0
credit_ok : 0 webcustomer : 1	credit_ok : 0 webcustomer : 1	credit_ok : 0 webcustomer : 1
credit_ok : 0 webcustomer : 0	credit_ok : 0 webcustomer : 0	credit_ok : 0 webcustomer : 0

Here, the top row describes the strategy choices of the telephone operator, while the left column describes the options for the website. The outcome of their choices is represented by the values in the cells of the matrix.

Suppose, for example, that the present state of the environment is given by the top-right box in the example above — the telephone operator did not approve the credit card rating of a web customer, but the website does — then the operator is able to change the value of credit_ok to 1 by changing her 'strategy.' However, she does not have this possibility if the present state is the one given by the outcome on the third row on the right: even if the values in the database are the same here, the telephone operator cannot, by herself, change the rating of the customer, because the website disapproves. They can, however, change the credit card rating *together* – by both changing the value of credit_ok to 1.

To reason about these kind of scenarios in a formal way, we use formulas of a simple modal language. Formulas of coalition logic are constructed from a given set of agents Ag and a given set of atomic variables At.

$$\phi ::= \top \mid p \mid \neg\phi \mid \phi \wedge \psi \mid \langle C \rangle \phi$$

Where $p \in \mathsf{At}$ and $C \subseteq \mathsf{Ag}$. The expression $\langle C \rangle \phi$ is a cooperation modality. The idea is that $\langle C \rangle \phi$ is true at some state just in case the agents in C can, by manipulating the values of the variables under their control, reach a state in which ϕ is true. We write $[C]$ for the dual of $\neg\langle C \rangle \neg$ of $\langle C \rangle$. The sentence $[C]\phi$ is true in case the agents in C cannot manipulate their variables in such a way that $\neg\phi$ becomes true: in other words, when the agents in C have no way of changing the truth value of ϕ from true to false.

DEFINITION 2 (INTERPRETATION).

$$\begin{array}{rcl}
\mathcal{M}, s \models p & \textit{iff} & \mathsf{outcome}(s)(p) = \mathsf{t} \\
\mathcal{M}, s \models \neg\phi & \textit{iff} & \mathcal{M}, s \not\models \neg\phi \\
\mathcal{M}, s \models \phi \wedge \psi & \textit{iff} & \mathcal{M}, s \models \phi \textit{ and } \mathcal{M}, s \models \psi \\
\mathcal{M}, s \models \langle C \rangle \phi & \textit{iff} & \textit{there is a state } t \textit{ such that} \\
 & & s(i) = t(i) \textit{for each } i \notin C, \textit{ and} \\
 & & \mathcal{M}, t \models \phi
\end{array}$$

So, a sentence of the form $\langle C \rangle \phi$ is true at a state s when it holds that the agents in C can unilaterally change their choice of strategy in such a way that in the resulting state, ϕ is true. So, in a precise sense, a sentence $\langle C \rangle \phi$ expresses al *local ability* of a group of agents in a state s: it is true in a state s just in case the agents in C are able to change the situation so that ϕ becomes true.

One of the interesting insights in [13] is that we also express 'global' properties of ability of agents that have been studied in Pauly's Coalition Logic ([9], [10]) and in ATL ([1]) using these 'local' operators.

We say that a group C is α-effective for an outcome ϕ, and write $\langle\langle C \rangle\rangle \phi$, when the players in the group can orchestrate their strategies in such a way that no matter what the other players do, ϕ will be true in the outcome.

$$G, s \models \langle\langle C \rangle\rangle \phi \text{ iff } G, s \models \langle C \rangle [\mathsf{Ag} \setminus C] \phi$$

This definition says that a group C is α-effective for ϕ just in case there is a combination of strategies for the agents in C such that, no matter what the agents outside of C (that is, those in the set $\mathsf{Ag} \setminus C$) choose to do, the resulting state will always be one where ϕ is true.

The notion of α-ability is a *global* notion, in the sense that the truth of a sentence $\langle\langle C\rangle\rangle\phi$ is independent of the state in which it is evaluated — it either is true in all states in a game, or in none of them. So, the fact whether $\langle\langle G\rangle\rangle\phi$ is true expresses a property of the whole game rather than of a particular state in it.

To turn back to our example: we saw that the website had the power to change the value of the variables credit_ok at will. Indeed, the sentence $\langle\langle$website$\rangle\rangle$webcustomer and the sentence $\langle\langle$website$\rangle\rangle\neg$webcustomer are both true. Neither the website nor the operator is α-effective to approve the credit card rating of mr. X: $\neg\langle\langle$website$\rangle\rangle$credit_ok holds, and so does $\neg\langle\langle$operator$\rangle\rangle$credit_ok, even if, for example, $\langle$website$\rangle$credit_ok is true in some states. However, together they are effective for setting credit_ok to 1, which is captured by the truth of $\langle\langle\{$website, operator$\}\rangle\rangle$credit_ok.

2.1 The logic of games of propositional control

It turns out that the logic of games of propositional control is located at an intersection point between different areas of mathematical logic: it is the logic of finite variable fragments of first order logic without identity, which is closely related to diagonal-free cylindric algebra [15, 14, 8], while its models are products of $S5$-models [3]. For this reason, it is relatively well-studied.

From this work, we know that the logic of propositional games is not finitely axiomatizable. Moreover, the logic is not decidable. There is, however, a sound and complete axiomatization, but it uses a non-standard rule. These are negative results, but the logic of propositional games is still of interest, because it can serve as a kind of 'minimal logic of propositional control': we know that the logic of any particular subclass of models (such as CL-PC) will include this this logic, so we will discuss its main features.

The following set of axioms and rules is shown to be sound and complete for the class of all propositional games from [8] for the language of cylindric algebra, which [15] translates into modal logic. (In the following, if C is a singleton set $\{i\}$, we will write $\langle i\rangle$ instead of $\langle\{i\}\rangle$.)

DEFINITION 3 (LOGIC OF PROPOSITIONAL GAMES).

propositional logic *all validities of propositional logic*

reduction $\langle\{i_0,\ldots,i_m\}\rangle\phi \leftrightarrow \langle i_0\rangle\ldots\langle i_m\rangle\phi$

asynchronicity $\langle i\rangle\langle j\rangle\phi \rightarrow \langle j\rangle\langle i\rangle\phi$

normality $[i](\phi\rightarrow\psi)\rightarrow([i]\phi\rightarrow[i]\psi)$

reflexivity $\phi\rightarrow\langle i\rangle\phi$

symmetry $\phi\rightarrow[i]\langle i\rangle\phi$

transitivity $\langle i\rangle\langle i\rangle\phi\rightarrow\langle i\rangle\phi$

Plus the following rules:

$$\frac{\vdash\phi}{\vdash[i]\phi}\qquad\frac{\vdash\phi,\vdash\phi\rightarrow\psi}{\vdash\psi}$$

Define $\tau(\chi)$ to be the sentence $\neg\langle A\rangle[(\bigwedge_{i\in A}\langle i\rangle\chi)\wedge\neg\chi]$. The logic contains the following non-standard rule:

$$\frac{(p\wedge\tau(p\wedge\neg\phi))\rightarrow\phi}{\phi}$$

provided that p does not occur in ϕ

When there are only two agents, this rule can be replaced with the following axiom

confluence $\langle i\rangle[j]p\rightarrow[j]\langle i\rangle p$.

The reduction axiom says that the modality $\langle C\rangle$ can be defined in terms of $\langle i\rangle$-operators for $i\in C$ – the ability of a set of agents can be decomposed in the abilities of the agents separately. The asynchronicity axiom says that the order in which the $\langle i\rangle$-operators are applied does not matter.

The reflexivity axiom states that if ϕ is true, then any agent can 'change' the current state (by doing nothing) to make ϕ true. Note that symmetry, reflexivity and transitivity are known as the $S5$ axioms that are familiar from classical modal logic as the axioms that characterize an equivalence relation.

More complicated is the non-standard rule. A full explanation would lead too far for the purposes of this paper. We refer the reader to the works quoted – and in any case, we will not need the rule for axiomatizing the logics we introduce below.

PROPOSITION 4 (COMPLETENESS [8, 14]). *The logic of definition 3 is sound and complete with respect to the class of games of propositional control defined in definition 1.*

proof: This follows from the completeness results for cylindric modal logic. For some details of how to connect those results to games of propositional control, see the appendix. □

We repeat the following results

PROPOSITION 5 ((UN)DECIDABILITY RESULTS [7, 5]).

- *If the number of agents is less than or equal to two, basic game logic is decidable.*
- *However, if there are more than 2 agents, basic game logic is not decidable.*

2.2 The Pareto Principle

The class of models defined in definition 1 is quite large. Many of the models that fall under the definition are hardly worthy of the name 'propositional control', as there need not be any systematic relation at all between the valuations that the agents choose and the actual outcome that results.

To do justice to the idea that the allocation function in a game of propositional control specifies some kind of control, we need some further constraints. There are many possible properties that are candidates for minimal conditions for a game to be called a game of propositional control, but one in particular stands out: the condition that if all agents that are allocated a given variable p choose the same value for p, then the outcome should reflect that choice.

DEFINITION 6 (PARETO PRINCIPLE).
Let $\mathcal{M}=\langle$Ag, At, alloc, strategy, outcome$\rangle$ be a game of propositional control.

The Pareto principle holds for $\mathcal{M}$ iff for each state $s=(s_0,\ldots,s_n)$ and for any i and j such that $p\in$ alloc(i) and $p\in$ alloc(j) it holds that if $s_i(p)=s_j(p)$, then outcome$(s)=s_i(p)$.

In the rest of this paper, we will only consider games for which the Pareto principle holds.

The Pareto principle is a property that is well known in social choice theory (which is where the name comes from). Social choice theory is concerned with finding a 'fair' way of

defining a preference order among a given set of alternatives, given the preferences of a group of agents (typical examples are political elections and auctions). It is perhaps useful to remark here that we are dealing with a situation that in certain respects is more simple than the topic usually dealt with in social choice theory. Here, we are dealing with variables that can each have only one out of two possible truth values. In particular, Arrow's Theorem, a central result that establishes that a 'fair' social choice function does not exist, does not arise as such within our framework. There are, however, interesting results from social choice theory that apply to games of propositional control such as they are defined here (see, for example, [6] or [11]) that show that given certain assumptions about 'fairness', fair outcome functions do not exist. It seems, however, that these kind of concerns are tangential to the kind of problem that we are concerned with in this paper.

3. LOGICS OF PROPOSITIONAL CONTROL

We have talked about games of propositional control in a very general way. It is now time to be more specific. In the rest of the paper, we will study a number of subclasses of games of propositional control, and provide them with sound and complete axiomatizations. Even if the proofs are fairly involved (they can be found in the appendix), the axiomatizations themselves are relatively straightforward, and have axioms that correspond directly with certain properties of the models.

3.1 Logic of Exclusive control

One particular subclass of games of propositional control is one in which no single variable is allocated to two different players. We will call such games *games of exclusive control*. The kind of game that is studied in CL-PC, which was the main inspiration for this paper, is an example of such a game.

DEFINITION 7 (GAMES OF EXCLUSIVE CONTROL). *Let $\mathcal{M} = (\mathsf{Ag}, \mathsf{At}, \mathsf{alloc}, \mathsf{strategy}, \mathsf{outcome})$ be a game.*

- *An allocation function* alloc *is* exclusive *when no two agents have control over the same variable, i.e. when* $\mathsf{alloc}(i) \cap \mathsf{alloc}(j) = \emptyset$ *whenever* $i \neq j$.
- *A* game of exclusive control *is a game for in which the Pareto principle holds, and that based on an exclusive allocation function* alloc.
- *A* game of actual control *is a game in which the allocation of a variable p to an agent i implies that i has a choice available where p is false and one where p is true: for each i and $p \in \mathsf{alloc}(i)$, a strategy s_i such that $s_i(p) = 1$, and a strategy s'_i such that $s'_i(p) = 0$.*
- *A* game of full control *is a game where* $\mathsf{strategy}(i)$ *contains a strategy for* each *valuation of* $\mathsf{alloc}(i)$.

A game of actual control is a game in which each agent, for each propositional variable p allocated to him, has at least one choice available where p is true and one where p is false. In a game of full control each player has all combinations of truth values of propositional variables available to him — this reflects an assumption that the variables can all be set independently of each other.

Note that the outcome function outcome of an exclusive game is determined completely by the choices of the players and the assumption that the Pareto principle holds – since no variable is allocated to two agents, obviously, their choices cannot conflict. Exclusive games of full propositional control are studied in [4] as 'distributed evaluation games', and are the models of CL-PC that are studied in [13] and [12].

EXAMPLE 8. *Suppose a player i can control two bits of a register, represented by the values of the bits p and q. She can set either bit to 0 or to 1, as she likes, but she cannot set both bits to 0. A second player j controls r. We can represent the game in a matrix:*

$i \setminus j$	r	$\neg r$
p, q	p, q, r	$p, q, \neg r$
$p, \neg q$	$p, \neg q, r$	$p, \neg q, \neg r$
$\neg p, q$	$\neg p, q, r$	$\neg p, q, \neg r$

This is an exclusive game of actual control. The players do not have full control, since i has no strategy for $\neg p, \neg q$.

It turns out that logic of games of exclusive control, and their extensions to real and full exclusive control, are fairly straightforward extensions of the minimal game logic of the previous section.

Before we introduce these axioms an abbreviation will be useful. We follow [13] and say that an agent *locally controls* a sentence ϕ iff it holds (in a state) that $\langle i \rangle \phi \wedge \langle i \rangle \neg \phi$. This sentence is true in a state just in case i can unilaterally change her strategy in such a way that ϕ becomes true, but also has a strategy available where ϕ becomes false. We write $\mathsf{controls}(i, \phi)$ for the sentence $\langle i \rangle \phi \wedge \langle i \rangle \neg \phi$

The property of exclusive control is characterized by the following axiom, that states that if an agent i can change the truth value of a propositional variable p, then no other player can do so.

Exclusive Control (EC) $\mathsf{controls}(i, p) \rightarrow \neg \mathsf{controls}(j, p,)$ for $i \neq j$ and $p \in P$.

In games of actual control, there is, for each propositional variable p, at least one player that controls it:

Actual Control (AC) $\bigvee_{i \in A} \mathsf{controls}(i, p)$ for each $p \in P$.

Similarly, in games of full control, if an agent controls all variables from a given set X, then she has the ability to change the outcome in such a way that any consistent boolean combination of the variables in X is satisfied:

Full Control (FC) $\bigwedge_{p \in X} \mathsf{controls}(i, p) \rightarrow \langle i \rangle \phi_v$, where ϕ_v is the conjunction of literals true in a valuation v for X.

We will write, for example, that $EC, FC \vdash \phi$ just in case ϕ is derivable in the logic of games of propositional control of definition 3 from any instance of the axiom schemas EC and FC.

PROPOSITION 9 (COMPLETENESS RESULTS).

$EC \vdash \phi$	*iff*	$G, s \models \phi$ *for all games G of exclusive control.*
$EC, AC \vdash \phi$	*iff*	$G, s \models \phi$ *for all games G of exclusive, actual control.*
$EC, FC \vdash \phi$	*iff*	$G, s \models \phi$ *for all games G of exclusive, full control.*

proof: See the appendix. It is perhaps important to note at this point that neither for this proposition, nor in any of the following ones, we need the full power of the logic of definition 3: we may drop the non-standard rule, and use the confluence axiom instead. □

3.2 Logic of Positive Control

If certain variables are allocated to more than one agent, we need a way of deciding what to do if one agent wants to set a variable to a different value than another. There are lots of options open. If there is an odd number of agents to which the variable is allocated, we can let the majority decide. In other scenarios we may have a constraint that a variable can only be set to a certain value with the consensus of all other players, such as in example in 2 in which the validity of the credit of a customer needs to be judged. In other situations, a constraint may be that if one of the players chooses a strategy in which p is true, then p is true in the outcome of the game.

Let us first consider games of the latter type:

DEFINITION 10 (GAMES OF POSITIVE CONTROL). *A game $\mathcal{M}$ is a* game of positive control *iff the Pareto principle holds, and it holds that if $s_i(p) = 1$ for some i, then $\mathsf{outcome}(s)(p) = 1$.*

Note that also in games of positive control, the Pareto principle implies that the outcome is completely determined by the strategies of the players.

Games of positive control have a particularly natural interpretation if we interpret the elements of the control variables $\mathcal{P}$ as *actions* that may be performed or not. Agents each have a repertoire of actions available that may overlap (or even be equal), and may choose to execute certain subsets of these actions (if we consider games of full control, they can execute any subset). The outcome such a game, then, consists of exactly the actions that have been executed. This behavior corresponds precisely to the definition of a game of positive control.

For example, if i chooses to execute p but not q, and j executes q, then the result will be that both p and q are executed. Such complex or concurrent actions can be described by a propositional formula; for example, $p \wedge \neg q$ is true of an outcome in which p is executed, but not q. The formula $\langle\langle i, j\rangle\rangle(p \wedge \neg q)$ then describes the game in which the group consisting of i and j has the ability to ensure that p is being executed, and to ensure that q is *not* done. In a game of positive control, it holds that $\langle\langle i, j\rangle\rangle(p \wedge \neg q)$ exactly when p is allocated to either i or j, while q is not allocated to any agent other than i or j.

Also positive control is characterized by a straightforward *axiom of positive control*:

Positive Control (POS) $p \rightarrow \bigvee_{i \in \mathsf{Ag}} [\mathsf{Ag} \setminus \{i\}]p$

That this axiom is sound can be seen as follows. If p is true, then by the Pareto principle, there must be an agent, say i, that has chosen a strategy in which p is true. Then, by the definition of a game of positive control, there is nothing that the other players can do about it, so $[\mathsf{Ag} \setminus \{i\}]p$ must be true.

PROPOSITION 11 (COMPLETENESS). *$POS \vdash \phi$ iff $\mathcal{M}, s \models \phi$ in all games of positive control.*

proof: See the appendix. □

3.3 Logic of Consensus Games

The mirror image of the games of positive control are games in which the truth-value of a propositional variable is determined by *consensus*: a propositional variable is true only if all players choose that proposition to be true.

DEFINITION 12 (CONSENSUS GAMES). *A game is a* consensus game *iff $\mathsf{outcome}(s)(p) = 1$ iff $s_i(p) = 1$ for each i such that $p \in \mathsf{alloc}(i)$*

A consensus game might also be called a game of 'negative' control, in which a variable is false in the outcome when at least one of the agents wants it to be false.

Consensus Axiom (CON) $\neg p \rightarrow \bigvee_{i \in N} [\mathsf{Ag} \setminus \{i\}]\neg p$.

The idea is similar to the axiom of positive control: if the outcome is $\neg p$, then, because of the Pareto principle, at least one of the players must have chosen a strategy in which p is false, which implies, by definition of the consensus game, that no matter what the other players will do, p will be false in the outcome.

EXAMPLE 13. *A simple safety mechanism is that two players must both give their consent for some action to be carried out (a customer and a seller confirm some cash transaction; two people lift a heavy table togethere). One very simple way is to describe this by the following game, where each player can either confirm p or not, and the result will be p only if both players give their consent:*

$a \setminus b$	p	$\neg p$
p	p	$\neg p$
$\neg p$	$\neg p$	$\neg p$

The minimal game logic together with the axiom of consensus is sound and complete with respect to all consensus games.

PROPOSITION 14. *$CON \vdash \phi$ iff $\mathcal{M}, s \models \phi$ in all consensus games $\mathcal{M}$*

proof: Analogous to the proof of proposition 11, which can be found in the appendix. □

4. CONCLUSIONS

We have defined a general model of 'propositional control' inspired by the Coalition Logic of Propositional Control of [13], and connected this work with work on mathematical logic (in particular with Cylindric Modal Logic) and with work on 'judgment aggregation' in social choice theory.

We then studied in more detail some particular examples of families of games of propositional control – in particular, we studied different forms of games of exclusive control – in which agents either have some or all strategies available, and provided sound and complete axiomatization for these logics. We also looked at games of 'positive control', in which a vote of one player suffices to make a proposition true, and at 'consensus games' in which a vote of a single player suffices to make a propositional variable false, and provides sound and complete axiomatization for these logics.

A number of open problems and questions are raised by this paper. We mention a few. First of all, there is a general question. Cylindrical Modal Logic, which we proposed as a kind of 'minimal logic of propositional control' is not

decidable, and has a 'strange' axiomatization with a non-standard rule. In contrast, the particular examples of logics we studied in section 3 are much better behaved – they are clearly decidable, and do not need special kinds of axiomatization. It is not really clear why this is the case, or where the 'borderline' is between decidability and undecidability. The answer to this question might lie with the class of games for which the Pareto principle holds true.

A more specific question regards the complexity of the logics discussed in this paper; we only know that the satisfiability and the model checking problems of the logics for games of full exclusive control are PSPACE-complete ([13]). (Satisfiabily and model-checking have the same complexity because of the strong restrictions on the kind of models that are allowed, which means that there are relatively few models to consider in the satisfaction problem. We do not expect the same results for our logics.) At last, there may be other types of logics of propositional control over and above the ones discussed in this paper that might be interesting to study.

To conclude, we list the main completeness results of this paper in a table:

class of games	characterizing axioms
exclusive	EC
exclusive, actual control	EC, AC
exclusive, full control	EC, AC, FC
games of positive control	POS
consensus games	CON

Appendix

In this appendix, we provide some formal background about the relation between games of propositional control and standard models of modal logic, and proofs of the main theorems.

Games of propositional control can be seen as a kind of Kripke models. The following definition makes the connection precise.

DEFINITION 15 (KRIPKE MODEL INDUCED BY A GAME). *Given a game* $\mathcal{M} = \langle \mathsf{Ag}, \mathsf{At}, \mathsf{alloc}, \mathsf{strategy}, \mathsf{outcome} \rangle$ *The* Kripke model induced by M *is a tuple* $(W, (\longrightarrow_i)_{i \in \mathsf{Ag}}, V)$, *where:*

- W *is the set of states of* $\mathcal{M}$ *(that is, the Cartesian product of the sets* $\mathsf{strategy}(i)$*)*
- $s \longrightarrow_i s'$ *iff* $s_j = s'_j$ *for each* $j \neq i$, *and*
- $V(s) = \mathsf{outcome}(s)$.

In the following proofs, we will often confuse a game and the Kripke model induced by it, and write, for example, that $s \longrightarrow_i s'$ in a game $\mathcal{M}$ when s and s' are two states that differ at most in the strategy of i.

This connection between propositional games and Kripke models preserves the truth of sentences.

OBSERVATION 16. *If* s *is a state of a propositional game* $\mathcal{M}$, *and* $\mathcal{K}$ *is the Kripke model induced by* $\mathcal{M}$, *then* $\mathcal{M}, s \models \phi$ *iff* $\mathcal{K}, s \models \phi$ *(using the standard definition of modal logic).*

With these observations, we have a way of transforming games into Kripke models that preserves the truth value of sentences. This gives us a way of applying known results about Kripke models to games of propositional control. In particular, we can tie the logic of games to the following definition and proposition come from [15], [8].

DEFINITION 17 (CUBES).
A cube *is a Kripke model* $(U^{|\mathsf{Ag}|}, (\longrightarrow_i)_{i \in \mathsf{Ag}}, V)$, *with* $s \longrightarrow_i s'$ *iff* $s_j = s'_j$ *for each* $j \neq i$.

PROPOSITION 18 ([15], [8]). *The set of cubes is axiomatized by the minimal logic of propositional control of definition 3.*

To show that the logic of cubes is the same as the logic of games of propositional control, we need to show that each cube corresponds to a game, and each game corresponds to

a cube. The Kripke models induced by a game of propositional control are not precisely cubes, however: they are more like 'rectangles' (if the players number two) or like '(hyper)-bricks' (if there are more than 2 players). 'Cubes' are a subclass of these kind of models; those induced by games in which all players have the same number of strategies available. We will not provide the formal details here, but it is fairly straightforward to transform a Kripke model that is shaped like a 'brick' into an equivalent model that is shaped like proper 'cube' (at least, if the number of agents is finite). Perhaps abusing the geometrical metaphor, one possible way to make a cube from a brick is to add, where needed, a new layer to the 'long' sides of the brick until the model has become a cube – to not affect the validities in the model, this new layer can simply be a copy of the side to which it is added.

In the completeness proofs that follow, we use the notion of a *bisimulation*.

DEFINITION 19 (BISIMULATION). *A pointed Kripke model is a pair (K, s), where K is a Kripke model, and s is a state in K.*

A relation $\sim$ between pointed Kripke models is a bisimulation *iff whenever $(K, s) \sim (K', s')$, it holds that:*

I. $V(s) = V'(s')$

II. If $s \longrightarrow_i t$, then there is a t' with $s' \longrightarrow'_i t'$ and $(K, t) \sim (K', t')$

III. If $s' \longrightarrow'_i t'$, then there is a t with $s \longrightarrow_i t$ and $(K, t) \sim (K', t')$

We say that two pointed Kripke models are bisimilar iff there exists a bisimulation connecting the two models.

A basic result says that two bisimilar Kripke models satisfy the same sentences. If it does not lead to confusion, we will write $s \sim s'$ for $(K, s) \sim (K', s')$. Also, we will be slightly sloppy, and talk about bisimilarity of a Kripke model and a game, meaning that the first Kripke model is bisimilar to the model induced by the game.

PROPOSITION 9. *$EC \vdash \phi$ iff $\mathcal{M}, s \models \phi$ in all games $\mathcal{M}$ of exclusive control.*

proof: Soundness is just a matter of checking that the axioms are valid in a game of exclusive control.

A sketch of the completeness proof before starting: first we construct a canonical Kripke model in the standard way ([2]), then we show that each world in the canonical model is bisimilar to a state in (the Kripke model induced by) a game. This means that all sentences in the maximal consistent set in the canonical model are true in the related game, and thus that any consistent set can be satisfied in some game.

The canonical model $K^{can} = (W, \longrightarrow_i, V)$ has as its domain all maximal consistent sets (mcs) Σ. We set $V(\Sigma)(p) = 1$ iff $p \in \Sigma$, and the accessibility relations are given by $\Sigma \longrightarrow_i \Gamma$ iff for all ϕ: if $[i]\phi \in \Sigma$ then $\phi \in \Gamma$. It is straightforward to prove that the *truth lemma* holds: $K^{\mathsf{can}}, \Sigma \models \phi$ iff $\phi \in \Sigma$.

The interesting part of the proof is the construction of a game G_Σ corresponding to each mcs Σ. First, we define an allocation function alloc_Σ by setting $\mathsf{alloc}_\Sigma(i) = \{p \mid \mathsf{controls}(i, p) \in \Sigma\}$. Because Σ includes the axiom of exclusive control, we know that alloc_Σ is exclusive.

We introduce some notation: if v is a valuation over a finite set X, let ϕ_v be the conjunction of all literals of X true in v. The strategies $\mathsf{strategy}_\Sigma(i)$ of a player i in G_Σ are exactly those valuation functions v on the set $\mathsf{alloc}_\Sigma(i)$ such that $\langle i\rangle\phi_v \in \Sigma$. In the game G_Σ, let s_Σ be the state such that $\phi_{s_\Sigma(i)} \in \Sigma$ for each i. Such a state is guaranteed to exist by the reflexivity axiom.

We claim that there is a bisimulation $\sim$ between maximal consistent sets in the canonical model K^{can} and states in the set of all (Kripke models induced by) exclusive games, given by:

$$\Sigma \sim (G, s) \text{ iff } (G, s) = (G_\Sigma, s_\Sigma).$$

To make our proof run a bit more smoothly, we will write that $(G, s) \longrightarrow_i (G', s')$ iff $G = G'$ and $s \longrightarrow_i s'$ in G. We check the three bisimulation clauses:

I. From the definition of G_Σ and the assumption that the Pareto principle holds for G_Σ, it follows that $\Sigma \models p$ iff $(G_\Sigma, s_\Sigma) \models p$.

II. Suppose that $\Sigma \longrightarrow_i \Gamma$. We claim that $(G_\Sigma, s_\Sigma) \longrightarrow_i (G_\Gamma, s_\Gamma)$. It follows from lemma 21 that $G_\Sigma = G_\Gamma$, and that for each $p \notin \mathsf{alloc}(i)$, $p \in \Sigma$ iff $p \in \Gamma$. That means that $s_\Sigma(j) = s_\Gamma(j)$ for each $j \neq i$, and that therefore $s_\Sigma \longrightarrow_i s_\Gamma$.

III. For the other direction, suppose that $(G_\Sigma, s_\Sigma) \longrightarrow_i (G_\Sigma, s')$. Let $s = s_\Sigma$. By definition of G_Σ, we have that $\langle i\rangle\phi_{s'_i} \in \Sigma$. That means that there is a Γ in the canonical modal such that $\Sigma \longrightarrow_i \Gamma$ and $\phi_{s'_i} \in \Gamma$. By exclusivity and lemma 20, it follows that $[i]\phi_{s_j} \vee [i]\neg\phi_{s_j} \in \Gamma$ for each $j \neq i$. Since by definition, $\phi_{s_j} \in \Sigma$, it follows that $\phi_{s_j} \in \Gamma$, and therefore that $s' = s_\Gamma$.

The proofs of completeness for the logics with the axioms AC and FC is straightforward given these results. □

LEMMA 20 (DERIVED THEOREMS).

1. $\vdash \langle i\rangle[j]\phi \rightarrow [j]\langle i\rangle\phi$ *(confluence)*
2. $EC \vdash \mathsf{controls}(i, p) \rightarrow [j]\mathsf{controls}(i, p)$
   Moreover, if ϕ is propositional and X is the set of propositional variables occurring in ϕ, it holds that:
3. $\bigwedge_{p\in X} \neg\mathsf{controls}(i, p) \vdash [i]\phi \vee [i]\neg\phi$
4. $EC, \bigwedge_{p\in X} \mathsf{controls}(j, p), \langle j\rangle\phi \vdash [i]\langle j\rangle\phi$

proof:

2. In $S5$, it follows from $\mathsf{controls}(i, p)$ that $[i]\mathsf{controls}(i, p)$. Using the axiom EC, we have then that $[i]([j]p \vee [j]\neg p)$, which is equivalent (using reflexivity and propositional logic) to $[i]((p \rightarrow [j]p) \wedge (\neg p \rightarrow [j]\neg p))$. Since we have that $\langle i\rangle p \wedge \langle i\rangle\neg p$, it follows in $S5$ that $\langle i\rangle[j]p \wedge \langle i\rangle[j]\neg p$. Using confluence, we conclude that $[j]\langle i\rangle p \wedge [j]\langle i\rangle\neg p$, and hence that $[j]\mathsf{controls}(i, p)$.

3. Prove this by induction on the structure of ϕ.

4. Suppose that $\bigwedge_{p\in X} \mathsf{controls}(j, p)$. With (3) and EC, we have that $\vdash \bigwedge_{p\in X} \mathsf{controls}(j, p) \rightarrow ([i]\phi \vee [i]\neg\phi)$, and with necessitation and some further reasoning, we conclude that $[j]([i]\phi \vee [i]\neg\phi)$. Since $[i]\phi \vee [i]\neg\phi$ is equivalent in $S5$ to $(\phi \rightarrow [i]\phi) \wedge (\neg\phi \rightarrow [i]\neg\phi)$, we have in particular that $[j](\phi \rightarrow [i]\phi)$. Together with our assumption that $\langle j\rangle\phi$, it follows that $\langle j\rangle[i]\phi$. Using confluence, then, $[i]\langle j\rangle\phi$. □

LEMMA 21. *Let $\longrightarrow_i$ be the accessibility relation in the canonical model, and let alloc_Σ be defined as above. It holds that:*

1. *If $\Sigma \longrightarrow_i \Gamma$ then $\mathsf{alloc}_\Sigma = \mathsf{alloc}_\Gamma$*

2. *If* $\Sigma \longrightarrow_i \Gamma$ *and* $p \notin \mathsf{alloc}_\Sigma(i)$*, then* $p \in \Sigma$ *iff* $p \in \Gamma$

3. *If* $\Sigma \longrightarrow_i \Gamma$ *and* s_j *is a valuation on* $\mathsf{alloc}_\Sigma(j)$*, then* $\langle j\rangle\phi_{s_j} \in \Sigma$ *implies that* $\langle j\rangle\phi_{s_j} \in \Gamma$ *for each* j*.*

proof:

1. Suppose $\Sigma \longrightarrow_i \Gamma$, and that $\mathsf{controls}(j,p) \in \Sigma$. Then, by lemma 20, $[i]\mathsf{controls}(j,p) \in \Sigma$, so $\mathsf{controls}(j,p) \in \Gamma$. Using symmetry, we can conclude that also if $\mathsf{controls}(j,p) \in \Gamma$, then $\mathsf{controls}(j,p)) \in \Sigma$. So $\mathsf{alloc}_\Sigma = \mathsf{alloc}_\Gamma$.

2. From exclusivity EC it follows that if $p \notin \mathsf{alloc}_\Sigma(i)$, then $[i]p \vee [i]\neg p \in \Sigma$. From there it is an easy step to conclude that $p \in \Sigma$ implies $p \in \Gamma$.

3. Clearly, it holds $\mathsf{controls}(j,p)$ for all propositional variables occurring in ϕ_{s_j}. Suppose $\langle j\rangle\phi_{s_j} \in \Sigma$. It follows from lemma 20 that $[i]\langle j\rangle\phi_{s_j} \in \Sigma$, and therefore that $\langle j\rangle\phi_{s_j} \in \Gamma$. □

PROPOSITION 11. *$POS \vdash \phi$ iff $\mathcal{M}, s \models \phi$ in all games of positive control $\mathcal{M}$*

proof: The structure of the completeness proof is similar to that of proposition 9. We construct the canonical model K^{can}, and construct games G_Σ for each maximal consistent set Σ, and show that the model (G_Σ, s_Σ) is bisimilar to (K^{can}, Σ).

First, we need some notation. If v is a valuation over a finite set X, ϕ_v^+ is the conjunction of all propositional variables of X that are true in v, i.e. $\phi_v^+ = \bigwedge\{p \mid v(p) = 1\}$. We will write $[-i]\phi$ for $[\mathsf{Ag} \setminus \{i\}]\phi$.

To construct our game G_Σ, we set $\mathsf{alloc}(i)$ to be the set of all variables for any i. So the strategies $\mathsf{strategy}_\Sigma(i)$ for agent i consist of valuations over *all* variables, and is given by $\mathsf{strategy}_\Sigma(i) = \{v \mid \langle i\rangle[-i]\bigwedge\{p \mid v(p) = 1\} \in \Sigma\}$. So, $\mathsf{strategy}_\Sigma(i)$ contains a strategy for each set of variables that i can *guarantee* to be true.

We now claim that the following relation $\sim$ is a bisimulation:

$$(K^{can}, \Sigma) \sim (G, s) \text{ iff } G = G_\Sigma \text{ and for each } i: \\ s_i(p) = 1 \Leftrightarrow [-i]p \in \Sigma.$$

We need to show that the three bisimulation clauses hold.

I. Suppose $G_\Sigma, s \models p$. Then there must be an agent i with $s_i(p) = 1$. By definition of $\sim$, it holds that $[-i]p \in \Sigma$. By necessitation, $p \in \Sigma$, and by construction of the canonical model that $K^{can}, \Sigma \models p$.

For the other direction, if $p \in \Sigma$, then, with the axiom of positive control, $\bigvee_{i\in N}[-i]p \in \Sigma$. Because Σ is maximal, we have that $[-i]p \in \Sigma$ for some i. But then, by definition of $\sim$, $s_i(p) = 1$, and so, $G_\Sigma, s \models p$.

II. Suppose that $\Sigma \longrightarrow_i \Gamma$ and that $\Sigma \sim G_\Sigma, s$. By standard $S5$-reasoning, if $\langle i\rangle\phi \in \Sigma$, then so is $[i]\langle i\rangle\phi$, which means that $\langle i\rangle\phi \in \Gamma$. By symmetry, the other direction works as well. Since the definition of the game G_Σ depends only on sentences from Σ that are of the form $\langle i\rangle\phi$, so we can conclude that $G_\Sigma = G_\Gamma$.

Consider now the state s' for which it holds for each j that $s'_j(p) = 1$ iff $[-j]p \in \Gamma$. We show that $s \longrightarrow_i s'$. To see that $s_j = s'_j$ for $j \neq i$, note that if $[-j]p \in \Sigma$ then, by $S5$ and asynchronicity, $[i][-j]p \in \Sigma$, and therefore that $[-j]p \in \Gamma$; with symmetry, it follows that $s_j = s'_j$. We also need to show that s'_i is a strategy in G_Σ. This follows from the observation that $[-i]\bigwedge\{p \mid s'_i(p) = 1\} \in \Gamma$, and therefore that $\langle i\rangle[-i]\bigwedge\{p \mid s'_i(p) = 1\} \in \Sigma$.

III. Suppose that $\Sigma \sim (G_\Sigma, s)$, and that $s \longrightarrow_i s'$. We need to find a Γ such that $\Sigma \longrightarrow_i \Gamma$ and $\Gamma \sim (G_\Sigma, s')$. It is enough to show that the set $\{[-j]p \mid s'_j(p) = 1$ and $j \in N\} \cup \{\phi \mid [i]\phi \in \Sigma\}$ is consistent; we can then extend it to a maximal consistent set to obtain our wanted Γ. Because $s_j = s'_j$ for $j \neq i$, it must hold that $\{[-j]p \mid s'_j(p) = 1$ and $j \neq i\} \subseteq \Sigma$, and by $S5$ and asynchronicity, we have that $[i][-j]p \mid s'_j(p) = 1$ and $j \neq i\} \subseteq \Sigma$. So, it is enough to show that $\{[-i]p \mid s'_i(p) = 1\} \cup \{\phi \mid [i]\phi \in \Sigma\}$ is consistent. Suppose it is not. By definition of G_Σ, we have that $\langle i\rangle[-i]\bigwedge\{p \mid s'_i(p) = 1\} \in \Sigma$. But then it would follow that $\langle i\rangle\bot \in \Sigma$, which is a contradiction in $S5$.

□

PROPOSITION 14. *$CON \vdash \phi$ iff $\mathcal{M}, s \models \phi$ in all consensus games $\mathcal{M}$*

proof: Analogous to the completeness proof of the logic of positive control. Define the set of strategies for i in the game G_Σ as $\mathsf{strategy}_\Sigma(i) = \{v \mid \langle i\rangle[-i]\bigwedge\{p \mid v(p) = 0\} \in \Sigma\}$, and then adapt the proof accordingly. □

On the Complexity of Practical ATL Model Checking

ABSTRACT

We investigate the computational complexity of reasoning about multi-agent systems using the cooperation logic ATL of Alur, Henzinger, and Kupferman. It is known that satisfiability checking is EXPTIME-complete for "full" ATL, and PSPACE-complete (in the general case) for the fragment of ATL corresponding to Pauly's Coalition Logic. In contrast, the model checking problems for ATL and Coalition Logic can both be solved in time polynomial in the size of the formula and the size of model against which the formula is to be checked. However, these latter results assume an *extensive* representation of models, in which all states of a model are explicitly enumerated. Such representations are not feasible in practice. In this paper we investigate the complexity of the ATL and Coalition Logic model checking problems for a more "reasonable" model representation known as SRML ("Simple Reactive Modules Language"), a simplified version of the actual model representation languages used for model checkers such as SMV and MOCHA. While it is unsurprising that, when measured against such representations, the model checking problems for ATL and Coalition Logic have a higher complexity than when measured against explicit state representations, we show that in fact the ATL and Coalition Logic model checking problems for SRML models have *the same complexity as the corresponding satisfiability problems*. That is, model checking ATL formulae against SRML models is EXPTIME-complete, and model checking Coalition Logic formulae against SRML models is PSPACE-complete. We conclude by investigating some technical issues around these results, and discussing their implications.

logic, verification, cooperation, complexity

1. INTRODUCTION

Cooperation logics – such as Pauly's Coalition Logic [19, 20, 9] and its temporal extension, the Alternating-time Temporal Logic (ATL) of Alur, Henzinger, and Kupferman [2] – have attracted much interest from the multi-agent systems community [23, 14, 15, 11]. Using such logics, it is possible to reason about the strategic powers of agents and coalitions of agents in game-like multi-agent scenarios.

If one aims to use logics such as ATL and Coalition Logic to reason about systems, then it is obvious to ask how complex the associated reasoning problems are for such logics. Given a particular (multi-agent) system ξ, there are essentially two approaches that may be adopted to reasoning about ξ: theorem proving (via satisfiability checking) and model checking [4]. The satisfiability problem for ATL is EXPTIME-complete, and is hence prohibitively expensive [7, 25]; satisfiability for Coalition Logic is "only" PSPACE-complete [19, 20, 21], and thus apparently easier, but of course this "easiness" is relative: PSPACE-completeness is an extremely negative complexity result!

In contrast, model checking approaches to reasoning about systems appear to be computationally easier. Model checking was originally developed as a technique for verifying that finite state concurrent systems satisfy specifications expressed in the language of temporal logic [8]. The basic idea is that the state transition graph of a system ξ can be understood as a model M_ξ for a temporal logic such as Computation Tree Logic (CTL): if we express desirable or undesirable properties of ξ as formulae φ of CTL, we can then check whether or not ξ has these properties by evaluating whether or not $M_\xi \models \varphi$, and this can be done in deterministic polynomial time [8, p.1044].

Now, one of the attractive features of ATL (and Coalition Logic) is that its model checking problem is apparently no harder than that of its ancestor CTL. More formally, the model checking problem, as discussed in [2] is as follows. We are given an ATS (i.e., an ATL model) S, a state q from S, a formula φ over S and we are asked whether $S, q \models \varphi$. It is shown in [2] that this problem is tractable: it can be solved in time $O(|S| \times |\varphi|)$, where $|S|$ is the size of S and $|\varphi|$ is the size of φ. However, this apparently positive result has a well-known catch. It assumes that the ATS S is *explicitly enumerated* in the input to the problem, and in particular, that all the states of S are listed in the input. Of course, if S has n Boolean variables, then there may be 2^n possibles states. Moreover, in a very recent result, Jamroga and Dix point out that this tractability result only goes through if the number of agents is *fixed*, and *not* considered a parameter of the problem [13]. They show that if

the number of agents is considered an input to the model checking problem, then model checking is NP-complete with respect to a representation of ATL models as *alternating transition systems*, and even worse – Σ_2^p-complete – for the representation of ATL models as *concurrent game structures*.

So, the tractability result for ATL model checking is perhaps misleading, since we have tractability *only* if we explicitly enumerate all states of the system in the input, and *only* if we assume the number of agents is fixed, and not part of the input.

The complexity of ATL model checking is thus particularly sensitive to the *representation* of the model given as input. An obvious question to ask is what kinds of representations are used *in practice*, by actual model checking systems. In fact, practical model checkers such as SMV (for CTL) [17], SPIN (for LTL) [12], and MOCHA (for ATL) [3] use a succinct *model specification language* for defining models. While the model specification languages used by these systems differ on details, they all have the flavour of programming languages, providing the verifier with a relatively high-level way of defining models. But this then raises the question of the extent to which the apparently positive complexity results for CTL, ATL, and Coalition Logic model checking hold when using such model representation languages. It comes as no surprise that model checking against such model representations will be harder. For example, a PSPACE-completeness result for CTL model checking against a representation of concurrent programs was obtained by Kupferman et al [16], and extended to combinations of CTL with knowledge in [22].

However, to date, the issue of complexity of ATL model checking for realistic model specification languages has not been investigated, and this is the aim of the present paper. The particular model specification language we focus on is called SRML ("Simple Reactive Modules Language"), and is a slightly simplified version of the REACTIVE MODULES LANGUAGE (RML) [1]. We are particularly interested in RML for several reasons: first, RML is the language that is actually used by the ATL model checking system MOCHA [3]; it has been shown to be well suited to building models of a range of multi-agent protocols; and RML programs can easily be used to code basic reactive agents. As we pointed out above, it is unsurprising that, assuming representations such as SRML, the model checking problems for ATL and Coalition Logic have a higher complexity than when measured against explicit state representations, particularly given the results of Jamroga and Dix [13]. However, we show that in fact the ATL and Coalition Logic model checking problems for SRML programs have *the same complexity as the corresponding satisfiability problems*! That is, model checking ATL formulae against SRML programs is EXPTIME-complete, and model checking Coalition Logic formulae against SRML programs is PSPACE-complete. There is thus a *huge* gulf – much larger than perhaps might be expected – between the provably tractable model checking problem for explicit state models and the provably *in*tractable model checking problem for "realistic" model representations. Indeed, it again raises the question of the relative merits of theorem proving *versus* model checking [10]. We begin by describing ATL and then SRML, the simplified variant of RML that we use throughout the paper. We present our main results in section 4. We conclude by investigating some technical issues around these results, and discussing their implications.

2. ATL

Alternating-time Temporal Logic (ATL) [2] can be understood as a generalisation of the well-known branching time temporal logic CTL [8], in which path quantifiers are replaced by *cooperation modalities*. A cooperation modality $\langle\langle C\rangle\rangle\varphi$, where C is a group of agents, expresses the fact that there exists a strategy profile for C such that by following this strategy profile, C can ensure φ. Thus, for example, the system requirement "agents 1 and 2 can cooperate to ensure that the system never enters a fail state" may be captured by the ATL formula $\langle\langle 1,2\rangle\rangle\,\Box\neg fail$. The "$\Box$" temporal operator means "now and forever more": additional temporal connectives in ATL are "$\Diamond$" ("either now or at some point in the future"), "$\mathcal{U}$" ("until"), and "$\bigcirc$" ("in the next state").

To give a precise definition of ATL, we must first introduce the semantic structures over which formulae of ATL are interpreted. An *alternating transition system* (ATS) is a 6-tuple

$$S = \langle \Pi, \Sigma, Q, Q_0, \pi, \delta \rangle, \text{ where:}$$

- Π is a finite, non-empty set of *Boolean variables*;
- $\Sigma = \{a_1, \ldots, a_n\}$ is a finite, non-empty set of *agents*;
- Q is a finite, non-empty set of *states*, with $Q_0 \subseteq Q$ representing the *initial* states of Q;
- $\pi : Q \to 2^{\Pi}$ gives the set of Boolean variables satisfied in each state;
- $\delta : Q \times \Sigma \to 2^{2^Q}$ is the system transition function, which maps states and agents to the choices available to these agents. Thus $\delta(q, a)$ is the set of choices available to agent a when the system is in state q. We require that this function satisfy the requirement that for every state $q \in Q$ and every set $Q_1, \ldots, Q_n$ of choices $Q_i \in \delta(q, a_i)$, the intersection $Q_1 \cap \cdots \cap Q_n$ is a singleton.

(Initial states Q_0 were not considered part of ATSs in the original publications on ATL: we introduce them to be consistent with the behaviour of model checkers for ATL, which check formulae against the initial state of the system: see below.)

An ATL formula, formed with respect to an alternating transition system $S = \langle \Pi, \Sigma, Q, Q_0, \pi, \delta \rangle$, is then defined by the following grammar:

$$\varphi ::= \top \mid p \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle\langle C\rangle\rangle \bigcirc \varphi \mid \langle\langle C\rangle\rangle \Box \varphi \mid \langle\langle C\rangle\rangle \varphi \,\mathcal{U}\, \varphi$$

where $p \in \Pi$ is a Boolean variable, and $C \subseteq \Sigma$ is a set of agents. We assume the remaining connectives of classical logic ("$\bot$", "$\rightarrow$", "$\leftarrow$", "$\leftrightarrow$", "$\wedge$") are defined as abbreviations in the usual way, and define $\langle\langle C\rangle\rangle \Diamond \varphi$ as $\langle\langle C\rangle\rangle \top \,\mathcal{U}\, \varphi$.

To give the semantics of ATL, we need some further definitions. For two states $q, q' \in Q$ and an agent $a \in \Sigma$, we say that state q' is an *a-successor* of q if there exists a set $Q' \in \delta(q, a)$ such that $q' \in Q'$. Intuitively, if q' is an a-successor of q, then q' is a possible outcome of one of the choices available to a when the system is in state q. We denote by $succ(q, a)$ the set of a-successors to state q, and say that q' is simply a *successor* of q if for all agents $a \in \Sigma$, we have $q' \in succ(q, a)$; intuitively, if q' is a successor to q, then when the system is in state q, the agents Σ can cooperate to ensure that q' is the next state the system enters.

A *computation* of an ATS $\langle \Pi, \Sigma, Q, Q_0, \pi, \delta \rangle$ is an infinite sequence of states $\lambda = q_0, q_1, \ldots$ such that for all $u > 0$, the state q_u is a successor of q_{u-1}. A computation $\lambda \in Q^\omega$ starting in state q is referred to as a *q-computation*; if $u \in \mathbb{N}$, then we denote by $\lambda[u]$ the u'th state in λ; similarly, we denote by $\lambda[0, u]$ and $\lambda[u, \infty]$ the finite prefix $q_0, \ldots, q_u$ and the infinite suffix $q_u, q_{u+1}, \ldots$ of λ respectively.

Intuitively, a *strategy* is an abstract model of an agent's decision-making process; a strategy may be thought of as a kind of plan for an agent. Formally, a strategy f_a for an agent $a \in \Sigma$ is a total

function $f_a : Q^+ \rightarrow 2^Q$, which must satisfy the constraint that $f_a(\lambda \cdot q) \in \delta(q, a)$ for all $\lambda \in Q^*$ and $q \in Q$. Given a set $C \subseteq \Sigma$ of agents, and an indexed set of strategies $F_C = \{f_a \mid a \in C\}$, one for each agent $a \in C$, we define $out(q, F_C)$ to be the set of possible outcomes that may occur if every agent $a \in C$ follows the corresponding strategy f_a, starting when the system is in state $q \in Q$. That is, the set $out(q, F_C)$ will contain all possible q-computations that the agents C can "enforce" by cooperating and following the strategies in F_C. Note that the "grand coalition" of all agents in the system can cooperate to uniquely determine the future state of the system, and so $out(q, F_\Sigma)$ is a singleton. Similarly, the set $out(q, F_\emptyset)$ is the set of all possible q-computations of the system.

We can now give the rules defining the satisfaction relation "$\models$" for ATL, which holds between pairs of the form S, q (where S is an ATS and q is a state in S), and formulae of ATL:

$S, q \models \top$;

$S, q \models p$ iff $p \in \pi(q)$ (where $p \in \Pi$);

$S, q \models \neg\varphi$ iff $S, q \not\models \varphi$;

$S, q \models \varphi \vee \psi$ iff $S, q \models \varphi$ or $S, q \models \psi$;

$S, q \models \langle\langle C \rangle\rangle \bigcirc \varphi$ iff there exists a set of strategies F_C, such that for all $\lambda \in out(q, F_C)$, we have $S, \lambda[1] \models \varphi$;

$S, q \models \langle\langle C \rangle\rangle \Box \varphi$ iff there exists a set of strategies F_C, such that for all $\lambda \in out(q, F_C)$, we have $S, \lambda[u] \models \varphi$ for all $u \in \mathbb{N}$;

$S, q \models \langle\langle C \rangle\rangle \varphi \mathcal{U} \psi$ iff there exists a set of strategies F_C, such that for all $\lambda \in out(q, F_C)$, there exists some $u \in \mathbb{N}$ such that $S, \lambda[u] \models \psi$, and for all $0 \leq v < u$, we have $S, \lambda[v] \models \varphi$.

Satisfaction for the ATL formula $\langle\langle C \rangle\rangle \Diamond \varphi$ is defined via equivalence to $\langle\langle C \rangle\rangle \top \mathcal{U} \varphi$.

We identify two important fragments of ATL which we will subsequently refer to:

- *Propositional logic* is the fragment of ATL in which no cooperation modalities are permitted. The truth of a propositional logic formula is determined on an ATS by using the first four items of the definition for satisfaction above.
- *Coalition Logic* is the fragment of ATL in which the only cooperation modalities allowed are of the form $\langle\langle C \rangle\rangle \bigcirc$ [19, 20, 9]. The truth of a Colition Logic formula is determined on an ATS by using the first five items of the definition for satisfaction above.

The (explicit state) *model checking* problem[1] is the problem of determining, for a given formula φ and ATS $S = \langle \Pi, \Sigma, Q, Q_0, \pi, \delta \rangle$, whether $S, q \models \varphi$ for all $q \in Q_0$. The model checking problems for ATL (and hence Coalition Logic) can be solved by a deterministic algorithm in time polynomial in the size of the inputs ATS S and the formula φ [2, pp.690–691] – assuming that ATS S in question is explicitly enumerated in the input in all its components, and the number of agents is considered fixed [13].

For the *satisfiability* problem, we are simply given a formula φ and asked whether there is an ATS S and state q in S such that $S, q \models \varphi$. The satisfiability problem for ATL is EXPTIME-complete [7, 25], while for Coalition Logic it is PSPACE-complete in the general case [19, p.63].

3. SRML

We have already observed that the positive tractability results for ATL and Coalition Logic model checking rely on the assumption that the model against which a formula is to be checked is explicitly enumerated in the input to the model checking algorithm, and that this assumption is both infeasible (there will be exponentially many states in the number of Boolean variables), and never used in practice. Instead, practical model checkers such as SMV [17], SPIN [12], and MOCHA [3] use model specification languages which permit the *succinct, high-level* specification of models. In this section, we describe the language used in this paper for this purpose: the Simple Reactive Modules Language (SRML). As its name suggests, this language is a strict subset of the RML language used in the MOCHA model checker[2]. Note that our choice of language is not arbitrary: we comment on it below. We begin with an informal overview.

3.1 Overview

Agents in RML are known as *modules*, and for consistency with the pre-existing literature on RML, we will stay with this terminology in SRML. An SRML module consists of:

- an *interface*, which defines the name of the module and lists the Boolean variables under the *control* of the module; and
- a number of *guarded commands*, which define the choices available to the module at every state.

The states of an SRML-defined model correspond to the possible valuations that may be given to the Boolean variables under the control of modules in the system: for the purposes of SRML, two states that agree on the valuation of all variables are the same[3].

The guarded commands of a module are divided into two sets: those used for *initialising* the variables under the module's control (`init` guarded commands), and those used for *updating* these variables subsequently (`update` guarded commands). A guarded command has two parts: a "condition" part (the "guard"), and a corresponding "action" part, which defines how to update the value of (some of) the variables under the control of a module. The intuitive reading of a guarded command $\varphi \rightsquigarrow e$ is "if the condition φ is satisfied, then *one* of the choices available to the module is to execute the assignment expression e". The assignment expression e is essentially a sequence of assignment statements, just as in conventional imperative programming languages: these assignment statements define how (some subset of) the module's controlled variables should be updated if the guarded command is executed. Notice that the truth of the guard φ does not mean that e *will* be executed: only that it is *enabled* for execution – it *may* be executed. If no guarded commands of a given module are enabled in some state, then the values of the variables in that module are assumed to remain unchanged in the next state: the module has no choice.

[1] Model checking is sometimes formulated as the problem of finding the set of states in a structure that satisfy a given formula; our formulation is chosen to be consistent with the way in which actual model checkers work, and it should be stressed that from the asymptotic analysis point of view, there is no difference in complexity between the formulations.

[2] For those familiar with RML and MOCHA, SRML assumes finite, propositional modules, with each module containing a single atom, in which no variable is awaited by any module.

[3] This is of course not the case in general in modal/temporal logic.

The choices available to a module wrt initialisation of its variables are thus defined by the `init` guarded commands of the module, while the choices available to a module wrt updating its variables are defined by the `update` guarded commands. To make this more concrete, here is an example guarded command:

$$\underbrace{(x \wedge y)}_{\text{guard}} \rightsquigarrow \underbrace{x' := \bot; y' := \top}_{\text{action}}$$

The guard is the propositional logic formula $x \wedge y$, so this guarded command will be enabled in any system state where both x and y take the value "$\top$". If the guarded command is chosen, then the effect is that in the next state of the system, the variable x will take value $\bot$, while y will take value $\top$. (The "prime" notation v' means "the value of variable v *after* the statement is executed".) We will write `skip` as an abbreviation for the empty assignment expression, which leaves the value of every variable controlled by a module unchanged.

Here is an example of a module, illustrating the concrete syntax that we will use for modules (which is essentially that of RML [1]).

```
module toggle controls x
  init
  [] ⊤ ⇝ x' := ⊤
  [] ⊤ ⇝ x' := ⊥
  update
  [] x ⇝ x' := ⊥
  [] (¬x) ⇝ x' := ⊤
```

This module, named *toggle*, controls a single Boolean variable, x. There are two `init` guarded commands and two `update` guarded commands. (The symbol "`[]`" is a syntactic separator.) The `init` guarded commands of *toggle* define two choices for the initialisation of this variable: assign it the value $\top$ or the value $\bot$. With respect to `update` guarded commands, the first command says that if x has the value $\top$, then the corresponding choice is to assign it the value $\bot$, while the second command says that if x has the value $\bot$, then it can subsequently be assigned the value $\top$. In other words, the module non-deterministically chooses a value for x initially, and then on subsequent rounds toggles this value. Notice that in this example, the `init` commands of this module are non-deterministic, while the `update` commands are deterministic.

3.2 Formal Definition

In this section, we will use Π to denote the set of Boolean variables in a system, as in ATL. Formally, a guarded command γ over Π is an expression

$$\gamma : \qquad \varphi \rightsquigarrow v_1' := \psi_1; \ldots; v_k' := \psi_k$$

where φ (the guard) is a propositional logic formula over Π, each v_i is a member of Π and ψ_i is a propositional logic formula over Π. We require that no variable v_i appears on the l.h.s. of two assignment statements in the same guarded command (hence no issue on the ordering of the updates arises). The intended interpretation is that if the formula φ evaluates to true against the interpretation corresponding to the current state of the system, then the statement is *enabled* for execution; executing the statement means evaluating each ψ_i against the current state of the system, and setting the corresponding variable v_i to the truth value obtained from evaluating ψ_i. We say that $v_1, \ldots, v_k$ are the *controlled variables* of γ, and denote this set by $ctr(\gamma)$. A set of guarded commands is said to be *disjoint* if their controlled variables are mutually disjoint.

Given a propositional valuation $\theta \subseteq \Pi$ and a guarded command $\gamma : \varphi \rightsquigarrow v_1' := \psi_1; \ldots; v_k' := \psi_k$ such that θ enables γ (i.e., $\theta \models \varphi$) we denote the result of *executing* γ on θ by $\theta \oplus \gamma$. For example, if $\theta = \{p, r\}$, and $\gamma = p \rightsquigarrow q' := \top; r' := p \wedge \neg r$, then $\theta \oplus \gamma = \{p, q\}$.

Given a propositional valuation $\theta \subseteq \Pi$, and set Γ of disjoint guarded commands over Π such that every member of Γ is enabled by θ, then the interpretation θ' resulting from Γ on θ is denoted by $\theta' = \theta \oplus \Gamma$: since the members of Γ are disjoint, we can pick them in any order to execute on θ.

As described above, there are two classes of guarded commands that may be declared in an atom: `init` and `update`. An `init` guarded command is only used to initialise the values of variables, when the system begins execution. Full RML allows for quite sophisticated initialisation schemes, but in SRML, we will assume that the guards to `init` command are "$\top$", i.e., every `init` command is enabled for execution in the initialisation round of the system.

An SRML *module*, m, is a triple:

$$m = \langle ctr, init, update \rangle \text{ where:}$$

- $ctr \subseteq \Pi$ is the (finite) set of variables controlled by m;
- $init$ is a (finite) set of *initialisation* guarded commands, such that for all $\gamma \in init$, we have $ctr(\gamma) \subseteq ctr$; and
- $update$ is a (finite) set of *update* guarded commands, such that for all $\gamma \in init$, we have $ctr(\gamma) \subseteq ctr$.

Given a module m, we denote the controlled variables of m by $ctr(m)$, the initialisation guarded commands of m by $init(m)$, and the update guarded commands of m by $update(m)$. An SRML system is then an $(n+2)$-tuple

$$\langle \Sigma, \Pi, m_1, \ldots, m_n \rangle$$

where $\Sigma = \{1, \ldots, n\}$ is a set of agents and Π is a vocabulary of Boolean variables, (as in ATSs), and for each $i \in \Sigma$, m_i is the corresponding module defining i's choices; we require that $\{ctr(m_1), \ldots, ctr(m_n)\}$ forms a partition of Π (i.e., every variable in Π is controlled by some agent, and no variable is controlled by more than one agent).

A *joint* guarded command (j.g.c.) for a coalition $C \subseteq \Sigma$ is an indexed tuple $\langle \gamma_1, \ldots, \gamma_k \rangle$, with a guarded command $\gamma_i \in m_i$ for each $i \in C$. A j.g.c. $\langle \gamma_1, \ldots, \gamma_k \rangle$ is enabled by a propositional valuation $\theta \subseteq \Pi$ iff all its members are enabled by θ.

Given an SRML system R, the corresponding ATS, which we denote by S_R, is defined in the obvious way:

- the states Q of S_R correspond to the possible valuations to variables Π, with Q_0 being the subset of Q that may be generated by the $init$ guarded commands of the modules in R; and
- the δ function of S_R is defined in each state for each possible coalition by the sets of enabled guarded commands (choices) for that coalition.

We write $R \models \varphi$ to indicate that $S_R, q_0 \models \varphi$ for every initial state q_0 in S_R: the SRML model checking problem is then the problem of checking, for given R and φ, whether or not $R \models \varphi$.

4. MAIN RESULTS

We now present our main results. Given the concerns of this paper – understanding the complexity of ATL model checking for a particular model representation – the first of these results may seem somewhat strange, but its role will become clear shortly. We show that, given an SRML system R, we can construct a formula

$mimic(R)$ of ATL such that $mimic(R)$ is *only* satisfied in models that are "equivalent" to S_R. We can thus understand $mimic(R)$ as representing the ATL *theory* of R. An important property of the construction of $mimic(R)$ is that this formula is of size polynomial in the size of R. For such a $mimic(R)$, we must characterize the behaviour of R in the sense that:

(a) abilities in R are transferred to models satisfying $mimic(R)$;

(b) agents should not be able to achieve more in any $mimic(R)$-model than the modules can do in R.

The construction of $mimic(R)$ is as follows. Let the variables $ctr(i)$ under control of module i be $v^i_1, \ldots, v^i_j$, and let the module i be $\langle ctr(i), init, update\rangle$. We are now going to define requirements $t(\mathtt{init}, i)$, (2), (3) and (4); they are supposed to take care of our condition (a). Regarding $init$, we do the following. Suppose there are c_i *init* guarded commands for agent i, and let a typical $init$ guarded command ι^i_a ($a \leq c_i$) for agent i be composed of a positive part $\iota^{+_i}_{a_u}$ and a negative part $\iota^{-_i}_{a_v}$ ($u \leq nu, v \leq nv$) as follows:

$$\iota^{+_i}_{a_u} \quad \top \rightsquigarrow v^{+_i}_{a_1} := \top, \ldots, \top \rightsquigarrow v^{+^i}_{a_{nu}} := \top,$$

$$\iota^{-_i}_{a_v} \quad \top \rightsquigarrow v^{-_i}_{a_1} := \bot, \ldots, \top \rightsquigarrow v^{-_i}_{a_{nv}} := \bot$$

Where no $v^{+_i}_{a_j}$ can be the same as any $v^{+_i}_{a_k}$, for any $j \leq nu$ and $k \leq nv$ (this is guaranteed by the fact that $\iota^{+_i}_a$ and $\iota^{-_i}_a$ represent one guarded command). Then denote

$$t(\mathtt{init}, i) = \bigvee_{a \leq c_i} \Big(\bigwedge_{j \leq nu} v^{+_i}_{a_j} \wedge \bigwedge_{k \leq nv} \neg v^{-_i}_{a_k} \Big) \tag{1}$$

This formula $t(\mathtt{init}, i)$ expresses the effect of executing one of the c_i guarded commands ι_a for agent i. Note that we do not have an *exclusive* disjunction here, since it might well be that the *effect* of executing one initialisation command ι_a may coincide with that of another. Given an SRML-system R, it is obvious that in its associated ATS S_R, a state q verifies $t(\mathtt{init}, i)$ iff q is one of the initial states in Q_0.

Now we turn to the *update* part of the module. Suppose it looks like the following (note that all v'^i_j are occurrences of i's variables, not the variables themselves).

$$\begin{array}{lllll}
\gamma^i_1: & \varphi_1 \rightsquigarrow & {v^i_{1_1}}' := \psi_{1_1} & \ldots & {v^i_{1_{n1}}}' := \psi_{1_{n1}} \\
\gamma^i_2: & \varphi_2 \rightsquigarrow & {v^i_{2_1}}' := \psi_{2_1} & \ldots & {v^i_{2_{n2}}}' := \psi_{2_{n2}} \\
\ldots & \ldots & \ldots & \ldots & \ldots \\
\gamma^i_m: & \varphi_m \rightsquigarrow & {v^i_{m_1}}' := \psi_{m_1} & \ldots & {v^i_{m_{nm}}}' := \psi_{m_{nm}}
\end{array}$$

Given an SMRL R, introduce for every ψ_{k_t} ($k \leq m, t \leq nk$) a new propositional variable x_{k_t}. The idea is that every x will store the old value of its corresponding ψ, so we stipulate:

$$\bigwedge_{k \leq m, t \leq nk} \langle\langle\rangle\rangle \Box (\psi_{k_t} \leftrightarrow \langle\langle\rangle\rangle \bigcirc x_{k_t}) \tag{2}$$

Some of i's variables will not be changed by executing a command, so we also need to keep track of the variables old values. For that, we introduce, for every $v^i_e \in ctr(i)$, variables y^i_e ($e \leq j$), and stipulate

$$\bigwedge_{e \leq j} \langle\langle\rangle\rangle \Box (v^i_e \leftrightarrow \langle\langle\rangle\rangle \bigcirc y^i_e) \tag{3}$$

We now look at our constraint (b), which should take care of the fact that the if σ is ATL-satisfiable, it should be in a context that is behaving well enough in order to be transferred to an SMRL R. To guarantee that an agent i cannot spontaneously bring about anything that is not triggered by the execution of a command γ^i_z, we introduce propositional variables $done(i,1), \ldots, done(i,m)$ and a special atom $none(i)$. The latter atom denotes that i did not execute any of its guarded commands. Now consider a command γ^i_z. As before, let $ctr(\gamma^i_z)$ be i's variables occurring in the command γ^i_z. Now represent γ^i_z by

$$\varphi_z \rightarrow \langle\langle i\rangle\rangle \bigcirc (new(i) \wedge rec(i,z)) \tag{4}$$

where

$$new(i) = \bigwedge_{v \in ctr(\gamma^i_z)} (v \leftrightarrow x) \wedge \bigwedge_{u \in ctr(i) \setminus ctr} (u \leftrightarrow y)$$

and

$$rec(i,z) = done(i,z) \wedge \bigwedge_{s \leq m, s \neq z} \neg done(i,s) \wedge \neg none(i)$$

$new(i)$ says that the values of the relevant ψ_{k_t} are, via x_{k_t}, copied in the corresponding variable $v^i_{k_t}$, and the other variables u of i receive their 'old' values through a copy of the corresponding variables y. This takes care of our goal specified as (a). For the (b)-part, $rec(i,z)$ takes a record of which guarded command has been applied. This ensures that agent i indeed 'only' executes guarded commands, if we add the global properties (5)–(8):

$$\langle\langle\rangle\rangle \Box ((\bigwedge_{k \leq m} \neg \varphi_k) \leftrightarrow \langle\langle\rangle\rangle \bigcirc none(i)) \tag{5}$$

$$\langle\langle\rangle\rangle \Box \bigwedge_{k \leq m} (\langle\langle\rangle\rangle \bigcirc done(i,k) \rightarrow \varphi_k) \tag{6}$$

$$\langle\langle\rangle\rangle \Box \bigwedge_{k \leq m} (done(i,k) \rightarrow (new(i) \wedge \neg none(i))) \tag{7}$$

$$\begin{array}{ll} \langle\langle\rangle\rangle \Box (& (\neg none(i) \rightarrow \bigtriangledown_{k \leq m} done(i,k)) \\ & \wedge (none(i) \rightarrow \bigwedge_{v \in ctr(i)} v \leftrightarrow y) \ ) \end{array} \tag{8}$$

Equation (5) expresses that agent i will only do nothing if all his guards are false; (6) says that i can only execute the k-th command if the k-th guard is true; (7) expresses that if a flag is set indicating that i executes the k-th command, then, indeed, this command is executed, and the $none(i)$-flag is not set to true, and, finally, (8) expresses that either i does nothing, or he executes exactly one of his guarded commands and that doing nothing implies keeping all the "old" values for i's variables.

We are now in a position to define $mimic(R)$:

$$\bigwedge_{i \leq n} (t(\mathtt{init}, i) \wedge (2) \wedge (3) \wedge (4) \wedge (5) \wedge (6) \wedge (7) \wedge (8))$$

Note that the size of $mimic(R)$ is polynomial in R, since we only add a given number of new variables, where the number depends on the number of local variables and the number of formulas ψ appearing at the right of a ":=" in any command, and each of the conjuncts in $mimic(R)$ is polynomial in R.

Now, suppose we have some S, q such that $S, q \models mimic(R)$. The states of S will not look exactly like the states of S_R, since

they will include propositional variables that will not be in S_R (i.e., the new variables we introduced in the translation). But nevertheless, the properties of agents – their abilities, with respect to the propositional variables of R – must be the same in the ATS S that satisfies $mimic(R)$ as in R. In short: *the model S must preserve the truth of* ATL *formulae over R.*

Returning to the main concerns of the paper, we now see the relevance of this construction.

THEOREM 1. *The* ATL *model checking problem for* SRML *is polynomial-time reducible to* ATL *unsatisfiability.*

PROOF. Let R be the given SRML system, and φ be the formula we want to check. Then the following are equivalent:

1. $R \models \varphi$
2. $mimic(R) \rightarrow \varphi$ is valid in ATL.

□

The rationale for stating this result will become clear in the following:

THEOREM 2. *The* ATL *model checking problem for* SRML *models is* EXPTIME*-complete.*

PROOF. Membership of EXPTIME follows from the fact, proved in Theorem 1, that the ATL model checking problem for SRML is polynomial time reducible to ATL unsatisfiability. Since the ATL satisfiability problem is EXPTIME complete [7, 25], then ATL unsatisfiability is in co-EXPTIME; but since EXPTIME is a deterministic complexity class, EXPTIME = co-EXPTIME, and we conclude that the SRML model checking for SRML is in EXPTIME.

We prove EXPTIME-hardness by reduction from the problem of determining whether a given player has a winning strategy in the two-player game PEEK-G_4 [24, p.158]. An instance of PEEK-G_4 is a quad:

$$\langle X_1, X_2, X_3, \varphi \rangle \text{ where:}$$

- X_1 and X_2 are disjoint, finite sets of Boolean variables, with the intended interpretation that the variables in X_1 are under the control of agent 1, and X_2 are under the control of agent 2;
- $X_3 \subseteq (X_1 \cup X_2)$ are the variables deemed to be true in the initial state of the game; and
- φ is a propositional logic formula over the variables $X_1 \cup X_2$, representing the winning condition.

The game is played in a series of rounds, with the agents $i \in \{1, 2\}$ alternating (with agent 1 moving first) to select a value (true or false) for one of their variables in X_i, with the game starting from the initial assignment of truth values defined by X_3. Variables that were not changed retain the same truth value in the subsequent round. An agent wins in a given round if it makes a move such that the resulting truth assignment defined by that round makes the winning formula φ true. The decision problem associated with PEEK-G_4 involves determining whether agent 2 has a winning strategy in a given game instance $\langle X_1, X_2, X_3, \varphi \rangle$. Notice that PEEK-$G_4$ only requires "memoryless" (Markovian) strategies: whether or not an agent i can win depends only on the current truth assignment, the distribution of variables, the winning formula, and whose turn it is currently. As a corollary, if agent i can force a win, then it can force a win in $O(2^{|X_1 \cup X_2|})$ moves.

Given an instance $\langle X_1, X_2, X_3, \varphi \rangle$ of PEEK-G_4, we produce an instance of SRML model checking as follows. For each Boolean variable $x \in (X_1 \cup X_2)$, we create a variable with the same name in our SRML model, and we create an additional Boolean variable $turn$, with the intended interpretation that if $turn = \top$, then it is agent 1's turn to move, while if $turn = \bot$, then it is agent 2's turn to move. We have a module $move$, the purpose of which is to control $turn$, toggling its value in each successive round, starting from the initial case of it being agent 1's move.

```
module move controls turn
  init
  [] ⊤ ⇝ turn' := ⊤
  update
  [] turn ⇝ turn' := ⊥
  [] (¬turn) ⇝ turn' := ⊤
```

For each of the two PEEK-G_4 players $i \in \{1, 2\}$, we create an SRML module ag_i that `controls` the variables X_i. The module ag_i is as follows. It begins by deterministically initialising the values of all its variables to the values defined by X_3 (that is, if variable $x \in X_i$ appears in X_3 then this variable is initialised to $\top$, otherwise it is initialised to $\bot$). Subsequently, when it is this player's turn, it can non-deterministically choose at most one of the variables under its control and toggle the value of this variable; when it is not this player's turn, it has no choice but to do nothing, leaving the value of all its variables unchanged. The general structure of ag_1 is thus as follows, where $X_1 = \{x_1, \ldots, x_k\}$.

```
module ag1 controls x1, ..., xk
  init
  // initialise to values from X3
  [] ⊤ ⇝ x1' := ...; xk := ...
  update
  [] turn ⇝ x1' := ⊥
  [] turn ⇝ x1' := ⊤
  ...
  [] turn ⇝ xk' := ⊥
  [] turn ⇝ xk' := ⊤
  [] ⊤ ⇝ skip
```

Notice that an agent can always `skip`, electing to leave its variables unchanged; and, if it is not this agent's turn to move, this is the *only* choice it has.

The SRML system under consideration contains just these three modules. It can be shown easily that player 2 has a strategy for φ in the PEEK-G_4 game $\langle X_1, X_2, X_3, \varphi \rangle$ iff the SRML system satisfies the formula $\langle\langle 2 \rangle\rangle (\neg\varphi) \mathcal{U} (\varphi \wedge turn)$. □

There are several small points of interest about this proof. First, notice that the reduction used for EXPTIME-hardness requires *only a fixed number of agents* (three). Thus we have the following, stronger result: ATL model checking for SRML models is EXPTIME complete for any fixed number n of modules, where $n \geq 3$. Second, notice the form of the guarded commands used in the reduction: on the rhs of any guard, we only change the value of at most one variable. Thus, again, we have a stronger result: EXPTIME hardness even when guarded commands are assumed to be of this particularly impoverished form.

Next, we turn our attention to significant subsets of ATL: first, Coalition Logic, the fragment in which the only temporal modality allowed is "$\bigcirc$" [19, 21, 9].

THEOREM 3. *The Coalition Logic model checking problem for* SRML *models is* PSPACE*-complete.*

PROOF. We first prove PSPACE-hardness, by reducing the problem of determining the truth of Quantified Boolean Formulae (QBF) [18, pp.456–458] to that of Coalition Logic model checking against SRML models.

An instance of QBF is given by a formula

$$\exists x_1 \forall x_2 \cdots Q_k \varphi(x_1, x_2, \ldots, x_k)$$

where $x_1, \ldots, x_k$ are Boolean variables, the quantifier Q_k is $\exists$ if k is odd, and $\forall$ if k is even, and $\varphi(x_1, \ldots, x_k)$ is a propositional logic formula over the variables $x_1, x_2, \ldots, x_k$. Such a formula is true if there exists a valuation for x_1 such that for all valuations for x_2, ..., such that the formula $\varphi(x_1, x_2, \ldots, x_k)$ is true. We proceed to create an SRML system containing three modules, $move$, $ag_\exists$, $ag_\forall$, the variables $x_1, x_2, \ldots, x_k$, and, in addition, k variables $m_1, m_2, \ldots, m_k$, such that m_i will be true if we are about to assign a value for variable x_i.

The module $turn$ simply passes the value $\top$ along each of the variables $m_1, m_2, \ldots, m_k$ in turn.

```
module turn controls m_1, ..., m_k
  init
  [] ⊤ ⇝ m_1' := ⊤, m_2' := ⊥; ...; m_k := ⊥
  update
  [] m_1 ⇝ m_1' := ⊥; m_2' := ⊤
  ...
  [] m_i ⇝ m_i' := ⊥; m_{i+1}' := ⊤
  ...
  [] m_{k-1} ⇝ m_{k-1}' := ⊥; m_k' := ⊤
```

Notice that at most one of the variables $m_1, m_2, \ldots, m_k$ will be true at any given time.

We define the modules $ag_\exists$ as follows. This module `controls` all odd numbered variables. On even rounds, the module simply `skip`s, leaving the values of its variables unchanged. On odd numbered rounds i, $1 \leq i \leq k$, the module will have two choices: make variable x_i true or make x_i false.

```
module ag_∃ controls ...// odd numbered variables
  init
  [] ⊤ ⇝ skip
update
  [] m_1 ⇝ x_1' := ⊥
  [] m_1 ⇝ x_1' := ⊤
  [] m_2 ⇝ skip
  [] m_3 ⇝ x_3' := ⊥
  [] m_3 ⇝ x_3' := ⊤
  [] m_4 ⇝ skip
  ...
```

We define $ag_\forall$ similarly, swapping "even" for "odd". Noting that (i) the module $turn$ plays no part in determining the value of variables other than the move variables $m_1, \ldots, m_k$; (ii) when it is player i's turn in round j, then the only choices i has are to assign truth or falsity to variable x_j; (iii) when it is not player is turn in round j, then j must leave all its variables unchanged; (iv) that the construction is clearly polynomial in the size of the input formula.

The QBF instance $\exists x_1 \forall x_2 \cdots Q_k \varphi(x_1, x_2, \ldots, x_k)$ is true iff the the SRML system above satisfies the formula

$$\langle\langle ag_\exists \rangle\rangle \bigcirc \neg \langle\langle ag_\forall \rangle\rangle \bigcirc \neg \cdots \varphi(x_1, x_2, \ldots, x_k).$$

To see that the model checking problem is decidable in PSPACE, we present an algorithm for deciding the problem that works in polynomial space: see Figure 1. The algorithm takes as input an

```
1.  function eval(φ, R) returns ⊤ or ⊥
2.    θ := ∅
3.    for each θ-enabled initial j.g.c. ⟨γ_1, ..., γ_n⟩ for Σ do
4.      if not aux(φ, θ ⊕ {γ_1, ..., γ_n}, R) then
5.        return ⊥
6.      end-if
7.    end-for
8.    return ⊤
9.  end-function eval

10. function aux(φ, θ, R) returns ⊤ or ⊥
11.   if φ ∈ Π then
12.     if φ ∈ θ then return ⊤ else return ⊥ end-if
13.   elsif φ = ¬ψ then
14.     return not aux(ψ, θ, R)
15.   elsif φ = ψ_1 ∨ ψ_2 then
16.     return aux(ψ_1, θ, R)
17.       or aux(ψ_2, θ, R)
18.   elsif φ = ⟨⟨C⟩⟩◯ψ then
19.     for each θ-enabled update j.g.c. ⟨γ_1, ..., γ_l⟩ for C do
20.       flag := ⊤
21.       for each θ-enabled update j.g.c. ⟨γ_{l+1}, ..., γ_n⟩ for Σ \ C do
22.         if not aux(ψ, θ ⊕ {γ_1, ..., γ_l, γ_{l+1}, ..., γ_n}, R) then
23.           flag := ⊥
24.         end-if
25.       end-for
26.       if flag then return ⊤ end-if
27.     end-for
28.     return ⊥
29.   end-if
30. end-function aux
```

Figure 1: A polynomial space algorithm for checking Coalition Logic formulae against SRML models.

SRML system R, and a formula φ of coalition logic to check against this system. The algorithm is in two parts: the first part (the function $eval(\cdots)$) generates each initial state of the system in turn from the initial guarded commands of the modules comprising R, and then invokes the auxiliary function $aux(\cdots)$ to check whether the input φ is true in these initial states. The $aux(\cdots)$ function is recursive; we note that the number of recursive calls will be bounded by the size of the input formula φ, with each call requiring only polynomial space. Termination and correctness are immediate from construction; it only remains to note that we can loop through the enabled initial guarded commands (lines 3–7) and the enabled update guarded commands (lines 19–23) in polynomial space. □

So, under standard complexity theoretic assumptions, model checking Coalition Logic against SRML models is "easier" than full ATL. Suppose we consider other restrictions on the logic that we check.

THEOREM 4. *The propositional logic model checking problem for* SRML *is co-*NP*-complete.*

PROOF. For membership, simply note that we can universally select all initial j.g.c.s $\langle \gamma_1, \ldots, \gamma_m \rangle$, and check that if $\langle \gamma_1, \ldots, \gamma_m \rangle$ is satisfied by the empty truth assignment $\theta_\emptyset$, then the interpretation $\theta_\emptyset \oplus \{\gamma_1, \ldots, \gamma_m\}$ satisfies φ. For completeness, we can reduce the problem TAUT, of checking that a propositional logic formula is a tautology, i.e., satisfied under all truth assignments. For each Boolean variable x appearing in the input instance φ, we create an agent controlling x, with two initial guarded commands, both enabled by the empty assignment $\theta_\emptyset$, which set x to $\top$ and $\bot$ respectively. The formula to be checked against this system is simply the TAUT instance φ. The initial states of the system thus constructed

correspond to all valuations of the variables of φ, and hence φ is a tautology iff φ holds in all initial states of the system. □

5. DISCUSSION

In this paper, we have shown that, for three important subsets of ATL (including ATL itself), the model checking problem has exactly the same complexity as the corresponding theorem proving problem, assuming that models are represented using SRML, a simplified version of RML [1]. This seems to us to be a striking result: *practical* model checking for ATL and Coalition Logic has the same complexity as theorem proving for these logics. We note that others have pointed out that ATL model checking is more complex than it might appear [13], and other results hint that practical ATL model checking might be more complex than it appears at first sight [5, 6]: we have obtained tight bounds on the complexity of these problems for a specific, practical representation for models.

It is important to note that the SRML language is *not* contrived: it is a strict subset of the RML language that is used by several practical model checking systems, including MOCHA, the ATL model checker [3]. Indeed, SRML is arguably the smallest "useful" subset of RML that one can imagine: it is hard to imagine how one could simplify it without making it unusable in practice. It is also worth noting that the guarded command structures used to define SRML models are also used (modulo syntactic differences) for the same purpose in other model checking systems such as SPIN [12] and SMV [17].

We note that one of the motivations for developing the Coalition Logic of Propositional Control (CL-PC), a simpler modal variation of ATL [11], was that the structure of controlled variables in languages like RML permitted a more direct (and simpler) semantics to cooperation modalities. This link – between the interpretation of cooperation modalities and the languages used to define models – is worth exploring further.

ABSTRACT

Reasoning about capabilities, strategies and knowledge is important in the analysis of multiagent systems. Alternating-time Temporal Epistemic Logic (ATEL) was designed with this aim. Nevertheless, the original interpretation of the language suffered from some counterintuitive properties. These are due to the fact that the strategies the agent applies in worlds that he cannot distinguish may not be uniform, in the sense that the same action is applied in all indistinguishable worlds. Several refinements of the original ATEL semantics were proposed since then. In this paper we argue that the STIT framework can easily account for uniform strategies. STIT is a logic of agency that has been proposed in the 90ies in the domain of philosophy of action. It is the logic of constructions of the form "agent a sees to it that φ". To support our claim, we first present a straightforward solution in STIT logic augmented by a modal operator of knowledge. Then we offer a simplification, by introducing a modal logic of knowledge-based uniform agency, for *one-step* strategies, alias choices.

1. INTRODUCTION

In the last years there has been increasing interest in logics enabling reasoning about strategies of agents and coalitions of agents, and the agents' knowledge about such strategies. Such logics combine two kinds of modal logics:

- logics of knowledge such as S5, and multiagent versions thereof; such logics have modal operators K_a, where $K_a\varphi$ is read "agent a knows that φ";
- logics of agency, including in particular Coalition Logic (CL) and Alternating-time Temporal Logic (ATL); such logics have constructions such as CL's $[A]\varphi$ or ATL's $\langle\langle A\rangle\rangle\mathbf{X}\varphi$, both (roughly) reading "group of agents A has an action to ensure that φ holds (whatever the other agents choose to do)".

While each of these logics is by now well-established, the interaction between knowledge and agency is less consensual. A straightforward combination of for example ATL and epistemic logic (called ATEL) was proposed in [14]. In ATEL one can express things such as "agent a has an action to ensure that φ, but ignores that". It turned out that ATEL has some counterintuitive properties. The problem can be highlighted by the following example.

EXAMPLE 1. *There is a switch, a lamp, and a blind agent a_1, which ignores whether the light is on or off. a_1 can toggle the switch (and he knows that), and a_1 can remain passive.*

Clearly, $\langle\langle\{a_1\}\rangle\rangle\mathbf{X}\texttt{light}$ holds here, i.e., a_1 can ensure that the light is on (viz. by toggling the switch if the light is off, and by doing nothing if the light is already on). We should also be able to conclude that a_1 does not *know* which action to perform in order to do this.

ATEL makes us conclude here that $K_{a_1}\langle\langle\{a_1\}\rangle\rangle\mathbf{X}\texttt{light}$, i.e. the blind agent a_1 knows that he has an action to ensure the light is on. The problem is that this action corresponds to w a strategy that is what has been called *non-uniform*: it makes a_1 choose different actions in possible worlds that are indistinguishable for him.

Multiagent variants of our example can be devised.

EXAMPLE 2. *There are two blind agents and two toggle switches such that the light is on exactly when both switches are in the same position. a_1 can toggle the first switch and a_2 the second one.*

Contrary to intuitions, ATEL makes us conclude that there is both distributed and common knowledge that there is a joint strategy to switch the light on. Another version that we will study involves one blind agent and one lame agent.

EXAMPLE 3. *There is a switch, a lamp, a blind agent a_1 and a lame agent a_2 (who knows whether the light is on, but cannot toggle). Initially the light is off. This is known by a_2, and ignored by a_1.*

This example is less problematic since there is distributed knowledge about a joint strategy, however ATEL also claims that there is common knowledge.

Several authors have proposed modified versions of ATEL, trying to accommodate in one way or another the notion of uniform strategy [8, 9, 15]. It seems to be fair to say that all these tentatives resulted in rather complex formalisms with heavy notations, and that there is no consensus up to now what the appropriate logic of knowledge and strategies is.

In this paper we take as our starting point a slightly different logic of agency that has been developed in philosophical logic. Just as ATL, the logic of "Seeing To It That" (STIT) is a modal logic enabling us to speak about time and agents' choices of actions. In STIT, CL's and ATL's $\exists$-$\forall$-quantification ("*there is* a strategy of group A such that *for all* actions of the other agents") is split up into two different modal operators:

- an operator of historical possibility $\Diamond$;
- an operator of "seeing to it that" *Stit*.

In previous work [3] we have shown that STIT is at least as powerful as Coalition Logic (CL). We have proved this by giving a translation t from CL into STIT. The main clause of the translation maps CL's $[A]\varphi$ ("group A has an action to ensure that φ") into STIT's $\Diamond Stit_A \mathbf{X} t(\varphi)$ ("it is possible that group A sees to it that next $t(\varphi)$"). This translation can be extended to ATL [4].

If by coalition we mean a set of agents that are able to deliberate about their knowledge and the collective strategy to adopt then reasoning about *common knowledge* does not seem to be relevant when dealing with coalitions. Suppose a_1 cannot distinguish two worlds w_1 and w_2, and a_2 cannot distinguish w_2 and w_3, by common knowledge they together cannot distinguish w_1, w_2 and w_3. However, when standing at w_2, agents a_1 and a_2 by *communicating*, should be able to discriminate incompatible worlds: here w_1 and w_3. By definition, the intersection of a_1's and a_2's knowledge state corresponds to distributed knowledge of the coalition $\{a_1, a_2\}$.

We assume that a coalition can ensure φ if by *sharing their knowledge* and acting together they can ensure that φ. For that purpose, we introduce an operator $Kstit_A\varphi$ of *knowledge-based agency*. "Agent a knows an action to ensure that φ" can thus be expressed in our epistemic extension of STIT by: "there is an action such that the agent knows that φ holds next". In formulas: $\Diamond Kstit_a \mathbf{X}\varphi$. Thus in Example 1 we expect $\neg\Diamond Kstit_{a_1}\mathbf{X}\mathtt{light} \wedge K_{a_1}\Diamond Stit_{a_1}\mathbf{X}\mathtt{light}$ to hold. This corresponds to the classical distinction between de re sentences such as $\exists x K_a p(x)$ and de dicto sentences such as $K_a \exists x p(x)$.

We present a discrete version of STIT logic in Section 2 and augment it with an epistemic operator in Section 3. In Section 4, we show how the problem of enforcing uniform strategies can be treated straightforwardly in the resulting framework. We simplify it in Section 5 by presenting a logic of knowledge-based agency for groups of agents. Section 6 offers a formulation of "knowing how to play" and examples to illustrate the logic. We show in Section 7 how to handle static knowledge (or knowledge in the sense of Hintikka), and future work is discussed in Section 8.

2. DISCRETE STIT FRAMEWORK

The semantics of STIT is embedded in the branching time framework. It is based on structures of the form $\langle W, <\rangle$, in which W is a nonempty set of moments, and $<$ is a tree-like ordering of these moments, such that for any w_1, w_2 and w_3 in W, if $w_1 < w_3$ and $w_2 < w_3$, then either $w_1 = w_2$ or $w_1 < w_2$ or $w_2 < w_1$.

A maximal set of linearly ordered moments from W is a *history*. $w \in h$ denotes that the moment w is *on* the history h. We define $Hist$ as the set of all histories of a STIT structure. $H_w = \{h | h \in Hist, w \in h\}$ denotes the set of histories passing through w. An *index* is a pair w/h, consisting of a moment w and a history h from H_w (i.e. a history and a moment in that history). Moreover, we make the following hypothesis (that is not made in the original STIT for reasons of generality):

HYPOTHESIS 1 (DISCRETENESS). $<$ *is* discrete.

That is to say, given a moment w_1 and a history h with $w_1 \in h$, there exists a successor moment $w_2 \in h$ such that $w_1 < w_2$, and there is *no* moment w_3 such that $w_1 < w_3 < w_2$.

2.1 Models of individual agency

A *STIT-model* is a tuple $\mathcal{M}_{\mathsf{STIT}} = \langle W, Choice, <, v\rangle$, where:

- $\langle W, <\rangle$ is a branching time structure;
- $Choice : \mathcal{A}gt \times W \to 2^{2^{Hist}}$ is a function mapping each agent and each moment w into a partition of H_w;
- v is a valuation function $v : \mathcal{A}tm \to 2^{W \times Hist}$.

The equivalence classes belonging to $Choice_a^w$ can be thought of as possible choices or actions available to agent a at w.

Given a history $h \in H_w$, $Choice_a^w(h)$ represents the particular choice from $Choice_a^w$ containing h, or in other words, the particular action performed by a at the index w/h. We must have $Choice_a^w \neq \emptyset$ and $Q \neq \emptyset$ for every $Q \in Choice_a^w$.

DEFINITION 1 (CURRENT MOMENT / CURRENT CHOICE). *At index w/h we shall call w the* current moment *and $Choice_a^w(h)$ the* current choice/action.

In STIT-models, moments may have different valuations, depending on the history they are living in (cf. [7, footnote 2 p. 586]). Thus, at any specific moment, we have different valuations. This was first suggested by Prior and Thomason, and permits a natural evaluation of statements about the future.

2.2 Models of group agency

In order to deal with group agency, Horty defines in [6, section 2.4], the notion of collective choice. Horty first introduces *action selection functions* s_w from $\mathcal{A}gt$ into 2^{H_w} associating to each $w \in W$ and $a \in \mathcal{A}gt$, some $s_w(a) \in Choice_a^w$. So, a given selection function s_w selects a particular action for each agent at w.

Then, for a given w, $Select_w$ is the set of all selection functions s_w. For every $s_w \in Select_w$, it is assumed that $\bigcap_{a \in \mathcal{A}gt} s_w(a) \neq \emptyset$. This constraint corresponds to the hypothesis that the agents' choices are independent, in the sense that agents can never be deprived of some choice due to the choices made by other agents.[1] Moreover, we suppose that intersection of *all* agents' choices must exactly be the set of histories passing through an immediate next moment:

HYPOTHESIS 2 (DETERMINISM). $\forall w \in W, \exists w' \in W\,(w < w'$ *and* $\nexists w'' \in W, w < w'' < w', \bigcap_{a \in \mathcal{A}gt} s_w(a) = H_{w'})$

As explained for ATL in [5], this determinism is not a limitation of the modeling capabilities of the language, since we could introduce a neutral agent *nature*, in order to accommodate non-deterministic transitions.

Using selection functions s_w, the *Choice* function can be generalized to apply to groups of agents ($Choice : 2^{\mathcal{A}gt} \times W \rightarrow 2^{2^{Hist}}$). A collective choice for a group of agents $A \subseteq \mathcal{A}gt$ is defined as:

$$Choice_A^w = \{\bigcap_{a \in A} s_w(a) | s_w \in Select_w\}.$$

Again, $Choice_A^w(h) = \{h' |$ there is $Q \in Choice_A^w$ such that $h, h' \in Q\}$.

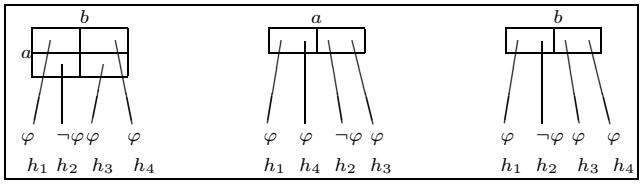

Figure 1: Group agency. $Choice_a^w = \{\{h_1, h_4\}, \{h_2, h_3\}\}$, $Choice_b^w = \{\{h_1, h_2\}, \{h_3, h_4\}\}$, $Choice_{\{a,b\}}^w = \{\{h_1\}, \{h_4\}, \{h_2\}, \{h_3\}\}$.

In Figure 1, a can choose between the upper and the lower row, and b can choose between the left and the right column. In the left model we can see that when a and b opt for a choice, the outcome is deterministic. However, actions of individual agents are not deterministic, as we can see on the two others schemes. And while both a and b can *see to it* that φ independently, they need to form a coalition in order to ensure $\neg\varphi$.

2.3 Truth conditions

[1]Note that from this constraint it follows that two agents cannot possibly have an identical set of choices at the same moment. It also follows that there are not less than $\prod_{a \in \mathcal{A}gt} |Choice_a^w|$ histories passing through a moment w. Moreover, at moments where the minimal number of histories satisfies this constraint, choices at future moments will be vacuous.

We write $\models_{\mathsf{STIT}} \varphi$ if $\mathcal{M}, w/h \models \varphi$ for every STIT-model $\mathcal{M}$, history h in $\mathcal{M}$ and moment w in h. A formula is evaluated with respect to a model and an index.

$$\begin{array}{lll} \mathcal{M}, w/h \models p & \iff & w/h \in v(p), p \in \mathcal{A}tm. \\ \mathcal{M}, w/h \models \neg\varphi & \iff & \mathcal{M}, w/h \not\models \varphi \\ \mathcal{M}, w/h \models \varphi \vee & \iff & \mathcal{M}, w/h \models \varphi \text{ or } \mathcal{M}, w/h \models \end{array}$$

Historical necessity (or inevitability) at a moment w in a history is defined as truth in all histories passing through w:

$$\mathcal{M}, w/h \models \Box\varphi \iff \mathcal{M}, w/h' \models \varphi, \forall h' \in H_w.$$

When $\Box\varphi$ holds at w then φ is said to be *settled true at* w. $\Diamond\varphi$ is defined in the usual way as $\neg\Box\neg\varphi$, and stands for historical possibility.

There are several STIT operators; we here introduce the so-called Chellas' STIT [7] which is defined as follows:

$$\mathcal{M}, w/h \models Stit_A\varphi \iff \mathcal{M}, w/h' \models \varphi, \forall h' \in Choice_A^w(h).$$

Intuitively it means that group A's current choices ensure φ, whatever other agents outside A do.[2] $Stit_A\varphi$ corresponds to $[A\,cstit\colon \varphi]$ in original notation.

As it is shown in [7], both Chellas' STIT and historical necessity are S5 modal operators, and $\models_{\mathsf{STIT}} \Box\varphi \rightarrow Stit_A\varphi$.

Since we here have discrete time, we can define the temporal operator $\mathbf{X}$ (*next*). We also introduce operator $\mathcal{U}$ (*until*):

$$\begin{array}{lll} \mathcal{M}, w/h \models \mathbf{X}\varphi & \iff & \exists w' \in h\,(w < w', \mathcal{M}, w'/h \models \varphi, \\ & & \nexists w'' \in h\,(w < w'' < w')). \\ \mathcal{M}, w/h \models \varphi\mathcal{U} & \iff & \exists w' \in h\,(w < w', \mathcal{M}, w''/h \models \quad , \\ & & \forall w''\,(w \quad w'' < w', \mathcal{M}, w''/h \models \varphi) \end{array}$$

$\mathbf{F}\varphi$ ("at some point in the future φ") is an abbreviation of $\top\mathcal{U}\varphi$, and $\mathbf{G}\varphi$ ("always in the future φ") is $\neg F\neg\varphi$.

3. ADDING EPISTEMIC FEATURES

In this section, we add imperfect knowledge to the STIT framework, assuming a particular structure of epistemic relations which will be constructed above agent choices' relations.

As a related work, we refer the reader to Pacuit et al. [11], which is as far as we know, the only to deal with epistemic notions in the STIT framework: an agent a is said to know that φ at a history h, if φ is true in every history in a's *local view*. We can enlighten differences with our notion of knowledge by the motivations, which are to investigate the relation between knowledge and obligation in Pacuit et al.'s work, while we are interested in epistemic based uniform agency.

3.1 Individual knowledge

If two moments are not distinguishable by an agent according to his knowledge, these moments are said to be *epistemically equivalent*.

Since the purpose is here to reason about actions and choices under imperfect knowledge, we should be able to identify identical choices (or choices involving actions of the same type)[3] at epistemically equivalent worlds.

[2]The more complex *deliberative* STIT can be defined as $Dstit_A\varphi =_{def} Stit_A\varphi \wedge \neg\Box\varphi$ [7].

[3]Intuitively, two actions are of the same *type* if *the way to*

Thus, in order to identify choices of the same type executable in moments epistemically equivalent, let $R_{UC_a} : W \times Hist \to 2^{W \times Hist}$ be a relation between indexes lying in equivalent choice types of epistemically equivalent moments for agent a. UC stands for "*U*niform *C*hoice". If two moment/history pairs are linked by a R_{UC_a} relation, the same type of choice is done by agent a at both indexes. We require

$$Choice_a^w(h) \quad \{h' \mid w'/h' \in R_{UC_a}(w/h)\}.$$

In Example 1, $R_{UC_{a_1}}$ respectively links indexes of the two moments that are possible for a_1 where the action `toggle` is executed, and indexes where a_1 does nothing (action `skip`).

For the sake of brevity we introduce $R_{UC} : \mathcal{A}gt \to (W \times Hist \to 2^{W \times Hist})$, which is a function associating a R_{UC_a} relation with each agent a. Hence, we obtain an *Epistemic STIT-model* (*ESTIT-model*) by adding R_{UC} to a *STIT-model*:

$$\mathcal{M}_{\mathsf{ESTIT}} = \langle W, <, Choice, R_{UC}, v \rangle$$

We can then offer a new kind of STIT operator $Kstit_a\varphi$, which reads "agent a knows that he ensures that φ". $Kstit_a$ can be seen as a Chellas' STIT adapted to imperfect knowledge:

$$\mathcal{M}, w/h \models Kstit_a\varphi \iff \forall w'/h' \in R_{UC_a}(w/h),\ \mathcal{M}, w'/h' \models \varphi.$$

It says that an agent ensures φ uniformly with its knowledge if among indistinguishable moments, and whatever the *current* one is, $Stit_a\varphi$ is true by doing the *current* choice type. Just as (static) knowledge, $Kstit_A$ is an $S5$ modality.

Hypothesis 3. *Two moments w_1 and w_2 are indistinguishable for an agent a only if for every choice open to a at w_1, there is a choice of the same type open to him at w_2.*

A corollary is that each agent knows which choices are open to him, or still that two moments with different sets of choices cannot be epistemically indistinguishable. Some authors have already used such an assumption ([13, 11]).

3.2 Group knowledge

We assume that agents of a group share their knowledge. Distributed knowledge of a group A is usually defined as the intersection of knowledge of individual agents of A. Hence,

$$R_{UC_A}(w/h) = \bigcap_{a \in A} R_{UC_a}(w/h).$$

In a straightforward manner, we will thus say that a group of agents A knows it ensures φ if among their indistinguishable moments, and whatever the current one is, $Stit_A\varphi$ is true by doing the *current* action type.

$$\mathcal{M}, w/h \models Kstit_A\varphi \iff \forall w'/h' \in R_{UC_A}(w/h),\ \mathcal{M}, w'/h' \models \varphi.$$

In Example 3 we intuitively have that $\Diamond Kstit_{\{a_1,a_2\}}\mathbf{X}\texttt{light}$, while in Example 2 we have $\neg\Diamond Kstit_{\{a_1,a_2\}}\mathbf{X}\texttt{light}$.

produce them or *the bodily movement part of the action* is the same. For example *turning off the light*, *turning on the light*, *toggle the switch* or *push the switch* are of the same type. Our aim is not to debate about types, so we stay at this intuitive definition.

4. UNIFORM STRATEGIES

In this section, we expose the problem of *uniform strategy* with a short summary of the state of the art of existing solutions. In order to support our claim that the STIT framework is appropriate for that purpose, we then show that we can adapt the semantics of the strategic STIT to obtain a rather simple solution to that problem.

4.1 The uniform strategies problem

Van der Hoek and Wooldridge's Alternating-time Temporal Epistemic Logic (ATEL) [14] was designed with the aim of reasoning about strategies and knowledge. Nevertheless, the original interpretation of the language suffered from counterintuitive properties. Situations such as Example 1 cannot be captured in such a way.

Some refinements were proposed [8, 9, 15]. They all aim at capturing the notion of a *uniform strategy*. Informally, a strategy σ is uniform if, when it is defined on a moment w epistemically equivalent to a moment w', then σ is also defined on w' and the choice type planned by the strategy is the same in both moments. In Example 1, a_1 has *no* uniform strategy to ensure `light`.

As far as we know, the most complete answer to the problem is offered in [9]. The authors propose two extensions to ATEL: ATOL, a logic of observation for agents with bounded recall of the past, and ATEL-R* for agents with both perfect and imperfect recall, and possibly reasoning about the past. Both formalisms are rather complex. In particular, the agency operator $\langle\langle A \rangle\rangle$ is indexed by epistemic formulas. This is corrected in a very recent work by Jamroga and Ågotnes [10]. They propose an interesting solution, but at the price of a non-standard negation operator (called *constructive* negation) which seems necessary to handle reasoning about non-strategic properties in their semantics.

4.2 Strategies and uniform strategies in STIT

Horty [6] and Belnap et al. [2] introduce strategies into STIT theory.

Definition 2. *A* strategy *for an agent a is a partial function σ such that $\sigma(w) \in Choice_a^w$ for each moment w from $Dom(\sigma)$, the domain of σ.*[4]

As we can see in the definition of the *Stit* operator, an agent's choice restricts the set of possible futures, in particular it restricts the histories to those corresponding with the choice being made. We expect a strategy to be a generalization of this, restricting histories to a set compatible to every choices at every moment of the domain.

Definition 3. *We say that a strategy σ* admits *a history h if and only if*

- *$Dom(\sigma) \cap h \neq \emptyset$ and*
- *for each $w \in Dom(\sigma) \cap h$ we have $h \in \sigma(w)$.*

The set of all histories admitted by a strategy σ is noted $Adh(\sigma)$.

We shall often use the notation σ_a to name a particular strategy of an agent a.

[4] σ is a partial function because there is no need to represent in σ an agent's choices in moments he will never reach if he follows σ.

DEFINITION 4 (COLLECTIVE STRATEGY). *A collective strategy for A $\mathcal{A}gt$ is a tuple $\sigma_A = \langle \sigma_a \rangle_{a \in A}$ (one strategy σ_a for every agent), and $Adh(\sigma_A) = \bigcap_{a \in A} Adh(\sigma_a)$.*

[6] proposes a characterization of a sort of properly-formed strategies with limited scope. It is necessary to introduce the notion of *field* at a moment w, which is a subset containing w of the subtree $Tree_w = \{w' \mid w < w' \text{ or } w = w'\}$ with a downward closure. With $Adm(\sigma) = \{m \mid m \in h, h \in Adh(\sigma)\}$, a strategy is properly-formed in M if it is *complete in the field* ($Adm(\sigma) \cap M$ $Dom(\sigma)$) and *irredundant* ($Dom(\sigma)$ $Adm(\sigma)$). Thus, an *ability* operator should be evaluated with respect to a field. But for simplicity, we do not use it here.[5]

However, just as it is done in [6] for "properly-formed" strategies, we here constrain strategies open to a group A at moment w to a set $Strategy_A^w$, such that every strategy in it is uniform. For notational convenience we say that two moments w_1 and w_2 are *indistinguishable*, if and only if every choice in w_1 has an indistinguishable choice in w_2, formally stated by

$w_1 \in R_{K_A}(w_2)$ iff $\forall h \in H_{w_1}, \exists h' \in H_{w_2}, w_1/h \in R_{UC_A}(w_2/h')$.

R_{K_A} is a relation of equivalence among moments.

$$Strategy_A^w = \{\sigma \mid \quad Dom(\sigma) \quad \bigcup_{w' \in R_{K_A}(w)} Tree_{w'}, \text{ and } \forall w' \in Dom(\sigma), \forall w'' \in R_{K_A}(w'), (w'' \in Dom(\sigma) \text{ and } \exists h' \in \sigma(w')), \exists h'' \in \sigma(w''), w''/h'' \in R_{UC_A}(w'/h'))\}$$

The set $Strategy_A^w$ contains strategies defined on moments lying in the future of the indistinguishable moments of w (included). Those strategies, if defined at a moment w' must also be defined at each moment w'' indistinguishable from w', where the strategy must apply the same choice type. The semantics of the operator for *S*trategic *A*bility with imperfect knowledge is then:

$$\mathcal{M}, w/h \models SAstit_A\varphi \iff \exists \sigma_A \in Strategy_A^w, \forall h' \in Adh(\sigma_A), \forall w' \in R_{K_A}(w) \cap h', \mathcal{M}, w'/h' \models \varphi$$

A possible reading is : "A has the ability to guarantee the truth of φ by carrying out an available strategy, and knows it". $SAstit_A\varphi$ corresponds to $\Diamond[A\,scstit : \varphi]$ in the original notation. We believe that this notation can be misleading, since the operator is atomic: Horty refers to it as a *fused* operator.

Figure 2 presents a scenario where a *blind* agent a enters a room. He does not know whether the light is on. At moments w_2 and w_3 he has the choice between switching the light (action `toggle`), remaining passive (action `skip`) or touching the light bulb (action `touch`). This last action is *informative*. Let strategy $\sigma = \{\langle w_1, \{h_1 \dots h_{12}\}\rangle, \langle w_2, \{h_3, h_4\}\rangle, \langle w_3, \{h_9, h_{10}\}\rangle, \langle w_5, \{h_4\}\rangle, \langle w_8, \{h_9\}\rangle\}$.[6] We can ckeck that σ is indeed in $Strategy_{\{a\}}^{w_1}$, i.e., that it is a uniform strategy for a at the moment w_1, and $Adh(\sigma) = \{h_4, h_9\}$. l holds

[5]It is easy to see that even histories are superfluous. We nevertheless keep them for uniformity.

[6]The notation is abusive: σ should be defined on the complete set $\{w_1 \dots w_{12}\}$, but it does not influence the set of admitted histories.

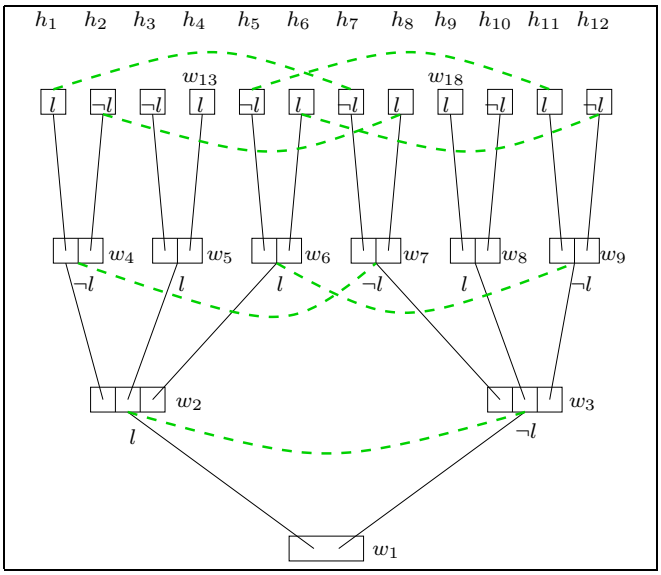

Figure 2: Suppose a blind agent a. For clarity, dotted lines are intended for R_{K_a} relations over moments, and R_{UC_a} relations can be deduced since choices of indistinguishable moments are the same: at w_1 $\{h_1 \dots h_{12}\}$ is for `enter`, at w_2 $\{h_1, h_2\}$ is for `toggle`, $\{h_3, h_4\}$ for `touch` and $\{h_5, h_6\}$ for `skip` (and identically for choices at w_3), at w_4 $\{h_1\}$ is for `toggle` and $\{h_2\}$ for `skip` (the same for moments $w_2 \dots w_9$). l stands for "the light is on", and time goes upward.

at both w_{13}/h_4 and w_{18}/h_9. Thus $\mathbf{F}l$ is true at w_1/h_4 and w_1/h_9 and it follows that considering σ, agent a knows how to play to ensure that the light is on in the future: $SAstit_a\mathbf{F}l$.

We can thus easily grasp the notion of uniform strategies in the STIT framework. This is due to the fact that the underlying semantics is more versatile than that of ATEL, because it allows to relate a moment/history pair w_1/h_1 to another w_2/h_2 via R_{UC_a} without relating all w_1/h_1' to w_2/h_2'. We here have changed the domain of quantification over strategies such that we just consider strategies satisfying the definition of uniformity. In the following, and for this preliminary work, we decide to simplify the framework into a STIT-like one, for *one-step* strategies.

5. TOWARDS A SIMPLIFICATION

The STIT branching time is based on the so called T × W logic for *historical necessity* (see [1]). Such a logic is a combination of tense and modal logic for worlds with the same time order. T×W semantics can be seen as a grid with tense on one dimension and set of histories on the other. In Figure 3 we have a grid with temporal aspects represented longitudinally, time going upward.

The aim of this section is to simplify the STIT-framework with imperfect knowledge into a semantics that does not involve histories. We focus on *one-step* strategies where the problem of uniform strategies already appears.

5.1 A logic of knowledge based uniform agency

We here deal with a framework permitting us to talk about agency, and more precisely, about agency with respect to

knowledge about actions. Thus, we do not deal with static knowledge in Hintikka's tradition: we are not interested here in sentences like "Mary knows that the light is on", but in sentences such as "Mary knows her current action makes sure that the light will be on". Nevertheless, we will briefly see in Section 7 how we can model the first case in that framework, too.

We propose a logic for *knowledge-based uniform agency* in which the knowledge scope stops at effects of actions. We keep on using the terminology of STIT. Thus, historically possible *indexes* lie in a same *moment*.

5.2 Syntax and Semantics

Given a finite set of agents $\mathcal{A}gt$ and a set of atomic propositions $\mathcal{A}tm$, a formula φ can have the following syntactic form:

$$\varphi ::= \bot \mid \mathrm{p} \mid \neg\varphi \mid \varphi \vee \varphi \mid \mathbf{X}\varphi \mid \Box\varphi \mid Kstit_A\varphi \mid Stit_A\varphi$$

with $p \in \mathcal{A}tm$ and $A \quad \mathcal{A}gt$.

A model is a tuple $\mathcal{M} = \langle W, R_X, R_\Box, R_{UC}, v\rangle$, where:

- W is a nonempty set of indexes;
- $R_X : W \to W$ is total function associating an index to its historical successor;
- $R_\Box$ is a relation between indexes;
- $R_{UC} : \mathcal{A}gt \to (W \to 2^W)$ is a function associating each agent $a \in \mathcal{A}gt$ to a relation. For every agent $a \in \mathcal{A}gt$ the relation $R_{UC}(a)$ will be noted R_{UC_a};
- $v : \mathcal{A}tm \to 2^W$ is an evaluation function.

$R_\Box(w)$ denotes the set of indexes lying in the same moment as w. R_{UC_a} is the relation between indexes of identical choices lying in moments indistinguishable by agent a.

For a group of agents A, we suppose that agents of A make choices collectively with distributed knowledge: they share their knowledge. We thus define the collective uniform choice relation as follows:

$$R_{UC_A}(w) = \bigcap_{a\in A} R_{UC_a}(w).$$

We make the same hypothesis as in STIT concerning the independence/consistency of choices of agents, and assume that for each index w, $R_{UC_{\mathcal{A}gt}}(w) \neq \emptyset$.

We assume models satisfy additional properties:

1. $(R_\Box \circ R_X)(w) \supseteq (R_X \circ R_\Box)(w)$
   If it is historically necessary that some state of affairs will hold next, then next, this state of affairs will be historically necessary.
2. $(R_\Box \circ R_{UC_A})(w) = (R_{UC_A} \circ R_\Box)(w)$
   The same types of choices are available at every indistinguishable moment.
3. $(R_{UC_A} \circ R_X)(w) \supseteq (R_X \circ R_\Box \circ R_{UC_A})(w)$
   If a coalition A makes a uniform choice to ensure a state of affairs at the next step, it will be historically inevitable at the next step that A knows that it ensures φ.

The first assumption forces a tree structure of moments. The second one is the translation of Hypothesis 3. The last assumption is motivated by the fact that it is not sufficient to say that a group of agents A knows how to play to ensure φ at moment w if A does not know when it has achieved φ. Nevertheless, agents know possible effects of their actions. We then adopt the principle that if agents know they ensure φ at the next step by doing the current choice, then at the very next step they will know that φ holds. It forces a *no forget* principle which seems realistic since we deal with *one-step* strategies.

A formula is evaluated with respect to a model and a world, which corresponds to STIT indexes and thus contains information about history.

$$\begin{array}{lcl}
\mathcal{M}, w \models p & \iff & w \in v(p),\ p \in \mathcal{A}tm \\
\mathcal{M}, w \models \neg\varphi & \iff & \mathcal{M}, w \not\models \varphi \\
\mathcal{M}, w \models \mathbf{X}\varphi & \iff & \mathcal{M}, R_X(w) \models \varphi \\
\mathcal{M}, w \models \Box\varphi & \iff & \forall w' \in R_\Box(w), \mathcal{M}, w' \models \varphi \\
\mathcal{M}, w \models Kstit_A\varphi & \iff & \forall w' \in R_{UC_A}(w), \mathcal{M}, w' \models \varphi \\
\mathcal{M}, w \models Stit_A\varphi & \iff & \forall w' \in (R_{UC_A} \cap R_\Box)(w), \\
 & & \mathcal{M}, w' \models \varphi
\end{array}$$

$w \models \mathbf{X}\varphi$ means that φ is true at the immediate successor of w on the history. $w \models \Box\varphi$ means that φ is true at each world lying in the same moment as w. $Kstit_a\varphi$ is an agency operator with an implicit epistemic feature. It means that a knows that if he performs his chosen action, he ensures that φ. $Stit_A\varphi$ still stands for "A's current choice makes sure that φ".

5.3 Some validities

$\mathbf{X}$ is a KD-modality, and $\Box$ and every $Stit_A$ and $Kstit_A$ are $S5$-modalities.

$(MonKstit)$ $Kstit_{A_1}\varphi \to Kstit_{A_2}\varphi$ if $A_1 \quad A_2$

$(MonStit)$ $Stit_{A_1}\varphi \to Stit_{A_2}\varphi$ if $A_1 \quad A_2$

$(KnowAct)$ $\Box Kstit_A\varphi \leftrightarrow Kstit_A\Box\varphi$

$(Linearity)$ $\neg\mathbf{X}\neg\varphi \to \mathbf{X}\varphi$

$(XBox)$ $\Box\mathbf{X}\varphi \to \mathbf{X}\Box\varphi$

$(NoForget)$ $Kstit_A\mathbf{X}\varphi \to \mathbf{X}\Box Kstit_A\varphi$

$(StitBox)$ $\Box\varphi \to Stit_A\varphi$

$(StitKstit)$ $Kstit_A\varphi \to Stit_A\varphi$

$(MonKstit)$ and $(MonStit)$ are valid by the construction of the collective uniform choice relation R_{UC_A}. $(KnowAct)$ is the immediate translation of the second constraint. $(Linearity)$ follows from the definition of the definition of the R_X function. $(XBox)$ is the translation of the first constraint. $(NoForget)$ is the direct translation of the third constraint.[7] $(StitBox)$ and $(StitKstit)$ are valid by the semantics of the $Stit$ operator.

[7]The link with the *no forget* principle is maybe not clear, but we say more about this in section 7.

6. KNOWING HOW TO PLAY

The fact that a group of agents A knows how to play to ensure φ at the next step can be captured by the formula

$$\Diamond Kstit_A \mathbf{X}\varphi.$$

A group of agents knows how to play to ensure φ at the next step if "A can make a choice such that it knows it ensures φ at the next step".

In order to illustrate the logic of Section 5, and particularly the capabilities of groups with incomplete knowledge, we present two scenarii constructed above examples 1 and 3. First we deal with one agent with lack of knowledge (the blind agent a_1). Then, we add another agent that cannot act (the lame agent a_2), and show how they can put their strengths together.

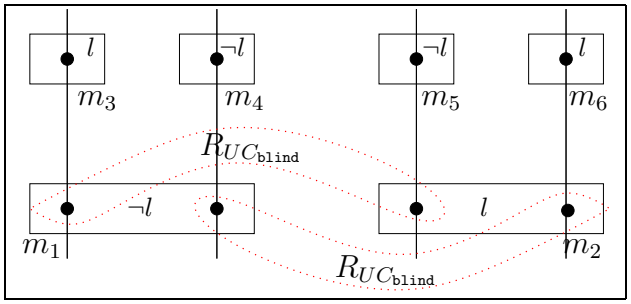

Figure 3: (Schematic of Example 1) Vertical lines represent histories, rectangles are historical necessity relations and delimit moments.

In Figure 3 the moments m_1 and m_2 are epistemically equivalent w.r.t. static knowledge. Suppose a blind person enters a room at moment m_0. The problem is to know whether he can ensure that the light is on. For that he has two possible actions, `toggle` and `skip`. If at m_1 or m_2 he can act such that the light is on, he cannot be aware of that: he has no uniform choice such that the result is always l. Let us call $w_{1,r}$ the right index of moment m_1, and $w_{1,l}$ the left one. The following holds:

- $w_{1,r} \models Stit_{\text{blind}}\mathbf{X}l \wedge \neg Kstit_{\text{blind}}\mathbf{X}l$
- $w_{1,l} \models \neg\Box\neg Stit_{\text{blind}}\mathbf{X}l \wedge \Box\neg Kstit_{\text{blind}}\mathbf{X}l$.

Figure 4 presents an example where the blind person from the previous example is helped by a lame person. While the blind does not know the current state of the light, the lame does. While the lame cannot act such that the light is on at the next step, the blind can. If we call $w_{1,l}$ the left index of the moment m_1 and $w_{1,r}$ the right one, the following holds:

- $w_{1,l} \models Stit_{\text{blind}}\mathbf{X}l \wedge \neg Kstit_{\text{blind}}\mathbf{X}l$
- $w_{1,r} \models \neg\Box\neg Stit_{\text{blind}}\mathbf{X}l \wedge \Box\neg Kstit_{\text{blind}}\mathbf{X}l$
- $w_{1,l} \models \neg Stit_{\text{lame}}\mathbf{X}l$
- $w_{1,r} \models \Box\neg Stit_{\text{lame}}\mathbf{X}l$

but,

- $w_{1,l} \models Kstit_{\{\text{blind,lame}\}}\mathbf{X}l$

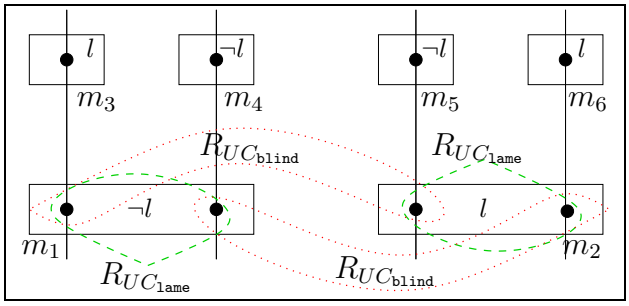

Figure 4: (Schematic of Example 3) The actual moment is m_1, where the light is off ($\neg l$). The lame agent cannot act but has complete knowledge. The blind agent does not know if the light is on or off, but can choose to toggle or not (`skip`). Individually, neither the lame agent nor the blind agent can ensure that the light is on, but together, they can form an effective coalition for that purpose.

- $w_{1,r} \models \neg\Box\neg Kstit_{\{\text{blind,lame}\}}\mathbf{X}l$

Now, we see that this last formula corresponds to the concept of *knowing how to play* that we wanted to grasp.

7. STATIC KNOWLEDGE

We have not included static knowledge in the language of our logic of knowledge-based uniform agency. However, it can be defined: we say that an agent a knows that φ if and only if whatever a chooses, it knows that it's choice makes sure that φ. We say that a group of agents A knows that φ if and only if whatever agents of A choose, they distributively know that their choices make sure that φ. We thus can define in our logic, a modal operator reading "group A knows that φ", as:

$$K_A\varphi =_{def} \Box Kstit_A\varphi.$$

"A knows that φ" is equivalent to "it is historically inevitable that A knows that it ensures φ". We also can reformulate the $(NoForget)$ validity by $Kstit_A\mathbf{X}\varphi \rightarrow \mathbf{X}K_A\varphi$, which makes sense now, and can be read as "if A knows it ensures that φ is true at the next step, then at the next step the group will know that φ holds". The following formulas are valid:

- $K_A\varphi \rightarrow \Box\varphi$
- $K_A Kstit_A\varphi \leftrightarrow K_A\varphi$
- $Kstit_A\neg\Box\neg\varphi \rightarrow K_A\neg\Box\neg\varphi$

Finally, the formulation of "a group of agents A know how to play to ensure that φ at the next step" is equivalent to

$$K_A\Diamond Kstit_A\mathbf{X}\varphi.$$

K_A focuses on what agents know at a moment, before doing a choice, or whatever the choice they do. $Kstit_A$ is about knowledge after having made a choice. The threshold from static knowledge to dynamic knowledge is monotonic: what is known before doing a choice is also known after ($K_A\varphi \rightarrow Kstit_A\varphi$ is valid). Thus $Kstit_A$ is a refinement of Hintikka's static knowledge.

This distinction is of interest even with perfect knowledge about the current world. Indeed, if Mary knows that the light is on, she is the only one to have the control on it, and that the switch is functioning well, she nevertheless ignores the state of the light at the next moment, until she makes her choice between toggling and remaining passive. But when she is committed to a choice, she knows the next state of the light, and this already before performing the action.

8. FUTURE WORK

A further extension is a strategic operator for global rather than local effectivity. Two paths open before us: (1) We can define an iterated operator $(\Diamond Kstit_A\mathbf{X})\ \varphi$, which we believe can be done in a rather simple manner, following [12, Chapter 4] and capitalizing on the *no forget* principle. However, this remains an idealization about knowledge of agents. (2) We can adapt strategies in our logic as we have done in Section 3.

Also, our aim was here to deal with cooperative coalitions of agents. We hence used distributed knowledge. It could be interesting to investigate refinements of group knowledge.

9. ACKNOWLEDGMENTS

This reasearch is part of the MOSTRO project, funded by the "Fondo provinciale per i progetti di ricerca" of the Provincia Autonoma of Trento.

We would like to thank Wojtek Jamroga and two anonymous reviewers for fruitful comments.

ABSTRACT

We present a novel procedure for automatically verifying the space and time requirements for resource-bounded reasoning agents. We represent agents as a finite state machines in which the states correspond the formulas currently held in the agent's memory and the transitions between states correspond to applying the agent's inference rules. To check whether an agent has enough memory to derive a formula ϕ, we specify the FSM as input to the model-based planner MBP, and check whether the agent has a plan (a choice of memory allocations and inference rule applications), all executions of which lead to states containing ϕ. Our approach is general enough to admit verification of reasoners with any set of inference rules which can be encoded as transitions between FSM states.

1. INTRODUCTION

The question of how much memory a reasoning agent needs to derive a formula is of considerable theoretical and practical interest. From a theoretical point of view, it is interesting to investigate how the deductive strength of a particular logic changes when only a fixed number of formulas are allowed to be 'active' in a derivation. This is different from the question of bounds on the size proofs [3], since we assume that the whole proof does not need to be held in memory (some intermediate steps may be overwritten).

From a practical point of view, the question of whether an agent will run out of memory or time before achieving its goal(s) is clearly a major concern for the agent developer. As agent tasks become more open ended, the amount of memory required to achieve them becomes harder to predict a priori. For example, the reasoning capabilities of agents assumed by many web service applications is non trivial (e.g., reasoning over complex ontologies or about business processes described by a set of business rules) and the memory requirements correspondingly difficult for the agent developer to determine a priori. At the same time trends towards mobile agents and agents which run on mobile devices such as PDAs and smart phones imply more processor and memory efficient agent designs.

In this paper, we present a novel procedure for automatically verifying the space and time requirements for resource-bounded reasoning agents. Specifically, we address the question: given an agent and a formula ϕ, does the agent have sufficient memory to derive ϕ, and, if it does, what is the length of the shortest derivation within the specified memory bound? In outline, our approach is as follows. We represent a reasoning agent as a finite state machine in which the states correspond the formulas currently held in the reasoner's memory and the transitions between states correspond to applying the reasoning rules. To check whether a reasoner has enough memory to derive a formula ϕ, we specify the FSM as input to the model-based planner MBP [2], and check whether the reasoner has a plan (a choice of memory allocations and inference rule applications), all executions of which lead to states containing ϕ.

Our approach is general enough to admit verification of reasoners with any set of inference rules, provided that those rules can be encoded as transitions between FSM states. To illustrate the generality of our approach, we show how to encode two example reasoners: a forward-chaining rule-based agent of the kind found in many applications employing ontological reasoning and business rules, and a classical propositional reasoner which can derive all classical consequences of its knowledge base given unlimited memory.

2. FORMAL MODEL

We model resource-bounded agents as finite state machines (FSM) or transition systems. Let the internal language of the agent be some language L (e.g. propositional language). The definition of a transition system is given relative to the following components: the bound n on the agent's memory size; the agent's reasoning rules; the agent's knowledge base $K \subseteq L$; the agent's goal formula $A_G \in L$. The set of all subformulas of K and A_G will be denoted by Ω. We abstract away from the size of the formulas. However, given K and A_G, the maximum size of any formula in the agent's state is fixed.

In the remainder of this section, we first define the language and transition systems for 'definite reasoning' agents and give an example of such an agent. We then introduce a more complex logic for agents that need to maintain a set of epistemic alternatives, such as classical reasoners.

2.1 Definite reasoners

The language of the logic BML^d (for bounded memory logic, definite case) is defined relative to the agent's internal language L. If A is a formula of L, then $\mathrm{B}\,A$ (the agent believes A) is a formula; the language is closed under the boolean connectives and unary modalities EX ('there exists a next state where...') and EF ('there exists a future state where...'). Other boolean connectives are defined in the usual way. We also define $\mathrm{AX}\,\phi$ as $\neg\mathrm{EX}\,\neg\phi$ and $\mathrm{AG}\,\phi$ as $\neg\mathrm{EF}\,\neg\phi$.

A transition system $M = (S, R, V)$ consists of a set of states S, a serial binary relation R on S (transitions between states) and an assignment $V : S \longrightarrow \mathcal{P}(\Omega)$ (assigning to the state the set of formulas the agent believes in that state). Notice that $V(s)$ is not a classical truth assignment, as it might contain complex formulas, e.g., $A \wedge B$, as well as contradictory formulas, e.g., $A \wedge B, \neg B \in V(s)$. To reflect the fact that the agents have bounded memory, we postulate that V can assign at most n formulas to any given state. The transitions which the agent can make depend on the agent's inference rules. In our model, we assume that one of the agent's possible transitions is 'reading' a K formula into its memory or 'active state'. Reading a formula may correspond to reading from flash memory, asking for user input, or reading data from the server over the network.

The definition of a formula being satisfied in $M, s \in S$ is as follows:

$M, s \models \mathrm{B}\,A$ iff $A \in V(s)$

$M, s \models \neg\phi$ iff $M, s \not\models \phi$

$M, s \models \phi \wedge \psi$ iff $M, s \models \phi$ and $M, s \models \psi$

$M, s \models \mathrm{EX}\,\phi$ iff there exists a state t such that $R(s,t)$ and $M, t \models \phi$.

$M, s \models \mathrm{EF}\,\phi$ iff there exists a sequence of states $t_1, \ldots, t_k$ such that for all $i \in \{1, \ldots, k-1\}$, $R(t_i, t_{i+1})$, $t_1 = s$ and $M, t_k \models \phi$

The bound n on the size of the agent's memory is expressed by the following axiom:

B(n) $\mathrm{B}\,A_1 \wedge \ldots \wedge \mathrm{B}\,A_n \rightarrow \neg\mathrm{B}\,A_{n+1}$ where $A_i \neq A_j$ for all $i, j \in \{1, \ldots, n+1\}$ such that $i \neq j$.

We can express that the agent can derive its goal A_G from its knowledge base K as $\mathrm{EF}\,\mathrm{B}\,A_G$ (there is some future state where the agent believes A_G). The fact that a formula is derivable in k steps can be expressed as $\mathrm{EX}^k\mathrm{B}\,A_G$ (where EX^k denotes k applications of the operator EX). Similarly, the fact that an agent needs at least $k+1$ steps to derive a formula A_G can be expressed as $\mathrm{AX}^k\neg\mathrm{B}\,A_G$.

A simple example of a definite reasoner would be an agent which reasons using rules, e.g., ontology rules, or business rules. We assume that agent's knowledge base consists of ground atomic formulas and rules of the form $A_1 \wedge \ldots \wedge A_n \rightarrow B$, where $A_1, \ldots, A_n, B$ are atomic formulas (see, for example, [4]). By generating all possible substitutions of constants occurring in the knowledge base into the rule, we can reduce the knowledge base to a purely propositional set of formulas, consisting of propositional variables and implications of the form $p_1 \wedge \ldots \wedge p_n \rightarrow q$. Then the only rules the agent needs to derive all 'rule-based' consequences are conjunction introduction and modus ponens.

Let $V(s)'$ stand for any subset of $V(s)$ which has cardinality at most $n-1$ and differs from $V(s)$ in at most one formula. The rule-based reasoner has the following transitions:

Read $R(s,t)$ if $V(t) = V(s)' \cup \{A\}$ for some $A \in K$.

AND $R(s,t)$ if $A_1, A_2 \in V(s)$ and $V(t) = V(s)' \cup \{A_1 \wedge A_2\}$.

MP $R(s,t)$ if $A_1 \in V(s)$, $A_1 \rightarrow A_2 \in V(s)$, and $V(t) = V(s)' \cup \{A_2\}$

Reflexivity $R(s,s)$

A complete axiomatisation of this logic is given in [1].

2.2 More general reasoners

It is also interesting to model reasoners which can reason by cases, or in general consider hypothetical states; this means that their transitions do not necessarily follow the logical consequence relation. We also extend the language to express disbelief as well as belief.

Consider a reasoner who believes $\{A \vee B, A \rightarrow C, B \rightarrow C\}$. To derive C, it has to reason by cases: assume A; derive C. Then, assume B; derive C. Hence, it is safe to believe C. However, if the process of assuming A corresponds to a transition to a state where A is believed, the modelling is not 'safe' — the agent's beliefs are not justified by valid inference steps. In the state where it assumes A, the agent should remember that this is just one of the epistemic alternatives, and that in others A is false and B is true.

To deal with such reasoners, we add an extra set of 'epistemic alternatives' or possible worlds to each state. Epistemic alternatives are introduced when the classical reasoner is applying non-deterministic rules, such as elimination of disjunction. Intuitively, a formula is now believed in a state if it is true in all of the epistemic alternatives associated with this state. We express this as $\Box\mathrm{B}\,A$.

The language of the logic BML (for bounded memory logic) extends the language of BML^d by adding extra clauses: if A is a formula of L, then $\overline{\mathrm{B}}\,A$ (the agent disbelieves A) is a formula; if ϕ is a formula, then $\Diamond\phi$ is a formula. We also define $\Box\phi$ as $\neg\Diamond\neg\phi$.

For such general reasoners, we can express that the agent can derive A_G from its knowledge base K as $\mathrm{EF}\,\Box\mathrm{B}\,A_G$ (there is some future state where in all epistemic alternatives the agent believes A_G).

A BML transition system $M = (S, W, R, U, T, F)$ consists of a set of states S, a set of possible worlds or epistemic alternatives W, a binary relation R on S, a function assigning to each state a set of epistemic alternatives $U : S \longrightarrow \mathcal{P}(W)$, and two assignments $T : W \longrightarrow \mathcal{P}(\Omega)$ and $F : W \longrightarrow \mathcal{P}(\Omega)$ which say whether the value of an (internal language) formula in a world is true or false (where, as before Ω is the set of subformulas of K and A_G). As before, to reflect the bound on the agent's memory, we require

$|T(w)| + |F(w)| \leq n$, for any given state w. Moreover, the truth assignments should be consistent, i.e., $T(w) \cap F(w) = \emptyset$. The following truth definitions have been added or modified compared to BML^d. Note that we talk about truth in a world and truth in a state:

$M, w \models \mathrm{B}\, A$ iff $A \in T(w)$

$M, w \models \bar{\mathrm{B}}\, A$ iff $A \in F(w)$

$M, s \models \Diamond\phi$ iff there exists w in $U(s)$, such that $M, w \models \phi$.

The bound n on the size of the agent's memory is expressed by the following axiom:

B'(n) $\Box(\widetilde{\mathrm{B}}\ A_1 \wedge \ldots \wedge \widetilde{\mathrm{B}}\ A_n \rightarrow \neg\ \widetilde{\mathrm{B}}\ A_{n+1})$, where $\widetilde{\mathrm{B}}\ A_i$ stands for either $\mathrm{B}\, A_i$ or $\bar{\mathrm{B}}\, A_i$ and $A_i \neq A_j$ for all $i, j \in \{1, \ldots, n+1\}$ such that $i \neq j$,

The transition relation R between states is defined in terms of expansion relation between epistemic alternatives $\preceq$. Expansion corresponds to applying an inference rule to formulas in the epistemic alternative. Formally, $R(s,t)$ holds if $U(s) = \{w_1, \ldots, w_m\}$, and for some $w_i \in U(s)$, $U(t) = (U(s) \backslash \{w_i\}) \cup \{v : w_i \preceq v\}$.

Note that the classical reasoner agent can construct new formulas in addition to decomposing formulas. We only allow the construction of formulas which are in Ω (the set of subformulas of K and A_G). This does not affect the completeness of agent's rules (since these are the only formulas it may possibly need in the derivation of A_G from K), but allows us to represent it as a finite state machine.

Since the agent can both believe and disbelieve formulas (and its language contains negation), an issue of inconsistent possible worlds arises. An agent *cannot* make a transition to a possible world where the same formula is assigned true and false. All rules therefore have to have a proviso that if $w \preceq v$ then it impossible, for any formula A, to have $A \in T(w)$ and $A \in F(v)$ or vice versa. If the agent starts with inconsistent state, it is allowed to assert any formula from Ω. A full list of transitions the classical reasoner is given in [1].

In [1], we prove that a classical reasoner with unbounded memory can derive A_G from K whenever A_G is a classical consequence of K.

3. VERIFYING REASONING CAPABILITIES

The problem of identifying the existence (and the minimal length) of a deduction for A_G from a knowledge base K for an agent with bounded memory modelled as a transition system M, can be recast as a *planning problem*: find a control strategy for M (a plan) which, starting from any state in K, leads to some state in A_G. In general, M is a *nondeterministic* transition system, since applying a rule may lead to several epistemic alternatives. Thus, we are interested in *strong* plans [2]: tree-structured plans such that their execution leads to the goal, for *every* possible outcome of the actions in the plan.

From the few planners capable of dealing with strong planning for nondeterministic domains we selected MBP, a system which combines effective algorithms with an input language which allows a concise description of transition systems in logical terms. In this section, we provide a high-level description of how the proof existence problem is recast as a planning domain in MBP.

States are identified with assignments $v : \Omega \longrightarrow \{\top, \bot, U\}$ (where U stands for 'undefined'). The transition relation is defined as having as argument the formula to be derived or decomposed, and the formula(s) to be overwritten. For example, the precondition of $\mathbf{Read}(A, B)$ is that A is in KB, and the postcondition is that in the next state, A is true and B is undefined (the agent believes A and does not believe or disbelieve B). If the state is not full, then it is possible that B is a special 'empty' formula (nothing gets overwritten). In some cases a transition may result in more than one formula being overwritten. For example, the precondition for disjunction elimination $\mathbf{elimOr}(A, B_1, B_2)$ is that A is of the form $A_1 \vee A_2$, and that in the current state, $v(A) \neq U$. The postcondition is that in the next state, the value of $v(A_1) \vee v(A_2)$ is equal to the assignment to A in the current state, and B_1, B_2 are assigned U. Note that if in the current state A is assigned $\top$, then the effect of this transition is non-deterministic, since several different values of $v(A_1), v(A_2)$ would satisfy the constraint.

Given this encoding, the planning problem is described by an initial state where $\forall A \in \Omega : v(A) = U$, and by a goal state $v(A_G) = \top$. The constraints on transitions are directly represented in MBP as TRANS constraints over R, allowing for a compact representation of the problem.

MBP implements a number of different search styles. We chose breadth-first backward search which guarantees that the shortest plan is selected. The computational burden imposed by this search style is effectively constrained by the use of symbolic representation techniques that allow a very compact encoding, and an efficient handling of extremely large state sets; details can be found in [2].

Experimental results can be found in [1].

4. CONCLUSIONS AND FUTURE WORK

In this paper, we have attempted to take seriously the idea that reasoning is a process which requires memory and time. While the temporal aspect of reasoning has been studied before, we believe that our treatment of the memory aspect is novel. We have proposed a new kind of epistemic logic where both resources are explicitly modelled. The logic is interpreted on state transition systems, where the agent's state can contain only a fixed finite number of formulas (beliefs), and transitions correspond to application of inference rules by the agent. By specifying the state transition system as an input to the MBP planner, we can automatically verify the lower bounds on space and time required by the agent to derive a certain formula.

In future work, we plan to model multi-agent systems, including agents which are capable of reasoning about other agents' beliefs and their reasoning in epistemic logic. We also would like to model reasoners in description logics, since verifying agents which do ontological reasoning is one of our prime motivations.

ABSTRACT

We present a new model of knowledge, belief, desire and intention, called the interpreted KBDI-system model (or KBDI-model for short). The key point of the interpreted KBDI-system model is that we express an agent's knowledge, belief, desire and intention as a set of runs (computing paths), which is exactly a *system* in the interpreted system model, a well-known agent model due to Halpern and his colleagues. Our KBDI-model is *computationally grounded* in that we are able to associate a KBDI-model with a computer program, and formulas, involving agents' knowledge, belief, desire (goal) and intention, can be understood as properties of program computations. We present a sound and complete proof system with respect to our KBDI-model and explore how symbolic model checking techniques can be applied to model checking multi-agent systems with KBDI-models.

1. INTRODUCTION

The *possible worlds semantics* [6] is a fruitful approach to formalizing agent systems via modal logics. The well-known theory of intention [3] and the formalism of the belief-desire-intention paradigm [10], for example, are along this line. However, it is still not very clear how to obtain concrete agent models with the belief, desire and intention accessibility relations from speci c agent programs.

The *interpreted system* model [4] offers a natural interpretation, in terms of the states of computer processes, to S5 epistemic logic. The salient point of the interpreted system model is that we are able to associate an interpreted system with a computer program, and formulas in epistemic logic that are valid with respect to the interpreted system can be understood as valid properties of program computations. In this sense, the interpreted system model is *computationally grounded* [14].

The aim of this paper is to present a computationally grounded model of knowledge, belief, desire and intention, called the interpreted KBDI-system model (or KBDI-*model* for short), by extending the interpreted system model. The key point of the KBDI-model is that an agent's beliefs, desires and intentions as well as its knowledge is characterized as a set of runs (computing paths), which is exactly a computationally grounded *system* in the interpreted system model.

Intuitively, a KBDI-model includes a system $\mathcal{K}$ as in the interpreted system model, as well as, for each agent i, its beliefs $\mathcal{B}_i$, desires $\mathcal{D}_i$ and intentions $\mathcal{I}_i$, which are subsystems or subsets of $\mathcal{K}$. Agent i's knowledge is determined by the set of those runs that are consistent with its local *observations* (or local state). Similarly, agent i's beliefs are de ned by the set of runs in $\mathcal{B}_i$ that are consistent with agent i's observations. Agent i's desires and intentions can also be de ned in the same way. Intuitively, runs in $\mathcal{B}_i$ are possible computing paths from the viewpoint of the agent and those in $\mathcal{D}_i$ are the computing paths that the agent desires. Thus, it is reasonable to assume that $\mathcal{D}_i \quad \mathcal{B}_i$ because every desired computing path should be possible. Nevertheless, we need not assume that $\mathcal{I}_i \quad \mathcal{D}_i$ or even $\mathcal{I}_i \quad \mathcal{B}_i$ because an agent's intention may fail to achieve its goal and the actual computing path may be beyond the agent's belief even though the agent has chosen and completed an intentional series of actions.

2. KBDI LOGIC

This section introduces a multimodal logic of knowledge, belief, desire and intention, referred to as Observation-based KBDI logic (KBDI). As shown below, the semantics of KBDI logic is given in terms of the interpreted KBDI-system model. According to this semantics, the computation of agents' knowledge, belief, desire, and intention is based on agents' *observations*, that is, local states.

2.1 Interpreted systems

Consider a system composed of multiple (say n) agents in an environment. We represent the system's state or the *global state* as a tuple $(s_e, s_1, \quad , s_n)$, where s_e is the *environment's local state* and, for $1 \quad i \quad n$, s_i is *agent i's local state*.

Let L_e be a set of possible local states of the environment and L_i a set of possible local states for agent i, for $i = 1, \quad , n$. We take $G \quad L_e \times L_1 \times \quad \times L_n$ to be the set of *reachable global* states of the system. A *run r* over G is a function from the time domain the natural numbers in our case to G. Thus, a run over G can be identi ed with a sequence of global states in G. A *point* is a pair (r, m) consisting of a run r and time m. Given a point (r, m), we denote the rst component of the tuple $r(m) = (s_e, s_1, \quad , s_n)$ by $r_e(m)$ $(= s_e)$ and, for each i $(1 \quad i \quad n)$, the $i+1$'th component of the tuple $r(m)$ by $r_i(m)$ $(= s_i)$. Thus, $r_i(m)$ is the local state of agent i in run r at time m.

The idea of the interpreted system semantics is that a run represents one possible computation of a system and a system may have

a number of possible runs, so we say a *system* is a set of runs. Assume that we have a set Φ of primitive propositions, which we can think of as describing basic facts about the system. An *interpreted system* I consists of a pair $(\mathcal{R}, \ )$, where $\mathcal{R}$ is a set of runs over a set of global states and is a valuation function, which gives the set of primitive propositions true at each point in $\mathcal{R}$ [4].

For every agent i, let the notation $(r,u) \ _i \ (r',v)$ denote that $r_i(u) = r'_i(v)$. Intuitively, $(r,u) \ _i \ (r',v)$ means that (r,u) and (r',v) are indistinguishable to agent i. We also use the notation $(r,u) \ _i^{spr} \ (r',v)$ to denote that $u = v$ and, for every $j \ u$, $r_i(j) = r'_i(j)$ (here *spr* stands for *synchronous* systems with *perfect recall*).

Let KL_n denote the language of propositional logic augmented by the future-time connectives $\bigcirc$ (next) and $\mathbf{U}$ (until) and a modal (knowledge) operator K_i for each agent i. The language KL_n can be interpreted by using an interpreted system. The related satisfaction relationship $\models_{KL_n}$ is as follows: Given $I = (\mathcal{R}, \ )$ and a point (r,u) in $\mathcal{R}$, we de ne $(I,r,u) \models_{KL_n}$ by induction on the structure of . When is of the form $K_i\varphi$, $(I,r,u) \models_{KL_n}$ iff $(I,r',v) \models_{KL_n} \varphi$ for all (r',v) such that $(r,u) \ _i \ (r',v)$.

2.2 Interpreted KBDI Systems

Given a set G of global states and system $\mathcal{K}$ over G, an agent's *mental state* over system $\mathcal{K}$ is a tuple $\langle \mathcal{B}, \mathcal{D}, \mathcal{I} \rangle$, where $\mathcal{B}$, $\mathcal{D}$ and $\mathcal{I}$ are systems (sets of runs over G) such that $\mathcal{I} \ \mathcal{K}$ and $\mathcal{D} \ \mathcal{B} \ \mathcal{K}$. A *KBDI-system* is a structure $\langle \mathcal{K}, \mathcal{M}_1, \ , \mathcal{M}_n \rangle$, where $\mathcal{K}$ is a system and for every i, $\mathcal{M}_i$ is agent i's mental state over $\mathcal{K}$.

Assume that we have a set Φ of primitive propositions which describe basic facts about agents and their environment. An *interpreted KBDI-system* I consists of a pair $(\mathcal{S}, \ )$, where $\mathcal{S}$ is a KBDI-system and is a valuation function, which gives the set of primitive propositions true at each point in G.

2.3 Syntax

Given a set Φ of propositional atoms, the language of KBDI logic is de ned by the following BNF notations:

$$\begin{aligned} \langle wff \rangle ::= \ & \text{any element of } \Phi \mid \neg\langle wff \rangle \mid \langle wff \rangle \wedge \langle wff \rangle \mid \\ & \bigcirc\langle wff \rangle \mid \langle wff \rangle \mathbf{U} \langle wff \rangle \mid \\ & \mid K_i\langle wff \rangle \mid B_i\langle wff \rangle \mid D_i\langle wff \rangle \mid I_i\langle wff \rangle \end{aligned}$$

Informally, $K_i\varphi$, $B_i\varphi$ and $D_i\varphi$ means that agent i knows, believes and desires φ, respectively, while $I_i\varphi$ denotes that φ holds under the assumption that agent i acts based on his intention. The formulas not containing modalities K_i, B_i, D_i and I_i ($i = 1, \ , n$) are called linear-temporal logic (LTL) formulas.

2.4 Semantics

We now proceed to interpret KBDI logic formulas in terms of interpreted KBDI-systems. In the following, we inductively de ne the satisfaction relation $\models_O$ between a formula φ and a pair of interpreted KBDI-system and a point. Given an interpreted KBDI-system $I = (\mathcal{S}, \ )$, suppose that $\mathcal{S} = \langle \mathcal{K}, \mathcal{M}_1, \ , \mathcal{M}_n \rangle$ and for every i, $\mathcal{M}_i = \langle \mathcal{B}_i, \mathcal{D}_i, \mathcal{I}_i \rangle$. Let r be a run in $\mathcal{K}$ and u a natural number, then we have that:

- $(I,r,u) \models_O K_i\varphi$ iff $(I,r',v) \models_O \varphi$ for those (r',v) such that $r' \in \mathcal{K}$ and $(r,u) \sim_i (r',v)$;
- $(I,r,u) \models_O B_i\varphi$ iff $(I,r',v) \models_O \varphi$ for those (r',v) such that $r' \in \mathcal{B}_i$ and $(r,u) \sim_i (r',v)$;
- $(I,r,u) \models_O D_i\varphi$ iff $(I,r',v) \models_O \varphi$ for those (r',v) such that $r' \in \mathcal{D}_i$ and $(r,u) \sim_i (r',v)$;
- $(I,r,u) \models_O I_i\varphi$ iff $(I,r',v) \models_O \varphi$ for those (r',v) such that $r' \in \mathcal{I}_i$ and $(r,u) \sim_i (r',v)$;

The semantics of atomic formulas or formulas of the form $\neg\varphi$, $\varphi \wedge \varphi'$, $\bigcirc\varphi$ or $\varphi\mathbf{U}\varphi'$ can be dealt with in the usual manner.

We use $\models_O \varphi$ to denote that φ is valid in every interpreted KBDI-system.

According to our de nition, $D_i\varphi$ is true iff φ is true along those runs that are desirable to agent i and consistent with agent i's observations. Thus, $D_i\varphi$ intuitively means that agent i's goal implies that formula φ holds.

For those agents with perfect recall and a global clock, we may use $\ _i^{spr}$ instead of $\ _i$ to interpret those formals with modalities B_i, D_i and I_i and get an alternative satisfaction relationship $\models_O^{spr}$.

PROPOSITION 1. *The following axioms are valid with respect to both $\models_O$ and $\models_O^{spr}$:*

- $K_i\varphi \Rightarrow \varphi$
- $\Delta_i(\varphi \Rightarrow \psi) \Rightarrow (\Delta_i\varphi \Rightarrow \Delta_i\psi)$
  $\Delta_i\varphi \Rightarrow K_i\Delta_i\varphi \qquad \neg\Delta_i\varphi \Rightarrow K_i\neg\Delta_i\varphi$
  where Δ stands for K, B, D or I.
- *Relationship between knowledge, belief, desire and intention*
  $B_i\varphi \Rightarrow D_i\varphi \qquad K_i\varphi \Rightarrow B_i\varphi \qquad K_i\varphi \Rightarrow I_i\varphi$
- *Temporal operators*
  $\bigcirc(\varphi \Rightarrow \psi) \Rightarrow (\bigcirc\varphi \Rightarrow \bigcirc\psi)$
  $\bigcirc(\neg\varphi) \Rightarrow \neg \bigcirc \varphi$
  $\varphi\mathbf{U}\psi \Leftrightarrow \psi \vee (\varphi \wedge \bigcirc(\varphi\mathbf{U}\psi))$

PROPOSITION 2. *The following axioms are valid with respect to $\models_O^{spr}$: $\Delta_i \bigcirc \varphi \Rightarrow \bigcirc\Delta_i\varphi$, where Δ stands for K, B, D and I.*

The formula $D_i \bigcirc \varphi \Rightarrow \bigcirc D_i\varphi$ says that if agent i's current goal implies φ holds at the next point in time, then at the next point in time her goal will imply φ, that is, agent i persists on her goal.

2.5 Proof system

We now discuss a proof system, called the KBDI proof system, for those agents with perfect recall and a global clock. The proof system contains the axioms of propositional calculus plus those in Propositions 1 and 2. It is closed under the propositional inference rules plus for every agent i: $\frac{\vdash \varphi}{\vdash K_i\varphi}$.

THEOREM 3. *The KBDI proof system for agents with perfect recall and a global clock is sound and complete with respect to interpreted KBDI-systems with satisfaction relation $\models_O^{spr}$.*

3. MODEL CHECKING KBDI LOGIC

The model checking problem is to give an algorithm to test whether a model satis es a concerned speci cation expressed by a formula. However, in order to make our model checking algorithm practically useful, we must consider from where our model, an interpreted KBDI-system, comes. It would be satisfactory if we can derive our model from a program implemented in, say C or Java. However, to simplify the matter, we may consider some abstract programs such as *nite-state programs*, which are expressive enough from the standpoint of theoretical computer science. Moreover, to make our model checking system practically ef cient, we use symbolic model checking techniques. Thus, a nite-state program in our approach is represented in a symbolic way.

3.1 Symbolic Representation of Interpreted KBDI System Model

A system as a set of in nite runs is not well suited to model checking directly as it is generally applied to nite state systems. However, we can represent an interpreted system as a *nite-state program* (G, G_0, R, V), where G is a set of states, G_0 a set of initial states, and R a total next time relation, and V associates each state with a truth assignment function. A set of in nite runs is then obtained by unwinding the relation R starting from initial states in G_0.

We can present a symbolic representation of a nite-state program (G, G_0, R, V) as $(\mathbf{x}, \theta(\mathbf{x}), (\mathbf{x}, \mathbf{x}'))$. Also, we represent a system as a (symbolic) *nite-state program with n agents*, which is de ned as a tuple $\mathcal{P} = (\mathbf{x}, \theta(\mathbf{x}), (\mathbf{x}, \mathbf{x}'), O_1, \ , O_n)$, where

1. $\mathbf{x}$ is a set of system variables;
2. θ is a boolean formula over $\mathbf{x}$, called the *initial condition*;
3. is a boolean formula over $\mathbf{x} \cup \mathbf{x}'$, called the *transition relation*; and
4. for each i, O_i $\mathbf{x}$, containing agent i's *local variables*, or *observable variables*.

For convenience, we may use $\mathcal{P}(\theta, \ )$ to denote a nite-state program with n agents $(\mathbf{x}, \theta(\mathbf{x}), (\mathbf{x}, \mathbf{x}'), O_1, \ , O_n)$, if $\mathbf{x}$ and $O_1, \ , O_n$ are clear from the context.

Given a nite-state program $\mathcal{P}(\theta, \ )$ with n agents , we de ne an *agent's internal program* over $\mathcal{P}(\theta, \ )$ as a tuple

$$\langle \mathcal{P}(\theta_1, \ _1), \mathcal{P}(\theta_2, \ _2), \mathcal{P}(\theta_3, \ _3) \rangle$$

where, for $j = 1, 2, 3$, $(\theta_j \Rightarrow \theta) \wedge \ _j \Rightarrow$ is valid, and $(\theta_2 \Rightarrow \theta_1) \wedge \ _2 \Rightarrow \ _1$ is valid.

Clearly, an agent's internal program is exactly related to an agent's mental state. Thus, we de ne a (symbolic) *BDI-program with n agents* as a tuple $P_A = (\mathcal{P}_K, P_1, \ , P_n)$, where $\mathcal{P}_K$ is a nite-state program with n agents and for each agent i, P_i is agent i's internal program over $\mathcal{P}_K$. We use I_{P_A} to denote the corresponding interpreted KBDI-system .

3.2 Simpli ed BDI Programs

To obtain a BDI-program with n-agents, one should de ne $1 + 3n$ nite-state programs. Our experience with a previous version of **MCKBDI** indicated that it is inconvenient for a programmer to code a BDI-program with n-agents because there may be many nite-state programs involved. Therefore, we should simplify the de nition of a BDI-program with n-agents.

DEFINITION 4. *Let $\mathcal{P} = (\mathbf{x}, \theta(\mathbf{x}), (\mathbf{x}, \mathbf{x}'), O_1, \ , O_n)$ be a nite-state program with n-agents, where, for each agent i, O_i contains at least 3 particular boolean variables $\mathtt{WB}_i$, $\mathtt{WD}_i$ and $\mathtt{WI}_i$. A simpli ed BDI-program with n-agents derived from $\mathcal{P}$ is a tuple $(\mathcal{P}, P_1, \ , P_n)$, where for each agent i, $P_i = \langle \mathcal{P}(\theta_1^i, \ _1^i), \mathcal{P}(\theta_2^i, \ _2^i), \mathcal{P}(\theta_3^i, \ _3^i) \rangle$ such that*

1. $\theta_1^i = \theta \wedge \mathtt{WB}_i$ *and* $\ _1^i = \ \wedge \mathtt{WB}_i$;
2. $\theta_2^i = \theta \wedge \mathtt{WB}_i \wedge \mathtt{WD}_i$ *and* $\ _2^i = \ \wedge \mathtt{WB}_i \wedge \mathtt{WD}_i$;
3. $\theta_3^i = \theta \wedge \mathtt{WI}_i$ *and* $\ _3^i = \ \wedge \mathtt{WI}_i$.

It is more convenient for a programmer to code a simpli ed BDI-program with n-agents, and it seems that the notion of a simpli ed BDI-Program does not lose much generality of that of a BDI-Program.

4. CONCLUDING REMARKS

We have proposed a new KBDI-model by using interpreted systems, and developed a computationally grounded BDI logic, called KBDI logic. We interpret KBDI logic via two different semantics. One of them is based on the assumption that agents have perfect recall and there is a global clock, with respect to which a sound and complete proof system has been presented. We have explored how symbolic model checking techniques can be applied to model checking BDI-agents and obtained encouraging preliminary experimental results.

This paper is inspired by Su [11] and Su *et al* [12], which also provide agent models by extending the interpreted system model. However, Su [11] does not consider agents' belief, desire and intention. The main advantages of the present paper over Su *et al* [12] are: (1) We introduce, for each agent i, not only belief, desire and intention modalities B_i, D_i and I_i, but also a knowledge modality K_i. Moreover, the resulting axiomatic system is more succinct and proved to be sound and complete. (2) A model checker with KBDI-models, called **MCKBDI**, is developed.[1] Empirical results are more comprehensive, supported by convincing and motivating examples, where agents' observations and actions are explicitly de ned.

Model checking multi-agent systems has become an active research topic in the community of multi-agent systems. Many efforts have been devoted to model checking knowledge in multi-agent systems [5, 13, 11, 7]. However, comparatively little work has been carried out on model checking BDI-agents. Some general approaches to model checking BDI-agents were proposed in Rao and Georgeff [9] and Benerecetti and Cimatti [1], but no method was given for generating models from actual systems, and so the techniques given there could not easily be applied to verifying real multi-agent systems. In Bordini *et al* [2], model checking techniques for AgentSpeak(L) [8] have been reported; however, AgentSpeak(L) has very simple semantics. The salient point of our work is that we present a general form of a BDI agent program, from which BDI agent models are generated and speci cations in full BDI logics can be veri ed by symbolic model checking techniques.

ABSTRACT

Agent-mediated electronic institutions belong to a new and promising field where interactions between a group of agents are regulated by means of a set of explicit norms. Current implementations of such open-agent systems are, however, mostly using constraints on the behaviour of the agents, thereby severely limiting the autonomy of the agents. To increase the autonomy of agents and possibly boost the efficiency of the overall system, a more flexible norm enforcement is required. However, as norms make extensive use of vague and ambiguous concepts and lack operational meaning (not expressing how the norm should be enforced), translating norms for usage with such a flexible enforcement mechanism might be difficult. In this paper we propose an extension to electronic institutions to allow for a flexible enforcement of norms, and manners to help overcome the difficulties of translating abstract norms.

1. INTRODUCTION

Agent-mediated institutions, introduced in [12, 13], are open agent systems that allow agents to enter and perform tasks. Because of the heterogeneous nature of the agents joining an electronic institution (e-institution), measures have to be taken to control and regulate the behaviour of these agents. These measures are needed to improve and guarantee the safety and stability of the system, as agents joining the institution might, (un)intentionally, break the system by behaving in non-expected or non-accepted manners. It has been widely accepted that norms can be used for ensuring this safety, since norms, which are vague and abstract in order to express various, different circumstances without the need for change, can be used for defining the legality and illegality of actions (and states) in e-institutions [3].

For these norms to be used in e-institutions, thereby regulating the agents joining the institution, enforcement mechanisms must be devised to implement them.Although the norms should be available to the agents joining the institution to allow them to work more efficiently in the regulated domain, it is not the agents reasoning and trying to adhere to the norms that provides the safety that the institution needs; it is the institution itself that has to ensure that this safety exists. This enforcement of norms, as discussed in [14], comes down to either: 1) defining constraints on unwanted behaviour, or 2) detecting violations of norms and reacting to these violations. The first approach is simpler and used by current implementations of e-institutions such as [5]. However, it seriously reduces the autonomy of the agents. To allow the agents in e-institutions more freedom and flexibility, while still complying to the norms, we would like to extend the implementation of e-institutions with the second approach to enforcement.

Previous work on normative systems (mainly focussed on deontic frameworks [10]) is mostly *declarative in nature*, while the implementation of norms and norm enforcement in e-institutions, as mentioned above, requires norms to have an *operational semantics* as well. Where the declarative nature of norms is necessary for reasoning about norms (reasoning about what is and what is not accepted), the operational semantics define how norms are to be implemented (e.g. what to do when norms are violated). Recent approaches on normative systems have begun to research

and express this operational meaning of norms, as seen in [14, 1, 11, 7]. These approaches represent norms and their operational meaning, but are not conclusive on how the implementation in an agent system, such as an e-institution, should be obtained. In this paper we are trying to bridge this gap, by proposing a translation from the (operational) approach proposed in [14] to elements usable for norm enforcement in AMELI ([5]).

In this paper we assume institutions to be defined as a set of norms, which are to be enforced by a distributed set of (internal) agents. Secondly we assume that the norms can sometimes be violated by agents in order to keep their autonomy, which can also be functional for the system as a whole as argued in [2]. The violation of norms is handled from the organisational point of view by violation and sanction mechanisms. And finally, we assume that the internal state of agents is neither visible, nor controllable from an institution's point of view, which, basically, means that enforcement of norms can only use the observable behaviour of agents to detect the violations.

2. IMPLEMENTING NORMS

E-institutions, as viewed here [4, 12, 13], are agent environments that restrict the behaviour of agents to ensure that agents interact in safe conditions. E-institutions constrain agent behaviour by defining the valid sequences of (dialogical) interactions that agents can have to attain their goals.

In order to be able to handle violations of norms we need a manner to express the violations that can occur in an institution, for which we introduce *integrity constraints* (derived from [6]):

DEFINITION 1. *Integrity constraints are first-order formulas of the form*

$$\left(\bigwedge_{i=1}^{n} uttered(s_i, w_{k_i}, \boldsymbol{i}_{l_i}) \wedge \bigwedge_{j=0}^{m} e_j\right) \rightarrow \bot$$

where s_i are scene identifiers or variables, w_{k_i} is a state k_i of scene s_i or a variable, $\boldsymbol{i}_{l_i}$ is an illocution scheme l_i matching the schema labelling an outgoing arc from w_{k_i} and e_j are boolean expressions over variables from uttered predicates.

Integrity constrains define sets of states that *should not* occur within an e-institution, i.e. if grounded illocutions matching the illocution schemes $\boldsymbol{i}_{l_1}, \ldots, \boldsymbol{i}_{l_n}$ are uttered in the corresponding scene states, and expressions $e_1, \ldots, e_m$ are satisfied, then a violation occurs ($\bot$).

This, however, is not enough to implement norms, as we need to define the reactions to the violations of the norms as well. These reactions (normally seen as sanctions and repairs, [14]) are expressed by using *dialogical constraints*:

DEFINITION 2. *Dialogical constraints are first-order formulas of the form:*

$$\left(\bigwedge_{i=1}^{n} uttered(s_i, w_{k_i}, \boldsymbol{i}^*_{l_i}) \wedge \bigwedge_{j=0}^{m} e_j\right) \Rightarrow \left(\bigwedge_{i=1}^{n'} uttered(s'_i, w'_{k_i}, \boldsymbol{i}'^*_{l_i}) \wedge \bigwedge_{j=0}^{m'} e_j\right)$$

where s_i, s'_i are scene identifiers or variables, w_{k_i}, w'_{k_i} are variables or states of scenes s_i and s'_i respectively, $\boldsymbol{i}^*_{l_i}$, $\boldsymbol{i}'^*_{l_i}$ are illocution schemes l_i matching the schema labelling an outgoing arc from w_{k_i} of scenes s_i and s'_i respectively, and e_j, e'_j are boolean expressions over variables from uttered predicates. These boolean expressions can include functions to check the state of the institution.

The intuitive meaning of a dialogical constraint is that, if the violation of the norm has been detected (expressed in the left-hand side of the constraint), the enforcers in the e-institution become obliged to perform a specific pattern of illocutions to punish the violator (this sanction is expressed in the right-hand side of the constraint).

The integrity constraints are then implemented in the infrastructure of the e-institutions, thereby providing the means to detect violations of norms, where the dialogical constraints are implemented in the enforcing agents which use them to determine the illocutions that should be uttered when a norm has been violated (thereby punishing the agent that violated the norm).

Semantics of the mentioned constraints, and an implementation for the AMELI platform can be given, but is omitted here due to space limitations.

3. CONTEXTUALISING NORMS

In the previous section we described how norm enforcement could be implemented in AMELI. However, the description of the norms should be given completely in terms of the utterances used in the e-Institution. However, usually norms are described in more abstract terms and need first to be "contextualised". The following norm, expressed in the formalism developed in [14]:

OBLIGED($(buyer$ DO $pay(Price,seller))$ IF $done(buyer,won(Item,Price)))$

can be translated into the utterances that would be used in an e-institution:

$uttered(payment,W,inform(A,buyer,B,payee,pay(Item,Price),T))$
$uttered(auction,w2,inform(C,auctioneer,A,buyer,won(Item,Price),T'))$

However, if we regard institutional norms that are derived (or translated) from human laws and regulations, the contextualisation becomes much harder, as laws contain vague and ambiguous concepts and cannot always be related to a single integrity constraint. In order to implement such norms with a high level of abstraction two steps must be taken: 1) interpreting the abstract concepts and link them to concrete concepts used in the institution (by using a *counts as* operator as described in [8, 9]), and 2) adding procedural information and artifacts to the institution to simplify (or allow) the enforcement of the norm.

The operational approach to norms developed in [14] tries to implement norms from an institutional perspective. It views norms as a way to describe how someone should behave. The norm frame used in this approach contains the *norm condition*, which defines obligations, permissions and prohibitions also known as the *declarative meaning of norms* (cf. [10]), of which an example was given above. However, since a system needs responses to the violations that occur, the norm frame also includes a definition of the responses to violations of the norms, which are known as sanctions and repairs (also known as the *operational meaning of the norm*). Finally, the norm frame includes the *violation condition* (obtained from the norm condition to express when a violation occurs) and the *detection mechanisms* (to describe the available resources on the platform that can be used for detecting violations).

Norms expressed in this formalism can be translated to

the constraints mentioned earlier. The integrity constraint is directly derivable from the violation condition of the formalism of [14]. Dialogical constraints are then formed by combining the violation condition and responses of the system to violations. For instance, if a norm with sanction S and repairs R (which can be obtained from the norm framework), can be translated to the integrity constraint $IC \rightarrow \bot$, the following rule can be created (automatically) to oblige the enforcers to utter the illocution (DC) that is derived from contextualising S and R:

$$IC \Rightarrow DC$$

Since these dialogical constraints are considered obligations to the enforcers, we can specify another integrity constraint to detect that this obligation has been violated, which is when the original norm was violated, but the enforcer did not punish the violating agent.

$$(IC \wedge \sim DC) \rightarrow \bot$$

4. CONCLUSIONS

With the development of electronic institutions, with the aim of implementing normative open-agent systems, comes the problem of ensuring the safety and stability of the system. Previous implementations of electronic institutions enforced norms by ensuring that the agents joining the system followed a pre-defined protocol, thereby guaranteeing norm compliance of the agents. As this approach severely limits the autonomy of the agents, a more flexible enforcement was desired. This paper proposes the use of integrity constraints and dialogical constraints to implement such a flexible enforcement of norms. This norm enforcement is based on the detection of and reacting to violations of norms.

In order for any kind of norm enforcement to be implemented, norms need to be expanded with an operational meaning, as the declarative nature of norms only defines what is legal/illegal, but never expresses how this legality/illegality is obtained/averted. In [14] we introduced several mechanisms for operationalising norms, where we annotated norms (expressed in deontic logic) with operational aspects, like sanctions and repairs. In this paper we have used this normative frame to design an implementation scheme usable for implementing norm enforcement in electronic institutions. However, before norms can be implemented using this scheme, the norms need to be contextualised. This contextualisation amounts to 1) connecting the abstract concepts of the norm to the concrete concepts used in the institution, and 2) extending the norm with additional procedural information before attempting to implement it. The contextualisation of the norms is, in fact, a further operationalisation of the norms, where, in contrast to declarative norms (which never change the world), the second step of this operationalisation changes the world in order to enforce the norm.

ABSTRACT

We investigate the dynamics of nested beliefs in the context of agent interactions. Nested beliefs represent what agents believe about the beliefs of other agents. We consider the *tell* KQML performative which allows agents to send their own beliefs to others. Whenever agents accept a new belief, or refuse to change their own beliefs after receiving a message, both receiver and sender enrich their nested beliefs by refining their beliefs about the other agent's beliefs, as well as the preferences of the other agent. The main objective of nested beliefs is to improve cooperation between agents. We propose a logical framework for the acquisition process of nested beliefs and preferences. This acquisition process is the first step toward the elaboration of sophisticated interaction protocols. In this short paper we provide an informal outline of the framework, guided by an intuitive running example.

Keywords

multi-agent systems, reasoning about action, belief revision

1. INTRODUCTION

In a multi-agent context *nested beliefs* represent what agents believe about the beliefs of other agents. Nested beliefs improve interaction and cooperation among agents [5, 2, 10, 14]. Few papers deal with the problem of how agents acquire nested beliefs [9, 4]. None of them considers this in the context of cooperative dialogues. We propose an acquisition process for nested beliefs which describes how agents construct nested beliefs as they receive information.This provides the foundation on which we can build sophisticated dialogues or cooperation protocols.

We consider multi-agent dialogues based on the *tell* KQML performative [6] which enables an agent to send a message to inform a receiver agent that a statement holds in its own belief base. We suppose that the sender provides the *source* of this statement [12]. The receiver may accept or ignore the incoming statement leading to non-prioritised revision of basic beliefs [8]. To perform revision agents need to be able to define preferences over their basic beliefs and thus the incoming statement may be considered as less preferred than conflicting basic beliefs. Preferences over basic beliefs is obtained by maintaining preferences over agents at the origin of basic beliefs, representing the reliability of the statement origin.

Based on this we define the acquisition of nested beliefs for the receiver of a *tell* performative. Regardless of the acceptance of the *tell* performative, the receiver is informed that the sender believes the incoming statement. After a *tell* performative the receiver performs non-prioritised revision on its nested beliefs about the sender. Since the sender provides the source of its beliefs, the receiver can deduce the nested preferences of the sender. The sender can also enrich its nested beliefs in several ways. For this, we introduce two performatives *accept* and *deny* which enable the receiver agent to inform the sender whether or not it actually changed its own beliefs after a *tell*. Using these performatives the sender can enrich its nested beliefs in several ways. After an *accept* the sender believes that the receiver believes in the content of the *tell*. If, during the revision process, an inconsistency occurs in the nested beliefs of the receiver, the sender can refine its knowledge about the preferences of the receiver. This is also the case after a *deny* statement.

To illustrate the issues involved, consider the following example. Agent Peter receiving messages from agent Paul and the police department. Suppose Peter considers Paul to be less reliable than the police department. At time 0, Paul tells Peter that *John is a murderer* (origin Paul). At time 1 Peter accepts the message. At time 2, Paul tells Peter that *if John is a murderer, John will go to jail* (origin Paul). Peter accepts the message and consequently Peter believes that *John will go to jail* at time 3. In addition, Peter believes that Paul believes both statements. After the second accept, Paul also believes that Peter believes both statements. At time 4, the police department tells Peter that *John is not a murderer* (origin Police). Because of its preferences, Peter accepts message at time 5 and now believes *John is not a murderer*. In addition, Peter believes that the police department believes *John is not a murderer*. After the accept message, the police believes that Peter believes *John is not a murderer*. Because it believes that Paul still believes that *John is a murderer*, at time 6, Peter tells Paul that *John is not a murderer* and the origin of this information is the police. Whether or not Paul accepts Peter's message, Paul has to change its nested beliefs about Peter. Paul now believes that Peter believes *John is not a murderer* and that Peter considers the police to be more reliable than himself.

The paper is structured as follows. Section 2 sketches a logical framework for reasoning about nested beliefs, preferences and the performatives *tell*, *accept*, and *deny*. Sections 3 and 4 give an overview of the mutual enrichment for the receiver and the sender. We conclude with a discussion on related, and future work.

2. THE LOGICAL FRAMEWORK

The *belief state* of an agent contains basic beliefs as well as nested beliefs. The basic beliefs of an agent a, denoted by B_a, are represented as signed statements, each consisting of a propositional sentence and the agent id of the source of the statement. Every agent a also maintains a set of signed statements for each of the other agents, representing what each of them currently believes, according to a (the nested beliefs of a). $B_{a,b}$ denotes what agent b believes according to agent a. We also assume that agents have preferences, arranged as a total preorder, over the set of agents A which describe the reliability of the sources of information [3, 12]. So $b \preceq_a c$ means: agent c is at least as preferred as b for agent a ($b \prec_a c$ and $b =_a c$ have the obvious meanings). Agents can also handle nested preferences. $c \preceq_{a,b} d$ means: agent a believes that for agent b agent d is at least as preferred as c. Together, these constitute the preference state of the agent.

We first present the language $\mathcal{L}_1$ for reasoning about basic beliefs and preferences. $\mathcal{L}_1$ is a restricted first order language which enables quantification over agent ids. It has a modal-like operator Bel for basic beliefs. $\mathsf{Bel}(a, \phi_0, t)$ means agent a believes ϕ_0 signed by t. We limit agent beliefs to propositional sentences. To represent preferences we introduce the notation $b \leqslant_a c$ which stands for: agent a considers agent c to be at least as preferred as b. We extend $\mathcal{L}_1$ to the language $\mathcal{L}_1^K$ to deal with nested beliefs. Nested beliefs are restricted to $\mathcal{L}_1$-formulae. We introduce the operator B to describe nested beliefs. Intuitively, $\mathsf{B}(a, \mathsf{Bel}(b, \phi_0, s))$ means agent a believes that agent b believes ϕ_0 signed by s, while $\mathsf{B}(a, c \leqslant_b d)$ means that agent a believes that agent b considers agent d to be at least as preferred as c. So, in our example, at time 3 agent $peter$ has the following belief state:

$$B_{peter} = \{\langle murd, paul\rangle, \langle murd \rightarrow jail, paul\rangle\}$$
$$B_{peter,paul} = \{\langle murd, paul\rangle, \langle murd \rightarrow jail, paul\rangle\}$$
$$B_{peter,police} = \emptyset$$

Considering that $peter$ does not know $paul$ and $police$'s preferences at the beginning, the preference state of $peter$ is:

$$paul \prec_{peter} peter \prec_{peter} police$$
$$paul =_{peter,paul} peter =_{peter,paul} police$$
$$paul =_{peter,police} peter =_{peter,police} police$$

We now formalise the communication between agents. We assume that agents exchange information about their basic beliefs. We represent interactions between agents using three performatives. $\texttt{Tell}(s, r, \phi_0, t)$ stands for: agent s informs r that it believes ϕ_0 signed by t according to the standard KQML semantics [6]. When receiving a `Tell` performative, agent r performs non-prioritised revision according to its preferences [8]. $\texttt{Accept}(r, s, p)$ stands for: agent r informs s that it accepts the `Tell` performative p. Let $p = \texttt{Tell}(s, r, \phi_0, t)$. Then $\texttt{Accept}(r, s, p)$ means that agent r has revised its basic beliefs by $\langle \phi_0, t\rangle$ and thus believes ϕ_0. $\texttt{Deny}(r, s, p)$ stands for: agent r informs s that it refuses to process the `Tell` performative p. If performative $p = \texttt{Tell}(s, r, \phi_0, t)$ it means that agent r has not revised its basic beliefs by $\langle \phi_0, t\rangle$.

The dynamics of the system is given by performatives. At each step one agent receives a performative and may change its state accordingly, i.e. performatives are viewed as transition functions. We extend $\mathcal{L}_1^K$ to a language $\mathcal{L}_2$ to handle performative actions by considering a modal-like action operator $[p]\phi$, which states that after performative action p, ϕ is true. With $\mathcal{L}_2$ we can specify the behaviour of agents when they interact. For instance, we can express the honesty postulate as follows.

$$[\texttt{Tell}(s, r, \phi_0, t)]\top \rightarrow \mathsf{Bel}(s, \phi_0, t) \qquad \textbf{(Hon)}$$

This postulate states that if a `Tell` performative occurs, then at the same time the sender believes the corresponding signed statement. Postulates such as (Hon) place constraints on the logical framework, ensuring that it behaves as required. Due to lack of space we shall, in the rest of the paper, only provide informal descriptions of the postulates required for our framework. The first such postulate, (KeNB1), requires that the nested beliefs and preferences of agents not involve in a dialogue do not change, and that the dialogue between the sender and the receiver is a two step process: first a `Tell` and then an `Accept` or a `Deny`.

3. DYNAMICS OF THE RECEIVER

In this section, we discuss the dynamics of the nested beliefs and nested preferences of agent r for the $\texttt{Tell}(s, r, \phi_0, t)$ performative, and then consider the acknowledgement sent by agent r to agent s. The nested beliefs and preferences of all agents except s have to remain unchanged. (KeNB2) propagates them to the next state and ensures that no new nested beliefs or preferences appear. Also, agent r changes its beliefs about s, whether or not it ignores the input statement. Because agents are supposed to be honest, agent r performs a standard prioritised revision of its nested beliefs about s by signed statement $\langle \phi_0, t\rangle$. (AdNB1) states that after the `Tell` performative r believes that s believes ϕ_0 and thus does not believe $\neg\phi_0$ anymore (because belief states are consistent). (ProNB1) states that all nested beliefs which hold after the `Tell` performative also hold at the previous state or are consequences of the new nested belief $\mathsf{B}(r, \mathsf{Bel}(s, \phi_0, t))$. (AdNB1) and (ProNB1) describe the expected behaviour of a revision operator for the nested beliefs but do not specify which nested beliefs have to be removed to facilitate the removal of $\neg\phi_0$ from the nested beliefs of r, since we do not insist on a specific method for revising nested beliefs.

(KeNP1) states that nested preferences about all agents except s are unchanged: it propagates them to the next state and ensures that no new preference appears. If agent r currently believes that s believes $\neg\phi_0$ signed by t' then it refines the s preferences as follows. According to the honesty principle and (AT) (see below), t is better than t'. (AdNBP1) formalises this intuition. (KeNP2) requires that the nested preferences of agent s about all agents except t are unchanged. But if r does not believe that s believes $\neg\phi_0$ then it cannot draw conclusion about agent s preferences. Agent r can refine preferences only if it faces inconsistencies during the revision process. (KeNP3) states that if r does not believe that s believes $\neg\phi_0$ then all nested preferences about s are unchanged.

This bring us to the receiver's acknowledgement. Whenever agent r receives $\texttt{Tell}(s, r, \phi_0, t)$, r determines if its beliefs are consistent with ϕ_0, and if not, which beliefs have to be dropped by taking into account its preference relation. Due to the non-prioritised aspect the receiver may deny or accept the `Tell` performative. If agent r believes $\neg\phi_0$ and the signatures of $\neg\phi_0$ are at least as preferred as t (the signature of ϕ_0), postulate (DT) requires that agent r deny the `Tell` performative. Otherwise there is no conflict or t is strictly more preferred than all the signatures of $\neg\phi_0$, and postulate (AT) requires that r accept the `Tell` performative.

4. DYNAMICS OF THE SENDER

In this section we describe the dynamics of the sender's nested beliefs and preferences with respect to the performatives `Accept` and `Deny`. (KeNB3) states that the nested beliefs of agents not involved in the `Accept` or `Deny` performative do not change. Next, we focus on the nested beliefs about r. According to (AT), if r accepts the message of s, agent s believes that r believes ϕ_0 and thus does not believe $\neg\phi_0$, as specified by (AdNB3). According to (DT), if r refuses the `Tell` performative then s concludes that r believes $\neg\phi_0$, as specified by (AdNB2). Like (ProNB1), postulates (ProNB2) and (ProNB3) state that all nested beliefs holding at the next state also hold at the current state, or are consequences of the new nested belief $\mathsf{B}(r, \mathsf{Bel}(s, \phi_0, t))$. So in both cases, s nested beliefs about r undergoes a prioritised revision: by $\langle \phi_0, t\rangle$ in the case of `Accept`, and by $\langle \neg\phi_0, t\rangle$ in the case of `Deny`.

This bring us to the sender's nested preferences. (KeNP4) states that the sender's nested preferences about agents other than r do not change. Next, agent s draws conclusions about t depending on whether r accepts or refuses a `Tell` performative. Whenever agent r accepts, agent s refines its nested preferences only if s currently believes that r believes $\neg\phi_0$. In that context s refines agent r's preferences. (AdNP2) requires that t be strictly more preferred than the signatures of $\neg\phi_0$ if r accepts the performative $\texttt{Tell}(s, r, \phi_0, t)$. (AdNP3) requires that if r refuses the message, the nested preferences of s about the signatures of $\neg\phi_0$ change. According to condtion (DT) they have to be as preferred as t. Finally, (KeNP5) and (KeNP6) deal with those nested preferences, about r, of s that do not change. They are similar to (KeNP2) and (KeNP3).

We now conclude our example. At time 4, the $police$ tells $peter$ that *John is not a murderer*, and $peter$ accepts it.

$$p_4 = \texttt{Tell}(police, peter, \neg murd, police)$$
$$p_5 = \texttt{Accept}(peter, police, p_4)$$

By (AdNB1) and (AdNB3) we get the new nested beliefs:

$$[p_4]\mathsf{B}(peter, \mathsf{Bel}(police, \neg murd, police))$$
$$[p_5]\mathsf{B}(police, \mathsf{Bel}(peter, \neg murd, police)))$$

At time 1 $peter$ accepted $paul$'s message that *John is a murderer* ($murd$) which gives

$$\mathsf{B}(paul, \mathsf{Bel}(peter, murd, paul) \wedge paul =_{peter} police)$$

according to (KeNB1). At time 6, this nested belief is still true according to the accepted behaviour of nested beliefs given by (KeNB1), (AdNB3), (ProNB2) and (KeNP6). At time 6 $peter$ tells $paul$ that *John is not a murderer*: $p_6 = \texttt{Tell}(peter, paul, \neg murd, police)$.

According to (AdNB1) and (AdNP2) we obtain the following new nested beliefs and preferences for $paul$:

$$[p_6]\mathsf{B}(paul, \mathsf{Bel}(peter, \neg murd, police))$$
$$[p_6]\mathsf{B}(paul, paul <_{peter} police)$$

So, at stage 6 $paul$ has refined its nested preferences about $peter$. At the beginning of the dialogue $paul$ does not know whether $peter$ prefers $paul$ or the $police$. At stage 6, $paul$ believes that $peter$ prefers the police to himself.

5. CONCLUSION

We have outlined a framework for handling the dynamics of nested beliefs and preferences in the context of agent interactions. We proposed a logical framework which allows for the expression of nested beliefs, preferences, and performatives, and showed how agents acquire nested beliefs and preferences. For this we have specified the expected behaviour of agents handling the `Tell`, `Accept` and `Deny` performatives.

Related work includes that of [4], which proposes a logic-based definition for nested belief change and mental state construction related to agent-communication languages. Our proposal differs from theirs in that it deals with preferences of agents. Our work is also closely related to [13, 12] where it is shown how to embed basic belief change in a logical system. We extend this by considering nested beliefs and preferences. Finally, our work is loosely related to the dynamics of preferences [1]. Our contribution is to formulate this dynamics in terms of agent interactions. We plan to extend our framework by considering nested *disbeliefs* [7]. Explicit disbeliefs allow for a more nuanced type of interaction between agents and provide new opportunities for the discovery of nested beliefs and preferences. We also plan to revisit persuasion protocols [11] so that agents can generate smarter arguments.

An Architecture of a Normative System

Counts-as Conditionals, Obligations and Permissions

ABSTRACT

Normative systems are traditionally described and analyzed using deontic logic, describing the logical relations among obligations and permissions. However, there is still a gap between deontic logic and normative multi-agent systems such as electronic institutions, which may be seen as an instance of the gap between on the one hand logical agent specification languages and on the other hand agent architectures and programming languages. To bridge the gap, in this paper we propose an architecture containing separate subsystems or components for counts-as conditionals, conditional obligations and conditional permissions. We add a norm database component in which the three kinds of rules are stored, and we use a channel based coordination model to describe the relations among the four normative components.

General Terms

MAS theory

Keywords

Normative systems, normative multi-agent systems

1. NORMATIVE ONTOLOGY

Searle [13, 14] distinguishes two types of norms: "Some rules regulate antecedently existing forms of behavior. For example, the rules of polite table behavior regulate eating, but eating exists independently of these rules. Some rules, on the other hand, do not merely regulate an antecedently existing activity called playing chess; they, as it were, create the possibility of or define that activity. The activity of playing chess is constituted by action in accordance with these rules. Chess has no existence apart from these rules. The institutions of marriage, money, and promising are like the institutions of baseball and chess in that they are systems of such constitutive rules or conventions" [13, p. 131].

Thus far the two kinds of norms have mainly been studied in isolation, which raises the question how regulative and constitutive norms are related. In the deontic logic literature, the interaction among obligations and permissions has been studied in some depth, see, e.g., [16, 7, 12]. In most formalizations, obligations, prohibitions and permissions have a conditional nature. Their conditions could directly refer to entities and facts of the commonsense world, but they often refer to a legal and more abstract classification of the world, making them more independent from the commonsense view. E.g., they refer to money instead of paper sheets, to properties instead of houses and fields. This more natural and economical way to model the relation between commonsense reality and legal reality uses constitutive norms, and allows regulative norms to refer to the legal classification of reality. In this way, it is not necessary that each regulative norm refers to all the conditions involved in the classification of paper as money or of houses and fields as properties. A constitutive norm has been defined by Searle as "X counts as Y in context C", and has been formalized as a counts-as conditional [10, 3, 9, 4].

Since all kinds of norms are represented by conditionals, we can represent them as subsystems within the normative system, or as input/output components in an architecture. This raises the question what kind of input and output these components have. According to Searle, institutional facts like marriage, money and private property emerge from an independent ontology of "brute" natural facts through constitutive norms of the form "such and such an X counts as Y in context C" where X is any object satisfying certain conditions and Y is a label that qualifies X as being something of an entirely new sort. Thus, the propositions describing the world are distinguished in two categories. First, "brute facts" are natural facts and events produced by actions of agents. Second, "institutional facts" are a legal classification of brute facts; they belong only to the beliefs of the normative system and have no direct counterpart in the world. Moreover, counts-as conditionals can be iterated, in the sense that X counts-as Y and Y counts-as Z (to construct the complexity of social reality), and therefore we also allow institutional literals in X. We call a set of brute literals a brute description, a set of institutional literals an institutional description, and a set of both brute and institutional literals a mixed description.

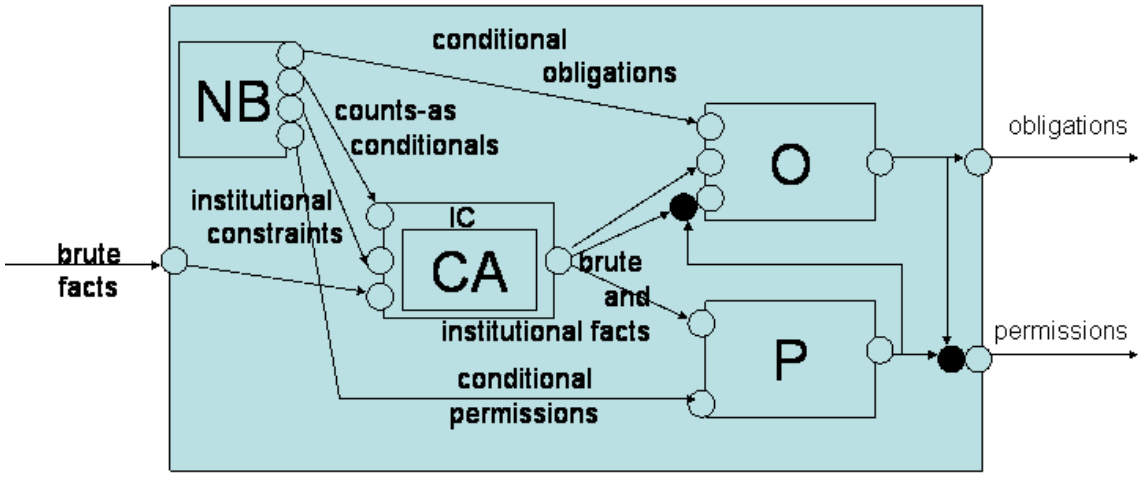

Figure 1: The Architecture of the Normative System.

2. NORMATIVE COMPONENTS

We follow the definition of normative systems proposed by Alchourrón and Bulygin [1], inspired by Tarski's definition of deductive systems. They consider as input factual descriptions and as output a classification of obligatory and permitted situations. Permissions are not closed under logical consequence, in the sense that a permission for p and a permission for $\neg p$ do not imply a permission for a contradiction. For technical reasons, we describe the permissions by sets of mixed descriptions. In our architecture, visualized in Figure 1, the input of the normative system is a context, a brute description, and the output is a set of obligations, a mixed description, and a set of permissions, a set of mixed descriptions.

There are four components in the architecture. Besides the ones for counts-as conditionals (CA), obligations (O) and permissions (P), there is a component that contains the norms (NB). The counts-as component has a wrapper (IC) to enable the connection with the other components. The components are connected by channels. The data flowing over the channels is not indexed by modal operators. So if a proposition p is flowing over a permission channel it is interpreted as a permission, usually represented in deontic logic by $P(p)$, and when it is flowing over an obligation channel it is interpreted as an obligation, usually represented by $O(p)$.

The norm database does not have any input, we therefore assume that the norms of the normative system are fixed. E.g., it can be extended with an input to update the norm database. We also assume that there can be background knowledge in the form of institutional constraints. The output contains sets of conditional obligations, conditional permissions, counts-as conditionals, and institutional constraints, four sets of pairs of mixed descriptions.

The counts-as component directly encodes Searle's conditional "X counts as Y in context C". Examples of constitutive norms are "X counts as a presiding official in a wedding ceremony", "this bit of paper counts as a five euro bill" and "this piece of land counts as somebody's private property". The input contains counts-as conditionals, X, a brute description, and C, a mixed description. The output is Y, an institutional literal.

The counts-as component is part of a component for institutional constraints, acting like a wrapper for the counts-as conditionals. Its input are the brute facts, the counts-as conditionals, and the institutional constraints. The output are the brute and institutional facts, a mixed description.

The notorious contrary-to-duty paradoxes like Chisholm's and Forrester's paradox have led to the use of constraints in deontic logic [11]. The strategy is to adapt a technique that is well known in the logic of belief change - cut back the set of norms to just below the threshold of making the current situation inconsistent. Therefore, the input of the obligation component contains conditional obligations, a set of pairs of mixed descriptions, a context, a mixed description, and constraints, a set of mixed descriptions. The output contains obligations, a mixed description.

The permission component is like an obligation component without constraints, since the issue of contrary-to-duty does not play a role for permissions. The input of the permission component is a set of conditional permissions, and a context of brute and institutional facts. As mentioned above in the description of the whole normative system, another distinction is that the output is a set of mixed descriptions. The input contains conditional permissions, a set of pairs of mixed descriptions, and a context, a mixed description. The output contains permissions, a set of mixed descriptions.

Finally, consider again the whole architecture. When designing a normative system, there is a tradeoff between obligations, permissions and counts-as conditionals, in the sense that there are many norm bases which have the same global output. For example, the same output can be obtained for example using many counts-as conditionals, or no counts-as conditionals at all. Likewise there is a tradeoff between obligations and permissions. Consequently, there is a need for a methodology to represent normative systems in our architecture. It is relatively straightforward to represent a piece of legal code in the architecture, as in legal code the three kinds of norms are usually clearly distinguished, but in general it is more problematic.

3. COORDINATION

A coordination model defines the interaction among components. In software engineering coordination models and languages based on tuplespaces are very popular, but such a coordination model does not reflect the topology of the architecture. Therefore, in this paper the coordination of the normative components is based on a channel-based coordination model. Our discussion is influenced by the coordination language Reo [2], which has also been used to coordinate agents and agent organizations [8].

Most of the channels are straightforward. The output of the norm database is connected to the input of the three other components. The output of the wrapper of the counts-as component is the context of the obligation and permission component, *et cetera*. All channels are synchronous, and we assume that they are all synchronized. This can be made explicit in the architecture. For example, in the Reo coordination language this can be achieved by connecting so-called SyncDrain channels between all channels. However, we did not represent this in the architecture to keep it as simple as possible. This synchronicity may seem like an unrealistic assumption, but it simply means that the calculation is atomic. This is a common way to model coordination in coordination languages. In actual implementations they do not have to be synchronous, but there is a mechanism in the coordination language to ensure the atomicity.

When there are multiple output channels on the same port, then the output is replicated to all channels. For example, the output of the wrapper of the counts-as component is replicated to the obligation and permission component, and the output of the permission component is replicated to the output of the normative system as well as to an input of the obligation component. When there are multiple input channels which are joined, then there are special merge nodes (a simple kind of component). In Reo there is one predefined merge as a non-deterministic choice among the inputs, if inputs are available at the same time. In the normative system architecture there are two mergers, represented by black circles. One merges the output of the counts-as component with the output of the permission component to result in the constraints for the obligation component, and the other merges the output of the obligation and permission component such that obligations are permitted. They cannot be modeled as a non-deterministic choice, but they are defined by $d \times \{d_1, \ldots, d_n\} = \{d \cup d_1, \ldots, d \cup d_n\}$. Since there are no cycles, it is straightforward to calculate the coordination.

The relation between the counts-as component and its wrapper is as follows. When the counts-as component outputs at least Y for input X and C, then the wrapper also outputs Y (and possibly more) when the input contains both X and C.

4. LOGICAL SPECIFICATIONS

The architecture is a bridge between logical specifications, for example based on deontic logic, and normative multi-agent systems. In a normative multi-agent system the components can be implemented in a variety of ways. The abstract behavior of the components and channels can be given in terms of real-timed timed data streams [2], based on general results in the Reo coordination language. The principles of deontic logic can be interpreted as functionality descriptions of the components [15, 6].

Though initially our motivation to develop the architecture of the normative system was to build such computer systems, we noticed that the architecture can be used too in deontic logic research. In particular, it can be used as a logical architecture to study interaction among logical systems by varying the logics to describe the components. For example, we can use either the logic for counts-as conditionals of Jones and Sergot [10], Artosi *et al.* [3], Grossi *et al.* [9], or our own proposal [4], and study its interaction with input/output logic [11], or some other deontic logic. To do so, we just have to find the flat conditional fragment of the logics, and ignore the modal operator. This is subject of further study [5].

ABSTRACT

We propose a non-standard semantics for Alternating-time Temporal Logic (ATL) with incomplete information, for which no commonly accepted semantics has been proposed yet. In our semantics, formulae are still interpreted with respect to ATL structures, but are interpreted in sets of states rather than in single states. We also propose a new epistemic operator for "constructive" knowledge, and we show that the new language is strictly more expressive than existing solutions, while retaining the same model checking complexity.

Alternating-time Temporal Logic, strategic ability, incomplete information, epistemic logic

1. INTRODUCTION

ATL [1] is probably the most important logic of strategic ability that has emerged in recent years. A combination of ATL and epistemic logic, called ATEL, was introduced in [9] to enable reasoning about agents acting under incomplete information. Still, it has been pointed out in several places that the meaning of ATEL formulae is somewhat counterintuitive. A number of ATEL revisions were proposed to overcome this problem [3, 5, 8, 6, 10, 2], yet none of them seems to be the ultimate definitive solution. Our aim is to come up with a logic of ability under incomplete information which is both general and elegant.

In this paper, we propose a non-standard semantics for the logic of strategic ability and incomplete information. In the semantics, formulae are interpreted over *sets of states* rather than single states. This reflects the intuition that the "constructive" ability to enforce φ means that the agents in question have a single strategy that brings about φ for *all* possible initial situations – and not that a successful strategy exists for *each* initial situation (because those could be different strategies for different actual situations). To do it in a flexible and general way, the type of the satisfaction relation in our proposal forces one to specify the set of initial states explicitly. In consequence, we write $M, Q \models \langle\langle A \rangle\rangle \varphi$ to express the fact that A must have a strategy which is successful for all states in a set Q. It should be emphasized that we do not propose new *models*: concurrent epistemic game structures have already been used for several years in ATEL-like logics. What we propose is a new *interpretation of formulae*. We also propose a new epistemic operator for "practical" or "constructive" knowledge that yields the set of states for which a single evidence (i.e., a successful strategy) should be presented (instead of checking if the required property holds in each of the states separately, like standard epistemic operators do). The new semantics and operators are presented in Section 3.

2. WHAT AGENTS CAN ACHIEVE

In this section, we present a very brief overview of ATL and its extensions for agents with incomplete information.

Alternating-time Temporal Logic. ATL [1] can be understood as a generalization of the branching time temporal logic CTL, in which path quantifiers are replaced with so called *cooperation modalities*. Formula $\langle\langle A \rangle\rangle \varphi$, where A is a coalition of agents, expresses that A have a collective strategy to enforce φ. ATL formulae include temporal operators: "$\bigcirc$" ("in the next state"), $\Box$ ("always from now on") and $\mathcal{U}$ ("until"). The semantics can be defined using *concurrent game structures*, each including: agents $\mathbb{A}\mathrm{gt} = \{1, \ldots, k\}$; states St; actions Act; atomic propositions Π; valuation $\pi : St \rightarrow \mathcal{P}(\Pi)$; function $d : \mathbb{A}\mathrm{gt} \times St \rightarrow \mathcal{P}(Act)$ defining actions available to an agent in a state; and a transition function o assigning an outcome state $q' = o(q, \alpha_1, \ldots, \alpha_k)$ to state q and tuple of actions $\langle \alpha_1, \ldots, \alpha_k \rangle$ that can be executed by $\mathbb{A}\mathrm{gt}$ in q. A *strategy* $s_a : St \rightarrow Act$ is a conditional plan that specifies what $a \in \mathbb{A}\mathrm{gt}$ is going to do in every possible situation. A *collective strategy* S_A is a tuple of strategies, one per agent from $A \subseteq \mathbb{A}\mathrm{gt}$. A *path* Λ in model M is an infinite sequence of states that can be effected by subsequent transitions. Function $out(q, S_A)$ returns the set of all

paths that may result from agents A executing strategy S_A from state q onward. Informally speaking, $M, q \models \langle\langle A\rangle\rangle\varphi$ iff there is a collective strategy S_A such that φ holds for every $\Lambda \in out(q, S_A)$.

Alternating-time Temporal Epistemic Logic. ATEL [9] adds to ATL operators for representing agents' knowledge: $K_a\varphi$ reads "agent a knows that φ". Additional operators $E_A\varphi$, $C_A\varphi$, and $D_A\varphi$ refer to "everybody knows", common knowledge, and distributed knowledge among the agents from A. Models for ATEL extend concurrent game structures with indistinguishability relations $\sim_1, ..., \sim_k \subseteq Q \times Q$ (one per agent) for modeling agents' uncertainty. Then: $M, q \models K_a\varphi$ iff φ holds for every q' such that $q \sim_a q'$.

Relations $\sim_A^E$, $\sim_A^C$ and $\sim_A^D$, used to model group epistemics, are derived from the individual relations of agents from A. First, $\sim_A^E$ is the union of relations $\sim_a$, $a \in A$. Next, $\sim_A^C$ is defined as the transitive closure of $\sim_A^E$. Finally, $\sim_A^D$ is the intersection of all the $\sim_a$, $a \in A$. Then, for $\mathcal{K} = C, E, D$: $M, q \models \mathcal{K}_A\varphi$ iff φ holds for every q' such that $q \sim_A^{\mathcal{K}} q'$.

Problems with ATEL. It has been pointed out in several places that the meaning of ATEL formulae is somewhat counterintuitive [3, 5, 6]. Most importantly, one would expect that an agent's ability to achieve φ should imply that the agent has enough control and knowledge to *identify* and *execute* a strategy that enforces φ. This problem is closely related to the distinction between knowledge *de re* and knowledge *de dicto*, well known in the philosophy of language [7]. Several variations on "ATL with incomplete information" have been proposed, yet none of them seems definitive. We summarize the most important proposals below.

ATL$_{ir}$. In the logic of ATL$_{ir}$ [8], cooperation modalities are presented with a subscript: $\langle\langle A\rangle\rangle_{ir}$ to indicate that they address agents with *imperfect information* and *imperfect recall*. Agents are required to use *uniform* strategies, i.e. ones that specify the same choices in indistinguishable states (if $q \sim_a q'$ then $s_a(q) = s_a(q')$). Formula $\langle\langle A\rangle\rangle_{ir}\varphi$ holds in M, q iff there is a uniform collective strategy S_A such that, for every $a \in A$, q' such that $q \sim_a q'$, and path $\Lambda \in out(q', S_A)$, we have that φ is true for Λ. In other words, there is a strategy such that *everybody in A knows* that executing this strategy will bring about φ. Note that it is not possible to express that A have common knowledge about the successful strategy, or that they can identify it if they share their knowledge, etc.

Alternating-time Observational Temporal Logic. ATOL, proposed independently in [5], follows the same perspective as ATL$_{ir}$. However, it includes also epistemic modalities in the object language (like ATEL), and it offers a richer language of strategic operators to express subtle differences between various kinds of collective abilities. The reading of $\langle\langle A\rangle\rangle_{\mathcal{K}(\Gamma)}\varphi$ is: "group A has a (memoryless, uniform) strategy to enforce φ, and agents Γ can identify the strategy as successful for A in the epistemic sense $\mathcal{K}$". That is, $M, q \models \langle\langle A\rangle\rangle_{\mathcal{K}(\Gamma)}\varphi$ iff there is a S_A such that for every q' such that $q \sim_\Gamma^{\mathcal{K}} q'$ and path $\Lambda \in out(q', S_A)$, φ is true for Λ. We observe that model checking ATL$_{ir}$ and ATOL is NP-complete in the size of the model and the formula [8, 4, 5].

"Feasible ATEL*".* The revision of ATEL from [6] extends ATEL with new modalities: $\langle\langle A\rangle\rangle^f$, $\langle\langle A\rangle\rangle^f_E$, $\langle\langle A\rangle\rangle^f_C$, $\langle\langle A\rangle\rangle^f_{K_a}$ and $\langle\langle A\rangle\rangle^f_{M_a}$, very similar to the ones of ATOL. The NP-completeness result carries over to "Feasible ATEL" (it subsumes ATL$_{ir}$ and can be seen as a subset of ATOL).

Other Approaches. Epistemic Temporal Strategic Logic [10] focuses on the concept of *undominated strategies*; in a way, $\langle\langle A\rangle\rangle\varphi$ in ETSL can be summarized as: "if A play *rationally* to achieve φ (meaning: they never play a dominated strategy), they will achieve φ". Another, very recent proposal [2] approaches the problem of strategic abilities within the framework of STIT (the logic of *seeing to it that*). We do not discuss these proposals further here due to lack of space.

In the original formulation of ATL, agents were assumed to have perfect recall of the game, in the sense that they could base their decisions on *sequences* of states rather than single states. Variants of ATL for perfect recall and incomplete information include ATL$_{iR}$ [8] and ATEL-R* [5]. However, as agents seldom have unlimited memory, and logics of strategic ability with incomplete information and perfect recall are believed to have undecidable model checking [1, 8], we do not investigate this kind of ability here.

3. A NEW SEMANTICS FOR ABILITY AND KNOWLEDGE, AND NEW EPISTEMIC OPERATORS

ATOL covers more cases than ATL$_{ir}$ and "Feasible ATEL", and it is not committed to any notion of rationality (unlike ETSL). One major drawback of ATOL is that it vastly increases the number of modal operators necessary to express properties of agents. For team A, a whole family of cooperation modalities $\langle\langle A\rangle\rangle_{\mathcal{K}(\Gamma)}$ is used to specify who should identify the right strategy for A, in what way etc. It would be much more elegant to modify the semantics of "simple" cooperation modalities $\langle\langle A\rangle\rangle$ and/or epistemic operators, so that they can be composed into sufficiently expressive formulae. However, the property of a strategy being successful (under incomplete information) with respect to goal φ is *not* local to the current state; *the same* strategy must be successful in all possible "opening" states. In order to capture this feature of strategic ability, we change the type of the satisfaction relation $\models$, and define what it means for a formula φ to be satisfied in a *set of states* $Q \subseteq St$ of model M. To our best knowledge, nobody has used this kind of semantics yet. Moreover, we extend the language of ATEL with unary "constructive knowledge" operators $\mathbb{K}_a$, one for each agent a, that yield the set of states, indistinguishable from the current state from a's perspective. Constructive common, "everybody's" and distributed knowledge is formalized via operators $\mathbb{C}_A, \mathbb{E}_A$, and $\mathbb{D}_A$.

3.1 Language and Semantics

The language is defined formally as follows, where $p \in \Pi$:

$$\varphi ::= p \mid \neg\varphi \mid\mid \varphi \wedge \varphi \mid \langle\langle A\rangle\rangle \bigcirc \varphi \mid \langle\langle A\rangle\rangle \Box\varphi \mid \langle\langle A\rangle\rangle \varphi \,\mathcal{U}\, \varphi \mid C_A\varphi \mid E_A\varphi \mid D_A\varphi \mid \mathbb{C}_A\varphi \mid \mathbb{E}_A\varphi \mid \mathbb{D}_A\varphi.$$

The models are again concurrent epistemic game structures, and we consider only memoryless uniform strategies. Now, we define the notion of a formula φ being satisfied by a set of states Q in a model M, written $M, Q \models \varphi$. We will also write $M, q \models \varphi$ as a shorthand for $M, \{q\} \models \varphi$. Let $\mathrm{img}(q, \mathcal{R})$ be the set of all states q' such that $q\mathcal{R}q'$. Moreover, we write $out(Q, S_A)$ for $\cup_{q\in Q} out(q, S_A)$, and $\mathrm{img}(Q, \mathcal{R})$ for $\cup_{q\in Q}\mathrm{img}(q, \mathcal{R})$. The new semantics is given through the

clauses below. Individual knowledge operators can be derived as: $K_a\varphi \equiv C_{\{a\}}\varphi$ and $\mathbb{K}_a\varphi \equiv \mathbb{C}_{\{a\}}\varphi$.

$M, Q \models p$ iff $p \in \pi(q)$ for every $q \in Q$, when $p \in \Pi$;
$M, Q \models \neg\varphi$ iff $M, Q \not\models \varphi$;
$M, Q \models \varphi \wedge \psi$ iff $M, Q \models \varphi$ and $M, Q \models \psi$;
$M, Q \models \langle\langle A\rangle\rangle \bigcirc \varphi$ iff there exists S_A such that, for every $\Lambda \in out(Q, S_A)$, we have that $M, \{\Lambda[1]\} \models \varphi$;[1]
$M, Q \models \langle\langle A\rangle\rangle \Box\varphi$ iff there exists S_A such that, for every $\Lambda \in out(Q, S_A)$ and $i \geq 0$, we have $M, \{\Lambda[i]\} \models \varphi$;
$M, Q \models \langle\langle A\rangle\rangle \varphi\, \mathcal{U}\, \psi$ iff there exists S_A such that, for every $\Lambda \in out(Q, S_A)$, there is an $i \geq 0$ for which $M, \{\Lambda[i]\} \models \psi$ and $M, \{\Lambda[j]\} \models \varphi$ for every $0 \leq j < i$;
$M, Q \models \mathcal{K}_A\varphi$ iff $M, q \models \varphi$ for every $q \in \mathrm{img}(Q, \sim_A^{\mathcal{K}})$,
$M, Q \models \hat{\mathcal{K}}_A\varphi$ iff $M, \mathrm{img}(Q, \sim_A^{\mathcal{K}}) \models \varphi$
(where $\hat{\mathcal{K}} = \mathbb{C}, \mathbb{E}, \mathbb{D}$ and $\mathcal{K} = C, E, D$, respectively).

3.2 Expressing Agents' Strategic Abilities

$M, q \models \mathbb{K}_a\langle\langle a\rangle\rangle\varphi$ expresses the fact that a has a single strategy that enforces φ from *all* states indiscernible from q, instead of stating that φ can be achieved from *every* such state *separately*. Note that the latter property is very much in the spirit of standard epistemic logic, and indeed can be captured with the standard knowledge operator (as $K_a\langle\langle a\rangle\rangle\varphi$). More generally, the first kind of formulae refers to *having a strategy "de re"* (i.e. having a successful strategy and knowing the strategy), while the latter refers to *having a strategy "de dicto"* (i.e. only knowing that *some* successful strategy is available; cf. [5]). Note also that the property of having a winning strategy for the current state (but not necessarily even knowing *about* it) is simply expressed with $\langle\langle a\rangle\rangle\varphi$. Capturing different ability levels of *coalitions* is analogous, with various "epistemic modes" of collective recognizing the right strategy.

THEOREM 1. *Let φ be a formula of* ATL$_{ir}$, ATOL *or "Feasible* ATEL*", and let tr be as follows:*

$$tr(p) = p \qquad tr(\neg\varphi) = \neg tr(\varphi)$$
$$tr(\varphi \wedge \psi) = tr(\varphi) \wedge tr(\psi) \qquad tr(\bigcirc\varphi) = \bigcirc tr(\varphi)$$
$$tr(\Box\varphi) = \Box tr(\varphi) \qquad tr(\varphi\, \mathcal{U}\, \psi) = tr(\varphi)\, \mathcal{U}\, tr(\psi)$$
$$tr(\langle\langle A\rangle\rangle_{ir}\varphi) = \mathbb{E}_A\langle\langle A\rangle\rangle\varphi \qquad tr(\langle\langle A\rangle\rangle_{\mathcal{K}(\Gamma)}\varphi) = \hat{\mathcal{K}}_\Gamma\langle\langle A\rangle\rangle\varphi$$
$$tr(\langle\langle A\rangle\rangle^f\varphi) = \langle\langle A\rangle\rangle\varphi \qquad tr(\langle\langle A\rangle\rangle^f_{\mathcal{K}}\varphi) = \hat{\mathcal{K}}_A\langle\langle A\rangle\rangle\varphi$$
$$tr(\langle\langle A\rangle\rangle^f_{K_b}\varphi) = \mathbb{K}_b\langle\langle A\rangle\rangle\varphi \qquad tr(\langle\langle A\rangle\rangle^f_{M_b}\varphi) = \neg K_b\neg\langle\langle A\rangle\rangle\varphi$$
$$tr(\mathcal{K}_A\varphi) = \mathcal{K}_A tr(\varphi)$$

where $\mathcal{K} = C, E, D$ and $\hat{\mathcal{K}} = \mathbb{C}, \mathbb{E}, \mathbb{D}$, respectively. Then:

$$M, q \models \varphi \text{ iff } M, q \models tr(\varphi).$$

REMARK 2. *The new language is strictly more expressive than* ATL$_{ir}$, ATOL *etc.: for example, formula $\mathbb{E}_A\mathbb{E}_A\langle\langle A\rangle\rangle\varphi$ cannot be expressed in any of the former logics.*

3.3 Model Checking

We define *general model checking* as the problem that asks whether formula φ holds in model M and *set of states* Q. Let $mctl(\varphi, M)$ be a CTL model checker that returns the set of all states that satisfy φ in M. Below, we sketch algorithm $mcheck(\varphi, M, Q)$ that returns "yes" if $M, Q \models \varphi$ and "no" otherwise, running in nondeterministic polynomial time.

- Cases $\varphi \equiv p, \varphi \equiv \neg\psi, \varphi \equiv \psi_1 \wedge \psi_2, \varphi \equiv \mathcal{K}_A\psi$: straightforward (proceed as usually).
- Case $\varphi \equiv \hat{\mathcal{K}}_A\psi$: return $mcheck(\psi, M, \mathrm{img}(Q, \sim_A^{\mathcal{K}}))$.
- Case $\varphi \equiv \langle\langle A\rangle\rangle \bigcirc \psi$: run $mcheck(\psi, M, q)$ for every $q \in St$, and label the states in which the answer was "yes" with a new proposition p. Then, guess the strategy of A, and "trim" model M by removing all the transitions inconsistent with the strategy (yielding a sparser model M'). Return "yes" iff $Q \subseteq mctl(\mathsf{A}\bigcirc\mathsf{p}, M)$. [For other temporal operators: analogous.]

Note that all the relevant strategies can be guessed *beforehand*, as a single complex (but still polynomial) witness (cf. [4]), which gives us the following result:

THEOREM 3. *General model checking for our logic is NP-complete in the size of the model and the formula.*

4. CONCLUSIONS

In this paper, we propose a non-standard semantics for the modal logic of strategic ability under incomplete information, in which formulae are interpreted over *sets of states* rather than single states. Moreover, we introduce new epistemic operators for "constructive" knowledge. It turns out that, in this new semantics, simple cooperation modalities $\langle\langle A\rangle\rangle$ can be combined with "constructive" epistemic operators into sufficiently expressive formulae. Indeed, the new logic *is strictly more expressive than most existing* ATL *versions for incomplete information*, while it retains the same model checking complexity as the least costly of them. The philosophical dimension of constructive knowledge is also natural: the constructive knowledge operators capture the notion of *knowing "de re"*, while the standard epistemic operators refer to *knowing "de dicto"*. We believe that we have finally obtained a satisfying logic of agents' strategies under uncertainty, and at the same time have come up with novel, meaningful epistemic operators that capture important properties of the interaction between knowledge, action and ability.

ABSTRACT

In multi-agent systems, it has long been recognized that the traditional approaches to protocols which often used a fixed sequence of interactive actions as the basis are too brittle, and more flexible methods are needed. A crucial aspect of the development of such methods is the notion of commitments, which provides a mechanism for regulating interactions between agents. In this paper we investigate a rule-based approach to the specification of flexible protocols by means of a reasoning system which incorporates both temporal reasoning and resources-based reasoning and uses the notion of commitments.

1. INTRODUCTION AND BACKGROUND

In traditional approaches to protocol specification, like those using Finite State Machines or Petri Nets in distributed computing or computer networks, protocols are often predetermined legal sequences of interactive behaviors. In frequently changing environments such as the Internet, such fixed sequences can quickly become outdated and are prone to failure. Hence, protocols in such environments need to be flexible, and in particular, interaction protocols should ensure that agents have autonomy over their interactive behaviors. Also, agents should be allowed to adjust their interactive actions to take advantages of opportunities or handle exceptions that arise during interaction.

Our approach is to specify protocols in a declarative manner, i.e. in terms of what is to be achieved rather then how agents should interact. The concept of *commitments* is used to allow agents to perform means-end reasoning to determine an appropriate course of action. We do this reasoning in *temporal linear logic* [3], which combines temporal and resource-sensitive reasoning. It is well-known that temporal logic, in particular, is quite suitable for describing and reasoning about temporal constraints, and has been used in many agent systems. It is also known that linear logic is suitable for modeling resources [1]. Hence we used temporal linear logic to construct a commitment based interaction framework which allows both temporal and resource-related reasoning for interaction protocols.

A commitment refers to a strong promise to undertake some courses of action. Persistence in commitments gives agents a certain level of predictability about the actions of other agents, which is fundamental for issues of interdependencies, global constraints or resource sharing [4]. Commitments have been adapted to make protocols more flexible via commitment machines [6]. Conventions are also used to provide monitoring mechanisms for commitments.

In linear logic, formulas are constrained to be used exactly once and hence treated as resources. The connective $\otimes$ also allows a natural expression of proportion. If A encodes "having one dollar" then $A \otimes A \neq A$ and means having two dollars. Moreover, as remarked in [2], connectives $\&$ and $\oplus$ allow choices to be made clear between internal choices (one's own), and external choices (others' choice). For instance, to specify that the choice of places A or B for goods' delivery is ours as the supplier, we use $A\&B$, or is the client's, we use $A \oplus B$. Linear logic is a natural mechanism to provide the ability to match consumption and supply of resources among agents and hence can simplify the specification of resource allocation [2].

Temporal Linear Logic (**TLL**) [3] is the result of introducing temporal logic into linear logic and hence is resource-conscious as well as deals with time. The temporal operators used are $\bigcirc$ (next), $\Box$ (anytime), and $\Diamond$ (sometime) [3]. Formulas with no temporal operators can be considered as being available only at present. Adding $\bigcirc$ to a formula A, i.e. $\bigcirc$A, means that A can be used only at the next time

and exactly once. Similarly, $\Box$A means that A can be used exactly once and at any time, and the choice is internally decided, as appropriate to one's own capability. $\Diamond A$ means that A can be used once at some time and the choice of time is externally decided by others.

Section 2 introduces our framework based around an example of online sale interactions. Then we discuss the advantages and limitations of using our framework to model interaction protocols and achieve flexibility as well as conclusions.

2. OUR FRAMEWORK

2.1 Encoding In Temporal Linear Logic

We consider encoding of resources, capabilities and commitments in agent interaction.

A unit of consumable resources is modeled as a proposition. We also include information about the location and ownership into the encoding of resources. We denote $A@\alpha_{\alpha}$ as that a resource A is located at (@) and owned (subscript $_{\alpha}$) by agent α and is equivalent to $A \otimes Locate(A, \alpha) \otimes Own(A, \alpha)$. Numeric figures are further used to abbreviate a multiplicative conjunction of the same instances. For instance, 2 $dollar = dollar \otimes dollar$. Moreover, such $\bigcirc^3 A$ is a shorthand for $\bigcirc \bigcirc \bigcirc A$.

The capabilities of agents refer to producing, consuming and relocating resources. The general representation form is $\Gamma \multimap$, in which Γ describes the conditions before and describes the condition after an application of the capability.

We model non-conditional commitments by negative formulas. For example, a commitment to provide a cricket bat is represented as $cricket\_b^{\perp}$. A non-conditional commitment is resolved when the committed agent brings about the respective resource or action as required by the commitment, which means there is a presence of a formula like $cricket\_b$, which can remove the negative formula.

A conditional commitment to bring about some effects given certain conditions can be modeled by connecting the conditions to the effects via a linear implication. A general form is $\Gamma \multimap$ where Γ is the condition part and is the effect part. If the condition Γ is derived, by consuming Γ, the linear implication will ensure that is resulted. If the conditions can not be achieved, the linear implication can not be applied and hence the commitment is then released.

Capabilities and conditional commitments, despite their distinct meanings, can be viewed as rules of interaction. Protocols can then be specified by appropriate interaction rules.

2.2 Example Scenario

We consider agents whose states are determined by a set of resources available, interaction rules and capabilities together with commitments. The scenario is an on-line sale of cricket bats from a merchant (Mer) to a customer (Cus).

At agent Cus

Cus has an amount of 50 dollars available at any time, and can pay by credit card: $\Box\$50@C \otimes \Box credit\_paym@C_C$.

Cus has a commitment of obtaining 2 cricket bats at some time: $[\Diamond(2cricket\_b@C_C)]^{\perp}$.

At agent Mer

Mer has available at any time 200 cricket bats for sale and 20 gifts: $200 \Box cricket\_b@M_M \otimes 20 \Box gift@M_M$.

Rule 1: Mer commits offering two cricket bats and a gift ($2cricket\_b@M_M^{\perp} \otimes gift@M_M^{\perp}$) to Cus ($2 \Box cricket\_b@C_C \otimes \Box gift@C_C$) if Cus pays 20 dollars ($20\$@C_C$) either via Paypal ($Paypal@C_C$) or by credit card ($credit\_paym@C_C$). The choice is at Cus. There are only 30 promotional offers like this.

$30 \Box [20\$@C_C \otimes (Paypal@C_C \oplus credit\_paym@C_C)$
$\multimap 20 \Box \$@M_M \otimes 2 \Box cricket\_b@C_C \otimes 2[cricket\_b@M_M]^{\perp} \otimes \Box gift@C_C \otimes gift@M_M^{\perp}]$

Rule 2: Similarly, Mer will offer a cricket bat to Cus if Cus pays 10 dollars either via Paypal or by credit card. Access to rule 2 can be times, up to Mer's policy.

$\Box [10\$@C_C \otimes (Paypal@C_C \oplus credit\_paym@C_C)$
$\multimap 10 \Box \$@M_M \otimes \Box cricket\_b@C_C \otimes cricket\_b@M_M^{\perp}]$

2.3 Interaction

To achieve goals, agents use TLL inference rules to construct proofs from state formulas and interaction rules. A simple model of negotiation is used. A rule can be proposed to another agent as a commitment it is willing to take. If the other agent agrees, both agents are involved in the commitment. Otherwise, the other agent can reject the proposal or counter-propose another rule.

The interaction begins by Cus trying to fulfill its pending commitment.

1. Cus asks Mer for two cricket bats to be delivered to Cus at some time.

C to M: **REQUEST** $[\Diamond(2cricket\_b@C_C)]^{\perp}$

To meet the request, Mer looks for applicable rules. One application of rule 1 or two applications of rule 2 at present or any future time t can derive $\bigcirc^t 2 \Box cricket\_b@C_C$ or $2 \bigcirc^t \Box cricket\_b@C_C, t \geq 0$ and either of them can remove $[\Diamond(2cricket\_b@C_C)]^{\perp}$.

2. Mer will propose each rule to Cus. n is any time up to Mer's choice. With similar analyzes, Cus determines that given their conditions can be satisfied, the proposals can help to derive its request.

We assume that Cus decides that it prefers having a gift and hence it will accept the proposal of rule 1 and refuse the proposal of rule 2.

M to C: **PROPOSE** $\bigcirc^n [20\$@C_C \otimes (Paypal@C_C \oplus credit\_paym@C_C) \multimap 20 \Box \$@M_M \otimes 2 \Box cricket\_b@C_C \otimes 2[cricket\_b@M_M]^{\perp} \otimes \Box gift@C_C \otimes gift@M_M^{\perp}]$

C to M: **ACCEPT**

M to C: **PROPOSE** $\bigcirc^n [10\$@C_C \otimes (Paypal@C_C \oplus credit\_paym@C_C) \multimap 10 \Box \$@M_M \otimes \Box cricket\_b@C_C \otimes cricket\_b@M_M^{\perp}]$

C to M: **REFUSE**

The conditions of the accepted proposal at the application time $n1$ is $\bigcirc^n (20\$@C_C \otimes (Paypal@C_C \oplus credit\_paym@C_C))$. One way to satisfy the conditions is for Cus, at the next n time points, to derive 20 dollars($\bigcirc^n 20\$@C_C$); and to pay via Paypal ($\bigcirc^n Paypal@C_C$) OR to pay by credit card ($\bigcirc^n credit\_paym@C_C$).

3. $\bigcirc^n 20\$@C_C$: as Cus has 50 dollars, it can use 20 dollars: $20 \Box \$@C_C \vdash \Box 20\$@C_C \vdash \bigcirc^n 20\$@C_C$.

There are two options for payment, the choice ($\oplus$) is at agent Cus.

4. We assume that Cus decides to use credit payment. We have $\Box credit\_paym@C_C \vdash \bigcirc^n credit\_paym@C_C$

5. (3) and (4) together allow the initial proposal to be applied to derive $\bigcirc^n \Box gift@C_C$ and $\bigcirc^n 2 \Box cricket\_b@C_C$ for Cus and commitments of Mer of $\bigcirc^n gift@M_M^{\perp}$ and $\bigcirc^n 2[cricket\_b@M_M]^{\perp}$, which are also resolved by the re-

sources $\Box gift@M_M$ and $2\Box cricket\_b@M_M$ available at Mer ($\bigcirc^n gift@M_M^{\perp} \otimes \Box gift@M_M \vdash \perp$ and $\bigcirc^n 2[cricket\_b@M_M]^{\perp} \otimes 2 \Box cricket\_b@M_M \vdash \perp$). Also, any value of n that satisfies $n \geq 0$ will allow Mer to fulfill Cus's initial request of $[\Diamond(2cricket\_b@C_C)]^{\perp}$. The interaction succeeds as all commitments are resolved.

2.4 Flexibility

The flexibility desired has been achieved in the example. Mer can choose the time n to apply the sale proposal. In step 2, Cus can choose among the sale proposals offered by Mer to explore the opportunity in the promotional period. Also, it is Cus's decision to proceed with the preferred payment method - step 4. Moreover, attempts at deriving 20 dollars in step 3 or carrying out payment - step 4 - can be switched order, as can be the attempts of Mer at fulfilling the commitments of giving 2 cricket bats and giving the gift in step 5.

3. DISCUSSION AND FURTHER WORK

The basic execution mechanism can be defined by proof construction, i.e. building a proof of the goal formula from the current state and the interaction rules. This means that an appropriate interaction sequence for the agents can be extracted from this proof.

As we have seen, TLL allows a natural and expressive specification of sequences of agent interaction. Temporal operators ($\bigcirc$, $\Box$ and $\Diamond$) and their combinations help to allocate resources or actions in time and express the time order of events. Linear implication ($\multimap$) can express a removal or a consumption together with its consequences. Hence, "consumed resources $\multimap$ produced resources" models resource transformation; "a resource at one agent $\multimap$ that at another agent" models resource relocation; "a resource owned by one agent $\multimap$ one owned by another agent" models ownership change; and "one state $\multimap$ another" models state update. Linear implication also reinforces the commitments that effects achieved only when their conditions are fulfilled.

Furthermore, given that flexibility includes the ability to make a sensible choice, having the choices expressed explicitly ($\&, \oplus, \Diamond$ and $\Box$) in the specification of interaction protocols provides agents with an opportunity to reason about the right choices during interaction and hence explore the flexibility in them.

In addition, by having the order of rules' applications be determined dynamically by the proof construction rather than be predefined, agents can gain flexibility. Moreover, because changes in the environment can be regarded as removing or adding formulas onto the current state formulas, the proof construction by agents on the current state formulas may require a different set of interaction rules to be used for interaction. This alteration of interactive behaviors to deal with changes brings flexibility into agent interaction.

Moreover, as the proof construction selects a sequence of interaction rules for interaction, selecting from all the possible combinations of interaction rules as in our framework gives more chances and flexibility than selecting from a few fixed (predefined) sequences. It is also more likely for agents to handle exceptions or explore opportunities that arise.

However, as all the temporal operators in TLL refer to concrete time points, one drawback is that we can not express durations in time faithfully. One major disadvantage of simulating a duration of an event by spreading copies of that event over adjacent time points continuously (like $\bigcirc A \otimes \bigcirc^2 A \otimes \ldots \bigcirc^{10} A$) is that it requires the time range to be provided explicitly.

Another disadvantage of our approach is that the rules for interaction require some detailed knowledge of the formulas of temporal linear logic. Clearly it would be beneficial to have a visually-based tool similar to UML diagrams which would allow non-experts to specify the appropriate rules without having to learn the details of the formulas themselves.

Similar works in [5] explore the advantages of TLL by using partial deduction techniques to help agents figure out the missing capabilities or resources and based on that, to negotiate with other agents about cooperation strategies. Our approach differs in bringing the concept of commitment into the modeling of interaction, and providing a more natural and detailed map for specifying interaction, especially about choices, time and updating using the full propositional TLL.

Many other approaches like using Commitment Machines [6] to model protocols use the commitment concept to bring more meaning into agents' interactive actions and hence allow them to be more flexible. However, these approaches use logic systems that are limited in their expressiveness to model resources.

Our further work will include using TLL to verify various properties of interaction protocols such as liveness and safety. Also, we will investigate modeling commitments that can be breached together with the conventions that monitor agents' handling of commitments. This also includes managing conflicts among commitments.

ABSTRACT

This paper is concerned with the problem of obtaining predictable interactions between groups of agents in open environments when individual agents do not expose their BDI logic. The most popular approaches to this in practise have been to model interaction protocols and to model the deontic constraints imposed by individual agents. Both of these approaches are appropriate and necessary but their combination creates the practical problem of ensuring that interaction protocols come into contact with agents that possess compatible deontic constraints. This is essentially an issue of property checking dynamically at run-time. We show how model checking can be applied to this problem.

1. INTRODUCTION

One of the most fundamental challenges of multi-agent system engineering is to enable predictable, reliable interaction amongst groups of agents without requiring a deep standardisation of the way in which they are engineered and while preserving as much as possible of their autonomy in individual reasoning. It is not plausible that agents built independently and with no agreement on forms of interaction could be predictably reliable, so researchers have searched for ways of standardising some aspects of coordination in the hope that this small amount of standardisation would provide predictability sufficient for important tasks. Two contrasting approaches to this problem have emerged:

- The use of explicit **models of interactions** (in a generic process or state-machine language) along with mechanisms by which agents can locate, reason about and participate in models of interaction that they judge appropriate. These are built to describe forms of interaction (thus are detached from individual agents) and typically are accessed when an agent anticipates it wants to initiate or join that type of interaction.
- The specification of constraints imposed by individual agents on the interactions they will allow: **deontic constraints**. These are built locally for an individual agent and typically accessed when a specific interaction is anticipated with an individual agent.

These two approaches are compatible, in the sense that they attack different aspects of a similar problem. They have not, however, been combined. Hitherto, this has not been a major problem, because neither approach had significant user communities. Those now are developing so that it is of practical importance to have a way of answering the question "Given an interaction model and an agent with given deontic constraints wishing to participate in that model, could that combination work?" This is a difficult question because both interaction models and deontic constraints are sophisticated logical objects, so the inference involved is not (say) simple term matching or subsumption. It also is difficult because in practise the question must be answered automatically and in real time, so inference mechanisms must be self contained and efficient. We show how a lightweight dynamic model checker can tackle this problem by allowing agents to invoke it at interaction time for verifying both the interaction and deontic models.

2. MOTIVATING EXAMPLE

Let us consider the travel agency scenario [1], where a customer agent, interested in making flight and hotel reservations, contacts a broker to find the most suitable travel agent for this scenario. The travel agent will have to deal with airline web services, query a hotel directory, and confirm customer's payments via a credit card web service.

The interaction model will specify the global rules of interaction. For example, it sates that the interaction starts

when the customer agent sends it vacation details (dates / destination) to the travel agent. Then, the travel agent sends a query to the involved airline web services with the given vacation details, and so on. The interaction model may be thought of as a state-space graph that specifies the allowed order of message passing actions between agents.

On the other hand, the deontic model specifies local individual constraints imposed on the various agents involved in the interaction. For example, a constraint on the broker agent is to not accept a travel agent that has no access to the selected hotel directory. Several constraints may be imposed on the customer agent. For example, it might not have access to a *MasterCard*, or it may be forced to encrypt its messages in a specific technology, say OpenPGP only. Similarly, other agents would have other sets of constraints.

The system is modelled through the combination of interaction and deontic models (Figure 1). Note that unlike the global interaction model which constructs a unique state-space graph for coordinating interactions, the deontic model is a collection of the involved agents' local constraints. These constraints could address a diverse collection of issues. They are usually used to tackle issues such as access control, authorisation, authentication, trust, security, etc.

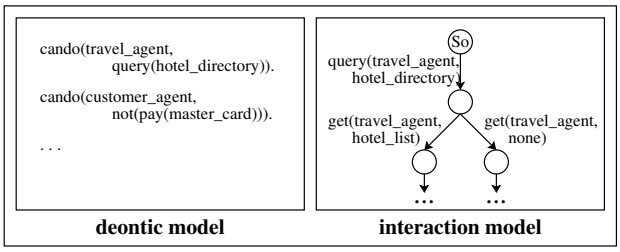

Figure 1: A conceptual model of the system model

Now let us consider the following complication. The customer agent contacts the broker agent requesting an appropriate travel agent. With the broker being responsible for finding suitable agents for a given interaction protocol, it should also be capable of verifying, at interaction time, that the protocol it has instantiated with agents is likely to work. This, however, relies on the correctness of the interaction protocol as well as the compatibility of the chosen agents. For example, trying to ally the customer agent with a travel agent that does not have access to a hotel directory will result in a scenario failure, regardless of whether the interaction protocol itself is error free or not. This requires a verifier that can handle both interaction and deontic constraints, and is capable of operating automatically at run-time.

3. DESIGN & IMPLEMENTATION PLANS

Our goal is to achieve a verifier which could be used by agents at interaction time for verifying MAS through the verification of the interaction and deontic rules. Figure 2 illustrates our design plan.

Because open systems consist of autonomous agents, it is necessary for agents to be capable of automatically verifying, at run-time, dynamic protocols affected by dynamic deontic rules. We choose model checking from amongst other verification techniques because it provides a fully automatic verification process which could be carried out by the agents

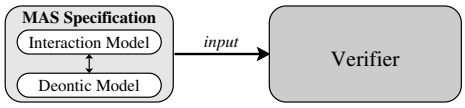

Figure 2: Design plan

during interaction time.

The Model Checking Problem. The model checking problem can be defined as follows: *Given a finite transition system S and a temporal formula ϕ, does S satisfy ϕ?* The model checking process is divided into three stages: modelling, specification, and verification. The system to be verified must first be modelled in the language of the model checker S. The properties (ϕ) to which the system model is verified upon should be specified using the model checker's temporal logic. Both the system model and the properties specification are fed to the model checker for verification. The model checker is, essentially, an algorithm that decides whether a model S satisfies a formula ϕ. In our case, the system model is a combination of interaction and deontic models. Figure 3 illustrates our model checking process.

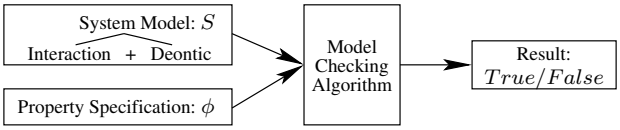

Figure 3: The model checking process

We choose the lightweight coordination calculus (LCC) [4] for specifying our interaction model, some policy language for specifying the deontic model, and the μ-calculus temporal logic for property specifications. The model checking technique implemented is a logic-based local model checking technique. The LCC language provides us with an executable specification that allows interaction models to be portable, and hence shared and global. This also supports dynamic model checking, where agents can automatically retrieve the protocol state and feed it to the model checker for verification. LCC also links cleanly to traditional process calculi used in model checking. The combination of μ-calculus and a logic-based local model checking technique results in an extremely compact size model checker, which actually throws the burden of the state-space search on the underlying tabled Prolog system. While [2] explores these issues in detail, this paper presents a higher-level description of the dynamic model checker irrespective of the specification details.

4. DYNAMIC MODEL CHECKING

At interaction time — when the conditions for verification are met and the related deontic models are obtained — the agent, interested in the satisfaction of property ϕ with respect to a given scenario, feeds the lightweight model checker with the following:

- the system model S (e.g. Figure 1), which consists of:
  - a global interaction model
  - a set of local deontic models
- the property ϕ to be verified

4.1 Example revisited

Figure 4 provides a section of the file that is fed to the model checker by the broker agent for verifying the travel agency scenario it is about to instantiate. The interaction model is a shared global model that specifies the rules of the interaction. The interaction model section presented in Figure 4 deals with a section of the interaction between the travel agent and the customer agent. More specifically, it shows that when the customer agent sends its chosen flight, the travel agent reacts by querying the hotel directory and sending a list of available hotels for the customer to choose from. The interaction model, written in LCC, is essentially a specification of the interaction's state-space graph.

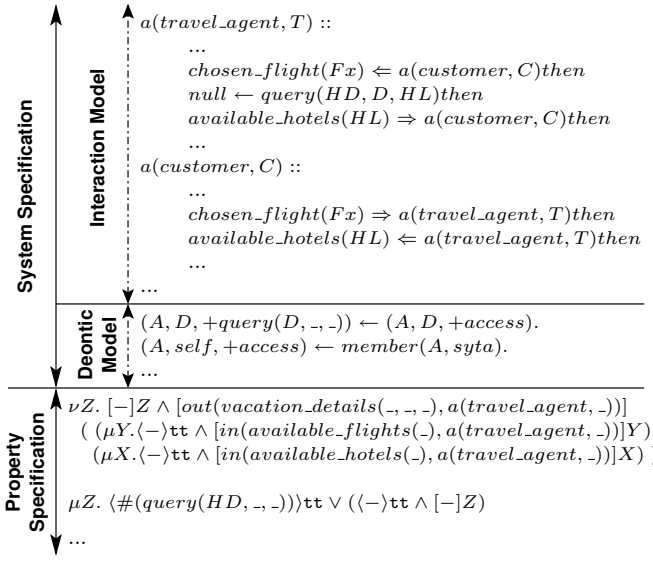

Figure 4: System model fed to the model checker

The deontic rules are constraints on the various agents engaged in the interaction. Unlike the interaction model, these do not impose constraints on the message passing action, but on any other action an agent can take. The first rule in the sample presented by Figure 4 specifies that an agent can query a directory only if it has access to it. This rule would belong to the broker agent who is interested in picking the right travel agent. The second rule specifies that an agent might access the directory only if it was a member of the student youth travel association (*stya*). This rule would belong to the hotel directory for specifying the appropriate authorisations.

Finally, the system model is to be verified against a given set of properties. The 'property specification' section of Figure 4 provides a sample of the properties that could be verified for our travel agency scenario. The first specifies that if the customer agent requests a vacation package, it will always eventually receive a list of flights and hotels. The second property specifies that in every run of the interaction, it is always the case that the hotel directory is eventually queried.

Now when the broker needs to verify that the interaction protocol will work properly for the selected set of agents, it will feed the file presented by Figure 4 to the dynamic model checker. The verification process is outlined below.

4.2 The verification process

The interaction model, specified with the LCC process calculus, is essentially a specification of the interaction's state-space graph. While global model checking is based on generating the whole state-space, local model checking partially constructs the state-space one step at a time until a solution is reached. Verification, in the case of our local model checker, starts at the initial state s_0 and tries to verify that the property ϕ is satisfied at s_0[1]. If it succeeds, the verifier terminates and the property is said to be *satisfied*. Otherwise, the verifier attempts to make a transition(s) to the next state(s) in the state-space[2]. If the transition(s) violates any of the deontic rules, then the verification process terminates and the property is *not satisfied*. Otherwise, the satisfaction of the property ϕ is verified with respect to the new state(s), and the whole process is repeated all over again.

This method raises two questions: (1) how do we ensure termination? and (2) how do we ensure correctness? Inspired by the XMC model checker [3], we build our model checker on top of XSB [5], a tabled Prolog system. Caching in tabled Prolog ensures termination, avoids redundant subcomputations, and computes the well-founded model of normal logic programs. Our model checker, unlike XMC, accepts LCC interaction models in parallel with deontic models.

5. CONCLUSION

This paper presents a verification technique for predicting and preventing failure — due to errors within the interaction protocol, conflicts between the interaction protocol and agents' rules and requirements, as well as clash of interests between agents — as early as possible in MAS scenarios. This is made possible by allowing the agents to invoke the model checker at runtime, when the conditions for verification are met, and verify that certain properties hold for the given combination of a shared interaction model and agents' local deontic models.

ABSTRACT
This paper presents an agent-oriented requirements engineering approach that combines informal *i** models with formal specifications in the CASL language through the use of Intentional Annotated Strategic Rationale diagrams. In the resulting framework, agent goals and knowledge are represented as their mental states, which allows for the formal analysis of, among other things, agent interactions and incomplete knowledge. CASL models can also serve as high-level specifications for multiagent systems.

1. INTRODUCTION
Agent technology is well-suited for constructing applications that are open, distributed, and adaptable to change. We need software engineering methods that are tailored for designing systems with multiple communicating agents that strive to achieve their assigned goals thereby delivering the desired application.

In requirements engineering (RE), *goal-oriented approaches* (e.g., Tropos [1]) have become prominent. In Goal-Oriented Requirements Engineering (GORE) high-level stakeholder objectives are modeled as goals and refined into fine-grained requirements or environment expectations. Their reliance on goals makes GORE methods and agent-oriented software engineering a great match. Therefore, it is natural to use a goal-oriented requirements engineering approach when developing MAS. With GORE, it is easy to make the transition from the requirements to the high-level MAS specifications. In this context, while it is possible to informally analyze small systems, formal analysis is needed for any realistically-sized one. Thus, the aim of this work is to devise an agent-oriented requirements engineering approach with a formal component that supports reasoning about agents' goals (and knowledge), thereby allowing for rigorous formal analysis of the requirements expressed as the objectives of the agents in a MAS.

In our approach, we integrate the *i** goal-oriented modeling framework [11] with CASL [8], a formal agent-oriented specification language that supports the modeling of agent mental states. This gives the modeler the flexibility and intuitiveness of the *i** notation as well as the powerful formal analysis capabilities of CASL. To bridge the gap between informal *i** diagrams and formal CASL specifications we propose an *intermediate notation* that can be easily obtained from *i** models and then mapped into CASL. With our *i**-CASL-based approach, a CASL model can be used both as a requirements analysis tool and as a formal high-level specification for a multiagent system that satisfies the requirements. This model can be formally analyzed using the CASLve [9] tool or other tools and the results can be fed back into the requirements model.

2. BACKGROUND
*i** [11] is an agent-oriented modeling framework used for requirements engineering, etc. The *i** framework has two main components. Firstly, the *Strategic Dependency (SD) model* provides an external view of actors and the intentional dependencies between them. There can be four types of dependencies based on what is being delegated – a goal, a task, a resource, or a softgoal dependency. Secondly, the *Strategic Rationale (SR) model* describes the internals of actors (see Figure 1). The same four types of nodes are used in SR models along with task decompositions and means-ends links. Softgoals are used to represent non-functional requirements. Softgoal contribution links in SR models specify how process alternatives fare with respect to quality concerns. In Figure 1, we see a fragment of an (annotated) SR model showing the interactions between a meeting initiator agent (MS) and a meeting scheduling system agent (MS). The MS depends on the MI for information on the suggested meeting date range. The diagram shows how some of the agents' tasks are decomposed.

The Cognitive Agents Specification Language (CASL) [8] is a formal specification language that combines theories of action [6] and mental states [7] expressed in the situation calculus [5] with ConGolog [2], a concurrent, non-deterministic agent-oriented

programming language with a formal semantics. CASL specifications consist of two parts: the model of the domain and its dynamics (the declarative part) and the specification of the agents' behaviour (the procedural part). The domain is modeled in terms of *agents*, *primitive actions* executed by agents, *situations*, which are states of the domain that result from the execution of sequences of actions, and *fluents*, which are predicates and functions that may change from situation to situation. Axioms of the following types are used: *action precondition axioms*, *successor state axioms* (SSA) [6] that specify how primitive actions affect fluents, and *initial state axioms* describing the initial state of the domain and the initial mental states of the agents. Agent behaviour is specified using a rich high-level programming language with recursive procedure declarations, loops, conditionals, non-determinism, concurrency, and interrupts [2].

CASL supports formal modeling of agents' goals and knowledge based on a *possible worlds semantics* incorporated into the situation calculus, where situations are viewed as possible worlds [7]. **Know***(agt,φ,s)* specifies that an agent knows some formula *φ*, while **Goal***(agt,ψ,s)* indicates that in situation *s* the agent *agt* has the goal that *ψ* holds. We commonly use the formula **Goal***(agt,***Eventually***(ψ),s)* to state that *agt* has the goal that *ψ* is eventually true. Primitive communication actions such as `request`, `inform`, and `cancelRequest` are defined, which affect the mental states of the agents involved in the obvious way.

3. THE APPROACH

3.1 Increasing Precision with iASR Models

Our goal is to tightly associate *i** models with formal specifications in CASL. The standard SR diagrams are geared to informal analysis and are imprecise. For instance, they do not provide any information on whether subtasks are to be executed sequentially or concurrently, under certain conditions, etc. However, CASL is a precise language. To handle this mismatch we use Intentional Annotated SR (iASR) models, which are precise graphical representation for the procedural part of CASL specifications.

To develop an iASR diagram for an actor, one starts with the regular SR diagram for that actor. It then can be appropriately transformed to become an iASR model every element of which can easily be mapped into CASL. The main steps for producing iASR models from SR ones are discussed below.

Annotations. The main tool for disambiguating SR models is *annotations* – textual constraints on SR models [10]. *Composition annotations* (sequence (";"), concurrency ("||"), prioritized concurrency (">>"), and alternative ("|")) are applied from right to left and specify how the subtasks/subgoals are to be combined to execute the supertask or achieve the goal. *Link annotations* are applied to subtasks/subgoals and specify how/under what condition they are supposed to be achieved/executed. These annotations are: *while* loop, *for* loop, *if* condition, the pick (non-deterministic choice of argument), the interrupt, and the guard (it blocks execution until its condition becomes true). The latter two are commonly used modify agents' behaviour based on changes in their mental states. *Applicability condition annotations* specify when the goal achievement alternatives are applicable.

Softgoals. Softgoals are imprecise and thus cannot be handled in a formal specifications language. Therefore, softgoals are used to choose the best process alternatives and then are removed before iASR models are produced. Alternatively, softgoals can be operationalized or metricized, thus becoming hard goals.

Providing agent interaction details. While *i** abstracts from modeling agent interaction details, CASL models requests for services, monitoring for such requests, etc., which are important for formally analyzing MAS. Thus, high-level aspects of agent interaction must be specified in iASR models. In the iASR model in Figure 1 we can see that the interaction between the MS and the MI to exchange the meeting date range information has been specified. Note the use of the interrupt annotation that triggers when the MI acquires the goal to inform the MS about the meeting the date range following the MS's request. We can see here how the goals of individual agents are explicitly modeled. iASR models can also refer to agents' knowledge. For example, the guard annotation on the MS ensures that it can only proceed when it knows the date range.

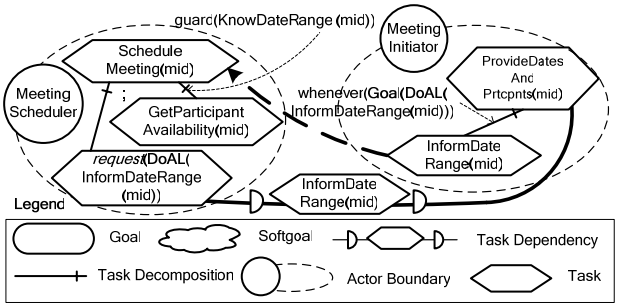

Figure 1. Adding agent interaction details to iASR model.

3.2 Mapping iASR Diagrams into CASL

Once all the necessary details have been introduced into an iASR diagram, it can be mapped into the corresponding formal CASL model, thus making the iASR model amenable to formal analysis.

The modeler defines a mapping **m** that maps every element (except for intentional dependencies) of an iASR model into CASL. This mapping associates iASR model elements with CASL procedures, primitive actions, and formulas so that a CASL program can be generated from an iASR model. Specifically, agents are mapped into CASL procedures that specify their behaviour; roles and positions (these can be played/occupied by agents) are mapped into similar procedures with an agent parameter so that they can be instantiated by individual agents; leaf-level task nodes are mapped into CASL procedures or primitive actions; composition and link annotations are mapped into the corresponding CASL operators, while conditions present in the annotations map into CASL formulas. Non-leaf task nodes are mapped into procedures that are automatically constructed from procedures/actions corresponding to the subtasks, which are combined based on the annotations used. For example, the task `ScheduleMeeting` in Figure 1 will be mapped into the following CASL procedure:

```
proc ScheduleMeeting(mid)
  request(MS,MI,DoAL(InformDateRange(mid)));
  guard(KnowDateRange(mid)) do
    GetParticipantAvailability(mid)
  endGuard
endProc
```

A goal node is mapped into a formula (its formal definition) and an achievement procedure that is automatically constructed based on the means for achieving the goal specified in the iASR model.

Intentional dependencies are not mapped into CASL per se – they are established by the associated agent interactions. iASR tasks requesting services from agents will be mapped into actions of the type `request(FromAgt,ToAgt,`**`Eventually`**`(φ))` for achievement goals φ. To ask an agent to execute a certain known procedure, the depender must request it with: `request(FromAgt,ToAgt,`**`DoAL`**`(Procedure))`. This requests the execution of the procedure while allowing `ToAgt` to perform other activities. The service provider must monitor for its mental state changes with appropriate interrupts (see Figure 1).

3.3 Formal Verification

Once an iASR model is mapped into CASL, it is ready to be formally analyzed. One tool that can be used is CASLve [9], a theorem prover-based verification environment that can be employed to verify executability of programs, their termination, etc.

Other approaches can also be used. However, tools based on techniques like simulation work with much less expressive languages than CASL requiring simplification of CASL specifications before these methods can be used on them. For example, most simulation tools cannot handle mental state specifications; these would then have to be operationalized before simulation is performed. The ConGolog interpreter can be used to directly execute such simplified specifications, as done in [10].

If expected properties of the system are not entailed by the CASL model, it means that the model is incorrect and needs to be fixed. The source of an error found during verification can usually be traced to a portion of the CASL code and to a part of its iASR model since our systematic mapping supports traceability.

4. DISCUSSION

In the approach presented in this paper and in [4], we produce CASL specifications from *i** models for formal analysis and verification. The approach is related to the Tropos framework [1] in that it is agent-oriented and is rooted in RE concepts. Our method is not the first attempt to provide formal semantics for *i** models. For example, Formal Tropos (FT) [3] supports formal verification of *i** models through model checking. Also, in the *i**-ConGolog approach [10], on which our method is based, SR models are associated with formal ConGolog programs for simulation and verification. The problem is that in these methods, goals of the agents are abstracted out of formal specifications. This is done due to the fact that the formal components of these approaches (the model checker input language for FT and the restricted situation calculus theories for the others) do not support reasoning about agent goals (or knowledge). However, most of the interactions among agents involve knowledge exchange and goal delegation since multiagent systems are developed as social structures. Thus, complementing informal modeling techniques such as *i** with formal analysis of agent goals and knowledge is very important in the design of multiagent systems. We propose a framework where goals are not removed from the agent specifications, but are modeled formally and can be updated following requests. This allows agents to reason about their objectives. Information exchanges among agents are also formalized as changes in their knowledge state. In our approach, goals are not system-wide properties, but belong to concrete agents. The same applies to knowledge. This subjective point of view provides support for new types of formal analysis on CASL specifications. Thus, this method is more agent-oriented and allows for precise modeling of stakeholder goals. Modeling of conflicting stakeholder goals, a common case in requirements engineering, and agent negotiations is also possible. All of the above can be useful for the later stages of AOSE since most specifications of agent communications model them as changing agents' mental states. Moreover, many agent implementation languages/tools are based on models of mental states.

ABSTRACT

There are numerous cases where a reasoning agent needs to reason about the behavior of an opponent agent. In this paper, we propose a hybrid probabilistic logic language within which we can express what actions an opponent may take in a given situation. We present the syntaxis and semantics of the language, and the concept of a Maximally Probable Course of Action.

Logic for agent systems, Formal models of agency

1. INTRODUCTION

There are numerous multiagent applications where we need to build a *model* of an opponent agent. For example, consider a computer implementation of a multi-player game such as *Diplomacy* or *Civilization* — in such a game, a human (or agent) player may wish to have a model of how another player might play in order to decide on the best move or moves. Likewise, in strategic decision making applications such as negotiations, it is a good idea to have one or more models of how an opponent might behave.

Alternatively, we have been building an application for reasoning about the actions that certain tribes involved in the opium business in the Pakistan Afghanistan borderlands might take. We have been developing a set of rules that would allow us to predict what possible reactions could arise when US forces take certain actions. This has clear benefits as US forces would like to take those actions that have a desirable outcome with a high probability.

The two classes of applications - games and real world cultural reasoning scenarios - have one significant difference. Games are limited in scope and are governed by strict rules. Cultural models are less strict and operate under very different rules. Second, and more important, in the case of games, one can try to mine rules automatically from large collections of past games. In the case of cultural models, this is far harder. We are yet to see a single mined collection of rules dealing with any culture at all.

Moreover, most opponent models are *handcrafted* in a language that is selected on a case by case basis. In this paper, we develop a single uniform language called SOMA within which opponent models may be expressed *by a human* for a wide variety of applications ranging from automated game playing programs to strategic adversarial reasoning problems. Of course, in the case of games, automatically extracting models from past histories is relatively easy compared to performing similar extractions in cases where relevant histories are harder to find.

In Section 2, we develop a formal syntax for SOMA-programs. Section 3 develops a formal model-theoretic semantics for SOMA-programs, and Section 4 includes a declarative definition of the 'most probable course of action" (MPCOA) for the opponent.

2. SYNTAX OF SOMA-RULES

Throughout this paper, we assume the existence of a *reasoning agent* which wishes to model and reason about an *opponent agent*. At any given point in time, the reasoning agent may have a state. This state may allow it to, for example, record the actions she has observed an opponent making and/or include the beliefs of the reasoning agent. Without loss of generality, we will assume that the state of the reasoning agent is logically describable using an alphabet consisting of a finite set of *predicate symbols* (each with an associated arity), a finite set of *constant symbols*, and an infinite set of variable symbols. We assume that no function symbols are present. As usual, a *term* is either a constant symbol or a variable symbol. If p is an n-ary predicate symbol and $t_1, \ldots, t_n$ are all terms (resp. constants), then $p(t_1, \ldots, t_n)$ is an atom (resp. *ground* atom). The *observable state* at any given point in time is a set of ground atoms.

In addition, the reasoning agent believes in the existence of some finite set of elementary actions that the opponent can take. This set is represented by a *finite* set $\mathcal{A}$ of symbols $\mathcal{A}$ called *action symbols* disjoint from the set of predicate symbols. Every $a \in \mathcal{A}$ has an associated arity; if a is an n-ary action symbol, and $t_1, \ldots, t_n$ are all terms (resp. constants), then $a(t_1, \ldots, t_n)$ is an *action atom* (resp. *ground* action atom).

DEFINITION 2.1 (ACTION FORMULA). *Every action atom is an action formula. If P and Q are action formulas, then so are $(P \wedge Q), (P \vee Q)$, and $\neg P$.*

An action formula denotes a complex action. For example, $\neg a$ is the action where the opponent does not perform a. $(a \wedge b)$ is the complex action where the opponent does both a and b.

DEFINITION 2.2 (SOMA-RULE). *If $B_1, \ldots, B_n$ are atoms, $0 \leq \ell \leq u \leq 1$ are probability values, and P is an action formula, then*

$$P : [\ell, u] \quad \leftarrow \quad B_1 \wedge \ldots \wedge B_n$$

The above rule is an elementary SOMA-rule *if P is an action atom.*

Intuitively, suppose $\mathcal{S}$ is the current state of the reasoning agent (including any beliefs about the opponent agent). The above rule states that if the state $\mathcal{S}$ satisfies all the atoms $B_1, \ldots, B_n$, then the opponent agent will take action(s) P with a probability between ℓ and u.

DEFINITION 2.3 (SOMA-PROGRAM). *A (elementary)* SOMA-*program is a finite set of (elementary)* SOMA-*rules.*

Here is an (admittedly simplistic) example of a simple SOMA-program – a more sophisticated and carefully developed program of this kind that extracts the rules using sample data such as *Gallup* poll data might enable an unprincipled politician to determine what stances will get him votes.

EXAMPLE 2.1. *Consider a simple example involving* politics. *By examining a set of surveys, we might be able to write down a set of rules applicable to an arbitrary member m of the population (opponent) as follows:*

$$\begin{aligned} vote\_myway : [0.2, 0.3] &\leftarrow democrat. \\ vote\_myway : [0.3, 0.6] &\leftarrow promise\_cut\_tax. \\ \neg vote\_myway : [0.3, 0.9] &\leftarrow promise\_cut\_tax. \end{aligned}$$

The first rule says that I (the reasoning agent) expect m to vote for me with 20 to 30% probability if I am a democrat. The probability goes up to 30 to 60% if I promise a tax cut (independently of whether I am a democrat or not). The probability that the example citizen either does not vote for me is 30 to 90% if I promise a tax cut.

SOMA-programs are variations of generalized probabilistic (gp) logic programs [Ng and Subrahmanian 1993] - the heads of SOMA-rules are more expressive than gp-logic program rule heads, but conversely the bodies of gp-logic programs are more expressive. The semantics of SOMA-programs builds on that of gp-programs and is briefly described below.

3. SEMANTICS OF SOMA-RULES

A reasoning agent can use a SOMA-program to represent its beliefs about an opponent agent and estimate what the opponent might do in a given situation.

A *course of action* (COA for short) that the opponent might take is any finite set of ground action atoms. Suppose $\mathcal{C}$ is the set of all possible courses of action. We assume the existence of a function ϕ which takes a course of action and a state as input, and returns either 0 or 1 denoting whether the course of action is feasible or not (a course of action may be infeasible, for example, if the actions in it are mutually incompatible or if the actions cannot be executed in the current state due to pre-conditions that do not hold or if the the new state that results does not satisfy some integrity constraints). In the following, we will write $gr(\mathcal{A})$ to denote the set of all ground action atoms. We first define what it means for a COA to satisfy an action formula P.

DEFINITION 3.1. *A course of action C* ***satisfies*** *a* ground *action formula P, denoted $C \mapsto P$ if:*

1. *P is an action atom and $P \in C$, or*
2. *P has the form $P_1 \wedge P_2$ and C satisfies P_1 and P_2, or*
3. *P has the form $P_1 \vee P_2$ and C satisfies P_1 or P_2, or*
4. *P has the form $\neg P_1$ and C does not satisfy P_1.*

A SOMA-interpretation defined below assigns a probability to each COA.

DEFINITION 3.2 (SOMA-INTERPRETATION). *A* SOMA-interpretation *I is a mapping from $\mathcal{C}$ to $[0, 1]$ such that $\Sigma_{X \in \mathcal{C}} I(X) = 1$.*

Intuitively, $I(X)$ represents the probability that the opponent will perform exactly those actions in X. Clearly, the opponent must choose some course of action which is why $\Sigma_{X \in \mathcal{C}} I(X) = 1$. Let us now return to our political example.

EXAMPLE 3.1. *We have two* COA*s: $C_1 = \{\}$; $C_2 = \{vote\_myway\}$. A* SOMA-*interpretation I_0 may assign 0.3 and 0.7 respectively to these two* COA*s.*

DEFINITION 3.3. *Suppose $\mathcal{S}$ is a state and I is a* SOMA-*interpretation. I is said to* ***satisfy*** *a ground rule*

$$P : [\ell, u] \quad \leftarrow \quad B_1 \wedge \ldots \wedge B_n$$

with respect to state $\mathcal{S}$ iff

1. *$\{B_1, \ldots, B_n\} \not\subseteq \mathcal{S}$ or*
2. *$\ell \leq \Sigma_{\phi(C, \mathcal{S}) = 1 \wedge C \mapsto P} I(C) \leq u$.*

We say that I satisfies a rule if and only if it satisfies all ground instances of the rule.

Let us return to our political example.

EXAMPLE 3.2. *Consider the first rule of example 2.1 and suppose the current state $\mathcal{S}_0 = \{democrat, promise\_cut\_tax\}$. The first rule is* not satisfied *by the interpretation I_0 of Example 3.1 because $I_0(vote\_myway) = 0.7 \notin [0.2, 0.3]$. Had the probability interval in the head of this rule been $[0.5, 0.8]$, then the rule would have been satisfied by I_0.*

We use the usual notion of consistency.

DEFINITION 3.4 (CONSISTENCY). *A* SOMA-*program Π is* consistent *with respect to state $\mathcal{S}$ if there is at least one* SOMA-*interpretation that satisfies all rules in Π.*

The following definition shows that we can associate a set of linear constraints with any SOMA-program.

DEFINITION 3.5 (CONS($\Pi, \mathcal{S}$)). *Suppose* Π *is a* SOMA*-program and* $\mathcal{S}$ *is a state. The* constraints associated with Π*, denoted* CONS($\Pi, \mathcal{S}$) *associates a variable* p_i *with each course of action* C_i *(denoting the probability of* C_i*) and are defined as follows:*

1. *If*

$$P : [\ell, u] \quad \leftarrow \quad B_1 \wedge \ldots \wedge B_n$$

is a ground instance of a rule in Π *and* $\{B_1, \ldots, B_n\} \subseteq \mathcal{S}$*, then the constraint:*

$$\ell \leq \Sigma_{\phi(C_i, \mathcal{S})=1 \wedge C_i \mapsto P} p_i \leq u$$

is in CONS($\Pi, \mathcal{S}$)*.*

2. $\Sigma_{\phi(C_i, \mathcal{S})=1} p_i = 1$ *is in* CONS($\Pi, \mathcal{S}$)*.*

EXAMPLE 3.3. *Consider the "political" example shown in Example 2.1 and suppose the state in question is* $\mathcal{S}_0 = \{democrat, promise\_tax\_cut\}$*. Let* C_1 *and* C_2 *be the two COAs from Example 3.1. The constraints in this case are:*

$0.2 \leq p_2 \leq 0.3$*;*
$0.3 \leq p_2 \leq 0.6$*;*
$0.3 \leq p_1 \leq 0.9$*;*
$\Sigma_{\phi(C_i, \mathcal{S})=1} p_i = 1$.

The following result shows that a SOMA-program Π is consistent w.r.t. a given state iff the set CONS($\Pi, \mathcal{S}$) of constraints has a solution.

4. MAXIMALLY PROBABLE COAS

When a reasoning agent builds a SOMA-program about another opposing agent, his goal is to determine what the opponent will do in a given state. We define below, the lower probability that the opponent will take a given course of action.

DEFINITION 4.1 (LOWER PROBABILITY OF A COA). *Let* Π *be a* SOMA*-program and* $\mathcal{S}$ *be a state. The* lower probability*,* low(C_i) *of course of action* C_i *is defined as follows:*

1. low(C_i) $= 0$ *if* $\phi(C_i, \mathcal{S}) = 0$*, i.e.* C_i *is not valid.*
2. *Otherwise,* low(C_i) $=$ **minimize** p_i ***subject to*** CONS($\Pi, \mathcal{S}$).

The *upper probability*, $up(C_i)$ of course of action C_i can be defined in a similar manner. Note that for an given course of action C, we cannot *exactly* determine the probability that the opponent will do C. This is true even if all rules in Π have a point probability in the head — this is because our framework does not make any simplifying assumptions (e.g. independence) about the probability that the agent will perform action b, given that he will do action a.

The following example explains what happens in the situation of our political example and the state $\mathcal{S}_0$ introduced in example 3.1.

EXAMPLE 4.1. *As we saw in example 3.3, there are 4 constraints that must be satisfied at once in order to find an interpretation that satisfies all rules in* Π *with respect to* $\mathcal{S}$*. It can be seen that* low(C_1) $= 0.3$*, and* low(C_2) $= 0.3$*. Similar calculations lead to* up(C_1) $= 0.9$*, and* up(C_2) $= 0.3$.

5. RELATED WORK

We are not aware of much work on probabilistic agent reasoning - the work that exists focuses on agents that are reasoning about an uncertain state and trying to figure out how best to act in such a situation. However, there are a few relevant works that we build on top of.

[Gmytrasiewicz and Durfee 1992] have developed a logic of knowledge and belief to model multiagent coordination. Their framework permits an agent to reason not only about the world and its own actions, but also to simulate and model the behavior of other agents in the environment. In an earlier paper, they show how one agent can reason with a probabilistic view of the behavior of other agents so as to achieve coordination.

[Dix et al. 2000] develop a model of probabilistic agents on top of legacy code — in their framework, an agent reasons about uncertainty in its state. However, there is no uncertainty about what the agent will do. A subsequent work by these authors [Dix et al. 2005] extends this framework to the case of temporal probabilistic reasoning agents that can reason with uncertainty about when certain things will be true in the state.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented a hybrid logic/statistical language called SOMA within which a reasoning agent can represent knowledge about the probability that an opponent agent may take one or more actions. We have developed a formal model theoretic semantics for such agents.

In the full version of this paper, we make several additional contributions: first, we prove that checking consistency of SOMA-programs is NP-hard. We have identified syntactic fragments of SOMA-agents for which consistency checking is polynomial. We show that checking if a given course of action has a probability exceeding a given threshold is NP-hard. We have developed an exact algorithm to find an MPCOA and several heuristic algorithms that can approximate the most probable course of action very quickly and with high degrees of accuracy.

ABSTRACT

Decentralized partially observable Markov decision processes (DEC-POMDPs) form a general framework for planning for groups of cooperating agents that inhabit a stochastic and partially observable environment. Unfortunately, computing optimal plans in a DEC-POMDP has been shown to be intractable (NEXP-complete), and approximate algorithms for specific subclasses have been proposed. Many of these algorithms rely on an (approximate) solution of the centralized planning problem (i.e., treating the whole team as a single agent). We take a more decentralized approach, in which each agent only reasons over its own local state and some uncontrollable state features, which are shared by all team members. In contrast to other approaches, we model communication as an integral part of the agent's reasoning, in which the meaning of a message is directly encoded in the policy of the communicating agent. We explore iterative methods for approximately solving such models, and we conclude with some encouraging preliminary experimental results.

1. INTRODUCTION

Planning refers to the process of computing a conditional sequence of actions that fulfill a given task as well as possible. It is a crucial part of any intelligent agent; human, robot or software agent alike. We are interested in planning under various forms of uncertainty for cooperative multiagent systems. First of all, the agent might be uncertain regarding the exact consequence of executing a particular action. Furthermore, the agent's sensors may be noisy or provide only a limited view of the environment. As the agent is part of a team, a third source of uncertainty are its teammates, as it should consider their actions as part of its own decision making. In this paper, we study scenarios in which agents have the ability to communicate, but bandwidth is limited and communication has a certain cost. The range of possible application domains is broad, including cooperative robotics [6], sensor networks [13], distributed space applications [4], communication networks [16] and supply chain management [7].

Single-agent planning under uncertainty has been formalized in the partially observable Markov decision process (POMDP) framework [12]. A POMDP defines stochastic models to capture the uncertain effects of actions and the fact that sensors are imperfect and have a limited scope. In particular, the transition model governs how the system's state is influenced by actions, and the observation model stochastically relates states to observations. Solving a POMDP provides the agent with an optimal plan for a given task, but it is intractable to compute exact solutions in general (as it is known to be PSPACE-complete [17]). However, recent years have seen much progress in the development of approximate methods [19, 20, 23, 24].

Planning for a team of agents proves to be significantly harder than planning for just a single agent. In order for the team to act optimally, each agent not only has to consider the consequences of its own action, but at the same time also the actions its teammates will execute. As each agent does not know what the other agents observe, it will be hard to predict their actions. Decentralized POMDPs (DEC-POMDPs) generalize the POMDP framework to cooperative multiagent settings, but solving finite horizon DEC-POMDPs has been proven to be NEXP-complete [2], a considerable jump in complexity from the single agent case. Besides brute-force enumeration and evaluation of all possible policy tuples, only one algorithm is known for computing optimal solutions [11], which in practice is limited to very small problems. As the general setting is very hard to solve optimally, research has focused on heuristic methods, which often also make additional assumptions on the planning domain [27, 8, 1, 10, 18].

Allowing agents to communicate with each other can increase team performance, as it mitigates two sources of uncertainty: a message from a teammate can either provide information about the state of the system, or about the teammate's intentions. In particular, if one assumes that

the agents have unlimited free access to a noise-free communication channel, the multiagent planning problem reduces to a single-agent one: each agent shares its observations with all teammates, which allows each one of them to select the optimal joint action, and execute its part of the joint action vector. However, although optimal, such an approach is not desirable for several reasons. First of all, in reality a communication channel is likely to be bounded in bandwidth, and sending a message will have a particular cost. Second, the resulting single agent POMDP will still be hard to solve, as the size of the problem description grows exponentially in the number of agents. Therefore, we choose to tackle the problem in a decentralized manner, in which each agent considers only its local state plus some shared uncontrollable state features, instead of the cross-product of the local states of all agents and the uncontrollable state space. Furthermore, we consider communication as an integral part of the system, and model it directly in the DEC-POMDP, in contrast with other approaches in which communication decisions are governed by a separate algorithm [8, 5, 14, 22].

We propose a decentralized model for tackling cooperative multiagent planning problems, which incorporates a communication channel. In contrast to most work on distributed POMDPs, we do not define an explicit communication language, but instead treat the semantics of communication as part of the optimization problem. We will present an iterative method for computing a joint policy for the team in a decentralized fashion. Given a set of fixed policies for all agents but agent i, we convert the DEC-POMDP to a POMDP from i's perspective which incorporates the expected contribution to the joint team reward of the other agents' policies. We propose a heuristic method for computing a communication policy and we conclude with encouraging preliminary experimental results in two domains.

2. PLANNING FOR MULTIAGENT TEAMS

We will start by reviewing the cooperative multiagent planning problem from a decision-theoretic perspective. First we will briefly introduce partially observable Markov decision processes (POMDPs), a rich mathematical framework for single-agent planning under uncertainty. Next, we will look at decentralized POMDPs which constitute a multiagent extension of the POMDP model, and at existing exact and approximate methods for solving them.

2.1 Partially observable Markov decision processes

A partially observable Markov decision process (POMDP) models the repeated interaction of an agent with a stochastic environment, parts of which are hidden from the agent's view [12]. The agent's goal is to perform a task by choosing actions which fulfill the task best. At each time step the environment is in a state $s \in S$, and the agent executes an action $a \in A$, which will move the environment to a new state s' according to a stochastic transition model $p(s'|s,a)$. As a by-product the environment will generate a scalar reward signal $R(s,a)$, which defines the agent's task. Next the agent receives an observation $o \in O$ which is stochastically related to s' according to $p(o|s',a)$, but in general will not uniquely identify s'. As such, the agent is uncertain about the true state of the system, which is often modeled as a probability distribution over all states. The probability distribution, or belief $b(s)$ in POMDP terminology, summarizes all relevant history and is updated using Bayes' rule:

$$b^{ao}(s') = \frac{p(o|s',a)}{p(o|a,b)} \sum_{s \in S} p(s'|s,a)b(s), \qquad (1)$$

where $p(o|a,b) = \sum_{s' \in S} p(o|s',a) \sum_{s \in S} p(s'|s,a)b(s)$ is a normalizing constant.

The goal of the agent is to compute an optimal policy $\pi(b)$ that maps beliefs to actions. Optimal is defined as maximizing a certain performance measure, for instance the expected discounted sum of rewards $E\big[\sum_{t=0}^{h} \gamma^t R\big]$, where h is the planning horizon and γ is a discount rate, $0 < \gamma < 1$. Without going into details of exact POMDP solving, it suffices to say that computing an optimal policy is intractable in general [17]. In recent years a number of approximate algorithms including PBVI [19], BPI [20], HSVI [23], and Perseus [24] have been proposed, which allow for solving larger POMDP domains by, e.g., exploiting structure in the domain.

2.2 Decentralized POMDPs

A straightforward extension of the POMDP framework to cooperative multiagent settings is called the decentralized POMDP (DEC-POMDP) model [2]. Instead of a single agent we now consider a set of agents, which share the same reward function. If the agents have individual (and differing) reward functions, the model is known as a partially observable stochastic game (POSG) [11]. A DEC-POMDP is defined as follows:

- $I = \{1, \ldots, n\}$ is a set of n agents.
- S is a finite set of states.
- A_i is a finite set of actions for agent i.
- O_i is a finite set of observations for agent i.
- $p(s'|s,a)$ is the joint transition model which defines the probability of jumping to state $s' \in S$ given that the team executed joint action $a \in A_1 \times \ldots \times A_n$ in $s \in S$.
- $p(o|s,a)$ is the joint observation model which defines the probability that after taking joint action a and ending up in state s results in joint observation $o \in O_1 \times \ldots \times O_n$.
- $R : S \times A_1 \times \ldots \times A_n \rightarrow \mathbb{R}$ is the reward function which gives a scalar reward signal to the team.
- $b_i^0 \in \quad (S)$ is the initial state distribution.
- γ is a discount rate, $0 \leq \gamma < 1$.
- h is the planning horizon.

Contrary to the single agent case, in a DEC-POMDP it is not possible in general to compute a belief state as an agent only knows its local observation o_i but not the complete observation vector o, which is required for computing the belief update (1). As such, each agent chooses its action a_i at time t based on its policy $\pi_i : \times_{t-1}(A_i \times O_i) \rightarrow A_i$, i.e., it only considers its own history of actions taken and observations received until time t. The goal of the team of agents is to compute a joint policy $\pi = \{\pi_1, \ldots, \pi_n\}$ which maximizes the future discounted reward $V^\pi = E_\pi\big[\sum_{t=0}^{h} \gamma^t R\big]$. Unfortunately, computing an optimal policy π^* is NEXP-complete [2], and there is only one known algorithm for computing an exact solution (apart from brute-force), which we will describe next [11].

2.3 Solving decentralized POMDPs

Hansen et al. [11] present a dynamic programming operator for finite horizon POSGs, which allows for incremental construction of policies: starting from a solution for horizon t it computes a solution for horizon $t+1$. When the POSG is a DEC-POMDP, i.e., the agents share the same reward function, the algorithm will result in a set of policies optimal for a certain planning horizon. A belief is maintained over the cross-product of the state of system and the future conditional plans, or policy trees, of all other agents. However, the set of possible policy trees grows doubly exponential in the planning horizon, which renders a brute-force approach infeasible in practice. To combat the growth, at every iteration (very weakly) dominated policy trees are pruned. A policy tree for agent i is dominated if its removal does not decrease the value of any belief for agent i. However, even with pruning at every iteration the algorithm can solve only very small problems before running out of memory.

As solving a DEC-POMDP is intractable in the general case, methods have been proposed for approximately solving more restricted DEC-POMDP variations. Simplified models that have been studied include extra assumptions regarding the observation model, in particular that an agent's observations are independent from those of its teammates [8] or that each agent can observe its own local state with full certainty, which reduces the problem to a decentralized MDP [27, 1, 10]. The latter assumption requires a factored state representation in which the state space is the cross-product of each agent's local state space and optionally a set of shared external state features which each agent can observe but not influence. Examples include time or any other external information relevant to the team's task. Given a factored state space one can further assume that the agents' transitions are independent [27, 1, 18], or impose a particular joint reward structure [1]. Apart from restricting the model one can also limit the expressive power of the solution method, for instance by only searching in the space of finite state controllers of a particular size [3, 25]. Another way of computing a locally optimal solution is to optimize one agent's policy while keeping the other policies fixed, and iterate over all agents until convergence [15, 5, 3].

A different dimension to tackle decentralized POMDP models is to assume the agents have a way to communicate with each other (which is not modeled in the DEC-POMDP). As we noted above, if a team of agents is allowed to communicate for free and without limitations, then each agent can broadcast at every time step its perceived observation to all of its teammates. As a result every agent knows the joint observation vector which it uses to update the joint belief of the team, based on which the next joint action is selected. As such, free communication reduces the distributed control problem to a centralized, single-agent one, which can be solved using standard POMDP solution techniques. However, in reality communication is often not free or unlimited, and modeling a team of agents in this way might not be desirable. Nevertheless, several methods treat the multiagent system as if communication were truly free, solve the large centralized POMDP, and execute the resulting joint policy in a distributed fashion while imposing communication constraints [5, 14, 22]. While executing the policy a limited form of communication is used to attempt to preserve coherent behavior of the team. Note that the communication decisions are not part of the centralized policy, but are made by a separate algorithm, which for instance monitors the uncertainty regarding the joint belief. We refer to [21, 9] for a detailed analysis of communication issues arising in DEC-POMDP settings.

In contrast, Xuan et al. [27] propose a model that incorporates the communication decision directly in the agent's policy. It adds a communication sub-stage to the decision process, in which an agent decides whether it will communicate with its teammates. In this way an agent can explicitly reason about communication, instead of relying on an independent instrument to handle communication issues. Extending this framework, Goldman and Zilberstein [8] present a formal model for decentralized control with communication decisions based on the DEC-POMDP model. In such decentralized models agents reason over their local state, instead of considering the state of all teammates. A decentralized model seems more appropriate for agents who cannot observe each other's state nor have free and unrestricted communication at their disposal. Decentralized models also do not suffer from the exponential growth in the size of the centralized state space when the number of agents increases. Limited communication abilities, however, can be exploited to improve the team's performance, by allowing agents to share information at a certain cost.

3. PROPOSED MODEL

In [8, 9] a framework for modeling cooperative multiagent systems as a decentralized POMDP with a global reward function is proposed. The agents reason explicitly over their communication decisions, but the observations of each agent are independent. We propose a different decentralized model which draws on [8, 9], but in which a communication channel is established by allowing agents to send messages as part of their action vector, and messages are received in the next time step as part of the recipients' observation vectors. In contrast to most work on distributed POMDPs, we do not manually define a communication language, but treat the semantics of communication as part of the optimization problem.

We refine the DEC-POMDP model as described in Sec. 2.2 as follows:

- The state space S factors into $n+1$ components: $S = S_0 \times S_1 \times \ldots \times S_n$, where S_i is the set of state features relevant to agent i and S_0 the set of external state features, which are shared by all agents but which cannot be controlled. A local state of an agent i is defined as $\bar{s}_i = (s_0, s_i)$, where $s_0 \in S_0, s_i \in S_i$.

- Σ_i is a finite set of possible messages, and $\_{}_i \in \Sigma_i$ denotes a message sent by agent i. Not sending any message is defined as sending the empty message $\_{}_i = \emptyset$.

- $A_i = A_i^d \times A_i^\sigma$ is the action set for agent i, where A_i^d is the set of domain level actions and A_i^σ the set of communication acts.

- $O_i = O_i^d \times O_i^\sigma$ is the observation set for agent i, where O_i^d is the set of domain level observations the agent receives through its sensors, and $O_i^\sigma = \Sigma_1 \times \ldots \times \Sigma_{i-1} \times \Sigma_{i+1} \times \ldots \times \Sigma_n$ the set of possible messages the agent can receive from any of its teammates.

- The joint transition model $p(s'|s,a)$ depends only on the domain level component of each agent's action (sending messages does not influence the state of the environment). We assume that the agents' transitions are independent, allowing us to factor the joint transition model:

$$p(s'|s,a) = p(s'_0|s_0) \prod_{i=1\ldots n} p(s'_i|s_i, a^d_i), \qquad (2)$$

where $s'_0, s_0 \in S_0$, $s'_i, s_i \in S_i$, and $a^d_i \in A^d_i$.

- The local observation model $p(o_i|\bar{s}_i, a_i)$ specifies the probability of receiving observation $o_i = (o^d_i, o^\sigma_i)$ after executing action a_i and ending up in $\bar{s}_i$.

- We define $p(o^\sigma_i|^-)$ as the probability that a message vector $^- = (\ _1, \ldots,\ _{i-1},\ _{i+1}, \ldots,\ _n)$ will be interpreted as a particular observation o^σ_i, which can be used to model noise in the communication channel.

- The reward function $R(s,a)$ gives the team of agents a scalar reward at each time step for taking joint action a in state s. It is defined as the sum of each agent's local reward function and the joint reward of the team:

$$R(s,a) = \sum_{i=1\ldots n} R_i(\bar{s}_i, a_i) + R(s_0, \ldots, s_n, a_1, \ldots, a_n). \qquad (3)$$

The local reward $R_i(\bar{s}_i, a_i)$ is defined as the sum of the reward for the domain level action $R_i(\bar{s}_i, a^d_i)$ and the communication cost $R_i(\bar{s}_i, a^\sigma_i)$:

$$R_i(\bar{s}_i, a^\sigma_i) = \begin{cases} 0 & \text{if } \ _i = \emptyset \\ r_c < 0 & \text{otherwise} \end{cases} \qquad (4)$$

- Initial belief b^0_i, discount rate γ, and planning horizon h as in Sec. 2.2.

In the remainder of this paper we shall limit our discussion to two agents, but our methods and experiments generalize to more than two agents. Broadcast communication is used, and we will focus on noise-free communication, fixing $p(o^\sigma_i|^-)$ to be the identity matrix.

3.1 Example: Multiagent Heaven or Hell

To give some intuition on the range of problems our model captures we will now discuss a very simple example application. The "Multiagent Heaven or Hell" problem (inspired by [26]) is a scenario in which two agents have to meet in one of two locations, one called "heaven" and the other one "hell", see Fig. 1. At the start of each trial heaven is positioned either in the bottom-left state ($s_0 = \textit{left}$) or in the bottom-right state ($s_0 = \textit{right}$) with equal probability, and hell will be located in the other state. If the agents meet in heaven the team receives a reward of $r_h > 0$, but meeting in hell is penalized with a reward of $-r_h$. However, each agent does not know the location of heaven or hell until it visits the "priest" state, in which it receives an observation indicating whether heaven is left or right. Visiting the priest results in an individual negative reward of $r_p < 0$ for the particular agent, and we assume that the reward obtainable in heaven makes visiting the priest a viable option, i.e., $r_h > -nr_p$.

If no communication is possible, or the communication cost ($-r_c$) is prohibitively large, the optimal policy could be for each agent to visit the priest, find out where heaven is located and go there. However, when communication is relatively cheap, i.e., $r_c > r_p$, more interesting scenarios become feasible. For instance, only agent i could ask the priest and inform agent j by sending it a message. This would save agent j the cost of visiting the priest and still be able to tell heaven from hell. However, instead of defining such semantics a priori, we would like the agents to learn when and how to communicate, and how to interpret incoming messages. In particular, the agents should optimize their use of communication with respect to the cost of sending a message r_c.

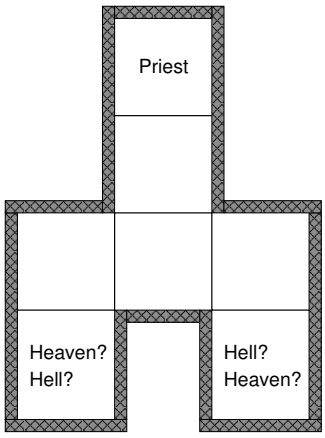

Figure 1: Multiagent Heaven or Hell environment. The priest (top state) can tell the agents where heaven is located (bottom-left or bottom-right state).

3.2 Belief tracking

In a general DEC-POMDP setting it is not possible for an agent to maintain an exact belief over the true state of the system, as it only receives its own part of the observation vector. As such, agent i has to reason about what observation agent j might have observed, but at the same time agent j is modeling agent i, which leads to the very high complexity class of solving DEC-POMDPs. As a result of the lack of independence between agents, only approximate beliefs can be computed. Alternatively, one can assume that agent i's observations are independent from those of agent j [15], which together with a common transition independence assumption precludes any use of direct communication in the DEC-POMDP model, as the agents cannot influence each other. In contrast, in our decentralized model the domain level component o^d_i of an observation $o_i = (o^d_i, o^\sigma_i)$ only depends on an agent's local state $\bar{s}_i$, but the communication component o^σ_i does depend on agent j, as follows

$$p(o_i|\bar{s}_i, a_i) = p(o^d_i, o^\sigma_i|\bar{s}_i, a_i) \qquad (5)$$

$$= p(o^d_i|\bar{s}_i, a_i) p(o^\sigma_i), \qquad (6)$$

where $p(o^\sigma_i)$ is the probability that the other agents send agent i a particular message vector in the previous time step, which we will approximate based on their policies. Consequently, we can only perform an approximate belief update, but it allows us to model a built-in communication channel.

Analogous to (1), agent i's belief b_i is updated as follows

when it takes action a_i and receives observation o_i:

$$b_i^{a_i o_i}(\bar{s}_i') = \frac{p(o_i^d|\bar{s}_i', a_i)p(o_i^\sigma)}{p(o_i^d, o_i^\sigma|a_i, b_i)} \sum_{\bar{s}_i \in (S_0 \times S_i)} p(\bar{s}_i'|\bar{s}_i, a_i) b_i(\bar{s}_i), \tag{7}$$

where $p(o_i^d, o_i^\sigma|a_i, b_i)$ is a normalizing constant. The probability that $b_i^{a_i o_i}$ will be the successor of b_i when agent i executes action a_i is defined as

$$p(b_i^{a_i o_i}|b_i, a_i) = p(o_i|b_i, a_i) \tag{8}$$

$$= \sum_{\bar{s}_i \in (S_0 \times S_i)} p(o_i|\bar{s}_i, a_i) b_i(\bar{s}_i). \tag{9}$$

Since individual beliefs can be defined through (7), local policies π_i can be defined as in a standard POMDP setting, i.e., as mappings $\pi_i : \quad (S_0 \times S_i) \rightarrow A_i$ from local beliefs b_i to actions. The only term not yet defined in (7) is $p(o_i^\sigma)$: the probability that agent i receives a message $\quad_j$ and interprets it as observation o_i^σ. It is defined by two factors: the probability that agent i receives $\quad_j$ as o_i^σ, as defined by the channel noise model $p(o_i^\sigma|\quad_j)$, times the probability that agent j actually sends $\quad_j$. The latter probability is estimated by computing the set of possible beliefs $\{b_{j,t}^\sigma\}$ in which agent j sends $\quad_j$ according to π_j, and summing the probabilities $p(b_{j,t})$ that any of those beliefs in $b_{j,t} \in \{b_{j,t}^\sigma\}$ will occur:

$$p_{t+1}(o_i^\sigma|\pi_j) = p(o_i^\sigma|\quad_j) \sum_{b_{j,t} \in \{b_{j,t}^\sigma\}} p(b_{j,t}), \quad \text{with} \tag{10}$$

$$\{b_{j,t}^\sigma\} = \{b_{j,t}|(a_j^d, a_j^\sigma) = \pi_j(b_{j,t}), a_j^\sigma = \quad_j\}. \tag{11}$$

where $p(b_{j,t})$ is the probability that agent j is in belief $b_{j,t}$ at time t. The following equation computes $p(b_{j,t})$ as a recursion from time step 0, at which we know agent j is in its initial belief b_j^0 with probability 1:

$$p(b_{j,t}) = \begin{cases} 1 & \text{if } t = 0 \\ p(b_{j,t}|b_{j,t-1}, \pi_j(b_{j,t-1}))p(b_{j,t-1}) & \text{otherwise} \end{cases} \tag{12}$$

which uses (9). The set $\{b_{j,t}\}$ of all possible beliefs which agent j could believe to be true at a particular time step is finite for any given t, as we have assumed finite models.

3.3 Communication

The previous section defined how each agent updates its belief and how j's policy affects i's belief update, and here we provide the intuition how this implements a communication channel. For a particular incoming message $\quad_j$ agent i can use its knowledge of π_j and the set of beliefs $\{b_{j,t}\}$ for agent j to compute the set $\{b_{j,t}^\sigma\}$ (11) from which agent j would send the particular message $\quad_j$. In this way, receiving message $\quad_j$ at time $t+1$ informs agent i about agent j's local state at time t:

$$p_{t+1}^{\sigma_j}(\bar{s}_j) = \sum_{b_{j,t} \in \{b_{j,t}^\sigma\}} b_{j,t}(\bar{s}_j) p(b_{j,t}), \tag{13}$$

combining (12) and (11). The crucial point is that, as agent j's local state $\bar{s}_j$ includes S_0, receiving message $\quad_j$ will provide agent i with information about s_0:

$$p_{t+1}^{\sigma_j}(s_0) = \sum_{s_j \in S_j} p_{t+1}^{\sigma_j}(\bar{s}_j) \quad \text{with} \quad \bar{s}_j = (s_0, s_j). \tag{14}$$

In summary, the fact that s_0 is shared by all agents allows for communication-based learning, by enabling an agent j to modify the observation model of some other agent i, via the term $p(o_i^\sigma)$ in (7).

Depending on the quality of agent j's communication policy, communication can improve team performance. For instance, if agent j communicates uniformly at random, agent i will not benefit from communication as the information content of the message is zero. However, in the Multiagent Heaven or Hell example described above, if agent j communicates $\quad_j = 1$ if it knows heaven is left, communicates $\quad_j = 2$ if it knows heaven is right, and does not communicate otherwise, then agent i can use $\quad_j$ to update its belief about the location of heaven in a useful manner and proceed to heaven without visiting the priest.

3.4 Discussion

When comparing with other recent approaches to planning for cooperative multiagent systems in partially observable environments, there are two main advantages to the proposed model. First of all, we treat communication as an integral part of an agent's reasoning, not as an add-on. In particular, we do not define a priori semantics for a message, but treat it as part of the optimization problem. The meaning of a particular message $\quad_i$ is defined by the situations in which agent i will send $\quad_i$. Of course, assuming a message set Σ_i with user-defined, high quality and fixed semantics simplifies the optimization problem, but we believe it is worthwhile to explore optimizing communication as part of (approximately) solving the DEC-POMDP.

The second feature of the proposed model is that it is decentralized, and does not require an (approximate) solution to the large single-agent POMDP resulting from truly free communication (as described in Sec. 2.3). The centralized state, action and observation spaces grow exponentially in the number of agents, rendering even approximate solutions infeasible. In our decentralized model, only the observation set for each agent grows with the number of agents, which can be limited by manipulating the size of possible messages Σ_i. One other possible solution to combat this exponential growth would be to assume that messages from different agents are conditionally independent given the state, which would allow us to factorize each agent's observation model. A factorized observation model induces a particular structure in an agent's POMDP (see next section), which can facilitate solving the POMDP.

We trade off exploiting an (approximately) optimal centralized solution for a potentially more scalable decentralized setting, in which each agent only considers it own local state (and some shared uncontrollable state features). Furthermore, a decentralized framework is more natural for modeling agents who cannot observe each other's state nor have truly free communication available.

4. SOLUTION METHOD

After proposing a decentralized model for planning for a team of communicating agents, we will now present an approach for computing a plan in our model. We propose to compute a joint policy for the team of agents in an iterative fashion [15, 5, 3]. We start with a (randomly selected) policy π_i for each agent i. We fix the policy for all agents except for one, our protagonist agent i. From i's perspective we can treat the other agents as part of the environment, and i can build a POMDP model of this environment, given that it knows the policies of the other agents. For the re-

sulting POMDP model it computes a policy using a standard (approximate) POMDP solver which replaces its current policy π_i. We then move on to the next agent and repeat the procedure from its perspective. This process is iterated until some convergence criterion is met, at which time the joint policy will have reached a local maximum. Multiple random restarts are necessary in general to reach good performance. We will solve the POMDP models using PERSEUS [24]. It computes a policy in the form of a value function $V_i : \quad (S_0 \times S_i) \rightarrow \mathbb{R}$, which for every belief estimates the amount of future discounted reward the agent can obtain.

4.1 Computing an agent's POMDP model

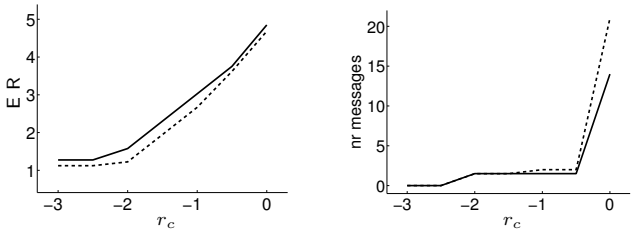
A crucial component is building the POMDP model from the known problem description and the policies of all teammates. In this POMDP model the reward function for agent i should not only consist of its local reward function R_i but also the expected contribution of the joint reward function R. For instance, in the Multiagent Heaven or Hell example described in Sec. 5.1, if agent i predicts that agent j's policy directs j to the heaven location, agent i's local reward function should report that if i goes to heaven too, it can receive the joint reward of r_h. We summarize the influence of the other agent by computing two statistics: $p(a_j|\bar{s}_j)$ is the probability agent j will execute a_j in $\bar{s}_j$, and $p(\bar{s}_j)$ is the probability that agent j will be in a particular state $\bar{s}_j$. We approximate these probabilities by simulating the belief tree for the team, given the pair of policies $\{\pi_i, \pi_j\}$. The root of the belief tree at $t = 0$ is the starting belief b_i^0 of each agent i. We compute the set of possible $t + 1$ beliefs for each agent by propagating each of its beliefs at time t:

$$\{b_{i,t+1}\} = \{b_{i,t}^{a_i o_i} | a_i = \pi_i(b_{i,t}), o_i \in O_i\}. \qquad (15)$$

In order to keep the memory requirements in check in general pruning will be necessary. From the belief sets at time step $\{b_{i,t}\}$ and the probability that each of the beliefs will be encountered (according to (12)) we can approximate the required statistics $p(a_j|\bar{s}_j)$ and $p(\bar{s}_j)$.

We use these statistics to define the local reward function R_{i,π_j} for agent i, which takes into account the expected contribution from agent j's policy π_j:

$$R_{i,\pi_j}(\bar{s}_i, a_i) = R_i(\bar{s}_i, a_i) + \sum_{\bar{s}_j \in (S_0 \times S_j), a_j \in A_j} R(s_0, s_i, s_j, a_i, a_j) p(a_j|\bar{s}_j) p(\bar{s}_j), \qquad (16)$$



with $(s_0, s_i) = \bar{s}_i$. From the same statistics the observation model for agent i can be computed, which will encode the information contained in incoming messages from agent j, as we described in Sec. 3.3. To complete the POMDP model, the transition model for agent i is given by

$$p(\bar{s}_i'|\bar{s}_i, a_i) = p(s_0', s_i'|s_0, s_i, a_i^d, a_i^\sigma) \qquad (17)$$

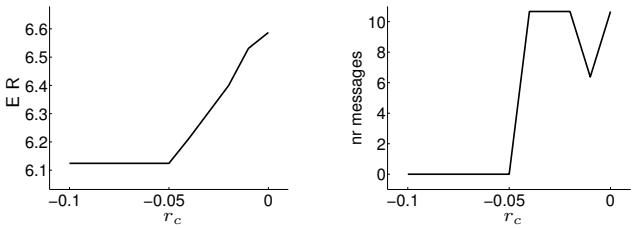
$$= p(s_0'|s_0) p(s_i'|s_i, a_i^d). \qquad (18)$$

4.2 Learning to communicate

The iterative scheme described above is able to react to any incoming communications, which are incorporated in the local reward model and exploited by the POMDP solver. However, it will not learn from scratch to send any messages, as the other agent's policy has not yet learned how it can benefit from incoming messages. Therefore we begin by equipping each agent with a fixed heuristic communication policy and iteratively optimize the agents' domain level component of their policies to exploit the incoming messages. Next we aim to optimize the communication component of each agent's policy with respect to the communication reward $r_c < 0$. In particular, initially all agents could at each time step send the last domain level observation they received, and we could improve team performance by only sending messages that are useful.

(a) Reward. (b) Nr. of messages.

Figure 2: Multiagent Heaven or Hell results. Solid lines indicate results for 2 agents, and dashed lines show results for a team of 3 agents. Plot (a) shows the expected discounted reward (E R) obtained for different communication rewards (r_c), and figure (b) plots the average number of messages sent.



A message is useful when it conveys some information which the other agent can use to improve team performance. As the meaning of a message is defined over s_0, the entropy of $p^{\sigma_j}(s_0)$ (14) measures the information content of a particular message. However, if a message has low entropy does not necessarily mean it is useful to send. One proposal for testing its value is to modify each agent's local reward model (16) to prefer communicating low entropy messages to not sending them, but only at states in which it would send the messages under the initial heuristic communication policy. This ensures the other agent will know how to respond to the incoming message. Next we repeat the process of iterative optimization, allowing the agents to adjust to the new communication behavior.

5. EXPERIMENTS

We will present experimental results in the Multiagent Heaven or Hell domain and in a game of tag, in which agents have to cooperate in order to tag an opponent. In these experiments we included the time step of the system in s_0, which allows for a single message to have a different meaning, depending on which time step it was sent. Adding time to s_0 requires no extra assumptions, but does allow the agents to more closely correlate their behavior. Providing correlation for agents in a DEC-POMDP has been shown to improve team performance [3].

5.1 Multiagent Heaven or Hell

First we will consider the Multiagent Heaven or Hell domain as introduced in Sec. 3.1. The environment contains seven grid cells ($|S_i| = 7$) and the shared state s_0 is the cross-product of the time index and {"heaven is in bottom-left grid cell","heaven is in bottom-right grid cell"}, where we set the horizon of the problem to 15. Each agent has a domain level action set $A_i^d = \{$*north, east, south, west,*

(a) Reward. (b) Nr. of messages.

Figure 3: Pack Tag results. Plot (a) shows the expected discounted reward (E R) obtained for different communication rewards (r_c), and figure (b) plots the average number of messages sent.

stay in place}, where the first four are movement actions that transport the agent one grid cell in the corresponding direction, and the last action is a no-op which has no effect on the agent's location. Each agent can observe whether there is a wall to the left or to the right of it, and in the priest state it can observe the location of heaven, resulting in six possible observations O_i^d ={*left, right, both, neither, heaven-left, heaven-right*}. Meeting in heaven by all agents is rewarded by $r_h = 10$ and meeting in hell by $-r_h$. Visiting the priest incurs a negative reward $r_p = -2$, every movement action a reward of -0.1, and the discount factor γ is set to 0.95. Both the transition and observation model are deterministic, and the agents always start in the center grid cell (the cell at the T-intersection).

Fig. 2 shows results obtained by using the local reward modification scheme described in Sec. 4.2, for teams of 2 and 3 agents. First, we see in Fig. 2(a) that the team performance increases when the penalty for communication decreases, i.e., r_c becomes less negative. In all cases one agent i will visit the priest, but it will only send a message indicating the location of heaven if the communication cost is low ($r_c \geq -2$), see Fig. 2(b). Otherwise the other agent(s) will go to one of the heaven/hell locations, and agent i will only join them if it is indeed the correct location. When communication is free, performance is best and a large number of messages are communicated, as one would expect. On the other extreme, when communication is expensive ($r_c = -3, -2.5$), the performance remains stable.

5.2 Pack Tag

The "Pack Tag" problem models a game of tag, in which two robots have to tag an opponent robot [19, 5]. The game is played on a $k \times k$ grid, with one robot starting in the bottom-left corner and the other one in the top-right corner. At the beginning of each game the opponent is positioned uniformly at random in one of the grid cells and remains stationary. The two robots have to occupy the same grid cell as the opponent and execute the *tag* action simultaneously in order to tag the opponent. The robots can move in any of the four compass directions, and their actions are deterministic. The two robots have a sensor which detects the opponent with full certainty when the opponent is sharing the same grid cell. Each robot receives a null observation otherwise, but remains perfectly localized due to the known starting position and noise-free motion. Each action incurs a reward of -0.1 and successfully tagging the opponent results in a reward of 10. The agents have to tag the opponent in 10 time steps, and γ was set to 0.95.

As in Sec. 5.1 we varied the communication cost while employing the local reward modification method, and using a grid size $k = 3$. Fig. 3 shows that when the communication cost is high, $r_c \leq -0.05$, the agents converge to a non-communicating policy pair. They both search the grid, and when one of them sees the opponent it waits for the other to join it before jointly tagging it. However, when communication is cheaper the agents communicate when they observe the opponents, which indicates to the other agent the location of the opponent. Here the benefit of including time in s_0 is manifested, as receiving the same message at a different time step has a different meaning: agent i knows agent j's policy, and therefore knows j's search pattern, and in this way knows in what grid cell agent j observed the opponent when j send its message. After receiving an informative message an agent abandons its search pattern and moves directly to its teammate's position, where they jointly tag the opponent. The policy pair computed for $r_c = -0.01$ has converged to better local maximum, which uses a more efficient form of communication.

6. CONCLUSIONS

In this paper we studied the problem of computing a plan for a team of agents. We considered a general problem setting, in which agents inhabit a stochastic environment that is only partially observable to them. The agents have the capability to communicate, but sending messages has a certain cost and the available bandwidth is limited. Decentralized partially observable Markov decision processes (DEC-POMDPs) formalize such multiagent planning problems for groups of cooperating agents. We presented a decentralized model for tackling these kinds of planning problems, which incorporates a communication channel. Decentralized models potentially scale better and are a more natural paradigm for modeling agents that cannot observe each other's state. Contrary to other recent approaches, we treat communication as an integral part of the model, and model it directly in the DEC-POMDP. We proposed an approximate iterative method for computing policies in the proposed model, and obtained encouraging preliminary experimental results in two domains.

As future work we would like to examine possibilities of simultaneous learning of communication-derived POMDPs for two or more agents, which could potentially improve upon the alternating-maximization paradigm. Furthermore, we would like to experiment on problems with more agents, which are too large to be solved by centralized methods. For problems that are still solvable by centralized algorithms, we intend to compare the centralized solution to the decentralized one, to gain more insight in how optimality is traded off for more efficient computation.

ABSTRACT

In this paper we incorporate autonomous agents' capability to perform parallel interactions into the cooperative search model, resulting in a new method which outperforms the currently used ones. As a framework for our analysis we use the electronic marketplace, where buyer agents have the incentive to search cooperatively. The new search technique is quite intuitive, however its analysis and the process of extracting the optimal search strategy are associated with several significant complexities. These difficulties are derived mainly from the unbounded search space and simultaneous dual affects of decisions taken in different world states. We provide a comprehensive analysis of the model, highlighting, demonstrating and proving important characteristics of the optimal search strategy. Consequently, we manage to come up with an efficient modular algorithm for extracting the optimal cooperative search strategy for any given environment. A computational based comparative illustration of the system performance using the new search technique versus the traditional methods is given, emphasizing the main differences in the optimal strategy's structure and the advantage of using the proposed model.

1. INTRODUCTION

Coalition formation is well recognized as a key process in a multi-agent systems, mostly desirable in environments where a group of agents can perform a task more efficiently than any single agent can [10]. In recent years many coalition formation models have been suggested, for various domains [18, 5], particularly for electronic commerce [19, 20, 16]. In the latter context, the most common coalition concerned is a coalition of buyers, derived mainly from the potential of obtaining volume discounts [19, 15] and the ability to search cooperatively for market opportunities in a more efficient manner [16].

The cooperative search incentive derives principally from the existence of search costs found in MAS, reflecting the resources (not necessarily monetary), that need to be invested/consumed while searching for opportunities in the environment (e.g. searching for an opportunity to buy a product in the context of the electronic marketplace) [16]. The scenario of having search costs is common in MAS where the agent needs (for its decision making process) immediate information concerning market opportunities. Given the richness of opportunities and the dynamic and open nature of these environments, central mechanisms are usually incapable of supplying such information with the level of completeness and accuracy required by the agent, certainly not without a cost. Thus the agent needs to spend some of its resources on search related activities. Despite the reduction in the magnitude of these search costs in the electronic commerce era, the continuous growth in the number of retailers and virtual stores over the Internet, followed by a phenomenal increase in the number of opportunities available, makes the overall search cost an important parameter affecting buyers' search strategy [4, 9, 16, 1].

By forming a coalition and delegating the search task to a representative agent (acting on behalf of the coalition[1]), the cooperative search offers the advantage of sharing, reusing and re-allocating opportunities among the coalition members (e.g. exploiting opportunities which would have been discarded otherwise if each of the agents would have performed an alternative separate search) [16]. Nevertheless, the process of forming and maintaining the coalition induces some overhead, derived mainly from the communication and coordination activities [15], thus the representative agent should set its search strategy in a cost/effective manner.

A classic example of the above in traditional markets is the procurement management officer of a corporation. Instead of having each individual in the cooperation spend time and resources on locating its specific requested supplies, the task is delegated to the procurement management officer. Here, in addition to the price discounts obtained for aggregated demands of identical items, the procurement management officer becomes highly updated with the

[1]As discussed in detail in [16], the use of a representative agent is a common and efficient means for executing the coalition's goal. Furthermore, given the option of side-payments the overall utility maximization strategy taken by the representative agent is always the preferred one by all coalition members (i.e. no conflict of interests), regardless of the pre-set coalition's payoff division protocol.

different offerings and specific supplies available by the different merchants in the markets. As a result the cost of locating the right deal for each request becomes significantly smaller (in comparison to the equivalent search conducted by each of the individuals).

The basic concepts by which a representative agent should manage the cooperative search, including an analysis and computational means for extracting its optimal search strategies are given in [16]. Nevertheless, the assumption used in that model for constructing the representative agent's strategy is that the representative agent interacts with one seller agent at a time as part of its search process. Such an assumption ignores an inherent strength of autonomous agents, which is their capability to efficiently interact with several other agents in parallel (enhanced by their improved communication capabilities and their ability to process an enormous amount of information in a short time, compared to people). The parallel interaction is preferable when an agent's search cost combines fixed components (e.g. operational costs) and/or non-linear dependency on the number of interactions maintained (e.g. advantage of size). In such cases the adoption of the parallel technique by the representative agent suggests a reduction in the average cost per interaction with seller agents. While the integration of parallel interactions technique into a single search process is quite intuitive, its integration into a coalition's search is not trivial at all. The major difficulty derives from the fact that different coalition members may have heterogeneous multi-attribute utility functions. In this paper we supply a comprehensive analysis of the parallel cooperative search model and present an algorithm which can facilitate the calculation process of the coalition strategy. The new searching technique results in at least as good (and in many environments significantly better) expected utility for the coalition.

Similar to the model introduced in [16], we apply the multi-attribute utility theory (MAUT) [8], to analyze preferences with multiple attributes in our agent based search mechanism. This enables a set of preferences to be represented by a numerical utility function. We consider the agents to be heterogeneous, each having its own utility function. The model is general, though several specific implementation aspects relating to the B2C (Business-to-Consumer) market, where sellers can supply almost any demanded volume, and the C2C (Consumer-to-Consumer) market, where sellers offer single items for sale, are emphasized. Based on the proposed analysis, the representative agent can calculate its optimal strategy given the utility functions of the coalition members and the specific environment in which it operates.

Notice that among the three basic stages that are common to all coalition formation models [14, 19]: coalition structure generation (where the agents form/join the coalition), executing the coalition task, and dividing the generated value among the coalition members, our focus is on finding the optimal search strategy for the coalition, given its structure and the opportunity distribution. As suggested in [16], the representative agent operates in its environment alongside many other agents that represent coalitions differing in their size, their members' utility functions and the products they are seeking. These other coalitions, as well as the different individual utility functions play an important role when studying the stability of a coalition and issues of revealing the true utility function (truth telling). The analysis of these important issues is based on the ability to properly derive the coalition's utility given any specific self structure (i.e. number of agents it represents and their reported, not necessarily true, utility functions) and the environment it is operating in. This paper aims to supply this functionality, laying the foundations and enabling research of many of the important aspects of coalition formation given above in the context of cooperative search (truth telling, stability, payoff division, etc.).

The main contributions of this paper are threefold: First, we formally model and analyze the parallel cooperative search problem of agents operating in a costly environment. This model is a general search model and can be applied in various domains in addition to the electronic marketplace that is being used as a framework for our work. Second, we show that in many environments the parallel cooperative search outperforms the traditional search strategies (either when each agent searches by itself or when using a cooperative sequential search). Furthermore, we draw attention to scenarios where traditional cooperative search is proven to be non-beneficial, however parallel cooperative search is a favorable technique. Finally, we supply an algorithm that facilitates the calculation of the coalition's optimal strategy, and significantly reduces the complexities associated with the attempt to extract this strategy from an appropriate set of equations.

In the following section we address relevant multi-agent and parallel search literature. The parallel cooperative search model assumptions and a formal description are given in sections 3 and 4, respectively. In section 5, we explore the unique characteristics of the representative agent's optimal strategy when using cooperative parallel search, leading to the introduction of an efficient algorithm for extracting it. In section 6 we demonstrate the unique properties of the parallel search method using as a reference two of the classical search models that our suggested model generalizes. We conclude and suggest directions for future research in section 7.

2. RELATED WORK

In many scenarios autonomous agents in multi-agent environments may cooperate in order to perform tasks. The need for cooperation may arise either when an agent is incapable of completing a task by itself or when operating as a group can improve their overall performance [3, 10, 19]. Group based cooperative behavior can be found in various domains, such as solving complex optimization problems [18], military and rescue domains [5], e-business applications [19, 20] and many more. In the electronic market domain, most authors focus on coalitions formed to obtain volume discount [19, 20]. Additional coalition formation models for the electronic marketplace consider extensions of the transaction-oriented coalitions into long-term ones [3], and for large-scale electronic markets [10]. Traditionally, the majority of this research effort has focused on issues concerning optimal division of agents into disjoint exhaustive coalitions [14, 20], division of coalition payoffs [20] and enforcement methods for interaction protocols. Only a few authors have considered the coalition's problem of determining its strategy in the electronic commerce domain, once the coalition is formed [7]. Nevertheless, other than in [16], none of the proposed models have considered a coalition's search in a costly environment, and in particular none of them (including [16]) have made use of the agent's capabilities to maintain parallel interactions.

The problem of a searcher operating in a costly environment, seeking to maximize his long term utility is addressed in classical search theory ([11, 12], and references therein). The three main search models that can be found in the literature are the fixed sample size model, the sequential model and the variable sample size model. In the fixed sample size model, introduced in [17], the searcher draws a single sample where all observations are taken simultaneously. In the sequential search model [11] the searcher draws one observation at a time, allowing multiple search stages. The third search model [2, 6, 13] suggests a combined approach in which several observations may be made at any period. This latter method, which outperforms the other two, is in fact the single agent's equivalent to our cooperative search model considered in this paper. In addition to the establishment of some general properties of a search rule, most of the papers mentioned above considered

mainly issues of uncertainty associated with the availability of the inspected offers [6], recall and fallback utilities [13], and the effect of a final decision horizon on the search strategy [2]. Nevertheless, the focus of the above works from the search theory domain is on a single agent's search, and the analysis of a cooperative search is lacking. As shown in [16], the transition from a single agent search to a cooperative search concept as the one we base our model on, is not trivial and encapsulates many complexities resulting in a different strategy structure. In the cooperative search model, the representative agent needs to take into consideration the affect of new opportunities found on any subset of utility functions associated with the different coalition members. Though the process of extracting the optimal strategy is very different from the one used by a single agent that tries to maximize a simple or an aggregated utility function with a single opportunity.

3. THE MODEL

We base our model description and formulation on the definitions given in [16] and extend them to reflect agents' parallel search capabilities. We consider an electronic marketplace where numerous buyer and seller agents can be found. Each agent is interested in buying or offering to sell a well defined product. A product can be offered by many different seller agents under various terms and policies (including price). We assume that while buyer agents are ignorant of individual seller agents' offers, they are acquainted with the overall distribution of opportunities (defining an opportunity as the option to buy the product under specific terms and policies) in the marketplace.

Assuming there are no central mechanisms or mediators which can supply the agents with full immediate information concerning current market opportunities, they need to search for appropriate opportunities to buy their requested product. Throughout the search the buyer agents locate seller agents and learn about their offers by interacting with them. Each buyer agent evaluates opportunities using its own multi-attribute utility function. Buyer agents may have heterogeneous preferences and thus the utility from a given opportunity differs according to the evaluating buyer agent.

In its most basic form, each buyer agent searches in such a way that it interacts with several sellers in parallel at each stage of its search thus learns about a new set of opportunities. Based on the agent's evaluation of the utility that can be gained from each opportunity in the set, the agent makes a decision whether to exploit any of the opportunities it encountered throughout its search (i.e. buy from any of the sellers) or resume its search in a similar method. A decision of resuming search is always accompanied with the number of parallel interactions to be executed next.

The search activity is assumed to be costly [4, 9, 16, 1]. For each search stage in which the buyer agent locates, interacts and evaluates seller agents, the process induces a search cost. This cost is a function of the number of parallel interactions initiated and maintained by the agent. The search cost structure is principally a parameter of the market's liquidity and volatility, and thus shared by all buyer agents operating in the specific marketplace. Recognizing the benefits of a cooperative search, buyer agents, interested in similar products or interchangeable products, may form coalitions [16]. Any coalition formed will always be represented by a representative agent, which conducts its search on behalf of the coalition in a similar method (encountering sellers and accumulating new opportunities). The representative agent's search cost increases both as a function of the number of parallel interactions it forms and the number of buyer agents it represents[2]. We assume a buyer agent's utility from a given opportunity may be interpreted into monetary terms. Thus the utilities are additive and the total search utility can be obtained by subtracting the search cost that the process induces from this value.

As part of its search process, the representative agent needs to set a strategy for determining, given any set of known opportunities, whether to terminate or resume its search. In the latter case, the agent also needs to determine the number of parallel interactions to be used in the next search round. The optimal strategy is the one maximizing its expected total search utility (opportunities utility minus search costs). Given the representative agent's goal of maximizing the overall coalition utility, its decision is not influenced by the payoff division protocol, nor by coalition stability considerations, but rather influences these two factors [16]. Any of the agents' pre-determined portion of the coalition's utility will increase in its absolute value along with the increase of the net coalition utility, thus the overall utility maximization strategy is the preferred strategy by all agents at every stage of the search.

4. PROBLEM FORMULATION

Let $B = (B_1, B_2, ..., B_k)$ be the set of the attributes defining any of the potentially available opportunities in the market, where each attribute B_i can be assigned a value from the finite set $(b^i_{min}, ..., b^i_{max})$. An opportunity's type is defined by the vector $\overrightarrow{o_i} = (b_1, b_2, ...b_k)$, assigning a value b_i to each specific attribute B_i. We denote by O the space of potential opportunity types the coalition may encounter. The opportunity types' distribution in the marketplace, is denoted by the probability function $p(\overrightarrow{o})$.

We consider a coalition $A = \{A_1, A_2, ..., A_m\}$ of a general size, where A_j is the $j-th$ buyer agent in the coalition. Each buyer agent, A_j, evaluates different opportunities using a utility function $U_j : O \rightarrow R$, where $U_j(\overrightarrow{o})$ is the agent's utility from opportunity type $\overrightarrow{o}$. The search cost associated with having a coalition of m agents maintaining w simultaneous interactions with seller agents over a search round is denoted by the function $c(w, m)$, satisfying $\lim_{w\rightarrow\infty} c(w, m) = \infty$ and $\frac{dc(w,m)}{dw} > 0, \frac{dc(w,m)}{dm} > 0$.

The set of opportunities known to the representative agent at a given stage of its search is denoted by θ_{known}. It is possible to have several opportunities of the same type in θ_{known}, as similar opportunities can be offered by several seller agents or a single seller agent may offer opportunities of a specific type with a quantity greater than one unit.

5. ANALYSIS

5.1 The search strategy

Let Θ be the collection of all possible sets of opportunities. Consider a function $alloc : \Theta \rightarrow O^m$ that maps a given set of opportunities θ to the coalition members in A (i.e. an allocation)[3] in a way that the aggregated agents' utility with such allocation is maximized[4]. Let $alloc(\theta) = (\overrightarrow{y_1}, ...\overrightarrow{y_m})$, $\overrightarrow{y_i} \in (\theta \cup \{\emptyset\})$ be the allocation, resulting from operating the function $alloc$ over the set θ, where $\overrightarrow{y_i}$ denotes the opportunity associated with agent A_i and $y_i = \emptyset$ denotes that no opportunity was allocated to agent A_i. The immediate utility for the coalition if it terminates the search at the

[2]The reasoning for correlating the coalition's search cost with the number of members being represented is mainly associated with some coordination overhead. See [16] for details.

[3]In B2C markets the same opportunity may be allocated to more than one agent, while in C2C markets each opportunity is restricted to only one agent.

[4]If there is more than one allocation that maximizes the overall coalition utility then the function $alloc$ will always choose one of them according to a pre-defined ordering.

current point given a set of known opportunities θ_{known}, is denoted as $U^s(\theta_{known})$ and can be calculated as:

$$U^s(\theta_{known}) = \sum_{j=1}^{m} U_j(\overrightarrow{y_j}) \quad (1)$$

where $U_j(\emptyset) = 0, \forall j$.

Notice that up until this point, the world states space on which the agent needed to define its strategy (reflected by the set Θ) was potentially infinite. Nevertheless, since there are only m agents represented by the coalition, any additional occurrence of an opportunity of type o_i in θ_{known} beyond the first m occurrences can neither improve the overall coalition utility nor the representative agent's strategy. As a result, the representative agent can reduce the set of known opportunities according to which it determines its strategy to a subset, s, of θ_{known} where each opportunity of a given type appears at most m times. We refer to s as a $state$, and define S as the set of all potential states. Given the $state$ definition, we define a strategy as a function $x : S \rightarrow N$, where $x(s) = 0$ if the agent decides to terminate its search; otherwise $x(s)$ is the number of parallel searches the representative agent should maintain next, when in state s. We denote the optimal strategy by x^*.

We define $V(s, w)$ as the expected utility when using w parallel searches when in state s (assuming any search decision taken at a future state $s' \neq s$ will make use of the optimal number of parallel searches). The term $V(s, 0)$ denotes the immediate utility obtained, if the agent decides to terminate the search at state s, thus: $V(s, 0) = U^s(s)$. The value w ($w \in N$, $w \geq 0$) that maximizes the coalition expected utility $V(s, w)$, is denoted as $x^*(s)$:

$$x^*(s) = \arg\max_w V(s, w) \quad (2)$$

In order to formulate the appropriate equation for $V(s, w)$ (from which $x^*(s)$ can be derived) we make use of several additional notations and definitions. Consider a search round in which the representative agent interacts simultaneously with w seller agents, yielding a set $\theta_w = \{\overrightarrow{o_1}, ..., \overrightarrow{o_w}\}, \overrightarrow{o_i} \in O$ of opportunities. Let Θ_w be the collection of all w-sized sets of opportunities that can be produced in the environment the representative agent is operating. We denote by $p_w(\theta_w)$ the probability of encountering a specific set of opportunities θ_w, when maintaining w random interactions with seller agents.

We define $next\_s(s, \theta_w)$ as a function that returns the new state s' of a representative agent, upon encountering the set θ_w given its initial state s.[5] For a given number of simultaneous interactions, w, and a given state s, let Θ^s_w be the collection of all w-sized sets of opportunities, θ_w, that change the agent's current state (formally stated as: $\Theta^s_w = \{\theta_w | \theta_w \in \Theta_w \; and \; next\_s(s, \theta_w) \neq s\}$). We denote the complementary set of Θ^s_w by $\bar{\Theta}^s_w$ (the set that includes all w-sized sets of opportunities θ_w that does not change the agent's current state). The expected utility when using w parallel searches while in state s, $V(s, w)$, can now be expressed as ($\forall w > 0$):

$$V(s,w) = -c(w,m) + \sum_{\theta_w \in \Theta^s_w} p_w(\theta_w) V(s', x^*(s')) + \sum_{\theta_w \in \bar{\Theta}^s_w} p_w(\theta_w) V(s,w) \quad (3)$$

where $s' = next\_s(s, \theta_w)$. This is derived from the stationary nature of the problem - if no better state was reached, the search resumes using the same strategy, yielding the same expected utility. After some simple math manipulations of the above term we obtain:

$$V(s,w) = \frac{-c(w,m) + \sum_{\theta_w \in \Theta^s_w} p_w(\theta_w) V(s', x^*(s'))}{\sum_{\theta_w \in \Theta^s_w} p_w(\theta_w)} \quad (4)$$

[5]The set returned by $next\_s$ is the union of opportunities in s and θ_w, where each opportunity type appears at most m times.

Notice that in the case where no new better state can be reached, the denominator becomes zero, and $V(s, w) = -\infty$. This is quite straightforward as the representative agent infinitely maintains a costly search. Here, the coalition's optimal strategy is inevitably to terminate the search. This important characteristic will be used later for designing the proposed solution algorithms.

At this point, one may attempt to compute the coalition's strategy x^* by solving a set of equations of types 1, 2 and 4. Nevertheless, this solution approach is accompanied by many inherent complexities, derived from the structure of the equations. First, notice that equation 4 is a recursive equation and one needs to know the optimal strategy taken in future states s' when extracting the optimal strategy of a given state s. Second, the computation of $V(s, w)$ in equation (4) is exponential in the number of parallel searches, w, used (affecting the number of sets in Θ^s_w, both in the denominator and numerator). Last, according to the above formulation, the potential number of parallel searches that may be used is not bounded, thus reaching a local maximum does not guarantee that a higher utility cannot be obtained.

In the next subsection we present a comprehensive analysis of the problem, emphasizing some unique characteristics of the representative agent's optimal strategy. These findings lead to an algorithm with a polynomial complexity (in the number of potential interactions, w) for computing $V(s, w)$ (which is the key component for computing $x(s)$).

5.2 Analysis

We begin our analysis by facilitating the state definition in a way that allows us to consider simple divisions of the search space into improving and non-improving areas with regard to the coalition's utility. For this purpose we introduce the concept of equivalence between different sets of opportunities within the context of cooperative search. We say that two sets of opportunities $\theta', \theta'' \in \Theta$ are equivalent sets $\theta' \equiv \theta''$, if the following hold: (a) $U^s(\theta'') = U^s(\theta')$; and (b) $U^s(\theta' \cup \theta) = U^s(\theta'' \cup \theta)$ for any set of opportunities $\theta \in \Theta$ that the agent may encounter in the future. For any two equivalent sets θ', θ'', the representative agent is indifferent to knowing the opportunities in θ' and the opportunities in θ''. This is because any set of opportunities the representative agent will encounter in the future results in a similar utility thus the overall coalition's utility will be the same in both cases. Moreover, since the agent's decisions are merely determined by the overall coalition utility and in both cases similar utilities are reached with similar probabilities, the agent will use the same number of parallel interactions for both sets.

Notice that according to the definition above $equivalent$ is a transitive relation ($\theta' \equiv \theta''$, $\theta'' \equiv \theta''' \rightarrow \theta' \equiv \theta'''$). Moreover, $\theta' \equiv \theta''$ implies that $(\theta' \cup \theta) \equiv (\theta'' \cup \theta), \forall \theta \in \Theta$. Given an allocation $\ell = (\overrightarrow{y_1}, ..., \overrightarrow{y_m})$ of a set θ, we denote the set of opportunities that appear in ℓ by $\{\ell\}$.

THEOREM 1. *Any set of opportunities θ is equivalent to the set of opportunities returned by the function $alloc(\theta)$. Formally stated: $\theta \equiv \{alloc(\theta)\}$.*

The above theorem is certainly non-trivial, particularly when considering the C2C market, where the optimal allocation is permutation based.

An immediate result obtained from theorem 1 above is that the representative agent's strategy is affected only by the subset of θ_{known} defined by $\{alloc(\theta_{known})\}$. Therefore we can now redefine $state$ to be the set of opportunities that are members in $alloc(\theta_{known})$. This latter definition significantly simplifies our analysis and enables us to suggest an efficient algorithm for extracting x^*. It is

notable that the computation method used by the function $alloc$ is market-dependent. While in B2C markets the function assigns each agent with the opportunity that maximizes its utility, $\vec{y_j}^* = \arg\max_{\vec{y} \in \theta} U_j(\vec{y}), j = 1, ..., m$, in C2C markets $alloc$ can be computed by solving a maximum weighted matching in a bipartite graph[6].

Given the analysis above, the set of all possible states, S, is given by $S = \{s | \exists \theta \in \Theta \; where \; s = \{alloc(\theta)\}\}$. Also, we can now denote by $S_s = (s_1, ...s_{|S|})$ the states constituting S ordered by their utilities, where s_1 is the state with the highest utility in S. Notice that now the function $next\_s(s, \theta_w)$ simply returns the set of opportunities in $alloc(s \cup \theta_w)$.

The above changes in the definition of a $state$ does not affect the definition of Θ^s_w and $\bar{\Theta}^s_w$. We denote by $p^{stay}(s, w)$ the probability the agent stays at the same state s after conducting w parallel searches. This can be calculated as the probability of having none of the encountered w opportunities change the representative agent's state:

$$p^{stay}(s, w) = (p^{stay}(s, 1))^w = (\sum_{\{\vec{o}\} \in \bar{\Theta}^s_1} p(o))^w \quad (5)$$

The term $1 - p^{stay}(s, w)$ can now be used as a better structured representation of the element $\sum_{\theta_w \in \Theta^s_w} p_w(\theta_w)$ that appears in equation (4). Similarly, we may consider the use of $V^{new}(s, k)$, defined as the coalition's expected utility obtained by potentially reaching new states (e.g. different than s) after maintaining k parallel interactions, while using the optimal strategy $x^*(s')$ for each new state s'. The term $V^{new}(s, k)$ does not take into account the cost associated with the current k interactions, however it does consider the search costs associated with any further search stages, originated in new (better) states. Notice that if the agent stays in state s during all k searches $v^{new}(s, k)$ is equal to zero. The term $V^{new}(s, w)$ is actually a representation of the element $\sum_{\theta_w \in \Theta^s_w} p_w(\theta_w) V(s', x^*(s'))$ in equation (4). Therefore, equation (4) can now be formulated as:

$$V(s, w) = \frac{-c(w, m) + V^{new}(s, w)}{1 - p^{stay}(s, w)} \quad (6)$$

The use of $V^{new}(s, w)$ in the above equation is a primary concept used in the algorithm suggested in the next section. Nevertheless, in order to extract $x^*(s)$ it is essential to supply the representative agent with an upper bound, w^s_{max}, for the optimal number of parallel searches to be used when in state s. The following proposition suggests an efficient bound for $x^*(s)$.

PROPOSITION 5.1. *For each state, s_i, an upper bound, $w^{s_i}_{max}$, to $x^*(s_i)$ can be calculated using $w^{s_i}_{max} = \lceil w \rceil$, where w is the solution of the following equation:*

$$c(w, m) = (U^s(s_1) - U^s(s_i))(1 - p^{stay}(s_i, w)) \quad (7)$$

The suggested bound is valid simply because for every value of w greater than $w^{s_i}_{max}$ the search cost associated with the following immediate search round is greater than any possible future improvement in the coalition's utility. Later on, we show that the above upper bound value is a by product of the main loop in our proposed algorithm, thus it does not even need to be directly calculated.

[6]For a set of opportunities $\theta \in \Theta$ found in the C2C market we construct a graph $G_\theta = (V_1, V_2, E)$, where each vertex of V_1 corresponds to an agent in A and each vertex in $V2$ corresponds to an opportunity $\vec{o} \in \theta$. An edge is connected between each agent A_j in V_1 and each opportunity $\vec{o}$ in V_2. The weight of such an edge is the utility for agent A_j from opportunity $\vec{o}$, $U_j(\vec{o})$. Here $alloc(\theta) = (\vec{y_1}, .., \vec{y_m})$, where $\{(A_1, \vec{y_1}), .., (A_m, \vec{y_m})\}$ is a maximum weighted matching in G_θ.

5.3 Algorithmic Approach

Recall that when attempting to solve the problem as a set of equations (see section 5.1) the potential number of parallel searches that may be used is unbounded. Furthermore even if we do manage to come up with a bound for $x^*(s)$ then the calculation of $V(s, w)$ (from which $x^*(s)$ can be derived) is exponential in the number of parallel interactions used, w. Our analysis, which is based on the restructuring of the different elements composing $V(s, w)$, allows us to bypass these two main complexities through the introduction of a finite algorithm with a polynomial computational complexity in w that will necessarily identify the optimal strategy for the representative agent.

In order to efficiently compute $V^{new}(s, w)$ in equation (4) we consider the w simultaneous interactions as w sequential interactions, associated with no search cost. This fully complies with the definition of $V^{new}(s, w)$ as given above (as the cost of the w interactions is already considered). The justification for the above representation method is given in the following lemma 1 which follows directly from theorem 1.

LEMMA 1. *A new state reached by obtaining a new set of opportunities is equivalent to a state reached by sequentially obtaining pairwise disjoint subsets of this set. Formally stated, given a set θ_w and any number of subsets $\theta^1_{w_1}, ..., \theta^r_{w_r}$, $\theta^i_{w_i} \subseteq \theta_w$, $\theta^i_{w_i} \cap \theta^j_{w_j} = \emptyset, i \neq j$, $\theta^1_{w_1} \cup ... \cup \theta^r_{w_r} = \theta_w$ and an initial state s, then the following holds:*

$$ns(s, \theta_w) \equiv ns(ns(...ns(ns(s, \theta^1_{w_1}), \theta^2_{w_2})..., \theta^{r-1}_{w_{r-1}}), \theta^r_{w_r}) \quad (8)$$

where $ns(s, \theta^i_{w_i}) = next\_state(s, \theta^i_{w_i})$. The proof is given in the full paper.

A specific case of the above lemma 1 is where each subset consists of a single opportunity. Thus the calculation of $V^{new}(s, k)$ can recursively rely on the values of $V^{new}(s', k-1)$ where s' represents any of the new states reached after obtaining one additional opportunity from O. Therefore in order to compute $V^{new}(s, k)$, we merely consider the expected utility after conducting one interaction from the planned k interactions. Here, with a probability of $p^{stay}(s, 1)$ the agent remains in the same state s, where the expected utility (having $k-1$ more interactions to go) is $V^{new}(s, k-1)$ (Recall that $V^{new}(s, 0) = 0$ according to the definition of this function that was given in the previous section). Otherwise, if a new state s' is reached after the single interaction, then there is the possibility of reaching further new states in the remaining $k-1$ interactions (taking these states' utility into consideration by the term $V^{new}(s', k-1)$) or with a probability of $p^{stay}(s', k-1)$ the agent will remain in the new state s' even after the additional $k-1$ interactions (in which case the utility is the one obtained by resuming the search from this state using the optimal strategy, $V(s', x^*(s'))$). The above description is encapsulated in the following recursive equation:

$$V^{new}(s, k) = p^{stay}(s, 1) V^{new}(s, k-1) + \quad (9)$$
$$+ \sum_{\{\vec{o}\} \in \Theta^s_1} p(\vec{o})(V^{new}(s', k-1) + p^{stay}(s', k-1) V(s', x^*(s')))$$

where $s' = next\_state(s, \overrightarrow{o})$. Notice that when repeating the calculation using the above equation with increasing k value, starting from $k = 1$, each iteration includes only a single unknown parameter, $(V^{new}(s, k))$.

The above analysis leads to the following algorithm for computing the agent's optimal strategy.

ALGORITHM 5.1. *An algorithm for computing the optimal search strategy x^*. **Input**: O - set of potential opportunity types in the*

market; $p(\vec{o})$ - opportunity types' probability function; m - coalition's size; $U_j()$, $j = 1, ..., m$ - coalition members' utility functions; $c(w, m)$ - search cost function;
***Output**: $x^*(s)\ \forall s \in S$ - the representative agent's optimal strategy.*

1. *Build the set of ordered states S_s;*
2. *For i=1 to $|S|$ {*
3. *Set $V(s_i, 0) = U^s(s_i)$ using equation 1*
4. *Set $w = 1$;*
5. *While $c(w, m) \leq (U^s(s_1) - U^s(s_{|S|}))$ {*
6. *Compute $V^{new}(s_i, w)$ using equation (9).*
7. *Compute $V(s_i, w)$ using equation (6); w++; }*
8. *Set $x^*(s_i) = \arg\max_{w' \in (0,..w)} V(s_i, w')$ }*
9. *Return($x^*(s_i)$, $i = 1, ..., s_{|S|}$)*

Notice that at each stage of its execution, algorithm 5.1 reuses components computed in earlier stages. For example, $V^{new}(s, w)$ appears both in the computation of $V(s, w)$ (equation (6)), in the computation of $V(s', w + 1)$ (equation (9)), where $\exists \vec{o}' \in O$ such that $next\_s(s', \vec{o}') = s$ and in the computation $V(s'', w+1)$ equation (9), where $\exists \vec{o}'' \in O$ such that $next\_s(s'', \vec{o}'') = s$. Storing in memory the result for each such computational element for the purpose of reusing it at later stages significantly improves the efficiency of the algorithm. This is accomplished by using two matrixes V and V^{new} of size $|S| \times (w_{max}^{s_{|S|}} + 1)$, where the corresponding $V(s, w)$ and $V^{new}(s, w)$ values are stored for each pair (s, w), representing a state and the correlated result for each number of simultaneous interactions used for calculation. Additionally, we store x^* values for reusing $x^*(s')$ in the computation of $v^{new}(s, w)$.

THEOREM 2. *Algorithm 5.1 returns the optimal strategy of the representative agent in a polynomial time of $w_{max}^{s_{|S|}}$.*

PROOF. In order to prove that the algorithm is polynomial in $w_{max}^{s_{|S|}}$, it is sufficient to prove that for each state s the computation of steps 3-8 are polynomial in $w_{max}^{s_{|S|}}$. Notice that the first elements being calculated are for state s_1 (i.e. the one with the maximum utility) according to the loop in step 2. Here, as explained in section 5.1, the expected utility from any strategy in which the search is resumed (i.e. using $w \geq 1$) is $V(s, w) = -\infty$ (formally, since $\Theta_w^{s_1} = \emptyset\ \forall w$ then $p^{stay}(s_1, w) = 1$ and $V^{new}(s_1, w) = ... = V^{new}(s_1, 1) = 0$, thus $V(s_1, w) = -\infty\ \forall w \in (1, .., w_{max}^{s_{|S|}})$). Thus the optimal strategy in state s_1 is to terminate the search, i.e. $x^*(s_1) = 0$ and $V(s_1, 0) = U^s(s_1)$. For any other state, s, when reaching step 6 of the algorithm, the agent has already computed both $V(s', x^*(s'))$ and $V^{new}(s', w)\ \forall w \in (0, ..w_{max}^{s_{|S|}})$ for all potential future new state s' of the state s. This is due to the fact that all future states of a state s appear before s in the set of ordered states S_s (either because having a higher utility, or equal utility yet sorted before s according to the function $alloc$). In addition, for any number of parallel interactions $w \geq 1$ the agent has already computed $V(s, w - 1)$. Therefore the computation time in step 6 does not depend on w. Then, when reaching step 7 of the algorithm, the numerator computation takes a constant time and the computation time of the denominator is polynomial in w. In step 8 the agent chooses the maximum value between $w_{max}^{s_{|S|}}$ values that have already been computed, therefore it is polynomial in $w_{max}^{s_{|S|}}$. The algorithm uses $w_{max}^{s_{|S|}}$ as an upper bound for the optimal number of interactions $x^*(s_i)$,$\forall i = 1, ..., |S|$ (Notice that for $s_{|S|}$ the term $(1 - p^{stay}(s, w))$ in equation 7 is 1). This bound is valid since according to equation 7 the value of $w_{max}^{s_i}$ decreases as a function of i. □

Further significant improvement of the above algorithm's performance can be achieved by calculating and using the specific upper bound, $w_{max}^{s_i}$, correlated with each state, s_i in step 5, according to equation 7. This might require at some points re-computation of $V(s_i, w)$ for w values that were not used in former algorithm execution stages; however the total number of calculations for each state s_i will significantly decrease[7].

Before we demonstrate some important properties of our search model, we wish to emphasize that the cooperative parallel search is a generalization of both the single agent parallel search and the cooperative sequential search models[8]. it is clear that the algorithm suggested in section 5.3 results in the same strategy as in the cooperative sequential search and in the single agent's parallel search, for the specific cases in which $\forall s_i\ w_{max}^{s_i} = 1$ parallel interactions or $m = 1$ agents, respectively.

Finally we wish to note the case where the agents are fully homogeneous (in terms of their utility functions) and operate in B2C markets. Here, we can prove that the optimal strategy of the representative agent is stationary (i.e. does not change according to the current state). Furthermore, we show that the stationary strategy characteristic holds not only for fully homogeneous agents but also when the agents have correlated preferences. We say that two agents A_i and A_j have correlated preferences if agent A_i prefers $\vec{o}'$ over $\vec{o}''$ if and only if agent A_j prefers opportunity $\vec{o}'$ over $\vec{o}''$, (i.e $\forall \vec{o}', \vec{o}'' \in O\ U_j(\vec{o}') \leq U_j(\vec{o}'') \leftrightarrow U_i(\vec{o}') \leq U_i(\vec{o}'')$).

THEOREM 3. *In B2C market if all agents have correlated preferences, the search strategy is based on a reservation value[9] U_{rv}. In such scenario the number of parallel interactions the representative agent uses according to the optimal strategy (in case it resumes the search) is fixed during the search ($\forall s \in S$ such that $U^s(s) < U_{rv}$ exists $x^*(s) = w_{fixed}$).*

PROOF. In the above scenario, the search can be represented as the search of a single agent with a utility function which equals the sum of the different agents' utilities, $U = U_1 + U_2 + ... + U_m$. In such case after terminating the search, each of the coalition members will always be assigned with the same opportunity. Therefore, the search strategy is reservation value based, and the search will be terminated upon reaching an opportunity with a utility exceeding some reservation value U_{rv}. Since the probability of reaching such opportunity does not depend on the agent's state, the number of parallel interactions used throughout the search is fixed. □

6. ILLUSTRATIVE EXAMPLES

Having an efficient means for calculating the representative agent's optimal strategy when using parallel search, we can now demonstrate some specific properties of this search method. As a reference we use the single agent's parallel search and the cooperative sequential search models introduced in [2, 6, 13] and [16], respectively.

When taking the cooperative sequential search as a baseline, in many cases the use of the cooperative parallel search results in a significantly improved joint expected utility for the agents constituting the coalition (in the worst case scenario, the optimal cooperative search strategy will yield equal utility). When considering

[7]The extent of the achieved improvement is highly correlated with the specific environment in which the representative agent is operating.

[8]Notice that in this context the single agent sequential search is a specific case of the single agent parallel search, where the agent interacts with a single seller agent at a time.

[9]See [16] for definition and discussion concerning reservation value based strategies in cooperative search.

single agents' parallel search, the cooperative parallel search has the potential to produce a significantly better expected utility (in comparison to the aggregated utility of the single searches) however, the decision of which of the two methods to use depends on the amount of coalition overhead costs induced by the cooperative search.

Figure 1 illustrates the above, depicting the expected utility per agent in any of the search methods[10] in the C2C market (left hand-side) and the B2C market (right hand-side) as a parameter of the similarity level (α) between the utility functions of the agents constituting the coalition. The results are based on the following environment, which was used originally for evaluating the performance of the cooperative sequential search [16]:

ENVIRONMENT 1. *A coalition of two agents, A_1 and A_2, searching for opportunities defined by two attributes, B_1 and B_2, where each attribute can have a value from the discrete range $(1, ..., 5)$ with an equal probability for each of the values. The agents are heterogeneous in respect to the way they evaluate each potential opportunity: agent A_1 is associated with the utility function $U_1(\overrightarrow{o}) = B_1 + B_2$ while agent A_2 with the utility function $U_2(\vec{x}) = 2(1-\alpha)B_1 + 2\alpha B_2$. Thus the parameter α indicates the level of agents' similarity/heterogeneity. The search cost of any single agent was taken to be $c(w, 1) = 0.15 + 0.05w$ and for a coalition $c(w, m) = c(w, 1)ln(m + 1)$, $\forall(m > 1)$.*

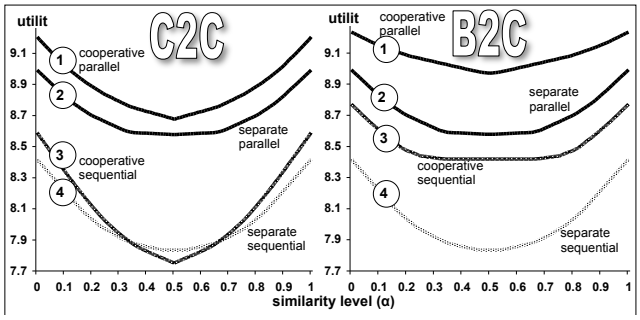

Figure 1: Average utility per buyer agent for different models in different markets

Curve 1 in each graph depicts the average expected utility when the two agents form a coalition, making use of the suggested parallel cooperative search. As expected our model outperforms the cooperative sequential search model (represented by curve 3) in terms of the expected utility for the agents. The other two curves describe the average expected utility of the agents when each is searching separately using the parallel (represented by curve 2) and the sequential (represented by curve 4) methods. In this specific environment the use of the cooperative parallel search also outperforms the single agent parallel search model though it is not always the case. Notice that the results obtained for the cooperative parallel search are consistent with a general characteristic of cooperative search [16] in a way that the usage of the method in the B2C market results with a better expected utility than in the C2C market. In the case of the separated single searches the market type does not affect the strategy structure nor the expected utility.

Figure 1 also reflects an interesting insight which contradicts an important strategy domination relationship found between single and cooperative sequential search techniques of fully homogeneous agents (i.e. with the same utility function, as in the case where $\alpha = 0.5$ in our environment). While for the sequential search the use of single agents' searches always outperforms cooperative search in C2C markets (when considering fully homogeneous agents) [16], here we have a true evidence that when parallel search is concerned, the cooperative search technique may outperform the aggregated result of the single homogeneous agents' search.

Next we introduce and make use of a simpler sample environment for demonstrating some additional properties of the cooperative parallel search.

ENVIRONMENT 2. *Similar to environment 1 above, except for the following changes: (1) each attribute has only two possible values $(1, 2)$ with an equal probability of $\frac{1}{2}$; (2) The utility functions used are $U_1(\overrightarrow{o}) = 1.9B_1 + 0.1B_2$ and $U_2(\overrightarrow{o}) = 0.1B_1 + 1.9B_2$. The search cost of any single agent was assumed to be $c(w, 1) = 0.5 + 0.05w$ and for a coalition $c(w, m) = c(w, 1) * ln(m + 1)$, $\forall(m > 1)$.*

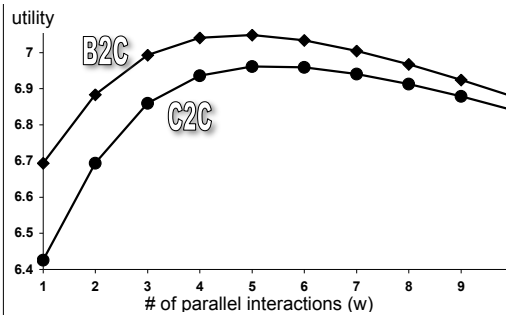

Figure 2: Coalition's overall utility as a function of w

Figure 2 depicts the expected coalition's overall utility with respect to the number of searches conducted at the beginning of the search (i.e. the first search stage, before the agent knows of any of the opportunities), assuming that in all the other states the agent uses the optimal number of parallel interactions, $x^*(s)$. Here, we can see the affect of two conflicting forces: as the number of parallel interactions the agent uses in this stage increases, the probability of associating a better opportunity with any of the two coalition members increases, however the overall search cost associated with the search stage increases. From the figure, we learn that the optimal number of parallel interactions to be used in this stage is $x*(\emptyset) = 5$.

An additional important characteristic of the cooperative parallel search we wish to emphasize concerns the number of parallel interactions used as part of the optimal search strategy along the search. While in a single agent's parallel search the search strategy is stationary (i.e. the number of parallel interactions used does not change along the search process) in our model the number of simultaneous interactions along the search that needs to be maintained depends on the agent's state (i.e. the set of known opportunities known to the representative agent). This is demonstrated in the directed acyclic graph (DAG) given in figure 3, which represents the feasible transitions from one state to other states in a B2C market described by environment 2. The state is determined according to the relevant set of known opportunities, correlated with the definition given in section 5.2. The relatively large number of parallel interactions used in the optimal strategy, allows the representative agent to reach all better states that are defined in this example. Notice that when reaching states $\{(1, 2), (2, 1)\}$ and $\{(2, 2), (2, 2)\}$ the optimal strategy of the agent is to terminate the search. For comparison purposes, notice that in any of the single agents' separate search (i.e. single agent parallel search model) the optimal strategy is to constantly use 4 parallel interactions (as long as resuming search).

[10]For the cooperative models the average expected utility per coalition member measure is used.

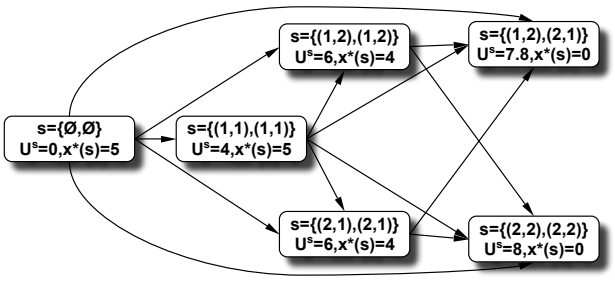

Figure 3: Potential transitions between states in a simple B2C market

7. DISCUSSION AND CONCLUSIONS

The capability of using parallel interactions as part of a search process is inherent in the infrastructure of autonomous information agents. When using the cooperative parallel search, the representative agent should use a new strategy, different in its structure in comparison to the optimal strategy used in the cooperative sequential search and in a single agent's parallel search. As expected, the use of the new model has the potential of significantly improving the coalition's expected utility as demonstrated in the previous section. Furthermore, we emphasize that the coalition's expected utility will never decrease when using our proposed mechanism in comparison to pure sequential cooperative search. This is mainly because in the case where maintaining more than a single interaction in some of the world states is not favorable the suggested algorithm will converge to one interaction at a time strategy, as used in the sequential cooperative search (which is a specific case of our model). Obviously if the search cost is linear and depends solely on the number of interactions being maintained, then the sequential cooperative search is the dominating strategy. Nevertheless, a scenario in which the representative agent's search cost combines additional fixed components and/or non-linear dependency on the number of interactions maintained are much more realistic [16]. In those scenarios the parallel cooperative search yields great benefits for searchers.

The novelty of the analysis given in this paper is twofold. First it supplies us with a better understanding of the opportunities space, dividing it into improving and non-improving areas, thus instead of having dual simultaneous dependencies between states we can now define a single directional dependency for each pair of states. Second, it supplies a bound for the optimum number of parallel interactions that the representative agent uses in each state in its optimal strategy. These two features allow us to overcome the main complexities associated with the attempt to solve the problem as a set of equations and offer a finite algorithm with a polynomial (rather than current exponential) computational complexity that inevitably reaches the optimal strategy. The model does not depend on attribute preferences or a specific cost function and with appropriate modification of the allocation function it can be generalized to additional markets other than C2C and B2C.

It is notable that the same considerations discussed in [16] concerning the potential for an actual implementation of cooperative search hold for the parallel (general) model presented in this paper. Similarly, future research in the area of parallel cooperative search should extend the scope of research to include additional topics associated with the coalition formation process such as the coalition stability, given the MAS settings and the division of payoffs (in terms of side payments) between the coalition members.

ABSTRACT

It is very difficult for beginners to define and find the most relevant literature in a research field. They can search on the web or look at the most important journals and conference proceedings, but it would be much better to receive suggestions directly from experts of the field. Unfortunately, this is not always possible and systems like CiteSeer and GoogleScholar become extremely useful for beginners (and not only). In this paper, we present an agent-based system that facilitates scientific publications search. Users interacting with their personal agents produce a transfer of knowledge about relevant publications from experts to beginners. Each personal agent observes how publications are used and induces behavioral patterns that are used to create more effective recommendations. Feedback exchange allows agents to share their knowledge and virtual communities of cloned experts can be created to support novice users. We present a set of experimental results, obtained using CiteSeer as a source of information, that show the effectiveness of our approach.

1. INTRODUCTION

The Web is a huge source of information where it is possible to find publications and scientific literature. However, the majority of papers are usually irrelevant to individual researchers. Beyond conventional search engines, users need specific tools and methods for an effective use of all the available scientific resources. For example, special search engines for scholar articles, like GoogleScholar [7], have recently gained a lot of popularity among professionals and specialists. Online libraries like CiteSeer [9] and ACM digital library [16] for computer science are more and more used by researchers to search and download papers that are relevant to their scientific area. These services provide search and browsing facilities based on the list of references of the papers. However, for a novice researcher it is still very hard to determine which papers are really significant among those available. It should be very nice for a beginner to receive suggestions directly from experts of the field. An expert knows which papers are more influential, which papers were published at top conferences and in prestigious journals, what is the state-of-the-art and so on. The expert takes into account a lot of implicit factors when determines if a paper is relevant or not. But, unfortunately, we cannot assign a personal expert for each area of interests to every novice researcher. This calls for systems able to facilitate scientific publication search.

Among the proposed solutions for the scientific publication search, personalization systems [4, 8] focus on the need of a certain user, maintaining his/her profile and notifying him/her periodically or on-demand about papers related to the user's interests. The main goal of these systems is to filter information flow delivering to the user only items related to his/her interests. Differently, recommendation systems [1, 12] usually exploit the knowledge obtained from different users of the system to generate useful recommendations. Many recommendation systems [11, 12] use collaborative filtering algorithms [14] to compare similarity between users in order to recommend to the target user previously unseen items contained in the profiles of similar users. To some extent, currently developed systems mitigate search of the relevant literature for the person that is a novice in the field. However, they have several shortcomings. For instance, there exists a lack of expert knowledge, when all the users are novices. Pro-active recommendations sometimes turn into a heavy flow of potentially interesting items. Finally, most of the systems require explicit feedback, which is not always convenient and often discouraged by users.

In this paper we present a multi-agent system that facili-

tates scientific publications search. The architecture of the system is distributed and includes several multi-agent platforms. Each platform represents an organizational community of users with similar research interests. Alternatively, virtual communities of cloned experts can be created to facilitate the search of the papers relevant to a specific topic. As said above, we cannot assign an expert to each novice, but we can assign to a novice user an agent which has access to the expert's knowledge, represented in other agents. Users interact with their personal agents which cooperate and produce a transfer of knowledge about relevant publications from experts to beginners. Agents in our system are based on Systems for Implicit Culture Support [3] that learn behavioral patterns by observing how publications are used, namely which papers users cite, download, etc. Agents use learnt patterns and exchange feedback to produce personal recommendations more effectively. The system also provides an opportunity to share opinions and information contained in single bibliographies. It is possible to have an external information source, e.g. CiteSeer, to obtain citation graph and to download desired documents.

Although personal internet assistant agents have been developed for more then ten years [6, 10], the idea of using agents to support search of scientific publications is relatively new (see e.g. [8, 12]). Unlike most currently developed systems we use implicit feedback, avoiding extra work of the users. The framework used for the recommendation creation is general, being able to recommend not only papers, but expert in the research area as well. The main contribution of this work is the architecture of the MAS and its application to publications search. The use of Implicit Culture as a component of the system is justified by a number of applications.

The paper has the following structure. Section 2 motivates our approach by example. In Section 3 we describe the general architecture of the system, whereas experimental results are presented in Section 4. We discuss related work in Section 5 and conclude in Section 6.

2. MOTIVATION

In this section we illustrate the possible use of the system and show the role of agents in the system.

2.1 Motivating Example

Ali is a first year PhD student who studies Data Mining. His tutor Nick has recommended him to have a look on the paper "Privacy-preserving data mining" by Agrawal and Srikant. Ali submits the title and the authors of the paper to the system and his personal agent asks personal agents of his colleagues whether they have the paper in their bibliographies. In our case, the other PhD students, who are working in the same research group with Ali, are Javed and Julia. The platform containing the personal agents of these students is depicted in the upper left part of Figure 1. Julia is the PhD student of the second year and she already has the paper requested by Ali in her bibliography. Her personal agent provides this information in response to the query of Ali's personal agent. Ali receives complete information about the paper, including its location on the Internet, or in the local intranet, and comments from Julia, if, of course, she wants to give them. Now Ali can download the paper and then cite it in his paper. If the information about the target paper has not been found on the platform,

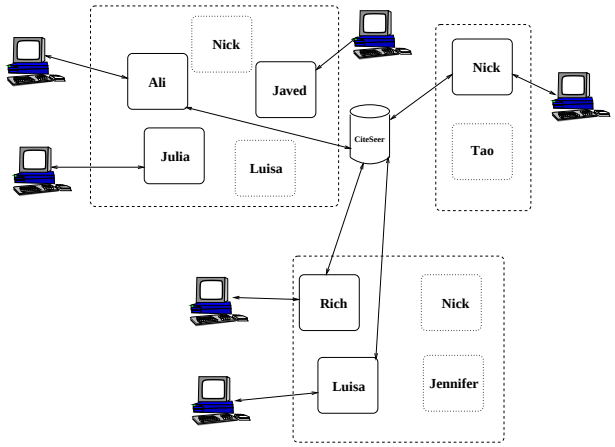

Figure 1: An example of several platforms with three ad hoc communities. Cloned expert agents are depicted with dotted squares. Julia, Ali and Javed also form an organizational community.

it is possible to contact other platforms or to query different information sources, e.g. CiteSeer.

To describe virtual community creation we introduce Luisa who is Ali's co-tutor, and works on Security. Ali wants to find relevant papers on the intersection of these two topics (Data Mining and Security), but his tutors are very busy. However, they agreed that Ali clones their personal agents. Ali's personal agent creates a virtual community cloning the personal agents of Nick and Luisa. Now, the corresponding expert agents run on the platform with Ali's personal agent. Each agent on the platform contains the information regarding behavior of its user, in particular Luisa's and Nick's citing, reading and browsing behavior. In our case, to find relevant papers on the intersection of Data Mining and Security, Ali's personal agent queries expert agents (Nick's and Luisa's) and shows to Ali the results ranking the papers recommended by both experts higher. The idea of combining Nick's and Luisa's results is to find papers that are relevant for them both. Moreover, being cloned and placed on another platform, the agents of Nick and Luisa adapt themselves to the local community, namely changing their recommendations towards the local common interests, or "culture".

In Figure 1 three ad hoc communities are depicted. For instance, Luisa and Rich work in the same research laboratory and consider research of Nick and Jennifer to be relevant to their current interests. Therefore cloned agents of Nick and Jennifer are running on the platform. Nick works with Tao and has his expert agent on the platform.

2.2 The Role of Agents

In our architecture, agents do the "dirty" work for their users. They perform bibliography maintenance, answer queries asked by other agents, and provide links where to download the desired papers. Among all this, they also represent the means of knowledge transfer from more experienced users to beginners.

Autonomy and mobility are capabilities that we exploit when we clone agents. Running in a new environment (the ad hoc community), the cloned agent uses the past experience of its user and its original community to support and

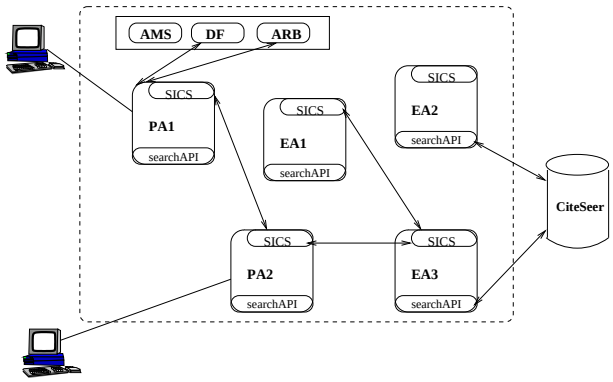

Figure 2: The architecture of a single system node. *Users* of the system node query their *personal agents* on the platform. Personal agents contact one another to find papers on a specified topic. They also use a search API to contact different information providers, e.g. CiteSeer. A SICS module inside the personal agent filters and re-ranks collected information. There are also *expert agents* running on the platform, which are the clones of the personal agents of the experts on the topic.

interact with the new community. The main idea here is that all the agents learn the "culture" of the community — i.e., knowledge about typical behavioral patterns of the members of the community — that can be used to select the relevant literature.

3. SYSTEM INTERNAL ARCHITECTURE

The system consists of several multi-agent platforms, or *system nodes*, which are able to communicate with one another. The system nodes are multi-agent systems implemented with Java Agent DEvelopment framework (JADE). A single platform runs on a dedicated computer and comprises one or several personal agents and several expert agents. The overall architecture of such a platform is depicted in Figure 2. It represents a community of users with similar research interests, e.g. personnel of a research lab or PhD students working in the same research field. Each user is assisted by a personal agent that helps to find relevant publications. The number of personal agents on the platform corresponds to the number of users of the system node. An expert agent is a clone of the personal agent of an expert user. Its task is to share its experience with other agents supporting them in their search. The platform also contains several auxiliary JADE agents. We describe system actors in more details in the next subsection.

The presence of several platforms where users are grouped by research interests helps us to handle scalability issues. Moreover, personal and expert agents running on the same platform and assisting users with similar interests are able to adapt to the specific needs of the community and to produce more valuable suggestions.

3.1 System Participants

- A *user* accesses the system using an html/php interface on the client side. It submits a query to the system, which can be either a *paper request* or an *information request*. In the case of the paper request, the user specifies the author(s) and the title of the paper. For the information request the user has to specify the topic he/she is interested in.
- A *personal agent* is a software agent running on the server side. The task of the personal agent is to assist the user in searching scientific publications. In case of a paper request it searches for the desired paper on the platform or queries an external information source using searchAPI. If the user submits an information request about a specific topic, then the personal agent starts the interaction with other personal and expert agents on the platform. The SICS module of the agent processes past actions, e.g. reading and citing, of its user and, partially (using feedback exchange), the actions of other users in order to find papers relevant to the given topic. The next subsection describes the SICS module in more detail.
- An *expert agent* is the clone of an expert's personal agent. It can represent, for instance, an author that is considered to be one of the top researchers in a certain area. In the best case, it represents a person and has information about how such a person usually browse the web searching for papers and which papers are eventually downloaded and read. In the worst (but anyway, quite good) case, the agent has the knowledge only about the use of citations by its user. This knowledge is extracted from the list of publications of the author. The papers that the expert agent suggests are considered to be of extreme importance and to form the state-of-the-art on the topic. It is also possible for the cloned agent to update its knowledge base, contacting the original personal agent.
- By an *external information source* we mean any database containing scientific publications and offering some kind of API to access them. For the experiments we used data from CiteSeer, but we could have chosen Google Scholar or any university or public library index.
- A *wrapper* is an agent which deals with those information sources that have no API. Typically, each information source requires a tailored wrapper dealing only with this particular source. The presence of wrapper(s) on the platform is optional.
- An *Agent Management System (AMS)* exerts a supervisory control over the platform. It provides the registration, the search, the deletion of agents and other services. It is an internal JADE agent running on every platform.
- A *Directory Facilitator (DF)* holds the list of services that are provided by an agent and provides a set of agents that offer a specific service. It provides agents with the IDs of other personal/expert agents. In our case both personal and expert agents have the service "PaperRecommender" that defines the agent's ability to answer queries about scientific articles.
- An *Agent Resource Broker (ARB)* provides a link between the platform and other platforms. Using this link, the agents can propagate requests of their users to different platforms. Contacting different system nodes

Table 1: The actions that can be observed by the system

action	object	attributes
participate	conference	paper, session_name, topic
publish	journal	paper, special_issue_title, topic
cite	paper	paper, topic
query		topic
download	paper	topic
view_details	paper	topic
reject	paper	topic

that correspond to different research groups it is possible to collect responses that represent several points of view.

3.2 Internal Agent Structure

Since expert agents are cloned personal agents, they have exactly the same structure. The agents have certain resources, e.g. database of past user actions or bibliography, and capabilities, in particular the searchAPI and the SICS module. A *bibliography* is collection of *bibitems*, each representing a single publication. It is stored as .bib file and can be used in LaTeX. A *searchAPI* is an API that agent uses to query an information source. Basically, it is a library that contains a set of functions to query the information source. It is dedicated to the specific source and is usually provided by the source owner.

3.2.1 SICS

SICS stands for System for Implicit Culture Support. It is responsible for recommendation creation process. It consists of the three modules: the *observer* that records users' actions, the *inductive module* that applies data mining techniques in order to induce a theory about these actions, and the *composer* that produces answers to the query by using the information saved by the observer and produced by the inductive module. The observer can partially collect information about actions of other users. It is possible due to feedback exchange which we describe in the next subsection. We refer the reader interested in more details of the SICS module to the paper of Blanzieri et al. [3].

Every *action* in our terminology has an *agent*, which executes the action, e.g. the user executing the action; an *object* which participates in the action, e.g. paper; and a set of *attributes*, which are the features that can be useful for the analysis of the actions, e.g. session name for the action of participating in a conference. In our application, the SICS module analyzes the actions presented in Table 1. An *agent* is always an author; therefore we omit it in the table. Every action is recorded being executed with respect to a certain topic. To determine topics related to an article, we can use the list of keywords given in the article. Furthermore, the keywords that were used to retrieve the article from an information source could be also considered as a list of topics, to which document is relevant.

We explain the information contained in the table in detail:

- *Participate.* An author can participate in a conference, publishing a paper in the conference proceedings. In order to observe this action it is just necessary to know the information about where the paper is published. We use a name of the conference session as an additional indicator of the topic of the paper.
- *Publish.* A paper can be published in a journal, related to a certain research field. Again, we observe this action if we have the information about where the paper is published. In case of publication in a special issue, the name of the special issue is an additional indicator of the topic of the paper
- *Cite.* This action indicates the papers cited by an author in his/her paper. This information is extracted from citation graph.
- *Query.* This action corresponds to an information request. Submitting the information request, a user specifies the topic.
- *Download.* This action can be performed when an author looks through the list of papers provided by his/her personal agent in response to a query.
- *View.* It indicates that an author clicked on the "view details" link corresponding to one of the papers provided by his/her personal agent.
- *Reject.* It comes with those papers that were recommended by a personal agent, but did not attract any attention (like view or download actions) from the user.

As it is possible to notice, some of the actions are observed directly in the system interface (query, download, view, reject) while others are inferred from the available information (participate, publish, cite). Both lists can be extended.

We would like to stress that we use keywords, or topics to separate papers of authors who have several research interests. This solves the problem mentioned by McNee et al. [11] of the irrelevant recommendations received by users who have only one topic in common with an author that has a wide range of research interests.

There is also a problem of interpretation of reject action. For example, reject from a novice user is more informative, since it can mean that the paper is rejected because it is irrelevant. An expert user can reject the paper just because he/she saw it many times already. We use the past history to analyze these details.

3.2.2 Implicit Culture

The goal of the SICS in general is to infer a cultural theory about users' actions and to encourage a novice to behave according to this theory. The cultural theory captures the users' knowledge about the environment, which is implicitly hidden in the actions. Here we use the actions listed in Table 1 and the formalism presented in [2] to give an example of the theory:

$$\forall a \in Authors, p \in Papers, t \in Topics : \\ \text{query}(a,t) \rightarrow \text{download}(a,p,t). \quad (1)$$

This theory expresses that "all authors who search papers on the topic t download the paper p".

Theory is induced by the inductive module of the SICS. It is extracted from past observations on user behavior using data mining techniques and can be updated after a certain period of time. The composer module produces recommendations taking into account the cultural theory and user preferences, encouraging the user to behave consistently

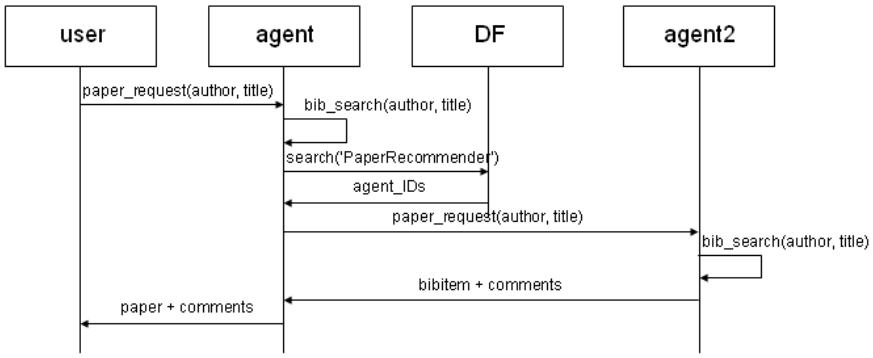

Figure 3: Sequence diagram in response to a paper request.

with the theory. For example, using (1), the composer module can suggest to have a look on the paper p.

We would like to achieve consistence with the theory because it is natural to assume that the way the experienced researchers select relevant papers is much more close to the optimal one than the novice's actions. Therefore, if the novice follows the recommendations, his/her behavior will converge to one nearer to optimal. The relationship characterized by this knowledge transfer is called *"Implicit Culture"*.

3.3 Search in the System

There are two types of user requests: a *paper request* and an *information request*.

3.3.1 Paper Request

When a user submits a paper request, he/she knows the title and the list of the authors. This is reasonable, because he/she could have found this information in another article, or on a conference website. The personal agent of the user checks if user's bibliography contains this item. In case it is present in the bibliography, the system locates the paper and shows it to the user. Otherwise, personal agent uses its previous experience to fill in a list of agents to ask. It is the task of the composer module to propose agents who can answer the query about the target paper. To find suitable agents, the composer module adopts the theory produced by the inductive module and the history of observations. In case the agent cannot fill the list itself, it contacts Directory Facilitator (DF) which returns IDs of agents that offer service "PaperRecommender" on the platform. The agent contacts every agent in the list, propagating user request. The contacted agents respond with bibitem that contains information and comments of their users. Using the bibitem, the agent locates the paper and shows it and the comments to the user. The sequence diagram corresponding to system actions during the search is given in Figure 3.

However, the requested paper can be absent in the bibliographies of other users. In this case, the personal agent contacts different data repositories, like CiteSeer which can be queried from the system. Once the paper is found, the personal agent offers the user either to read the abstract or to download the paper.

3.3.2 Information Request

If a user submits an information request, he/she has to specify the topic he/she is interested in. The personal agent checks if agents of the experts in this topic are present on the platform. If they are on the platform, the agent propagates the user's information request to them. The goal of the virtual community of expert agents is to recommend items that are considered relevant to the topic and to include them in so-called "reading list". To fill it with the items relevant to the topic the agents analyze citations, search and reading behaviors of the community members. Then, the personal agent shows the obtained results to the user. The results of the information request can be supplemented with the results obtained from CiteSeer or from another community.

If there are no topic experts on the platform, the personal agent contacts other agents on the platform, or external platforms in order to find experts in the topic. Note, that here the SICS module of queried agent simulates some kind of reputation scheme by discovering which agent can be an expert. To determine the level of user's expertise it is possible to analyze how often his/her paper is cited. This information can be obtained using CiteSeer. After the list of top experts in the field is filled, the personal agent clones experts' personal agents thus creating an ad hoc community running on the user PC and answering user's queries.

The user browses through a list of results being able to execute a set of basic actions that can be applied to a single item: it is possible to view the details (e.g. abstract) of a paper; a paper can be downloaded or rejected. Information about the actions that user executes (view, download, reject) is recorded by the observer module of the SICS and is also sent to the agents which participated in the search. They use this *feedback* to produce more effective recommendations next time. The personal agent of the user uses this information in further searches too. The sequence diagram of system actions during an information search is depicted in Figure 4.

3.3.3 Feedback Exchange

The goal of feedback exchange is to propagate information about users' actions to the other agents. When an agent contacts other agents in order to receive suggestions, it keeps the list of agents from which it received the results. When the user of the agent-requester accesses one of these results (e.g. view, download, reject) the agent communicates this information to the agent-suggestor. Thus, the agents partially observe actions of other users.

For example, in Figure 4, *agent2* sends results to *agent* in response to the information request. *Agent* shows results

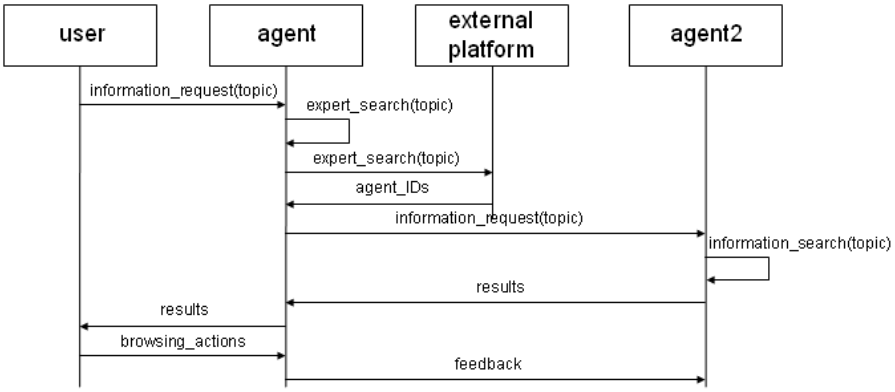

Figure 4: Sequence diagram in response to an information request.

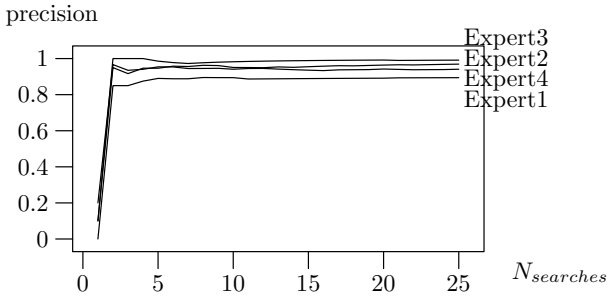

Figure 5: Average precision of 10 simulations with different number of searches.

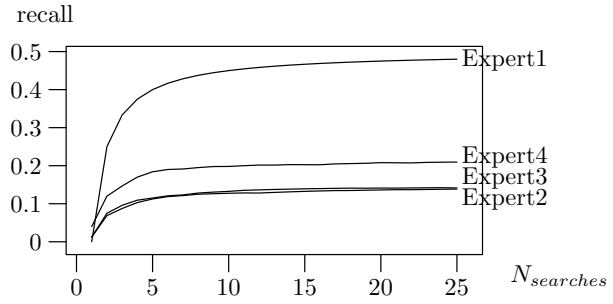

Figure 6: Average recall of 10 simulations with different number of searches.

to its user and records his/her browsing actions. The information about these actions is sent to *agent2* which is able to store them in a database of observations and use in further interactions with *agent* for producing more qualitative suggestions.

4. EVALUATION

In this section we present the experimental results obtained using the platform. We also define the measures we used to estimate the quality of suggestions produced by the SICS.

The aim of the experiment is to check the hypothesis that agents with the SICS are able to produce recommendations in accordance with the "community culture" and adapting

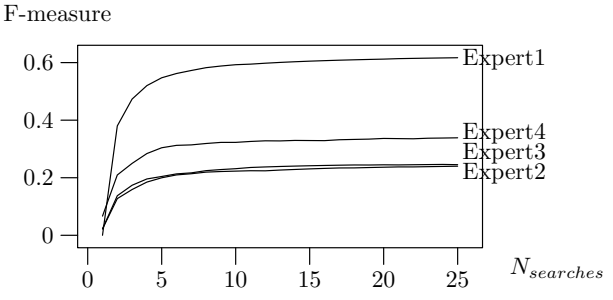

Figure 7: Average F-measure of 10 simulations with different number of searches.

their suggestions to the needs of a single community. We build a community of several experts, and we build their preferences. We expect that personal agent will be able to adapt suggestions to expert preferences.

In our experiment we add in each expert agent a piece of code that imitates behavior of the real user. The main function of this replacement is to generate pseudo-user response to the recommendations. The responses are generated according to a user profile. The user profile determines click-through ratio of the acceptance of the possible results. The dataset contains m results each corresponding to a particular paper. The dataset is used during simulations instead of contacting CiteSeer. The profile determines the probabilities $p(j)$ of choosing the j-th paper, $j \in \{1, \ldots, m\}$ while searching for a specified topic. We assume that the user accepts one and only one paper during search, so $\sum_{j=1}^{m} p(j) = 1$. In our experiment, the number of papers m is equal to 10. However, we would like to stress that the architecture of SICS does not depend on a particular user model, it is rather general being able to incorporate a number of different techniques.

To produce suggestions personal agents in the experiments did not infer any theory, using just comparison of the past actions therefore making algorithm equivalent to collaborative filtering. However, in general, our architecture allows using more complex techniques, like association rules, or clustering.

We use the following measures in order to evaluate the quality of suggestions:

Table 2: Profiles of the experts

	Common rank of the paper									
Expert name	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
Expert1	0	0	0	0	0	0	0	0.5	0	0.5
Expert2	0.23	0.18	0.14	0.14	0.14	0.07	0.05	0	0.05	0
Expert3	0.19	0.14	0.14	0.14	0.1	0.14	0.05	0	0.1	0
Expert4	0.29	0.29	0.14	0	0.14	0	0.14	0	0	0

- We call a paper **relevant** to a topic if the probability of its acceptance, as specified in the user profile, is non-zero.
- **Precision** is the ratio of the number of suggested relevant papers to the total number of suggested papers, relevant and irrelevant.
- **Recall** is the ratio of the number of proposed relevant papers to the total number of relevant papers.
- **F-measure** is a trade-off between precision and recall. It is calculated as follows:

$$\text{F-measure} = \frac{2 * \text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}}.$$

In order to build a small community of expert agents we generate four different profiles, each representing one expert agent. As experts we select the most cited authors, namely authors of the most cited papers that CiteSeer returns for the keyword "Data Mining". To determine papers the expert consider to be relevant, we take the first five of the most cited papers by each expert and look at the papers they cite. The top ten papers they cite all together are considered to be relevant to the selected group of authors. Then, we create a personal profile for every expert. The profile contains the probability that the expert considers the paper from the top ten selected to be relevant. These probabilities are calculated from the expert's citations, as follows:

$$p(j) = \frac{c_j}{\sum_{i=1}^{m} c_i}, \quad j = 1 \ldots m.$$

Here c_j is the number of times an expert cites the j-th paper in his/her five most cited papers that we select for the experiment. Of course, some of the selected papers are not relevant to a particular expert, being relevant to a group as a whole. The profiles are given in Table 2. The information that we need to determine experts and the information about citations is taken from CiteSeer using a specially developed wrapper.

We repeat searches for the keyword "Data Mining" 25 times, measuring precision, recall and F-measure of the recommendations after every search. We model user acceptance behavior as follows: given a keyword, accepted result is generated randomly according to the distribution that is specified in the profile. Other papers obtained from the SICS and agents are marked as rejected. At the end of 25-searches' session the observation data are deleted. We repeat the search sessions several times in order to control the effect of the order of paper acceptance.

The results contain precision, recall and F-measure of the papers recommended by the SICS module and by the agents queried by expert's personal agent. Lines in Figure 5 represent precision of the recommendations that are produced by the four personal agents for the experts, which names are shown on the right part of the figure. In Figure 6 and Figure 7 we have analogous curves for recall and F-measure, correspondingly.

From these figures we can note that the SICS modules of the personal agents are able to track users' interest, adapting suggestions to the needs of the community. The precision keeps on a very high level (due to the high number of relevant papers in our experiments) while recall and, as a result, F-measure tend to increase over time, reaching adequate values just after five searches.

5. RELATED WORK

In a previous paper [1], we applied Implicit Culture concepts to the development of a multi-agent recommendation system for web search. Although this paper is about web search too, the context of application is completely different. The two architectures are similar, but there are some significant differences. Firstly, here we consider a possibility of ad hoc community creation for information filtering, while in the previous work we were more focused on an organizational community. Secondly, we consider a rather wide set of actions here, while in the previous work it was reduced to *request, accept,* and *reject.* Finally, in the case of web search a lot of repetitions, namely searches for the same keyword several times, occur. In the case of scientific papers, the actions tend to transform from several actions of search type to the actions of citation type, which can be repeated many times for good papers or can be performed only once or even never for bad papers.

A CiteSeer extension aimed at personalization of the search is presented in [4]. This paper describes the mechanism of user profiles creation and maintenance. The information in the profiles indicates user interests and can be used to generate a list of potentially interesting papers. The main difference between our architecture and the one presented in the paper is that we propose collaboration of the users that should lead to the more qualitative search results for all the collaborators. Unlike their approach, we do not require any explicit feedback from the user, collecting information by means of observations and implicit inferences.

There are a number of papers presenting different approaches to facilitating scientific literature search. Bradshaw et al. [5] describe Rosetta, a system that indexes papers based on the way they have been described when cited in other articles. Using this information they find the items that correspond to the different variations of the user query, grouping them by topics. GroupLens group in [11] explores the use of collaborative filtering to recommend research papers. Torres et al. [15] combine content-based and collaborative filtering approaches. They have also shown that different algorithms are more suitable for recommending different kinds of papers. Middleton et al. [12] propose an ontological approach to build a recommendation system for scientific articles. The research interests are organized in an ontology

according to which papers are classified. The papers corresponding to the classes of the ontology that represents user's interests are recommended to the user. The system records relevance feedback to compute users' interests and to recommend papers using collaborative filtering.

The system proposed in this paper has an architecture that permits to deal with several information sources. We have used the notion of Implicit Culture that is more general than collaborative filtering [2]. Moreover, the use of agents in our approach provides several advantages, such as possibility of sharing bibliographies and creation of virtual communities. Finally, with our framework it is possible to recommend not only papers, but also the experts.

6. CONCLUSION AND FUTURE WORK

In this paper, we have presented a multi-agent system that facilitates scientific publication search and helps in finding relevant papers on a specified topic. Agents applying Implicit Culture concepts observe users' behaviors and infer knowledge about users' actions. The system finds relevant papers analyzing citation graph and action history of the user. Personal agents produce via interaction a transfer of knowledge about relevant publications from experts to beginners. The experimental results have proved that the SICS is able to adapt suggestions to the user preferences. However, the results are still preliminary and as part of our future work we plan to complete the evaluation.

As a future work we would like to extend the inductive module. For instance, association rules can be used to find papers usually cited together with other papers. Clustering techniques can be applied to distinguish between several topics of the same author. Clusters should contain the papers that deal with similar topics. We also plan to use CiteSeer API [13] for conducting further experiments. We are also planning to do real-user experiments as future work.

7. ACKNOWLEDGEMENTS

We would like to thank the participants of the poster session at 2K* 2005 symposium for their valuable comments. This work is funded by research projects EU SERENITY "System Engineering for Security and Dependability", COFIN "Artificial Intelligence Techniques for the Retrieval of High Quality Information on the Web" and by Fondo Progetti PAT, MOSTRO "Modeling Security and Trust Relationships within Organizations" and QUIEW (Quality-based indexing of the Web), art. 9, Legge Provinciale 3/2000, DGP n. 1587 dd. 09/07/04.

The authors would like to thank the anonymous reviewers for their helpful comments.

ABSTRACT

Security in multiagent systems is commonly defined as the ability of the system to deal with intentional threats from other agents. This paper focuses on domains where such intentional threats are caused by unseen adversaries whose actions or payoffs are unknown. In such domains, action randomization can effectively deteriorate an adversary's capability to predict and exploit an agent/agent team's actions. Unfortunately, little attention has been paid to intentional randomization of agents' policies in single-agent or decentralized (PO)MDPs without significantly sacrificing rewards or breaking down coordination. This paper provides two key contributions to remedy this situation. First, it provides three novel algorithms, one based on a non-linear program and two based on linear programs (LP), to randomize single-agent policies, while attaining a certain level of expected reward. Second, it provides Rolling Down Randomization (*RDR*), a new algorithm that efficiently generates randomized policies for decentralized POMDPs via the single-agent LP method.

Safety and Security in Agent Systems, Teamwork, MDP, POMDP, Decentralized POMDP

1. INTRODUCTION

In many adversarial domains, it is crucial for agent and agent teams based on single-agent or decentralized (PO)MDPs to randomize policies in order to avoid action predictability. Such policy randomization is crucial for security in domains where we cannot explicitly model our adversary's actions and capabilities or its payoffs, but the adversary observes our agents' actions and exploits any action predictability in some unknown fashion. Consider agents that schedule security inspections, maintenance or refueling at seaports or airports. Adversaries may be unobserved terrorists with unknown capabilities and actions, who can learn the schedule from observations. If the schedule is deterministic, then these adversaries may exploit schedule predictability to intrude or attack and cause tremendous unanticipated sabotage. Alternatively, consider a team of UAVs (Unmanned Air Vehicles)[2] monitoring a region undergoing a humanitarian crisis. Adversaries may be humans intent on causing some significant unanticipated harm — e.g. disrupting food convoys, harming refugees or shooting down the UAVs — the adversary's capabilities, actions or payoffs are unknown and difficult to model explicitly. However, the adversaries can observe the UAVs and exploit any predictability in UAV surveillance, e.g. engage in unknown harmful actions by avoiding the UAVs' route.

While we cannot explicitly model the adversary's actions, capabilities or payoffs, in order to ensure security of the agent/agent-team we make two worst case assumptions about the adversary. (We show later that a weaker adversary, i.e. one who fails to satisfy these assumptions, will in general only lead to enhanced security.) The first assumption is that the adversary can estimate the agent's state or belief state. In fully observable domains, the adversary estimates the agent's state to be the current world state which both can observe fully. If the domain is partially observable, we assume that the adversary estimates the agent's belief states, because: (i) the adversary eavesdrops or spies on the agent's sensors such as sonar or radar (e.g., UAV/robot domains); or (ii) the adversary estimates the most likely observations based on its model of the agent's sensors; or (iii) the adversary is co-located and equipped with similar sensors. The second assumption is that the adversary knows the agents' policy, which it may do by learning over repeated observations or obtaining this policy via espionage or other exploitation.

Thus, we assume that the adversary may have enough information to predict the agents' actions with certainty if the agents followed a deterministic policy. Hence, our work maximizes policy randomization to thwart the adversary's prediction of the agent's actions based on the agent's state and minimize adversary's ability to cause harm . Unfortunately, while randomized policies are created as a side effect [1] and turn out to be optimal in some stochastic games [10], little attention has been paid to intentionally maximizing randomization of agents' policies even for single agents. Obviously, simply randomizing an MDP/POMDP policy can degrade an agent's expected rewards, and thus we face a randomization-reward tradeoff problem: how to randomize policies with only a limited loss in expected rewards. Indeed, gaining an explicit understanding of the randomization-reward tradeoff requires new techniques for policy generation rather than the traditional single-objective maximization techniques. However, generating policies that provide appropriate randomization-reward tradeoffs is difficult, a difficulty that is exacerbated in agent teams based on decentralized POMDPs,

as randomization may create miscoordination.

This paper provides two key contributions to remedy this situation. First, we provide novel techniques that enable policy randomization in single agents, while attaining a certain expected reward threshold. We measure randomization via an entropy-based metric (although our techniques are not dependent on that metric). In particular, we illustrate that simply maximizing entropy-based metrics introduces a non-linear program that does not guarantee polynomial run-time. Hence, we introduce our CRLP (Convex combination for Randomization) and BRLP (Binary search for Randomization) linear programming (LP) techniques that randomize policies in polynomial time with different tradeoffs as explained later. The second part of the paper provides a new algorithm, RDR (Rolling Down Randomization), for generating randomized policies for decentralized POMDPs, given a threshold on the expected team reward loss. RDR starts with a joint deterministic policy for decentralized POMDPs, then iterates, randomizing policies for agents turn-by-turn, keeping policies of all other agents fixed. A key insight in RDR is that given fixed randomized policies for other agents, we can generate a randomized policy via CRLP or BRLP, i.e., our efficient single-agent methods.

The motivation for use of entropy-based metrics to randomize our agents' policies stems from information theory. It is well known that the expected number of probes (e.g., observations) needed to identify the outcome of a distribution is bounded below by the entropy of that distribution [15]. Thus, by increasing policy entropy, we force the opponent to execute more probes to identify the outcome of our known policy, making it more difficult for the opponent to anticipate our agent's actions and cause harm. In particular, in our (PO)MDP setting, the conflict between the agents and the adversary can be interpreted as a game, in which the agents generate a randomized policy above a given expected reward threshold; the adversary knows the agent's policy and the adversary's action is to guess the exact action of the agent/agent-team by probing. For example, in the UAV setting, given our agent's randomized policy, the adversary generates probes to determine the direction our UAV is headed from a given state. Thus, in the absence of specific knowledge of the adversary, we can be sure to increase the average number of probes the adversary uses by increasing the lower bound given by the entropy of the policy distribution at every state.

2. RANDOMIZATION: SINGLE AGENTS

Before considering agent teams, we focus on randomizing single agent MDP policies, e.g. a single MDP-based UAV agent is monitoring a troubled region, where the UAV gets rewards for surveying various areas of the region, but as discussed above, security requires it to randomize its monitoring strategies to avoid predictability.

An MDP is denoted as a tuple: $\langle S, A, P, R\rangle$. S is a set of world states $\{s_1, \ldots, s_m\}$, A the set of actions $\{a_1, \ldots, a_k\}$, P the set of tuples $p(s, a, j)$ representing the transition function and R the set of tuples $r(s, a)$ denoting the immediate reward. If $x(s, a)$ represents the number of times the MDP visits state s and takes action a and α_j represents the number of times that the MDP starts in each state $j \in S$, then the optimal policy, maximizing expected reward, is derived via the following linear program [4]:

$$\begin{aligned} \max \quad & \sum_{s\in S}\sum_{a\in A} r(s,a)x(s,a) \\ \text{s.t.} \quad & \sum_{a\in A} x(j,a) - \sum_{s\in S}\sum_{a\in A} p(s,a,j)x(s,a) = \alpha_j \qquad \forall j \in S \\ & x(s,a) \geq 0 \qquad \forall s \in S, a \in A \end{aligned} \tag{1}$$

If x^* is the optimal solution to (1), optimal policy π^* is given by (2) below, where $\pi^*(s, a)$ is the probability of taking action a in state s. It turns out that π^* is deterministic and uniformly optimal regardless of the initial distribution $\{\alpha_j\}_{j\in S}$ [4] i.e., $\pi^*(s, a)$ has a value of either 0 or 1. However, such deterministic policies are undesirable in domains like our UAV example.

$$\pi^*(s,a) = \frac{x^*(s,a)}{\sum_{\hat{a}\in A} x^*(s,\hat{a})} \; . \tag{2}$$

2.1 Randomness of a policy

We borrow from information theory the concept of entropy of a set of probability distributions to quantify the randomness, or information content, in a policy of the MDP. For a discrete probability distribution $p_1, \ldots, p_n$ the only function, up to a multiplicative constant, that captures the randomness is the entropy, given by the formula $H = -\sum_{i=1}^{n} p_i \log p_i$ [15]. We introduce a *weighted entropy* function to quantify the randomness in a policy π of an MDP and express it in terms of the underlying frequency x. Note from the definition of a policy π in (2) that for each state s the policy defines a probability distribution over actions. The weighted entropy is defined by adding the entropy for the distributions at every state weighted by the likelihood the MDP visits that state, namely

$$\begin{aligned} H_W(x) &= -\sum_{s\in S} \frac{\sum_{\hat{a}\in A} x(s,\hat{a})}{\sum_{j\in S}\alpha_j} \sum_{a\in A} \pi(s,a)\log\pi(s,a) \\ &= -\frac{1}{\sum_{j\in S}\alpha_j} \sum_{s\in S}\sum_{a\in A} x(s,a)\log\left(\frac{x(s,a)}{\sum_{\hat{a}\in A} x(s,\hat{a})}\right) \; . \end{aligned}$$

We note that the randomization approach we propose works for alternative functions of the randomness yielding similar results. For example we can define an *additive entropy* taking a simple sum of the individual state entropies as follows:

$$\begin{aligned} H_A(x) &= -\sum_{s\in S}\sum_{a\in A} \pi(s,a)\log\pi(s,a) \\ &= -\sum_{s\in S}\sum_{a\in A} \frac{x(s,a)}{\sum_{\hat{a}\in A} x(s,\hat{a})} \log\left(\frac{x(s,a)}{\sum_{\hat{a}\in A} x(s,\hat{a})}\right) \; , \end{aligned}$$

We now present three algorithms to obtain random solutions that maintain an expected reward of at least $E_{\min}$ (a certain fraction of the maximal expected reward E^* obtained solving (1)). These algorithms result in policies that, in our UAV-type domains, enable an agent to get a sufficiently high expected reward, e.g. surveying enough area, using randomized flying routes to avoid predictability.

2.2 Maximal entropy solution

We can obtain policies with maximal entropy but a threshold expected reward by replacing the objective of Problem (1) with the definition of the weighted entropy $H_W(x)$. The reduction in expected reward can be controlled by enforcing that feasible solutions achieve at least a certain expected reward $E_{\min}$. The following problem maximizes the weighted entropy while maintaining the expected reward above $E_{\min}$:

$$\begin{aligned} \max \quad & -\frac{1}{\sum_{j\in S}\alpha_j} \sum_{s\in S}\sum_{a\in A} x(s,a)\log\left(\frac{x(s,a)}{\sum_{\hat{a}\in A} x(s,\hat{a})}\right) \\ \text{s.t.} \quad & \sum_{a\in A} x(j,a) - \sum_{s\in S}\sum_{a\in A} p(s,a,j)x(s,a) = \alpha_j \qquad \forall j \in S \\ & \sum_{s\in S}\sum_{a\in A} r(s,a)x(s,a) \geq E_{\min} \\ & x(s,a) \geq 0 \qquad \forall s \in S, a \in A \end{aligned} \tag{3}$$

$E_{\min}$ is an input domain parameter (e.g. UAV mission specification). Alternatively, if E^* denotes the maximum expected reward from (1), then by varying the expected reward threshold $E_{\min} \in [0,E^*]$ we can explore the tradeoff between the achievable expected reward and entropy, and then select the appropriate $E_{\min}$. Note that for $E_{\min} = 0$ the above problem finds the maximum weighted entropy policy, and for $E_{\min} = E^*$, Problem (3) returns the maximum expected reward policy with largest entropy. Solving Problem (3) is our first algorithm to obtain a randomized policy that achieves at least $E_{\min}$ expected reward (Algorithm 1).

Algorithm 1 MAX-ENTROPY($E_{\min}$)

1: Solve Problem (3) with $E_{\min}$, let $x_{E_{\min}}$ be optimal solution
2: **return** $x_{E_{\min}}$ (maximal entropy, expected reward $\geq E_{\min}$)

Unfortunately entropy-based functions like $H_W(x)$ are neither convex nor concave in x, hence there are no complexity guarantees in solving Problem (3), even for local optima [16]. This negative complexity motivates the polynomial methods presented next.

2.3 Efficient single agent randomization

The idea behind these polynomial algorithms is to efficiently solve problems that obtain policies with a high expected reward while maintaining some level of randomness. (A very high level of randomness implies a uniform probability distribution over the set of actions out of a state, whereas a low level would mean deterministic action being taken from a state). We then obtain a solution that meets a given minimal expected reward value by adjusting the level of randomness in the policy. The algorithms that we introduce in this section consider two inputs: a minimal expected reward value $E_{\min}$ and a randomized solution $\bar{x}$ (or policy $\bar{\pi}$). The input $\bar{x}$ can be any solution with high entropy and is used to enforce some level of randomness on the high expected reward output, through linear constraints. For example, one such high entropy input for MDP-based problems is the uniform policy, where $\bar{\pi}(s,a) = 1/|A|$. We enforce the amount of randomness in the high expected reward solution that is output through a parameter $\beta \in [0,1]$. For a given β and a high entropy solution $\bar{x}$, we output a maximum expected reward solution with a certain level of randomness by solving (4).

$$\begin{aligned} \max \quad & \sum_{s\in S}\sum_{a\in A} r(s,a)x(s,a) \\ \text{s.t.} \quad & \sum_{a\in A} x(j,a) - \sum_{s\in S}\sum_{a\in A} p(s,a,j)x(s,a) = \alpha_j \qquad \forall j \in S \\ & x(s,a) \geq \beta\bar{x}(s,a) \qquad \forall s \in S, a \in A\ . \end{aligned} \tag{4}$$

which can be referred to in matrix shorthand as

$$\begin{aligned} \max \quad & r^T x \\ \text{s.t.} \quad & Ax = \alpha \\ & x \geq \beta\bar{x}\ . \end{aligned}$$

As the parameter β is increased, the randomness requirements of the solution become stricter and hence the solution to (4) would have smaller expected reward and higher entropy. For $\beta = 0$ the above problem reduces to (1) returning the maximum expected reward solution E^*; and for $\beta = 1$ the problem obtains the maximal expected reward (denoted $\overline{E}$) out of all solutions with as much randomness as $\bar{x}$. If E^* is finite, then Problem (4) returns $\bar{x}$ for $\beta = 1$ and $\overline{E} = \sum_{s\in S}\sum_{a\in A} r(s,a)\bar{x}(s,a)$.

Our second algorithm to obtain an efficient solution with a expected reward requirement of $E_{\min}$ is based on the following result which shows that the solution to (4) is a convex combination of the deterministic and highly random input solutions.

THEOREM 1. *Consider a solution $\bar{x}$, which satisfies $A\bar{x} = \alpha$ and $\bar{x} \geq 0$. Let x^* be the solution to (1) and $\beta \in [0,1]$. If x_β is the solution to (4) then $x_\beta = (1-\beta)x^* + \beta\bar{x}$.*

proof: We reformulate problem (4) in terms of the slack $z = x - \beta\bar{x}$ of the solution x over $\beta\bar{x}$ leading to the following problem :

$$\begin{aligned} \beta r^T\bar{x} + \quad \max \quad & r^T z \\ \text{s.t.} \quad & Az = (1-\beta)\alpha \\ & z \geq 0\ , \end{aligned}$$

The above problem is equivalent to (4), where we used the fact that $A\bar{x} = \alpha$. Let z^* be the solution to this problem, which shows that $x_\beta = z^* + \beta\bar{x}$. Dividing the linear equation $Az = (1-\beta)\alpha$, by $(1-\beta)$ and substituting $u = z/(1-\beta)$ we recover the deterministic problem (1) in terms of u, with u^* as the optimal deterministic solution. Renaming variable u to x, we obtain $\frac{1}{1-\beta}z^* = x^*$, which concludes the proof. □

Since $x_\beta = (1-\beta)x^* + \beta\bar{x}$, we can directly find a randomized solution which obtains a target expected reward of $E_{\min}$. Due to the linearity in relationship between x_β and β, a linear relationship exists between the expected reward obtained by x_β (i.e $r^T x_\beta$) and β. In fact setting $\beta = \frac{r^T x^* - E_{\min}}{r^T x^* - r^T \bar{x}}$ makes $r^T x_\beta = E_{\min}$. We now present below algorithm CRLP based on the observations made about β and x_β.

Algorithm 2 CRLP($E_{\min}, \bar{x}$)

1: Solve Problem (1), let x^* be the optimal solution
2: Set $\beta = \frac{r^T x^* - E_{\min}}{r^T x^* - r^T \bar{x}}$
3: Set $x_\beta = (1-\beta)x^* + \beta\bar{x}$
4: **return** x_β (expected reward $= E_{\min}$, entropy based on $\beta\bar{x}$)

Algorithm CRLP is based on a linear program and thus obtains, in polynomial time, solutions to problem(4) with expected reward values $E_{\min} \in [\overline{E}, E^*]$. Note that Algorithm CRLP might unnecessarily constrain the solution set as Problem(4) implies that at least $\beta\sum_{a\in A}\bar{x}(s,a)$ flow has to reach each state s. This restriction may negatively impact the entropy it attains, as experimentally verified in Section 5. This concern is addressed by a reformulation of Problem (4) replacing the flow constraints by policy constraints at each stage. For a given $\beta \in [0,1]$ and a solution $\bar{\pi}$ (policy calculated from $\bar{x}$), this replacement leads to the following linear program

$$\begin{aligned} \max \quad & \sum_{s\in S}\sum_{a\in A} r(s,a)x(s,a) \\ \text{s.t.} \quad & \sum_{a\in A} x(j,a) - \sum_{s\in S}\sum_{a\in A} p(s,a,j)x(s,a) = \alpha_j, \quad \forall j \in S \\ & x(s,a) \geq \beta\bar{\pi}(s,a)\sum_{b\in A} x(s,b), \qquad \forall s \in S, a \in A\ . \end{aligned} \tag{5}$$

For $\beta = 0$ this problem reduces to (1) returning E^*, for $\beta = 1$ it returns a maximal expected reward solution with the same policy as $\bar{\pi}$. This means that for β at values 0 and 1, problems (4) and (5) obtain the same solution if policy $\bar{\pi}$ is the policy obtained from the flow function $\bar{x}$. However, in the intermediate range of 0 to 1 for β, the policy obtained by problems (4) and (5) are different even if $\bar{\pi}$ is obtained from $\bar{x}$. Thus, theorem 1 holds for problem (4) but not for (5). Table 1, obtained experimentally, validates our claim by showing the maximum expected rewards and entropies obtained (entropies in parentheses) from problems (4) and (5) for various settings of β, e.g. for β = 0.4, problem (4) provides a maximum expected reward of 26.29 and entropy of 5.44, while problem (5) provides a maximum expected reward of 25.57 and entropy of 6.82.

Table 1 shows that for the same value of β in Problems (4) and

(5) we get different maximum expected rewards and entropies implying that the optimal policies for both problems are different, hence Theorem 1 does not hold for (5). Indeed, while the expected reward of Problem (4) is higher for this example, its entropy is lower than Problem (5). Hence to investigate another randomization-reward tradeoff point, we introduce our third algorithm BRLP, which uses problem (5) to perform a binary search to attain a policy with expected reward $E_{\min} \in [\overline{E}, E^*]$, adjusting the parameter β.

Beta	.2	.4	.6	.8
$Problem(4)$	29.14 (3.10)	26.29 (5.44)	23.43 (7.48)	20.25 (9.87)
$Problem(5)$	28.57 (4.24)	25.57 (6.82)	22.84 (8.69)	20.57 (9.88)

Table 1: Maximum expected rewards(entropies) for various β

Algorithm 3 $\mathrm{BRLP}(E_{\min}, \bar{x})$

1: Set $\beta_l = 0$, $\beta_u = 1$, and $\beta = 1/2$.
2: Obtain $\bar{\pi}$ from $\bar{x}$
3: Solve Problem (5), let x_β and $E(\beta)$ be the optimal solution and expected reward value returned
4: **while** $|E(\beta) - E_{\min}| > \epsilon$ **do**
5: **if** $E(\beta) > E_{\min}$ **then**
6: Set $\beta_l = \beta$
7: **else**
8: Set $\beta_u = \beta$
9: $\beta = \frac{\beta_u + \beta_l}{2}$
10: Solve Problem (5), let x_β and $E(\beta)$ be the optimal solution and expected reward value returned
11: **return** x_β (expected reward $= E_{\min} \pm \epsilon$, entropy related to $\beta\bar{x}$)

Given input $\bar{x}$, algorithm BRLP runs in polynomial time, since at each iteration it solves an LP and for tolerance of ϵ, it takes at most $O\left(\frac{E(0)-E(1)}{\epsilon}\right)$ iterations to converge (E(0) and E(1) expected rewards correspond to 0 and 1 values of β).

2.4 Incorporating models of the adversary

Throughout this paper, we set $\bar{x}$ based on uniform randomization $\bar{\pi} = 1/|A|$. By manipulating $\bar{x}$, we can accommodate the knowledge of the behavior of the adversary. For instance, if the agent knows that a specific state s cannot be targeted by the adversary, then $\bar{x}$ for that state can have all values 0, implying that no entropy constraint is necessary. In such cases, $\bar{x}$ will not be a complete solution for the MDP but rather concentrate on the sets of states and actions that are under risk of attack. For $\bar{x}$ that do not solve the MDP Theorem 1 does not hold and therefore Algorithm CRLP is not valid. In this case, a high-entropy solution that meets a target expected reward can still be obtained via Algorithm BRLP.

Before turning to agent teams next, we quickly discuss applying these algorithms in single agent POMDPs. For single-agent finite-horizon POMDPs with known starting belief states[12], we convert the POMDP to (finite horizon) *belief MDP*, allowing BRLP/CRLP to be applied; returning a randomized policy. However, addressing unknown starting belief states is an issue for future work.

3. FROM SINGLE AGENT TO AGENT TEAMS

The logical first step in moving to agent teams would be to start with multiagent MDPs, where a centralized planner provides policies to multiple agents in a fully observable setting. However, such multiagent MDPs are equivalent to single agent MDPs [14]. Indeed, assuming a shared, observable random device — justified, given a fully observable setting — our BRLP/CRLP algorithms can already generate randomized policies for such multiagent MDPs. Hence, this section focuses on the more general decentralized POMDPs, that are not equivalent to single agent POMDPs [3].

3.1 MTDP: A Decentralized POMDP model

We use notation from MTDP (Multiagent Team Decision Problem) [14] for our decentralized POMDP model; other models are equivalent [3]. Given a team of n agents, an MTDP is defined as a tuple: $\langle S, A, P, \Omega, O, R\rangle$. S is a finite set of world states $\{s_1, \ldots, s_m\}$. $A = \times_{1\le i\le n} A_i$, where $A_1, \ldots, A_n$, are the sets of action for agents 1 to n. A joint action is represented as $\langle a_1, \ldots, a_n\rangle$. $P(s_i, \langle a_1, \ldots, a_n\rangle, s_f)$, the transition function, represents the probability that the current state is s_f, if the previous state is s_i and the previous joint action is $\langle a_1, \ldots, a_n\rangle$. $\Omega = \times_{1\le i\le n}\Omega_i$ is the set of joint observations where Ω_i is the set of observations for agents i. $O(s, \langle a_1, \ldots, a_n\rangle, \omega)$, the observation function, represents the probability of joint observation $\omega \in \Omega$, if the current state is s and the previous joint action is $\langle a_1, \ldots, a_n\rangle$. We assume that observations of each agent are independent of each other's observations, i.e. $O(s, \langle a_1, \ldots, a_n\rangle, \omega) = O_1(s, \langle a_1, \ldots, a_n\rangle, \omega_1) \cdot \ldots \cdot O_n(s, \langle a_1, \ldots, a_n\rangle, \omega_n)$. The agents receive a single, immediate joint reward $R(s, \langle a_1, \ldots, a_n\rangle)$. For deterministic policies, each agent i chooses its actions based on its policy, Π_i, which maps its observation history to actions. Thus, at time t, agent i will perform action $\Pi_i(\vec{\omega}_i^t)$ where $\vec{\omega}_i^t = \omega_i^1, ..., \omega_i^t$. $\Pi = \langle \Pi_1, ..., \Pi_n\rangle$ refers to the joint policy of the team of agents. In this model, execution is distributed but planning is centralized; and agents don't know each other's observations and actions at run time.

Unlike previous work, in our work, policies are randomized and hence agents obtain a probability distribution over a set of actions rather than a single action. Furthermore, this probability distribution is indexed by a sequence of action-observation tuples rather than just observations, since observations do not map to unique actions. Thus in MTDP, a randomized policy maps $\mathbf{\Psi_i^t}$ to a probability distribution over actions, where $\mathbf{\Psi_i^t} = \langle \psi_i^1, \ldots, \psi_i^t\rangle$ and $\psi_i^t = \langle a_i^{t-1}, \omega_i^t\rangle$. Thus, at time t, agent i will perform an action selected randomly based on the probability distribution returned by $\Pi_i(\mathbf{\Psi_i^t})$. Furthermore we denote the probability of an individual action under policy Π_i given $\mathbf{\Psi_i^t}$ as $P^{\Pi_i}(a_i^t|\mathbf{\Psi_i^t})$.

3.2 Illustrative UAV team Domain

To demonstrate key concepts in our algorithms, we introduce a simple UAV team domain that is analogous to the illustrative multi-agent tiger domain [11] except for an adversary – indeed, to enable replicable experiments, rewards, transition and observation probabilities from [11] are used. Consider a region in a humanitarian crisis, where two UAVs execute daily patrols to monitor safe food convoys. However, these food convoys may be disrupted by landmines placed in their route. The convoys pass over two regions: Left and Right. For simplicity, we assume that only one such landmine may be placed at any point in time, and it may be placed in any of the two regions with equal probability. The UAVs must destroy the landmine to get a high positive reward whereas trying to destroy a region without a landmine disrupts transportation and creates a high negative reward; but the UAV team is unaware of which region has the landmine. The UAVs can perform three actions *Shoot-left, Sense* and *Shoot-right* but they cannot communicate with each other. We assume that both UAVs are observed with equal probability by some unknown adversary with unknown capabilities, who wishes to cause sabotage. Our worst case assumption about the adversary is as stated in Section 1: (a) the adversary has access to UAV policies due to learning or espionage (b) the adversary eavesdrop or estimates the UAV observations. Thus, if the policy is not randomized, the adversary may exploit UAV action predictability in some unknown way such as jamming UAV sensors, shooting down UAVs or attacking the food convoys, etc. Since little is known about the adversary's ability to cause sabo-

tage, the UAV team must maximize the adversary's uncertainty via policy randomization, while ensuring an above-threshold reward.

When an individual UAV takes action *Sense*, it leaves the state unchanged, but provides a noisy observation OR or OL, to indicate whether the landmine is to the left or right. The *Shoot-left* and *Shoot-right* actions are used to destroy the landmine, but the landmine is destroyed only if both UAVs simultaneously take either *Shoot-left* or *Shoot-right* actions. Unfortunately, if agents miscoordinate and one takes *Shoot-left* and the other *Shoot-right* they incur high negative reward as the landmine is not destroyed but the food-convoy route is damaged. Once the shoot action occurs, the problem is restarted (the UAVs face a landmine the next day).

4. RANDOMIZATION: AGENT TEAMS

Let p_i be the probability of adversary targeting agent i, and $H_W(i)$ be the weighted entropy for agent i's policy. We design an algorithm that maximizes the *multiagent weighted entropy*, given by $\sum_{i=1}^{n} p_i * H_W(i)$, in MTDPs while maintaining the team's expected joint reward above a threshold. Unfortunately, generating optimal policies for decentralized POMDPs is of higher complexity (NEXP-complete) than single agent MDPs and POMDPs [3], i.e., MTDP presents a fundamentally different class where we cannot directly use the single agent randomization techniques.

Hence, to exploit efficiency of algorithms like BRLP or CRLP, we convert the MTDP into a single agent POMDP, but with a method that changes the state space considered. To this end, our new iterative algorithm called RDR (Rolling Down Randomization) iterates through finding the best randomized policy for one agent while fixing the policies for all other agents — we show that such iteration of fixing the randomized policies of all but one agent in the MTDP leads to a single agent problem being solved at each step. Thus, each iteration can be solved via BRLP or CRLP. For a two agent case, we fix the policy of agent i and generate best randomized policy for agent j and then iterate with agent j's policy fixed.

Overall RDR starts with an initial joint deterministic policy calculated in the algorithm as a starting point. Assuming this fixed initial policy as providing peak expected reward, the algorithm then rolls down the reward, randomizing policies turn-by-turn for each agent. Rolling down from such an initial policy allows control of the amount of expected reward loss from the given peak, in service of gaining entropy. *The key contribution of the algorithm is in the rolling down procedure that gains entropy (randomization)*, and this procedure is independent of how the initial policy for peak reward is determined. The initial policy may be computed via algorithms such as [6] that determine a global optimal joint policy (but at a high cost) or from random restarts of algorithms that compute a locally optimal policy [11, 5], that may provide high quality policies at lower cost. The amount of expected reward to be rolled down is input to RDR. RDR then achieves the rolldown in $1/d$ steps where d is an input parameter.

The turn-by-turn nature of RDR suggests some similarities to JESP [11], which also works by fixing the policy of one agent and computing the best-response policy of the second and iterating. However, there are significant differences between RDR and JESP, as outlined below: (i) JESP uses conventional value iteration based techniques whereas RDR creates randomized policies via LP formulations. (ii) RDR defines a new extended state and hence the belief-update, transition and reward functions undergo a major transformation. (iii) The d parameter is newly introduced in RDR to control number of rolldown steps. (iv) RDR climbs down from a given optimal solution rather than JESP's hill-climbing up solution.

RDR Details: For expository purposes, we use a two agent domain, but we can easily generalize to n agents. We fix the policy of one agent (say agent 2), which enables us to create a single agent POMDP if agent 1 uses an extended state, i.e. at each time t, agent 1 uses an extended state $e_1^t = \langle s^t, \mathbf{\Psi_2^t} \rangle$. Here, $\mathbf{\Psi_2^t}$ is as introduced in the previous section. By using e_1^t as agent 1's state at time t, given the fixed policy of agent 2, we can define a single-agent POMDP for agent 1 with transition and observation function as follows.

$$\begin{aligned} P'(e_1^t, a_1^t, e_1^{t+1}) &= P(\langle s^{t+1}, \mathbf{\Psi_2^{t+1}} \rangle | \langle s^t, \mathbf{\Psi_2^t} \rangle, a_1^t) \\ &= P(\omega_2^{t+1} | s^{t+1}, a_2^t, \mathbf{\Psi_2^t}, a_1^t) \\ &\quad \cdot P(s^{t+1} | s^t, a_2^t, \mathbf{\Psi_2^t}, a_1^t) \cdot P(a_2^t | s^t, \mathbf{\Psi_2^t}, a_1^t) \\ &= P(s^t, \langle a_2^t, a_1^t \rangle, s^{t+1}) \cdot O_2(s^{t+1}, \langle a_2^t, a_1^t \rangle, \omega_2^{t+1}) \\ &\quad \cdot P^{\Pi_2}(a_2^t | \mathbf{\Psi_2^t}) \end{aligned} \tag{6}$$

$$\begin{aligned} O'(e_1^{t+1}, a_1^t, \omega_1^{t+1}) &= \Pr(\omega_1^{t+1} | e_1^{t+1}, a_1^t) \\ &= O_1(s^{t+1}, \langle a_2^t, a_1^t \rangle, \omega_1^{t+1}) \end{aligned} \tag{7}$$

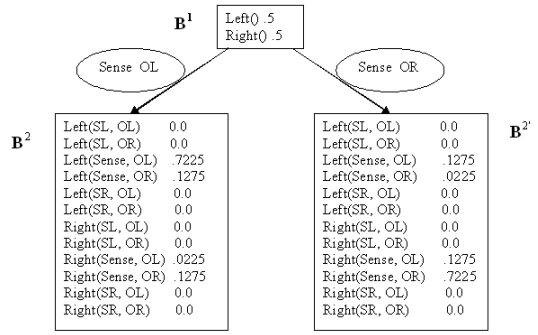

Figure 1: RDR applied to UAV team domain

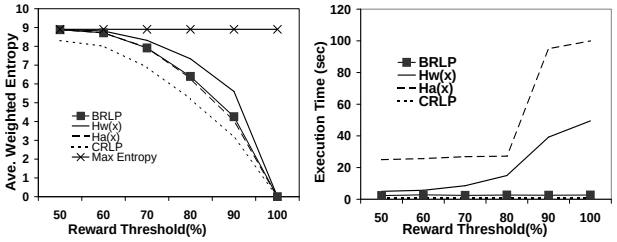
Thus, we can create a belief state for agent i in the context of j's fixed policy by maintaining a distribution over $e_i^t = \langle s^t, \mathbf{\Psi_j^t} \rangle$. Figure 1 shows three belief states for agent 1 in the UAV domain. For instance B^2 shows probability distributions over e_1^2. In $e_1^2 = (\text{Left}\langle Sense, OL \rangle)$, Left implies landmine to the left is the current state, Sense is the agent 2's action at time 1, OL (Observe Left) is agent 2's observation at time 2. The belief update rule derived from the transition and observation functions is given in (8), where denominator is the transition probability when action a_1 from belief state B_1^t results in ω_1^{t+1} being observed. Immediate rewards for the belief states are assigned using (9).

$$\begin{aligned} B_1^{t+1}(e_1^{t+1}) = \sum_{s^t} & B_1^t(e_1^t) \cdot P(s^t, (a_1^t, a_2^t), s^{t+1}) \cdot P^{\Pi_2}(a_2^t | \mathbf{\Psi_2^t}) \\ & \cdot O_2(s^{t+1}, (a_1^t, a_2^t), \omega_2^{t+1}) \cdot O_1(s^{t+1}, (a_1^t, a_2^t), \omega_1^{t+1}) \\ & / P(\omega_1^{t+1} | B_1^t, a_1) \end{aligned} \tag{8}$$

$$\Re(a_1^t, B_1^t) = \sum_{e_1^t} B_1^t(e_1^t) \cdot \sum_{a_2^t} R(s^t, (a_1^t, a_2^t)) \cdot P^{\Pi_2}(a_2^t | \mathbf{\Psi_2^t}) \tag{9}$$

Thus, RDR's policy generation implicitly coordinates the two agents, without communication or a correlational device. Randomized actions of one agent are planned taking into account the impact of randomized actions of its teammate on the joint reward. Algorithm 4 (at the end of paper) presents the pseudo-code for RDR for two agents, and shows how we can use beliefs over extended states e_i^t to construct LPs that maximize entropy while maintaining a certain expected reward threshold. The inputs to this algorithm are the parameters d, *percentdec* and $\bar{x}$. The parameter d specifies the number of iterations taken to solve the problem. It also decides the amount of reward that can be sacrificed at each step of the algorithm for improving entropy. Parameter *percentdec* specifies the



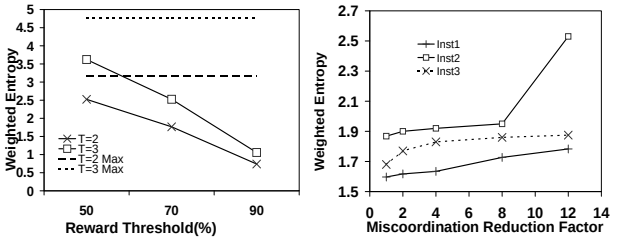
percentage of expected reward the agent team forgoes for improving entropy. As with Algorithm 2, parameter $\bar{x}$ provides an input solution with high randomness; and it is obtained using a uniform policy as discussed in Section 2.3. Step 1 of the algorithm uses the Compute joint policy() function which returns a optimal joint deterministic policy from which the individual policies and the expected joint reward are extracted. Obtaining this initial policy is not RDR's main thrust, and could be a global optimal policy obtained via [6] or a very high quality policy from random restarts of local algorithms such as [11, 5]. The input variable *percentdec* varies between 0 to 1 denoting the percentage of the expected reward that can be sacrificed by RDR. The step size as calculated in the algorithm, denotes the amount of reward sacrificed during each iteration. RDR then iterates 1/d times(step 3).

The function GenerateMDP generates all reachable belief states (lines 2 through 6) from a given starting belief state *B* and hence a belief MDP is generated. The number of such belief states is $O(|A_1||\Omega_1|)^{T-1}$ where T is the time horizon. The extended states in each B increases by a factor of $|A_2||\Omega_2|$ with increasing T. Thus the time to calculate B(e) for all extended states e, for all belief states B in agent 1's belief MDP is $O(|S|^2(|A_1||A_2||\Omega_1||\Omega_2|)^{T-1})$. Lines 7 through 12 compute the reward for each belief state. The total computations to calculate the reward is $O(|S||A_1||A_2|(|A_1||A_2||\Omega_1||\Omega_2|)^{T-1})$. The belief MDP generated is denoted by the tuple $\langle B, A, trans, R\rangle$. We reformulate the MDP obtained to problem 4 and use our polynomial BRLP procedure to solve it, using $\bar{x}$ as input. Thus, algorithm RDR is exponentially faster than an exhaustive search of a policy space, and comparable to algorithms that generate locally optimal policies [11].

5. EXPERIMENTAL RESULTS

We present three sets of experimental results. Our first set of experiments examine the tradeoffs in run-time, expected reward and entropy for single-agent problems. Figures 2a and 2b show the results for these experiments based on generation of MDP policies. The results show averages over 10 MDPs where each MDP represents a flight of a UAV, with state space of 28-40 states. The states represent the regions monitored by the UAVs. The transition function assumes that a UAV action can make a transition from a region to one of four other regions, where the transition probabilities were selected at random. The rewards for each MDP were also generated using random number generators. These experiments compare the performance of our four methods of randomization for single-agent policies. In the figures, *CRLP* refers to algorithm 2; *BRLP* refers to algorithm 3; whereas $H_W(x)$ and $H_A(x)$ refer to Algorithm 1 with these objective functions. Figure 2a examines the tradeoff between entropy and expected reward thresholds. It shows the average weighted entropy on the y-axis and reward threshold percent on the x-axis. The average maximally obtainable entropy for these MDPs is 8.89 (shown by line on the top) and three of our four methods (except CRLP) attain it at about 50% threshold, i.e. an agent can attain maximum entropy if it is satisfied with 50% of the maximum expected reward. However, if no reward can be sacrificed (100% threshold) the policy returned is deterministic.

Figure 2b shows the run-times, plotting the execution time in seconds on the y-axis, and expected reward threshold percent on the x-axis. These numbers represent averages over the same 10 MDPs as in Figure 2a. Algorithm CRLP is the fastest and its runtime is very small and remains constant over the whole range of threshold rewards as seen from the plot. Algorithm BRLP also has a fairly constant runtime and is slightly slower than CRLP. Both CRLP and BRLP are based on linear programs and hence their small and fairly constant runtimes. Algorithm 1, for both $H_A(x)$ and $H_W(x)$ objectives, exhibits an increase in the runtime as the expected reward threshold increases. This trend that can be attributed to the fact that maximizing a non-concave objective while simultaneously attaining feasibility becomes more difficult as the feasible region shrinks.



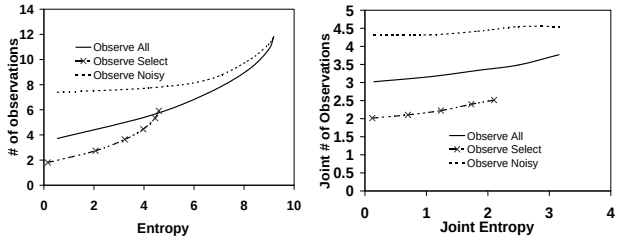
(a) (b)

Figure 2: Comparison of Single Agent Algorithms

We conclude the following from Figure 2: (i) CRLP is the fastest but provides the lowest entropy. (ii) BRLP is significantly faster than Algorithm 1, providing 7-fold speedup on average over the 10 MDPs over the entire range of thresholds. (iii) Algorithm 1 with $H_W(x)$ provides highest entropy among our methods, but the average gain in entropy is only 10% over BRLP. (iv) CRLP provides a 4-fold speedup on an average over BRLP but with a significant entropy loss of about 18%. In fact, CRLP is unable to reach the maximal possible entropy for the threshold range considered in the plot. Thus, BRLP appears to provide the most favorable tradeoff of run-time to entropy for the domain considered, and we use this method for the multiagent case. However, for time critical domains CRLP might be the algorithm of choice and therefore both BRLP and CRLP provide useful tradeoff points.

Reward Threshold	1	.5	.25	.125
90%	.67(.59)	1.73(.74)	3.47(.75)	7.07(.75)
50%	.67(1.53)	1.47(2.52)	3.4(2.62)	7.47(2.66)

Table 2: RDR: Avg. run-time in sec and (Entropy), $T = 2$



(a) (b)

Figure 3: Results for RDR

Our second set of experiments examine the tradeoffs in run-time, expected joint reward and entropy for the multiagent case. Table 2 shows the runtime results and entropy (in parenthesis) averaged over 10 instances of the UAV team problem based on the original transition and observation functions from [11] and its variations. d, the input parameter controlling the number of rolldown steps of algorithm 4, varies from 1 to 0.125 for two values of percent reward threshold (90% and 50%) and time horizon T=2. We conclude that as d decreases, the run-time increases, but the entropy remains fairly constant for $d \leq .5$. For example, for reward threshold of 50%, for d = 0.5, the runtime is 1.47 secs, but the run-time increases more than 5-fold to 7.47 when d = 0.125; however, entropy only changes from 2.52 to 2.66 with this change in d.

Thus in our next set of graphs, we present results for d = .5, as it provides the most favorable tradeoff, if other parameters remain fixed. Figure 3a plots RDR expected reward threshold percent on the x-axis and weighted entropy on the y-axis averaged over the same 10 UAV-team instances. Thus, if the team needs to obtain 90% of maximum expected joint reward with a time horizon $T = 3$, it gets a weighted entropy of 1.06 only as opposed to 3.62 if it obtains 50% of the expected reward for the same d and T. Similar to the single-agent case, the maximum possible entropy for the multiagent case is also shown by a horizontal line at the top of the graph. Figure 3b studies the effect of changing miscoordination cost on RDR's ability to improve entropy. As explained in Section 3.2, the UAV team incurs a high cost of miscoordination, e.g. if one UAV shoots left and the other shoots right. We now define miscoordination reduction factor (MRF) as the ratio between the original miscoordination cost and a new miscoordination cost. Thus, high MRF implies a new low miscoordination cost, e.g. an MRF of 4 means that the miscoordination cost is cut 4-fold. We plot this MRF on x-axis and entropy on y-axis, with expected joint reward threshold fixed at 70% and the time horizon T at 2. We created 5 reward variations for each of our 10 UAV team instances we used for 3a; only 3 instances are shown, to reduce graph clutter(others are similar). For *instance 2*, the original miscoordination cost provided an entropy of 1.87, but as this cost is scaled down by a factor of 12, the entropy increases to 2.53.

Based on these experiments, we conclude that: (i) Greater tolerance of expected reward loss allows higher entropy; but reaching the maximum entropy is more difficult in multiagent teams — for the reward loss of 50%, in the single agent case, we are able to reach maximum entropy, but we are unable to reach maximum entropy in the multiagent case. (ii) Lower miscoordination costs allow higher entropy for the same expected joint reward thresholds. (iii) Varying d produces only a slight change in entropy; thus we can use d as high as 0.5 to cut down runtimes. (iv) RDR is time efficient because of the underlying polynomial time BRLP algorithm.

(a) (b)

Figure 4: Improved security via randomization

Our third set of experiments examine the tradeoffs in entropy of the agent/agent-team and the total number of observations (probes) the enemy needs to determine the agent/agent-team actions at each state. The primary aim of this experiment is to show that maximizing policy entropy indeed makes it more difficult for the adversary to determine/predict our agents' actions, and thus more difficult for the adversary to cause harm, which was our main goal at the beginning of this paper. Figures 4a and 4b plot the number of observations of enemy as function of entropy of the agent/agent-team. In particular for the experiment we performed, the adversary runs yes-no probes to determine the agent's action at each state, i.e. probes that return an answer yes if the agent is taking the particular action at that state in which case the probing is stopped, and a no otherwise. The average number of yes-no probes at a state is the total number of observations needed by the adversary to determine the correct action taken by the agent in that state. The more deterministic the policy is, the fewer the probes the adversary needs to run; if the policy is completely deterministic, the adversary need not run any probes as it knows the action. Therefore, the aim of the agent/agent-team is to maximize the policy entropy, so that the expected number of probes asked by the adversary is maximized.

In contrast, the adversary minimizes the expected number of probes required to determine the agents' actions. Hence, for any given state s, the adversary uses the Huffman procedure to optimize the number of probes [8], and hence the total number of probes over the entire MDP state space can be expressed as follows. Let $S = \{s_1, s_2, ..., s_m\}$ be the set of MDP states and $A = \{a_1, a_2, ..., a_n\}$ be the action set at each state. Let $p(s, a) = \{p_1, ..., p_n\}$ be the probabilities of taking the action set $\{a'_1, ..., a'_n\}$, $a'_i \in A$ at state s sorted in decreasing order of probability. The number of yes-no probes at state s is denoted by $\zeta_s = p_1 * 1 + ... + p_{n-1} * (n-1) + p_n * (n-1)$. If the weight of the states (see notion of weight introduced in section 2) is $W = \{w_1, w_2, ..., w_m\}$, then the number of observations over the set of states is denoted *Observe-all* $= \sum_{s=1...m} \{w_s * \zeta_s\}$. Setting some weights to zero implies that the adversary was not concerned with those states, and the number of observations in this situation is denoted *Observe-select*. While the number of observations in both Observe-all and Observe-select are obtained assuming the adversary obtains an accurate policy of the agent or agent team, in real situations, an adversary may obtain a noisy policy, and the adversary's number of observations in such a case is denoted Observe-noisy.

Figure 4a demonstrates the effectiveness of entropy maximization using the BRLP method against an adversary using yes-no probes procedure as his probing method for the single agent case. The plot shows the number of observations on y-axis and entropy on the x-axis averaged over the 10 MDPs we used for our single-agent experiment. The plot has 3 lines corresponding to the three adversary procedures namely *Observe-all*, *Observe-select* and *Observe-noisy*. *Observe-all* and *Observe-select* have been plotted to study the effect of entropy on the number of probes the adversary needs. For example, for *Observe-all*, when entropy is 8, the average number of probes needed by the adversary is 9. The purpose of the *Observe-noisy* plot is to show that the number of probes that the adversary requires can only remain same or increase when using a noisy policy, as opposed to using the correct agent policy. The noise in our experiments is that two actions at each state of the MDP have incorrect probabilities. Each data point in the *Observe-noisy* case represents an average of 50 noisy policies, averaging over 5 noisy policies for each reward threshold over each of the 10 MDPs.

Figure 4b plots a similar graph as 4a for the multiagent case, averaged over the 10 UAV-team instances with two UAVs. The plot has three lines namely *Observe-all*, *Observe-select* and *Observe-noisy* with the same definitions as in the single agent case but in a distributed POMDP setting. However, in plot 4b the y-axis represents joint number of yes-no probes and the x-axis represents joint entropy. Both these parameters are calculated as weighted sums of the individual parameters for each UAV, assuming that the adversary assigns equal weight to both the UAVs.

We conclude the following from plots 4a and 4b: (i) The number of observations(yes-no probes) increases as policy entropy increases, whether the adversary monitors the entire state space (*observe-all*) or just a part of it (*observe-select*). (ii) If the adversary obtains a noisy policy (*observe-noisy*), it needs a larger number of observations when compared to the adversary obtaining an accurate policy. (iii) As entropy increases, the agents' policy tends to become more uniform and hence the effect of noise on the number of yes-no probes reduces. In the extreme case where the policy is totally uniform the *Observe-all* and *Observe-noisy* both have same number of

probes. This can be observed at the maximal entropy point in plot 4a. The maximal entropy point is not reached in plot 4b as shown in the results for RDR. From the above we conclude that maximizing entropy has indeed made it more difficult for the adversary to determine our agents' actions and cause harm.

6. SUMMARY AND RELATED WORK

This paper focuses on security in multiagent systems where intentional threats are caused by unseen adversaries, whose actions and capabilities are unknown, but the adversaries can exploit any predictability in our agents' policies. Policy randomization for single-agent and decentralized (PO)MDPs, with some guaranteed expected rewards, are critical in such domains. To this end, this paper provides two key contributions: (i) provides novel algorithms, in particular the polynomial-time CRLP and BRLP algorithms, to randomize single-agent MDP and POMDP policies, while attaining a certain level of expected reward; (ii) provides RDR, a new algorithm to generate randomized policies for decentralized POMDPs. RDR can be built on BRLP or CRLP, and thus is able to efficiently provide randomized policies. Finally, while our techniques are applied for analyzing randomization-reward tradeoffs, they could potentially be applied more generally to analyze different tradeoffs between competing objectives in single/decentralized (PO)MDP. More details about this work can be accessed at http://www-scf.usc.edu/ paruchur/japan.ppt.

Randomization as a goal has received little attention in the literature, and is seen as a means or side-effect in attaining other objectives, e.g., in resource-constrained MDPs [1] or memoryless POMDP policy generators [9] (for breaking loops). In [13] coordination of multiple agents executing randomized policies in a distributed MDP setting is discussed, but there randomization occurs as a side-effect of resource constraints; furthermore, agents communicate to resolve the resulting team miscoordination. In contrast, our work explicitly emphasizes maximizing entropy in policies, and attains implicit coordination (no communication) over randomized policies in decentralized POMDPs. Significant attention has been paid to learning in stochastic games, where agents must learn dominant strategies against explicitly modeled adversaries [10, 7]. Such dominant strategies may lead to randomization, but randomization itself is not the goal. Our work in contrast does not require an explicit model of the adversary and, in this worst case setting, hinders any adversary's actions by increasing the policy's weighted entropy through efficient algorithms, such as BRLP.

ABSTRACT

Characters in real-time computer games need to move smoothly and thus need to search in real time. In this paper, we describe a simple but powerful way of speeding up repeated A* searches with the same goal states, namely by updating the heuristics between A* searches. We then use this technique to develop a novel real-time heuristic search method, called Real-Time Adaptive A*, which is able to choose its local search spaces in a fine-grained way. It updates the values of all states in its local search spaces and can do so very quickly. Our experimental results for characters in real-time computer games that need to move to given goal coordinates in unknown terrain demonstrate that this property allows Real-Time Adaptive A* to follow trajectories of smaller cost for given time limits per search episode than a recently proposed real-time heuristic search method [5] that is more difficult to implement.

1. INTRODUCTION

Agents need to use different search methods than the off-line search methods often studied in artificial intelligence. Characters in real-time computer games, for example, need to move smoothly and thus need to search in real time. Real-time heuristic search methods find only the beginning of a trajectory from the current state of an agent to a goal state [9, 4]. They restrict the search to a small part of the state space that can be reached from the current state with a small number of action executions (local search space). The agent determines the local search space, searches it, decides how to move within it, and executes one or more actions along the resulting trajectory. The agent then repeats this process until it reaches a goal state. Real-time heuristic search methods thus do not plan all the way to a goal state which often results in smaller total search times but larger trajectory costs. Most importantly, real-time heuristic search methods can satisfy hard real-time requirements in large state spaces since the sizes of their local search spaces (= their lookaheads) are independent of the sizes of the state spaces and can thus remain small. To focus the search and prevent cycling, they associate heuristics with the states and update them between searches, which accounts for a large chunk of the search time per search episode. In this paper, we describe Real-Time Adaptive A*, a novel real-time heuristic search method. It is a contract anytime method [12] that is able to choose its local search spaces in a very fine-grained way, updates the heuristics of all states in the local search space and is able to do so very quickly. Our experimental results for goal-directed navigation tasks in unknown terrain demonstrate that Real-Time Adaptive A* follows trajectories of smaller cost for given time limits per search episode than a recently proposed real-time heuristic search method [5] because it updates the heuristics more quickly, which allows it to use larger local search spaces and overcompensate for its slightly less informed heuristics. At the same time, Real-Time Adaptive A* is easier to implement.

2. MAIN IDEA

Our main idea is simple but powerful. Assume that one has to perform several A* searches with consistent heuristics in the same state space and with the same goal states but possibly different start states. Adaptive A* makes the heuristics more informed after each A* search in order to speed up future A* searches. We now explain the main idea behind Adaptive A*.

A* [3] is an algorithm for finding cost-minimal paths in state spaces (graphs). For every state s, the user supplies a heuristic $h[s]$ that estimates the goal distance of the state (= the cost of a cost-minimal path from the state to a goal state). The heuristics need to be consistent [10]. For every state s encountered during the search, A* maintains two values: the smallest cost $g[s]$ of any discovered path from the start state s_{curr} to state s (which is initially infinity), and an estimate $f[s] := g[s] + h[s]$ of the distance from the start state s_{curr} via state s to a goal state. A* then operates as follows: It maintains a priority queue, called open list, which initially contains only the start state s_{curr}. A* removes a state s with a smallest f-value from the priority queue. If state s is a goal state, it terminates. Otherwise, it expands the state, meaning that it updates the g-value of each successor state of the state and then inserts those successor states into the open list whose g-value decreased. It then repeats

the process. After termination, the g-value of every expanded state s is equal to the distance from the start state s_{curr} to state s.

We now explain how one can make the heuristics more informed after each A* search in order to speed up future A* searches. Assume that s is a state that was expanded during such an A* search. We can obtain an admissible (= non-overestimating) estimate of its goal distance $gd[s]$ as follows: The distance from the start state s_{curr} to any goal state via state s is equal to the distance from the start state s_{curr} to state s plus the goal distance $gd[s]$ of state s. It clearly can not be smaller than the goal distance $gd[s_{\text{curr}}]$ of the start state s_{curr}. Thus, the goal distance $gd[s]$ of state s is no smaller than the goal distance $gd[s_{\text{curr}}]$ of the start state s_{curr} (= the f-value $f[\bar{s}]$ of the goal state $\bar{s}$ that was about to be expanded when the A* search terminates) minus the distance from the start state s_{curr} to state s (= the g-value $g[s]$ of state s when the A* search terminates).

$$\begin{aligned} g[s] + gd[s] &\geq gd[s_{\text{curr}}] \\ gd[s] &\geq gd[s_{\text{curr}}] - g[s] \\ gd[s] &\geq f[\bar{s}] - g[s] \end{aligned}$$

Consequently, $f[\bar{s}] - g[s]$ provides an admissible estimate of the goal distance $gd[s]$ of state s and can be calculated quickly. More informed heuristics can be obtained by calculating and assigning this difference to every state that was expanded during the A* search and thus is in the closed list when the A* search terminates. (The states in the open list are not updated since the distance from the start state to these states can be smaller than their g-values when the A* search terminates.) We evaluated this idea experimentally in [7]. We now use it to develop a novel real-time heuristic search method, called Real-Time Adaptive A* (RTAA*), which reduces to the case discussed above if its lookahead is infinity.

3. NOTATION

We use the following notation to describe search tasks: S denotes the finite set of states. $s_{\text{curr}} \in S$ denotes the start state of the search, and *GOAL* $\subset S$ denotes the set of goal states. $A(s)$ denotes the finite set of actions that can be executed in state $s \in S$. $c[s,a] > \epsilon$ (for a given constant $\epsilon > 0$) denotes the cost of executing action $a \in A(s)$ in state $s \in S$, whereas *succ*$(s,a) \in S$ denotes the resulting successor state. The action costs c can increase during the search but we require the goal distances of all states to remain bounded from above by some constant.

4. REAL-TIME ADAPTIVE A*

Figure 1 shows the pseudo code of RTAA*. The legend explains the constants, variables, and functions that we will refer to in the following. The variables annotated with [USER] have to be initialized before RTAA* is called. s_{curr} needs to be set to the start state of the agent, c to the initial action costs, and h to the initial heuristics, which need to be consistent for the initial action costs, that is, need to satisfy $h[s] = 0$ for all goal states s and $h[s] \leq h[\textit{succ}(s,a)] + c[s,a]$ for all non-goal states s and actions a that can be executed in them [10]. Variables annotated with [A*] are updated during the call to astar() {03} (= line 3 in the pseudo code), which performs a (forward) A* search guided by the current heuristics from the current state of the agent toward the goal states until a goal state is about to be expanded or *lookahead* > 0 states have been expanded. After the A* search, we require $\bar{s}$ to be the state that was about to be expanded when the A* search terminated. We denote this state with $\bar{s}$ consistently throughout this paper. We require that $\bar{s} =$ *FAILURE* if the A* search terminated due to an empty open list, in which case there is no finite-cost trajectory from the current state to any goal state and RTAA* thus returns failure {05}. We require *CLOSED* to contain the states expanded during the A* search and the g-value $g[s]$ to be defined for all generated states s, including all expanded states. We define the f-values $f[s] := g[s] + h[s]$ for these states s. The expanded states s form the local search space, and RTAA* updates their heuristics by setting $h[s] := f[\bar{s}] - g[s] = g[\bar{s}] + h[\bar{s}] - g[s]$ {06-07}. (The heuristics of the other states are not changed.) RTAA* then executes actions along the trajectory found by the A* search until state $\bar{s}$ is reached (or, equivalently, a state is reached that was not expanded or, also equivalently, the local search space is left), *movements* > 0 actions have been executed, or the cost of an action on the trajectory increases {09-16}. It then repeats the process until it reaches a goal state, in which case it returns success {17}.

constants and functions

S	set of states of the search task, a set of states
GOAL	set of goal states, a set of states
$A(\,)$	sets of actions, a set of actions for every state
succ$(\,)$	successor function, a state for every state-action pair

variables

lookahead	number of states to expand at most, an integer larger than zero
movements	number of actions to execute at most, an integer larger than zero
s_{curr}	current state of the agent, a state [USER]
c	current action costs, a float for every state-action pair [USER]
h	current (consistent) heuristics, a float for every state [USER]
g	g-values, a float for every state [A*]
CLOSED	closed list of A* (= all expanded states), a set of states [A*]
$\bar{s}$	state that A* was about to expand when it terminated, a state [A*]

```
procedure realtime_adaptive_astar():
{01} while (s_curr ∉ GOAL) do
{02}   lookahead := any desired integer greater than zero;
{03}   astar();
{04}   if s̄ = FAILURE then
{05}     return FAILURE;
{06}   for all s ∈ CLOSED do
{07}     h[s] := g[s̄] + h[s̄] − g[s];
{08}   movements := any desired integer greater than zero;
{09}   while (s_curr ≠ s̄ AND movements > 0) do
{10}     a := the action in A(s_curr) on the cost-minimal trajectory from s_curr to s̄;
{11}     s_curr := succ(s_curr, a);
{12}     movements := movements − 1;
{13}     for any desired number of times (including zero) do
{14}       increase any desired c[s, a] where s ∈ S and a ∈ A(s);
{15}     if any increased c[s, a] is on the cost-minimal trajectory from s_curr to s̄ then
{16}       break;
{17} return SUCCESS;
```

Figure 1: Real-Time Adaptive A*

The values of *lookahead* and *movements* determine the behavior of RTAA*. For example, RTAA* performs a single A* search from the start state to a goal state and then moves the agent along the trajectory found by the A* search to the goal state if it always chooses infinity for *lookahead* and *movements* and no action costs increase.

We now prove several important properties of RTAA* that hold no matter how it chooses its values of *lookahead* and *movements*. We make use of the following known properties of A* searches with consistent heuristics: First, they expand every state at most once. Second, the g-values of every expanded state and state $\bar{s}$ are equal to the distance from the start state to state s and state $\bar{s}$, respectively. Thus, one knows cost-minimal trajectory from the start state to all expanded states and state $\bar{s}$. Third, the f-values of the series of expanded states over time are monotonically nondecreasing. Thus, $f[s] \leq f[\bar{s}]$ for all expanded states s and $f[\bar{s}] \leq f[s]$ for all generated states s that remained unexpanded.

THEOREM 1. *The heuristics of the same state are monotonically nondecreasing over time and thus indeed become more informed over time.*

Proof: Assume that the heuristic of state s is updated on line

{07}. Then, state s was expanded and it thus holds that $f[s] \leq f[\bar{s}]$. Consequently, $h[s] = f[s] - g[s] \leq f[\bar{s}] - g[s] = g[\bar{s}] + h[\bar{s}] - g[s]$ and the update cannot decrease the heuristic of state s since it changes the heuristic from $h[s]$ to $g[\bar{s}] + h[\bar{s}] - g[s]$. ■

THEOREM 2. *The heuristics remain consistent.*

Proof: We prove this property by induction on the number of A* searches. The initial heuristics are provided by the user and consistent. It thus holds that $h[s] = 0$ for all goal states s. This continues to hold since goal states are not expanded and their heuristics thus not updated. (Even if RTAA* updated the heuristic of state $\bar{s}$, it would leave the h-value of that state unchanged since $f[\bar{s}] - g[\bar{s}] = g[\bar{s}] + h[\bar{s}] - g[\bar{s}] = h[\bar{s}]$. Thus, the heuristics of goal states would remain zero even in that case.) It also holds that $h[s] \leq h[succ(s, a)] + c[s, a]$ for all non-goal states s and actions a that can be executed in them. Assume that some action costs increase on lines {13-14}. Let c denote the action costs before all increases and c' denote the action costs after all increases. Then, $h[s] \leq h[succ(s, a)] + c[s, a] \leq h[succ(s, a)] + c'[s, a]$ and the heuristics thus remain consistent. Now assume that the heuristics are updated on lines {06-07}. Let h denote the heuristics before all updates and h' denote the heuristics after all updates. We distinguish three cases:

- First, both s and $succ(s, a)$ were expanded, which implies that $h'[s] = g[\bar{s}] + h[\bar{s}] - g[s]$ and $h'[succ(s, a)] = g[\bar{s}] + h[\bar{s}] - g[succ(s, a)]$. Also, $g[succ(s, a)] \leq g[s] + c[s, a]$ since the A* search discovers a trajectory from the current state via state s to state $succ(s, a)$ of cost $g[s]+c[s, a]$ during the expansion of state s. Thus, $h'[s] = g[\bar{s}] + h[\bar{s}] - g[s] \leq g[\bar{s}]+h[\bar{s}]-g[succ(s, a)]+c[s, a] = h'[succ(s, a)]+c[s, a]$.
- Second, s was expanded but $succ(s, a)$ was not, which implies that $h'[s] = g[\bar{s}] + h[\bar{s}] - g[s]$ and $h'[succ(s, a)] = h[succ(s, a)]$. Also, $g[succ(s, a)] \leq g[s] + c[s, a]$ for the same reason as in the first case, and $f[\bar{s}] \leq f[succ(s, a)]$ since state $succ(s, a)$ was generated but not expanded. Thus, $h'[s] = g[\bar{s}] + h[\bar{s}] - g[s] = f[\bar{s}] - g[s] \leq f[succ(s, a)] - g[s] = g[succ(s, a)]+h[succ(s, a)]-g[s] = g[succ(s, a)]+h'[succ(s, a)] - g[s] \leq g[succ(s, a)] + h'[succ(s, a)] - g[succ(s, a)] + c[s, a] = h'[succ(s, a)] + c[s, a]$.
- Third, s was not expanded, which implies that $h'[s] = h[s]$. Also, $h[succ(s, a)] \leq h'[succ(s, a)]$ since the heuristics of the same state are monotonically nondecreasing over time. Thus, $h'[s] = h[s] \leq h[succ(s, a)] + c[s, a] \leq h'[succ(s, a)] + c[s, a]$.

Thus, $h'[s] \leq h'[succ(s, a)] + c[s, a]$ in all three cases and the heuristics thus remain consistent. ■

THEOREM 3. *The agent reaches a goal state.*

Proof: Assume that the heuristics are updated on lines {06-07}. Let h denote the heuristics of RTAA* before all updates and h' denote the heuristics after all updates. The heuristics of the same state are monotonically nondecreasing over time, according to Theorem 1. Assume that the agent moves from its current state s to some state s' (with $s \neq s'$) along a cost-minimal trajectory from state s to state $\bar{s}$. It holds that $h'[s] = f[\bar{s}] - g[s] = f[\bar{s}]$ since state s is the start of the search and its g-value is thus zero and since it was expanded and its heuristic was thus updated. Furthermore, it holds that $h'[s'] = f[\bar{s}] - g[s']$ since either state s' was expanded and its heuristic was thus updated or $s' = \bar{s}$ and then $h'[s'] = h'[\bar{s}] = h[\bar{s}] = f[\bar{s}] - g[\bar{s}] = f[\bar{s}] - g[s']$. Thus, after the agent moved from state s to state s' and its current state thus changed from state s to state s', the heuristic of the current state decreased by $h'[s] - h'[s'] = f[\bar{s}] - (f[\bar{s}] - g[s']) = g[s']$ and the sum of the heuristics of all states but its current state thus increased by $g[s']$, which is bounded from below by a positive constant since $s \neq s'$ and we assumed that all action costs are bounded from below by a positive constant. Thus, the sum of the heuristics of all states but the current state of the agent increases over time beyond any bound if the agent does not reach a goal state. At the same time, the heuristics remain consistent, according to Theorem 2 (since consistent heuristics are admissible), and are thus no larger than the goal distances which we assumed to be bounded from above, which is a contradiction. Thus, the agent is guaranteed to reach a goal state. ■

THEOREM 4. *If the agent is reset into the start state whenever it reaches a goal state then the number of times that it does not follow a cost-minimal trajectory from the start state to a goal state is bounded from above by a constant if the cost increases are bounded from below by a positive constant.*

Proof: Assume for now that the cost increases leave the goal distances of all states unchanged. Under this assumption, it is easy to see that the agent follows a cost-minimal trajectory from the start state to a goal state if it follows a trajectory from the start state to a goal state where the h-value of every state is equal to its goal distance. If the agent does not follow such a trajectory, then it transitions at least once from a state s whose h-value is not equal to its goal distance to a state s' whose h-value is equal to its goal distance since it reaches a goal state according to Theorem 3 and the h-value of the goal state is zero since the heuristics remain consistent according to Theorem 2. We now prove that the h-value of state s is then set to its goal distance. When the agent executes some action $a \in A(s)$ in state s and transitions to state s', then state s is a parent of state s' in the A* search tree produced during the last call of astar() and it thus holds that (1) state s was expanded during the last call of astar(), (2) either state s' was also expanded during the last call of astar() or $s' = \bar{s}$, (3) $g[s'] = g[s] + c[s, a]$. Let h denote the heuristics before all updates and h' denote the heuristics after all updates. Then, $h'[s] = f[\bar{s}] - g[s]$ and $h'[s'] = f[\bar{s}] - g[s'] = gd[s']$. The last equality holds because we assumed that the h-value of state s' was equal to its goal distance and thus can no longer change since it could only increase according to Theorem 1 but would then make the heuristics inadmissible and thus inconsistent, which is impossible according to Theorem 2. Consequently, $h'[s] = f[\bar{s}] - g[s] = gd[s'] + g[s'] - g[s] = gd[s'] + c[s, a] \geq gd[s]$, proving that $h'[s] = gd[s]$ since a larger h-value would make the heuristics inadmissible and thus inconsistent, which is impossible according to Theorem 2. Thus, the h-value of state s is indeed set to its goal distance. After the h-value of state s is set to its goal distance, the h-value can no longer change since it could only increase according to Theorem 1 but would then make the heuristics inadmissible and thus inconsistent, which is impossible according to Theorem 2. Since the number of states is finite, it can happen only a bounded number of times that the h-value of a state is set to its goal distance. Thus, the number of times that the agent does not follow a cost-minimal trajectory from the start state to a goal state is bounded. The theorem then follows since the number of times that a cost increase does not leave the goal distances of all states unchanged is bounded since we assumed that the cost increases are

bounded from below by a positive constant but the goal distances are bounded from above. After each such change, the number of times that the agent does not follow a cost-minimal trajectory from the start state to a goal state is bounded. ■

5. RELATIONSHIP TO LRTA*

RTAA* is similar to a version of Learning Real-Time A* recently proposed in [5], an extension of the original Learning Real-Time A* algorithm [9] to larger lookaheads. For simplicity, we refer to this particular version of Learning Real-Time A* as LRTA*. RTAA* and LRTA* differ only in how they update the heuristics after an A* search. LRTA* replaces the heuristic of each expanded state with the sum of the distance from the state to a generated but unexpanded state s and the heuristic of state s, minimized over all generated but unexpanded states s. (The heuristics of the other states are not changed.) Let $\bar{h}'$ denote the heuristics after all updates. Then, the heuristics of LRTA* after the updates satisfy the following system of equations for all expanded states s:

$$\bar{h}'[s] = \min_{a \in A(s)} (c[s,a] + \bar{h}'[succ(s,a)])$$

The properties of LRTA* are similar to the ones of RTAA*. For example, its heuristics for the same state are monotonically nondecreasing over time and remain consistent, and the agent reaches a goal state. We now prove that LRTA* and RTAA* behave exactly the same if their lookahead is one and they break ties in the same way. They can behave differently for larger lookaheads, and we give an informal argument why the heuristics of LRTA* tend to be more informed than the ones of RTAA* with the same lookaheads. On the other hand, it takes LRTA* more time to update the heuristics and it is more difficult to implement, for the following reason: LRTA* performs one search to determine the local search space and a second search to determine how to update the heuristics of the states in the local search space since it is unable to use the results of the first search for this purpose, as explained in [5]. Thus, there is a trade-off between the total search time and the cost of the resulting trajectory, and we need to compare both search methods experimentally to understand this trade-off better.

THEOREM 5. *RTAA* with lookahead one behaves exactly like LRTA* with the same lookahead if they break ties in the same way.*

Proof: We show the property by induction on the number of A* searches. The heuristics of both search methods are initialized with the heuristics provided by the user and are thus identical before the first A* search. Now consider any A* search. The A* searches of both search methods are identical if they break ties in the same way. Let $\bar{s}$ be the state that was about to be expanded when their A* searches terminated. Let h denote the heuristics of RTAA* before all updates and h' denote the heuristics after all updates. Similarly, let $\bar{h}$ denote the heuristics of LRTA* before all updates and $\bar{h}'$ denote the heuristics after all updates. Assume that $h[s] = \bar{h}[s]$ for all states s. We show that $h'[s] = \bar{h}'[s]$ for all states s. Both search methods expand only the current state s of the agent and thus update only the heuristic of this one state. Since $s \neq \bar{s}$, it holds that $h'[s] = g[\bar{s}] + h[\bar{s}] - g[s] = g[\bar{s}] + h[\bar{s}]$ and $\bar{h}'[s] = \min_{a \in A(s)}(c[s,a] + \bar{h}'[succ(s,a)]) = \min_{a \in A(s)}(g[succ(s,a)] + \bar{h}'[succ(s,a)]) = \min_{a \in A(s)}(g[succ(s,a)] + \bar{h}[succ(s,a)]) = g[\bar{s}] + \bar{h}[\bar{s}] = g[\bar{s}] + h[\bar{s}]$. Thus, both search methods set the heuristic of the current state to the same value and then move to state $\bar{s}$. Notice that *lookahead* $= 1$ implies without loss of generality that *movements* $= 1$. Consequently, they behave exactly the same. ■

We now give an informal argument why the heuristics of LRTA* with lookaheads larger than one tend to be more informed than the ones of RTAA* with the same lookahead (if both real-time heuristic search methods use the same value of *movements*). This is not a proof but gives some insight into the behavior of the two search methods. Assume that both search methods are in the same state and break ties in the same way. Let h denote the heuristics of RTAA* before all updates and h' denote the heuristics after all updates. Similarly, let $\bar{h}$ denote the heuristics of LRTA* before all updates and $\bar{h}'$ denote the heuristics after all updates. Assume that $h[s] = \bar{h}[s]$ for all states s. We now prove that $h'[s] \leq \bar{h}'[s]$ for all states s. The A* searches of both search methods are identical if they break ties in the same way. Thus, they expand the same states and thus also update the heuristics of the same states. We now show that the heuristics h' cannot be consistent if $h'[s] > \bar{h}'[s]$ for at least one state s. Assume that $h'[s] > \bar{h}'[s]$ for at least one state s. Pick a state s with the smallest $\bar{h}'[s]$ for which $h'[s] > \bar{h}'[s]$ and pick an action a with $a = \arg\min_{a \in A(s)}(c[s,a] + \bar{h}'[succ(s,a)]$. State s must have been expanded since $h[s] = \bar{h}[s]$ but $h'[s] > \bar{h}'[s]$. Then, it holds that $\bar{h}'[s] = c[s,a] + \bar{h}'[succ(s,a)]$. Since $\bar{h}'[s] = c[s,a] + \bar{h}'[succ(s,a)] > \bar{h}'[succ(s,a)]$ and state s is a state with the smallest $\bar{h}'[s]$ for which $h'[s] > \bar{h}'[s]$, it must be the case that $h'[succ(s,a)] \leq \bar{h}'[succ(s,a)]$. Put together, it holds that $h'[s] > \bar{h}'[s] = c[s,a] + \bar{h}'[succ(s,a)] \geq c[s,a] + h'[succ(s,a)]$. This means that the heuristics h' are inconsistent but we have earlier proved already that they remain consistent, which is a contradiction. Consequently, it holds that $h'[s] \leq \bar{h}'[s]$ for all states s. Notice that this proof does not imply that the heuristics of LRTA* always dominate the ones of RTAA* since the search methods can move the agent to different states and then update the heuristics of different states, but it suggests that the heuristics of LRTA* with lookaheads larger than one tend to be more informed than the ones of RTAA* with the same lookaheads and thus that the trajectories of LRTA* tend to be of smaller cost than the trajectories of RTAA* with the same lookaheads (if both real-time heuristic search methods use the same value of *movements*).

In the remainder of the paper, we assume that the agents always choose the same constant for *lookahead*, which is an external parameter, and always use infinity for *movements*, both for LRTA* and RTAA*.

6. APPLICATION

Real-time heuristic search methods are often used as alternative to traditional search methods for solving offline search tasks [9]. We, however, apply RTAA* to goal-directed navigation in unknown terrain, a search task that requires agents to execute actions in real time. Characters in real-time computer games, for example, often do not know the terrain in advance but automatically observe it within a certain range around them and then remember it for future use. Figure 2 shows an example. To make these agents easy to control, the users can click on some position in known or unknown terrain and the agents then move autonomously to this position. If the agents observe during execution that their current trajectory is blocked, then they need to search for another plan. The searches need to be fast since the agents need to move smoothly even if the processor is slow, the other game components use most of the available processor cycles and there are a large number of agents that all have to search repeatedly. Thus, there is a time limit per A* search, which suggests that real-time heuristic search methods are a good fit for our navigation tasks. To apply them, we discretize the terrain into cells that are either blocked or unblocked, a common practice in the context of real-time computer games [1]. The agents initially do not know which cells are blocked but use a navigation strat-

Figure 2: Total Annihilation

egy from robotics [8]: They assume that cells are unblocked unless they have the cells already observed to be blocked (freespace assumption). They always know which (unblocked) cells they are in, observe the blockage status of their four neighboring cells, raise the action costs of actions that enter the newly observed blocked cells, if any, from one to infinity, and then move to any one of the unblocked neighboring cells with cost one. We therefore use the Manhattan distances as consistent heuristic estimates of the goal distances. The task of the agents is to move to the given goal cell, which we assume to be possible.

7. ILLUSTRATION

Figure 3 shows a simple goal-directed navigation task in unknown terrain that we use to illustrate the behavior of RTAA*. Black squares are blocked. All cells have their initial heuristic in the lower left corner. We first compare RTAA* with lookahead infinity to LRTA* with the same lookahead and forward A* searches. All search methods start a new search episode (= run another search) when the cost of an action on their current trajectory increases and break ties between cells with the same f-values in favor of cells with larger g-values and remaining ties in the following order, from highest to lowest priority: right, down, left and up. We do this since we believe that systematic rather than random tie-breaking helps the readers to understand the behavior of the different search methods better since all search methods then follow the same trajectories. Figures 4, 5, and 6 show the agent as a small black circle. The arrows show the planned trajectories from the current cell of the agent to the goal cell, which is in the lower right corner. Cells that the agent has already observed to be blocked are black. All other cells have their heuristic in the lower left corner. Generated cells have their g-value in the upper left corner and their f-value in the upper right corner. Expanded cells are grey and, for RTAA* and LRTA*, have their updated heuristics in the lower right corner, which makes it easy for the readers to compare them to the heuristics before the update in the lower left corner. Notice that forward A* searches, RTAA* with lookahead infinity and LRTA* with the same lookahead follow the same trajectories if they break ties in the same way. They differ only in the number of cell expansions, which is larger for forward A* searches (23) than for RTAA* (20) and larger for RTAA* (20) than for LRTA* (19). The first property is due to RTAA* and LRTA* updating the heuristics while forward A* searches do not. Thus, forward A*

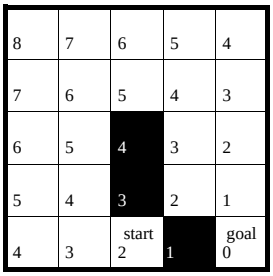

Figure 3: Example

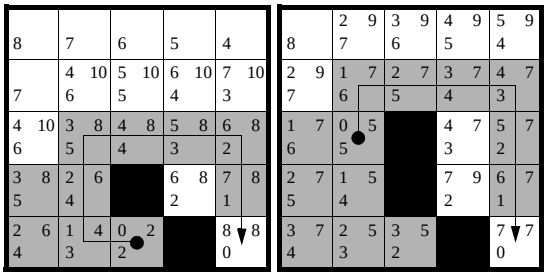

Figure 4: Forward A* Searches

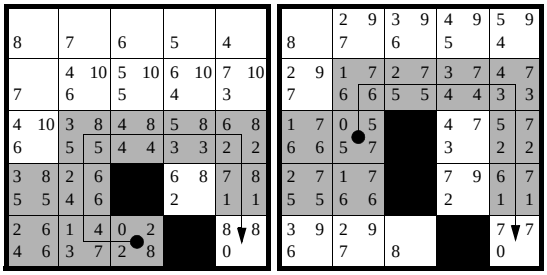

Figure 5: RTAA* with *lookahead* $= \infty$

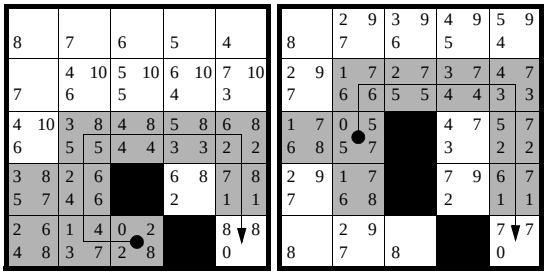

Figure 6: LRTA* with *lookahead* $= \infty$

searches fall prey to the local minimum in the heuristic value surface and thus expand the three leftmost cells in the lowest row a second time, while RTAA* and LRTA* avoid these cell expansions. The second property is due to some updated heuristics of LRTA* being larger than the ones of RTAA*. Notice, however, that most updated heuristics are identical, although this is not guaranteed in general. We also compare RTAA* with lookahead four to RTAA* with lookahead infinity. Figures 5 and 7 show that decreasing the lookahead of RTAA* increases the trajectory cost (from 10 to 12) but decreases the number of cell expansions (from 20 to 17) because smaller lookaheads imply that less information is used dur-

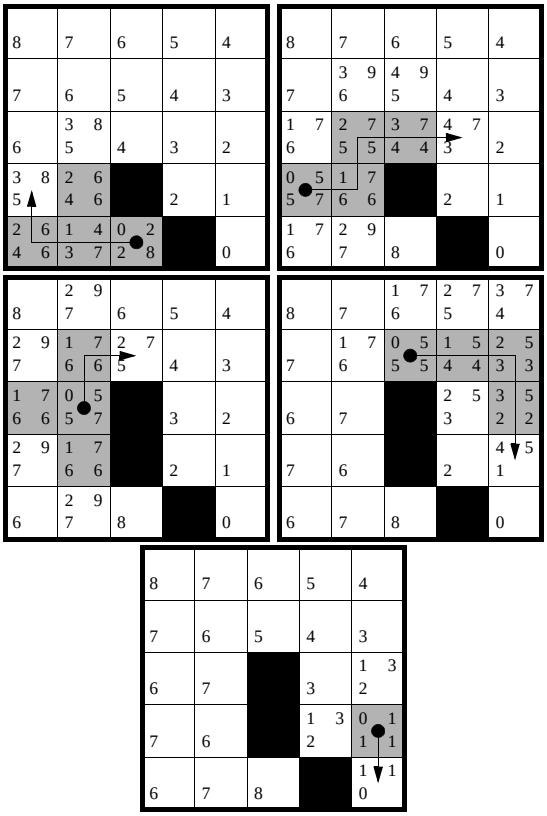

Figure 7: RTAA* with *lookahead* $= 4$

ing each search episode. (Notice that the last search episode of RTAA* with lookahead four expands only one cell since the goal cell is about to be expanded next.) We now perform systematic experiments to see whether they confirm the trends shown in our examples.

8. EXPERIMENTAL RESULTS

We now run experiments to compare RTAA* to forward A* searches and LRTA*, as in the previous section. All three search methods search forward. We also compare RTAA* to two search methods that search backward, namely backward A* searches and D* Lite [6] (an incremental version of backward A* searches that is similar to but simpler than D* [11]), which is possible because there is only one goal cell.[1] All search methods use binary heaps as priority queues and now break ties between cells with the same f-values in favor of cells with larger g-values (which is known to be a good tie-breaking strategy) and remaining ties randomly.

[1]Notice that the total number of cell expansions and total search time of forward A* searches are significantly smaller than the ones of backward A* searches. The big impact of the search direction can be explained as follows: The agent observes blocked cells close to itself. Thus, the blocked cells are close to the start of the search in the early phases of forward A* searches, but close to the goal of the search in the early phases of backward A* searches. The closer the blocked cells are to the start of the search, the more cells there are for which the Manhattan distances are perfectly informed and thus the faster A* searches are that break ties between cells with the same f-values in favor of cells with larger g-values since they expand only states along a cost-minimal trajectory from cells for which the Manhattan distances are perfectly informed to the goal of the search.

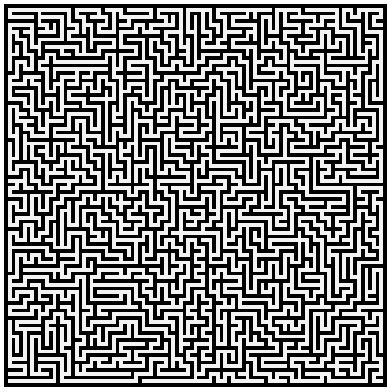

Figure 8: Test Terrain: Mazes

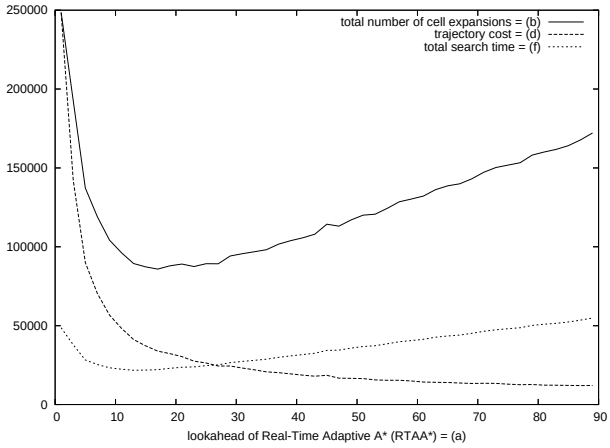

Figure 9: Performance of Real-Time Adaptive A*

We perform experiments on a SUN PC with a 2.4 GHz AMD Opteron Processor 150 in randomly generated four-connected mazes of size 151×151 that are solvable. Their corridor structure is generated with depth-first search. The start and goal cells are chosen randomly. Figure 8 shows an example (of smaller size than used in the experiments). We use the Manhattan distances as heuristics. The performance measures in Table 1 are averaged over the same 2500 grids. We show the standard deviation of the mean for three key performance measures in square brackets to demonstrate the statistical significance of our results, namely the total number of cell expansions and the total search time on one hand and the resulting trajectory cost on the other hand. We first verify the properties suggested in the previous sections:

- RTAA* with lookahead infinity, LRTA* with the same lookahead, D* Lite and forward and backward A* searches follow the same trajectories if they break ties in the same way and their trajectory costs are indeed approximately equal. (The slight differences are due to remaining ties being broken randomly.) The total number of cell expansions and the total search time are indeed larger for forward A* searches than RTAA*, and larger for RTAA* than LRTA*, as suggested in "Illustration."

- Decreasing the lookahead of RTAA* indeed increases the trajectory cost but initially decreases the total number of cell expansions and the total search time, as suggested in "Il-

lustration." Increasing the trajectory cost increases the total number of search episodes. If the lookahead is already small and continues to decrease, then eventually the speed with which the total number of search episodes increases is larger than the speed with which the lookahead and the time per search episode decreases, so that the number of cell expansions and the total search time increase again, as the graphs in Figure 9 show. (The graph also shows that the total number of cell expansions and the total search time are proportional, as expected.)

- RTAA* with lookaheads larger than one and smaller than infinity indeed increases the heuristics less than LRTA* with the same lookaheads per update, as suggested in "Relationship to LRTA*." Consequently, its trajectory costs and total number of cell expansions are larger than the ones of LRTA* with the same lookaheads. However, it updates the heuristics much faster than LRTA* with the same lookaheads, resulting in smaller total search times.

- RTAA* with lookahead one and LRTA* with the same lookahead follow the same trajectories and update the same states if they break ties in the same way and their trajectory costs and total number of cell expansions are indeed approximately equal, as suggested in "Relationship to LRTA*."

One advantage of RTAA* is that its total planning time with a carefully chosen lookahead is smaller than that of all other search methods, although its trajectory costs then are not the smallest ones. This is important for applications where planning is slow but actions can be executed fast. However, the advantage of RTAA* over the other search methods for our particular application is a different one: Remember that there is a time limit per search episode so that the characters move smoothly. If this time limit is larger than 20.99 microseconds, then one should use D* Lite for the search because the resulting trajectory costs are smaller than the ones of all other search methods whose search time per search episode is no larger than 20.99. (The table shows that the trajectory costs of forward A* search are smaller but, as argued before, this difference is due to noise.) However, if the time limit is smaller than 20.99 microseconds, then one has to use a real-time heuristics search method. In this case, one should use RTAA* rather than LRTA*. Assume, for example, that the time limit is 20.00 microseconds. Then one can use either RTAA* with a lookahead of 67, resulting in a trajectory cost of 13657.31, or LRTA* with a lookahead of 43, resulting in a trajectory cost of 16814.49. Thus, the trajectory cost of LRTA* is about 23 percent higher than the one of RTAA*, which means that RTAA* improves the state of the art in real-time heuristic search. A similar argument holds if the search time is amortized over the number of action executions, in which case there is a time limit per action execution. If this time limit is larger than 6.62 microseconds, then one should use D* Lite for the search because the resulting trajectory costs are smaller than the ones of all other search methods whose search time per action execution is no larger than 6.62. However, if the time limit is smaller than 6.62 microseconds, then one has to use a real-time heuristics search method. In this case, one should use RTAA* rather than LRTA*. Assume, for example,

that the time limit is 4.00 microseconds. Then one can use either RTAA* with a lookahead of 79, resulting in a trajectory cost of 12699.99, or LRTA* with a lookahead of 53, resulting in a trajectory cost of 14427.80. Thus, the trajectory cost of LRTA* is about 13 percent higher than the one of RTAA*, which again means that RTAA* improves the state of the art in real-time heuristic search.

9. CONCLUSIONS

In this paper, we developed Real-Time Adaptive A* (RTAA*). This real-time heuristic search method is able to choose its local search spaces in a fine-grained way. It updates the values of all states in its local search spaces and can do so very quickly. Our experimental results for goal-directed navigation tasks in unknown terrain demonstrated that this property allows RTAA* to move to the goal with smaller total search times than a variety of tested alternative search methods. Furthermore, we showed that RTAA* follows trajectories of smaller cost for given time limits per search episode than a recently proposed real-time heuristic search method because it updates the heuristics more quickly, which allows it to use larger local search spaces and overcompensate for its slightly less informed heuristics. It is future work to extend RTAA* to inconsistent heuristics, compare it to real-time heuristic search methods besides LRTA* and combine the idea behind RTAA* with other ideas of enhancing real-time heuristic search methods, for example, the ones described in [2] and [4]. In particular, it would be interesting to study a hierarchical version of RTAA*.

ABSTRACT

Distributed Partially Observable Markov Decision Problems (Distributed POMDPs) are evolving as a popular approach for modeling multiagent systems, and many different algorithms have been proposed to obtain locally or globally optimal policies. Unfortunately, most of these algorithms have either been explicitly designed or experimentally evaluated assuming knowledge of a starting belief point, an assumption that often does not hold in complex, uncertain domains. Instead, in such domains, it is important for agents to explicitly plan over continuous belief spaces. This paper provides a novel algorithm to explicitly compute finite horizon policies over continuous belief spaces, without restricting the space of policies. By marrying an efficient single-agent POMDP solver with a heuristic distributed POMDP policy-generation algorithm, locally optimal joint policies are obtained, each of which dominates within a different part of the belief region. We provide heuristics that significantly improve the efficiency of the resulting algorithm and provide detailed experimental results. To the best of our knowledge, these are the first run-time results for analytically generating policies over continuous belief spaces in distributed POMDPs.

1. INTRODUCTION

Distributed Partially Observable Markov Decision Problems (Distributed POMDPs) are evolving as a popular approach for modeling multiagent teamwork [13, 18, 14, 6, 3]. Distributed POMDPs provide a particularly useful model for domains ranging from sensor nets to disaster rescue, where agents need to work in a team in the presence of domain costs and uncertainties. Since optimal policy computation for these models has been proven to be NEXP-Complete [3], researchers have pursued two approaches in building algorithms for distributed POMDPs. The first approach restricts the domain, limiting agents' interactions (transition independence) [2, 14] or approximating observability of the local state [6]. The second approach, in-line with the thrust of this work, does not restrict the domains, but finds local optimal solutions [11, 7, 16].

Unfortunately, these approaches often assume knowledge of the starting belief state when generating policies[16, 11, 14, 10]. However, in many domains, including sensor nets and disaster rescue, such an assumption is a significant restriction, since it requires that starting belief state be known in advance. Alternatively, policy computation must be done on-line, which, given significant runtime for generating policies for distributed POMDPs, would prevent agents from generating a high-quality response in real-time.

Thus, there is a need in distributed POMDPs to generate policies for continuous belief spaces rather than just an initial single belief point, so policies may be computed off-line or without the need for a known starting belief state. This would allow agents to respond in real-time in time-critical domains. Unfortunately, while some of the approaches for locally optimal policy generation in distributed POMDPs can be applied or directly extended to apply to policy generation over continuous belief spaces[16, 7], these are based on finite-state controllers, which restrict policy representations; a restriction that is even more significant when planning over continuous belief spaces. Alternatively, a globally optimal policy generation algorithm has been suggested for continuous spaces[8], but this approach must surmount the substantial computational barrier given the NEXP-complete complexity result. In fact, no experimental evaluations are currently available for run-time efficiency when generating policies over continuous belief spaces with either of these approaches.

To remedy this situation, we present a novel algorithm for locally optimal policy generation for continuous starting belief region that does not restrict the space of policies considered. In particular, we build on the "Joint Equilibrium-based Search for Policies" (JESP) algorithm[11] which finds locally optimal policies from an unrestricted set of possible policies, with a finite planning horizon. However, JESP currently assumes a known starting belief state. To enable planning over continuous belief spaces, we combine JESP with algorithms that plan optimal policies over continuous belief spaces for single agent POMDPs [1, 5, 15]. In particular, whereas the original JESP performed iterative best-response computations from a single starting belief state, the combined algorithm exploits the single-agent POMDP techniques to perform best-response computations over continuous regions of the belief space.

The paper thus presents a new algorithm, CS-JESP (Continuous Space JESP), that allows us to generate a piece-wise linear and

convex value function over continuous belief spaces for the optimal policy of one agent in the distributed POMDP, given fixed policies of other agents — the familiar cup-like shape of this value function is what we reference in the title of this paper [9]. The cup-shape implies that when dealing with a continuous starting belief space, agents usually have more than one policy, each of which dominates in a different region of the belief space. This region-wise dominance highlights the three important challenges addressed in CS-JESP. First, CS-JESP requires computation of best response policies for one agent, given that different policies dominate over different regions of the belief space for the second agent. To efficiently compute best response policies per belief region, it is critical to employ techniques that prune out unreachable future belief states. To that end, we illustrate application of the belief bound techniques[15] for improved efficiency. Second, owing to these best response calculations for different belief regions, often the policies for contiguous belief regions can be identical. To address this inefficiency, we implement a merging method that combines such adjacent regions with equivalent policies. Third, to improve the performance of the algorithm, we implement region-based convergence, i.e. once policies have converged for a region, these are not considered for subsequent best response computations.

2. BACKGROUND

As mentioned earlier, this paper presents a solution that combines value iteration algorithms of single agent POMDPs and JESP. In this section, we present a brief overview of these techniques.

2.1 Single Agent POMDPs and DB-GIP

A single-agent POMDP can be represented using the tuple $\left\langle \hat{\mathcal{S}}, \hat{\mathcal{A}}, \hat{\mathcal{P}}, \hat{\Omega}, \hat{\mathcal{O}}, \hat{\mathcal{R}} \right\rangle$, where $\hat{\mathcal{S}}$ is a finite set of states; $\hat{\mathcal{A}}$ is a finite set of actions; $\hat{\Omega}$ is a finite set of observations; $\hat{\mathcal{P}}(s, a, s')$ provides the probability of transitioning from state s to s' when taking action a; $\hat{\mathcal{O}}(s', a, o)$ is probability of observing o after taking an action a and reaching s'; $\hat{\mathcal{R}}(s, a)$ is the reward function. We use, $\hat{\mathcal{B}}$ to denote the feasible belief space for a POMDP. A belief point $b \in \hat{\mathcal{B}}$, is a probability distribution over the set of states $\hat{\mathcal{S}}$. A value function over a belief state is defined as:
$V(b) = \max_{a \in \hat{\mathcal{A}}} \left\{ \hat{\mathcal{R}}(b, a) + \gamma \, \Sigma_{b' \in \hat{\mathcal{B}}} \Pr(b'|b, a) V(b') \right\}$. Currently, the most efficient exact algorithms for POMDPs are value iteration algorithms, specifically GIP [1] and RBIP [5]. These are dynamic programming algorithms, where at each iteration the value function is represented with a minimal set of dominant vectors called the parsimonious set. Given a parsimonious set at time t, $\mathcal{V}_t$, we generate the parsimonious set at time $t-1$, $\mathcal{V}_{t-1}$ as follows (notation similar to that in [1] and [5]):

1. $\left\{ v_{t-1}^{a,o,i}(s) = \hat{\mathcal{R}}(s, a)/|\hat{\Omega}| + \gamma \, \Sigma_{s' \in \hat{\mathcal{S}}} \Pr(o, s'|s, a) v_t^i(s') \right\} = \hat{\mathcal{V}}_{t-1}^{a,o}$ where $v_t^i \in \mathcal{V}_t$.
2. $\mathcal{V}_{t-1}^{a,o} = PRUNE(\hat{\mathcal{V}}_{t-1}^{a,o})$
3. Doing crosssum ($\oplus$) of vectors .
   $\mathcal{V}_{t-1}^{a} = PRUNE(\cdots(PRUNE(\mathcal{V}_{t-1}^{a,o_1} \oplus \mathcal{V}_{t-1}^{a,o_2}) \cdots \oplus \mathcal{V}_{t-1}^{a,o_{|\hat{\Omega}|}})$
4. $\mathcal{V}_{t-1} = PRUNE(\bigcup_{a \in \hat{\mathcal{A}}} \mathcal{V}_{t-1}^{a})$

Each $PRUNE$ call executes a linear program (LP) which is recognized as a computationally expensive phase in the generation of parsimonious sets [1, 5]. As shown in [15], the performance of these dynamic programming algorithms can be improved considerably by exploiting the dynamics of the domain.

DB-GIP: This is an exact (not approximate) technique that builds on top of GIP, to provide significant performance improvements. There are two key ideas in DB-GIP (we focus on DB-GIP as it is shown to be more efficient than DB-RBIP)[15]. The first technique called DB, prunes unreachable belief spaces, given information about the starting belief space, B_0. To that end, it computes belief bounds over states at future time steps given B_0. These belief bounds are obtained by solving the maximization and minimization problems on the equation for belief probability as follows. Given an action a and observation ω, we can express the maximization problem as

$$\max_{b_t \in B_t} b_{t+1}^{a,\omega}(s_{t+1}) \quad \text{s.t.} \quad b_{t+1}^{a,\omega}(s_{t+1}) = c^T b_t / d^T b_t$$

where $c(s_t) = \hat{\mathcal{O}}_t(s_{t+1}, a, \omega)\hat{\mathcal{P}}_t(s_t, a, s_{t+1})$ and
$d(s_t) = \sum_{s_{t+1} \in \hat{\mathcal{S}}_{t+1}} \hat{\mathcal{O}}_t(s_{t+1}, a, \omega)\hat{\mathcal{P}}_t(s_t, a, s_{t+1})$.

Rewriting the problem in terms of the new variables as follows:

$$\min_x \left(-c^T x / d^T x \right) \quad \text{s.t.} \quad \sum_i x_i = 1, \; 0 \le x_i \le b_t^{\max}(s_i) =: \bar{x}_i$$

where $\sum_i b_t^{\max}(s_i) \ge 1$ to ensure existence of a feasible solution.

Expressing this problem as a Lagrangian enables efficient polynomial time solution that provides us a bound on the belief probability over a state at time step t+1, given the belief probabilities over states at time t. By bounding the belief probability over states, we can significantly improve the run-time of the LP, since the LP now performs the PRUNE operations mentioned above over narrower ranges of the belief space. DB leads to orders of magnitude improvement in existing algorithms [15] .

A second idea in DB-GIP is the Dynamic States (DS) technique, that exploits dynamic state spaces. Given an initial set of starting states, this technique initially finds the reachable states at each iteration, by using the transition function. Then, it finds dominant policies at each iteration over all belief probabilities of only these reachable states rather than over all belief probabilities of all the states. This reduction in reachable belief space, can significantly improve the performance of the existing algorithms[15]. DS in essence is a specialization of DB in that DS may be considered to impose a bound of 0 or 1 on the maximum belief probabilities over states, whereas DB may find a bound in between (e.g. 0.63).

2.2 Distributed POMDPs: MTDP

The distributed POMDP model that we base our work on is MTDP [17], however other models [3] could also be used. These distributed POMDP models are more than just two single agent POMDPs working independently. In particular, given a team of n agents, an MTDP [17] is defined as a tuple: $\langle S, A, P, \Omega, O, R \rangle$. S is a finite set of world states $\{s_1, \ldots, s_m\}$. $A = \times_{1 \le i \le n} A_i$, where $A_1, \ldots, A_n$, are the sets of action for agents 1 to n. A joint action is represented as $\langle a_1, \ldots, a_n \rangle$.
$P(s_i, \langle a_1, \ldots, a_n \rangle, s_f)$, the transition function, represents the probability that the current state is s_f, if the previous state is s_i and the previous joint action is $\langle a_1, \ldots, a_n \rangle$. $\Omega = \times_{1 \le i \le n} \Omega_i$ is the set of joint observations where Ω_i is the set of observations for agents i.
$O(s, \langle a_1, \ldots, a_n \rangle, \omega)$, the observation function, represents the probability of joint observation $\omega \in \Omega$, if the current state is s and the previous joint action is $\langle a_1, \ldots, a_n \rangle$. For the purpose of this paper, we assume that observations of each agent is independent of each other's observations. Thus the observation function can be expressed as $O(s, \langle a_1, \ldots, a_n \rangle, \omega) = O_1(s, \langle a_1, \ldots, a_n \rangle, \omega_1) \cdot \ldots \cdot O_n(s, \langle a_1, \ldots, a_n \rangle, \omega_n)$. The agents receive a single immediate joint reward $R(s, \langle a_1, \ldots, a_n \rangle)$ which is shared equally.

Each agent i chooses its actions based on its local *policy*, π_i,

which is a mapping of its observation history to actions. Thus, at time t, agent i will perform action $\pi_i(\vec{\omega}_i^t)$ where $\vec{\omega}_i^t = \omega_i^1, \ldots, \omega_i^t$. $\pi = \langle \pi_1, \ldots, \pi_n \rangle$ refers to the joint policy of the team of agents. In this model, execution is distributed but planning is centralized.

2.3 Illustrative Domain

We consider the standard multiagent tiger problem from [11]. Two agents are in a corridor facing two doors "left" and "right". Behind one door lies a hungry tiger, and behind the other lies a reward. The set of states, S, is {SL, SR}, where SL indicates tiger behind the left door, and SR indicates tiger behind right door. The agents can jointly or individually open either door. In addition, the agents can independently listen for the presence of the tiger. Thus, the set of actions, A1 = A2 = {'OpenLeft', 'OpenRight', 'Listen'}. The transition function, P specifies that the problem is reset whenever an agent opens one of the doors. However, if both agents listen, the state remains unchanged. After every action each agent receives an observation about the new state. The observation functions are identical and will return either TL or TR with different probabilities depending on the joint action taken and the resulting world state. For example, if both agents listen and the tiger is behind the left door (state is SL), each agent independently receives the observation TL with probability 0.85 and TR with probability 0.15. For more details on this domain, refer to [11].

2.4 JESP algorithm for MTDPs

Given the NEXP-complete complexity of generating globally optimal policies for distributed POMDPs[3], locally optimal approaches [16, 4, 11] have emerged as viable solutions. In this paper, we build on the "JESP" (Joint Equilibrium-Based Search for Policies) [11] algorithm, outlined below (Algorithm 1). The key idea is to find the policy that maximizes the joint expected reward for one agent at a time, keeping policies of the other $n-1$ agents fixed. This process is repeated until an equilibrium is reached (local optimum is found). Multiple local optima are not encountered since planning is centralized. Key innovation in JESP is based on the realization that if policies of all other $n-1$ agents are fixed, then the remaining agent faces a normal single-agent POMDP, but with an extended state space. Thus, in line 4, given a known starting belief state, we use dynamic programming over belief states of this newer more complex single-agent POMDP, to compute agent 1's optimal response to fixed policies of the remaining $n-1$ agents.

Algorithm 1 JESP()

```
1: Π' ← randomly selected joint policy, prevVal ← value of Π',
   conv ← 0, Π ← Π'
2: while conv ≠ n do
3:   for i ← 1 to n do
4:     val, Π_i ← OPTIMALBESTRESPONSE(b, Π', T)
5:     if val = prevVal then
6:       conv +← 1
7:     else
8:       Π'_i ← Π_i, prevVal ← val, conv ← 1
9:     if conv = n then break
10: return Π
```

The key is then to define the extended state in JESP. For a two agent case, for each time t, the extended state of agent 1 is defined as a tuple $e_1^t = \langle s^t, \vec{\omega}_2^t \rangle$, where $\vec{\omega}_2^t$ is the observation history of the other agent. By treating e_1^t as the state of agent 1 at time t, we can define the transition function and observation function for the resulting single-agent POMDP for agent 1 as follows:

$$\begin{aligned} P'(e_1^t, a_1^t, e_1^{t+1}) &= \Pr(e_1^{t+1} | e_1^t, a_1^t) \\ &= P(s^t, (a_1^t, \pi_2(\vec{\omega}_2^t)), s^{t+1}) \\ &\quad \cdot O_2(s^{t+1}, (a_1^t, \pi_2(\vec{\omega}_2^t)), \omega_2^{t+1}) \end{aligned} \quad (1)$$

$$\begin{aligned} O'(e_1^{t+1}, a_1^t, \omega_1^{t+1}) &= \Pr(\omega_1^{t+1} | e_1^{t+1}, a_1^t) \\ &= O_1(s^{t+1}, (a_1^t, \pi_2(\vec{\omega}_2^t)), \omega_1^{t+1}) \end{aligned} \quad (2)$$

In other words, when computing agent 1's best-response policy via dynamic programming given the fixed policy of its teammate, we maintain a distribution over the extended states e_1^t, rather than over the world states s^t. Figure 1 shows a trace of the belief state evolution for the multi-agent tiger domain, described in Section 2.3, e.g. e_1^2 of SL(TR) indicates an extended state where the tiger is behind the left door and agent 2 has observed TR. However, as noted above, the main shortcoming of this technique is that it computes a locally optimal policy assuming a fixed starting belief state, and this assumption is embedded in its dynamic programming as shown in line 4 of algorithm 1 — it does not generate policies over continuous belief spaces.

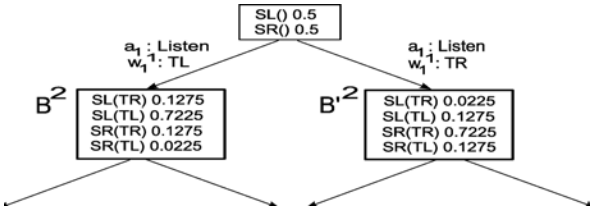

Figure 1: Trace of tiger scenario in JESP

3. CONTINUOUS SPACE JESP (CS-JESP)

One of the key insights in CS-JESP is the synergistic interaction between the JESP algorithm for distributed POMDPs and the DB-GIP technique of single agent POMDPs. We illustrate these interactions with a two-agent example in Section 3.1, and present key ideas in Section 3.2. Further, we describe the algorithm for n agents in Section 3.3 and some theoretical guarantees in Section 3.4.

Unlike previous work, our work focuses on continuous starting belief spaces and thus requires modifications for policy representation. In particular, because different policies may be dominant over different regions in the belief space, we introduce the notion of a *general policy*. A *general policy*, Π_i for an agent i is defined as a mapping from belief regions to policies. Π_i is represented as the set $\{(B_0^1, \pi_i^1), \ldots (B_0^m, \pi_i^m)\}$, where $B_0^1, .., B_0^m$ are belief regions in the starting belief space B_0 and $\pi_i^1, ..\pi_i^m$ are the policies that will be executed starting from those regions. Henceforth we refer π_i^k as *specialized policies*. Thus, given a starting belief point $b_0^k \in B_0^k$, agent i on receiving observations $\omega_i^1, \ldots, \omega_i^t$ will perform the action $\pi_i^k(\vec{\omega}_i^t)$ where $\vec{\omega}_i^t = \omega_i^1, \ldots, \omega_i^t$. $\Pi = \langle \Pi_1, \ldots, \Pi_n \rangle$ refers to the joint general policy of the team of agents.

3.1 Illustrative Example

For ease of explanation, initially the algorithm is explained with two agents, Agent1 and Agent2. However, as we will show in Section 3.3, this algorithm is easily extendable to n agents. Initially, each agent selects a random general policy, Π_i, which will be a singleton set, $\{(B_0, \pi_i)\}$, i.e. a single *specialized policy*,π_i, over the entire starting belief space, B_0. While for exposition purposes this example describes policy computations by individual agents,

in reality in CS-JESP these computations are performed by a centralized policy generator. CS-JESP begins when one agent, say Agent2, fixes its *general policy* Π_2, and other agent, Agent1, finds the best response for Agent2's *general policy*. Fixing Agent2's *specialized policy*, π_2, Agent1 creates a single agent POMDP with an extended state space, as explained in Section 2.4. Agent1 solves this POMDP using DB-GIP technique, explained in Section 2.1, with starting belief space as B_0, and obtains a new general policy Π_1, containing a set $\{(B_0^1, \pi_1^1), ...(B_0^m, \pi_1^m)\}$. Each $B_0^k \in B_0$ is a belief region and is represented by a minimum and maximum value for each of the $|S| - 1$ dimensions that represent the belief space. Now, Agent1 freezes its *general policy*, Π_1, and Agent2 solves a POMDP for each $\pi_1^j \in \Pi_1$, with the starting belief region as B^j. Thus, Agent2 solves m POMDPs, and obtains a new *general policy* Π_2. At this point, bordering regions in Π_2 that have identical policies are merged. This process continues until the solutions converge, and a local optimal is reached, i.e. no agent can improve its value vectors in any belief region.

Figure 2 illustrates the working of the algorithm with the multi-agent tiger scenario (Section 2.3) for time horizon, $T = 2$. Each tree in Figure 2 represents a *specialized policy*. All the trees on the left side of the figure are part of the *general policies* of Agent1, and trees on the right are part of the *general policies* of Agent2. For instance, at the end of iteration 3, both agents contain two specialized policies in their *general policy*. Within each tree (specialized policy), the letter inside each node indicates the action, and edges indicate the observation received. Thus, for the highlighted tree in the top left corner, the root node indicates the Listen(L) action, and upon either observing TL or TR, the *specialized policy* requires the agent to take a Listen(L) action. In this example, belief region over which a *specialized policy* dominates, consists of two numbers, namely the minimum and maximum belief probability of the state SL. These belief regions are indicated below each *specialized policy* in the figure. For instance, for the highlighted tree it is [0,1], but for other trees, regions such as [0.18,0.85] are shown.

The algorithm begins with both agents randomly selecting a *specialized policy* for the entire belief space [0,1]. In iteration 1, Agent2 fixes its *general policy*, and Agent1 comes up with its best response *general policy*. For calculating the best response, the Agent1 solves a POMDP with the starting belief range as [0,1], since Agent2's general policy is defined over this range. After the first iteration, Agent1 contains three *specialized policies* as part of its *general policy*, dominating over ranges [0,0.15], [0.15,0.85], [0.85,1]. In iteration 2, Agent1 fixes its *general policy*, and Agent2 begins its best response calculation with region [0,0.15]. For this range [0,0.15], Agent2 has only one dominant *specialized policy* and same is the case for [0.85,1]. However, for the range [0.15,0.85], Agent2 has two dominant *specialized policies*, one that dominates in the range [0.15,0.5], and the other that dominates in the range [0.5,0.85]. Thus after iteration 2, Agent2 has four *specialized policies* as part of its best response *general policy*. However, regions highlighted (with dotted rectangular boxes) have identical policies and thus after merging we are left with only two *specialized policies*. This algorithm continues with Agent2 fixing its *general policy* at iteration 3. Finally at convergence, each agent contains two *specialized policies* as part of their *general policies*.

3.2 Key Ideas

In this section, we explain in detail the key ideas in the CS-JESP algorithm, namely: (a) JESP and DB-GIP synergy; (b) Calculation of dominanant belief regions for *specialized policies*; (c) Region-based convergence; and (d) Merging of adjacent regions with identical *specialized policies*.

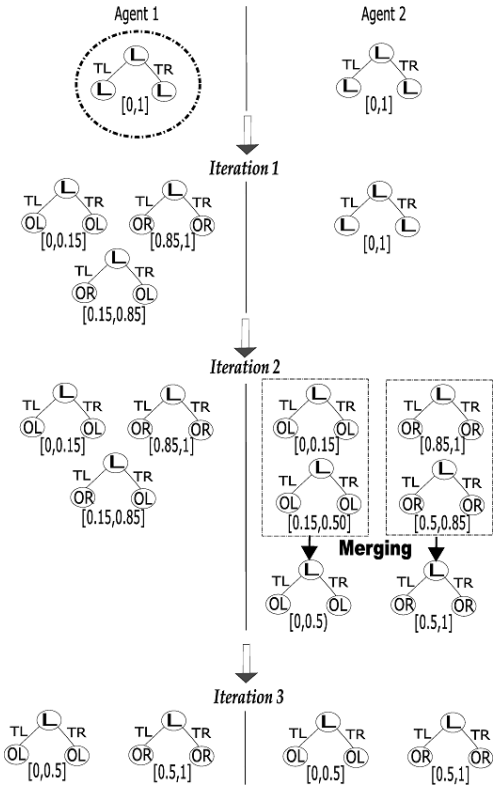

Figure 2: Trace of the algorithm for T=2 in Multi Agent tiger example with a specific starting joint policy

JESP and DB-GIP synergy: Both the DS and DB techniques of DB-GIP can provide significant performance improvements in CS-JESP. First, with respect to DS, JESP's state space is dynamic, where the set of states reachable at time t, e_i^t differ from the set of states at $t + 1$, e_i^{t+1}. DS can exploit this dynamism by computing dominant policies at time t over the belief space generated by the states in e_i^t thus reducing the dimensionality of the state space considered. For instance, in Figure 1, we have two initial states e_1^1= SL or SR, while there are four states e_1^2, e.g.$SL(TL), SL(TR)$ etc. Given a time horizon of T=2, instead of constructing a belief space over (2+4=) 6 dimensions, DS will lead to constructing a belief space over two states at the first time step and four states over the second time step. Such dimensionality reduction leads to significant speedups in CS-JESP. Second, with respect to DB, each agent solves a POMDP over the belief regions in the *general policies* of the other agents. DB is able to exploit forward projections of such starting belief regions to bound the maximum probabilities over states, and thus again restrict the belief space over which dominant policies are planned per belief region, obtaining additional speedups. For instance in Figure 2, at iteration2, Agent2 solves three POMDPs — these POMDPs are defined over extended states given three separate fixed policies of Agent1— one with the starting belief region as [0,0.15], another with [0.15,0.85], and a third with [0.85,1]. Thus, in solving the POMDP starting with the belief range [0,0.15], DB helps prune all the unreachable portions of the belief space given that the starting range is [0,0.15]. In all three POMDPs, the belief region is narrower compared to [0,1].

Region-based convergence: Given continuous initial belief space, we obtain value vectors (vector containing values for all the states)

for all the belief regions in the *general policy*. Thus, convergence is attained when for all agents the value vectors at the current iteration for all the belief regions are equal to those in the previous iteration. For instance, in Figure 2, the convergence is attained in the fourth iteration, with the *general policy* of Agent2 containing the two exact same *specialized policies* from iteration 3. However, once one region has converged — the value vectors for all agents do not change from one iteration to the next for that region — CS-JESP will not test that region further for convergence, but only continue changing policies in regions that have failed to converge.

Merging of adjacent regions with identical *specialized policies*: Merging such regions can be important as the other agent would have to solve fewer number of POMDPs in the next iteration. For instance, in the *general policy* of Agent2 before merging at iteration 2, belief regions [0,0.15] and [0.15,0.5] have identical specialized policies. Similarly, regions [0.5, 0.85] and [0.85,1] have identical specialized policies. Thus Agent2 has only two *specialized policies* after merging (instead of four before merging) and this leads to agent1 solving two instead of four POMDPs at iteration 3.

Merging requires identifying regions adjacent to each other. In the Tiger domain, this is done by doing adjacency check for regions along one dimension. However, finding bordering regions in a $|S|$ dimensional state space requires comparisons along $|S|-1$ dimensional space.

Calculation of dominant belief regions for *specialized policies*: One standard way of representing solutions in single agent POMDPs is through value vectors. In this representation, the best policy for a belief point, b, is computed by testing for a vector that provides the maximum expected value for that belief point.
$\pi_1^* \leftarrow argmax_{\pi \in \{\pi_1\}} v_\pi \cdot b$.

However, in CS-JESP, one agent uses the belief regions of the other agent to calculate the best responses over each of those belief regions. We develop a linear program to address the dominant belief region computation for each policy. Algorithm 2 computes the maximum belief probability of a state, s_j, where a policy or value vector,v dominates all the other policies or value vectors, $\mathcal{V} - v$ in the final policy. Constraint 1 in Algorithm 2, computes points where v dominates all the other vectors in $\mathcal{V}$. Objective function of the algorithm is a maximization over $b(s_j)$, thus finding highest possible belief probability for state s_j amongst all those dominating points. In a similar way, the minimum for s_j can be found by doing a minimize, instead of maximize, in line 1 of the LP. The belief region is calculated by solving these max, min LPs for each state $s_j \in S$. Thus, requiring $2 * |\mathcal{V}| * |S|$ number of LPs to be solved for the computation of an entire belief region.

Algorithm 2 MAXIMUMBELIEF$(s_j, v, \mathcal{V}, B^{min}, B^{max})$

Maximize $b(s_j)$
subject to constraints
1. $b.(v - v') > 0, \forall v' \in \mathcal{V} - v$
2. $\Sigma_{s \in S} b(s) = 1$
3. $B^{min}(s) < b(s) < B^{max}(s), \forall s \in S$

3.3 Algorithm for n agents

In this section, we present the CS-JESP algorithm (Algorithm 3) for n agents. In the initialization stage (lines 1-4), each agent i has only one belief region that corresponds to its entire belief space (Π'_i.*beliefPartition*). Also, each agent has a single randomly selected *specialized policy*, $\Pi'_i.\pi[\langle [0,1], \ldots, [0,1] \rangle]$ (i.e. π is the *specialized policy*), for the entire belief space (line 3). Every *general policy* has "*count*" for each belief region, to track the convergence of policies in that belief region (region-based convergence) — if the *count* reaches n then the region has converged, because no agent will change any further. The flag "*converged*" monitors if joint *general policies* in all the regions have converged.

In each iteration (one execution of lines 6-23) of Algorithm 3, we choose an agent i and find its optimal response to the fixed *general policies* of the remaining agents by calling OPTIMALBESTRESPONSE(). This is repeated until no agent acting alone can improve upon the joint expected reward by changing its own *general policy*.

Although each agent i starts off with the same belief set partition, Π'_i.*beliefPartition*, this will not be true after calling OPTIMALBESTRESPONSE() as seen in Figure 2. The function UPDATEPARTITION() (Algorithm 4) is responsible for creating a new belief set partition for an agent i, depending on the belief regions of the other $n-1$ agents. This new belief set partition is obtained by splitting the overlapping belief regions of the $n-1$ agents, in a way that no two resulting belief regions, which now belong to this partition, overlap. Furthermore, this function computes the Π_i.*count* for all the new regions, from the $count$ values for the regions in Π'_j, where j was the free agent in the last iteration (i.e the agent who computed the best response in the last iteration).

FINDNEWPARTITION() (Algorithm 5) takes two arguments, (i) *partition* and (ii) a belief region, br, and it generates all feasible partitions from the two arguments. To illustrate the working of this function, we provide an example with three states $\{s_1, s_2, s_3\}$. Belief regions in the corresponding belief space can be represented with minimum and maximum belief probabilities for just s_1 and s_2, i.e. $\{(b^{min}[s_1], b^{max}[s_1]), (b^{min}[s_2], b^{max}[s_2])\}$. For example, let *partition* $=\{\langle [0, 0.8], [0.5, 0.9] \rangle\}$ (has only one region) and $br = \{[0.4, 0.9], [0.3, 0.6]\}$. In the first step (line 3), partitions are found for each state, s_i separately. Thus, for the first state, s_1, $[0, 0.8]$ and $[0.4, 0.9]$ yields partitions, $[0, 0.4]$, $[0.4, 0.8]$, $[0.8, 0.9]$. Similarly for the second state, s_2, the partitions found are $[0.3, 0.5]$, $[0.5, 0.6]$,$[0.6, 0.9]$. In the second step (line 4), we compute the cross product of these individual dimension partitions. This gives rise to nine belief regions, viz. $\{[0, 0.4], [0.3, 0.5]\}, \ldots, \{[0.8, 0.9], [0.4, 0.8]\}$, $\{[0.8, 0.9], [0.8, 0.9]\}$. Finally, in the third step (line 5), we prune regions which do not contain any valid points, i.e. $\sum_{s \leq |S|-1} b^{min}[s] > 1$. For instance, the region {[0.8,0.9],[0.4,0.8]} can be pruned, because a belief point in this region has probability of atleast 1.2 $(= 0.8 + 0.4)$.

The function OPTIMALBESTRESPONSE() (Algorithm 6) is then called separately for each belief region in agent i's belief set partition. It returns a new partitioniong of the initial belief space and the optimal policy for each belief region in this partition. CONSTRUCTEXTENDEDPOMDP() constructs a POMDP with extended state space, as explained in Section 2.4, while the function CALCULATEBELIEFREGION() computes the belief regions where each vector v $(\in \mathcal{V})$ dominates.

After computing best responses, CS-JESP() ensures that the number of belief partitions obtained are finite (in lines 14-16) and that Π.*count* is updated correctly for each belief region (in lines 18-21).

It is possible that an agent's best response in adjacent belief regions is the same policy. The function MERGEBELIEFREGIONS() (Algorithm 3.3) is responsible for merging such kind of regions (lines 4-7). Further, once the policies in a belief region have converged, that region is not considered for subsequent merging phases (first part of the condition on line 4).

3.4 Theoretical Results

Algorithm 3 CS-JESP()

1: **for** $i \leftarrow 1$**to** n **do**
2: Π'_i.*beliefPartition* $\leftarrow \{\langle [0,1], \ldots, [0,1]\rangle\}$
3: $\Pi'_i.\pi[\langle [0,1], \ldots, [0,1]\rangle] \leftarrow$ random specialized policy
4: Π'_i.*count*$[\langle (0,1), \ldots, (0,1)\rangle] \leftarrow 0$
5: *converged* $\leftarrow$ false; $i \leftarrow n$;
6: **while** *converged* $=$ false **do**
7: $i \leftarrow (i$ *MOD* $n) + 1$; *converged* $\leftarrow$ true
8: UPDATEPARTITION(i, Π_i, Π')
9: **for all** br **in** Π_i.*beliefPartition* **do**
10: **if** Π_i.*count*$[br] < n$ **then**
11: *converged*$\leftarrow$false
12: $\{\Pi_i,$ *regions*$\} \leftarrow$ OPTIMALBESTRESPONSE(i, Π', br)
13: **for all** br_1 **in** *regions* **do**
14: $\pi \leftarrow \Pi_i.\pi[br_1]$; REMOVE$(\Pi_i, br_1)$
15: **for** *dim* $\leftarrow 1$ **to** $|S| - 1$ **do**
16: br_1[*dim*] $\leftarrow$ ROUNDOFF$(br_1$[*dim*], *precision*$)$
17: **if** VOLUME$(br_1) > 0$ **then**
18: ADD$(\Pi_i$.*beliefPartition*$, br_1, \pi)$
19: **if** $\Pi_i.\pi[br_1] = \Pi'_i.\pi[br]$ **then**
20: Π_i.*count*$[br_1] \leftarrow \Pi'_i$.*count*$[br] + 1$
21: **else**
22: Π_i.*count*$[br_1] \leftarrow 1$
23: MERGEBELIEFREGIONS(Π_i)
24: $\Pi'_i \leftarrow \Pi_i$
25: **return** Π

Algorithm 4 UPDATEPARTITION(i, Π)

1: $\Pi_i \leftarrow \Pi_{(i \text{ MOD } n)+1}$
2: **for all** j **in**$\{1, \ldots, n\} - \{i, (i$ *MOD* $n) + 1\}$ **do**
3: **for all** br_1 **in** Π_j.*beliefPartition* **do**
4: **if** Π_i.*count*$[br_1] < n$ **then**
5: Π_i.*beliefPartition* $\leftarrow$ FINDNEWPARTITION$(\Pi_i$.*beliefPartition*$, br_1)$
6: **if** $i = 1$ **then** $j \leftarrow n$**else** $j \leftarrow i - 1$
7: **for all** br_2 **in** Π_i.*beliefPartition* **do**
8: $br_3 \leftarrow$ OVERLAPPINGREGION$(\Pi_j$.*beliefPartition*$, br_2)$
9: Π_i.*count*$[br_2] \leftarrow \Pi_j$.*count*$[br_3]$
10: **return**

Algorithm 5 FINDNEWPARTITION((*partition*, br))

1: *newPartition* $\leftarrow \emptyset$
2: **for** *dim* $\leftarrow 1$ **to** $|S| - 1$ **do**
3: *1DPartition* $\leftarrow$ SPLITDIMENSION(*dim*, br, *partition*)
4: *newPartition* $\leftarrow$ CROSSPRODUCT(*newPartition*, *1DPartition*)
5: *newPartition* $\leftarrow$ PRUNE(*newPartition*)
6: **return** *newPartition*

Algorithm 6 OPTIMALBESTRESPONSE(i, Π', br)

1: $k \leftarrow 0$
2: *extendedPOMDP* $\leftarrow$ CONSTRUCTEXTENDEDPOMDP(i, Π', br)
3: $\{\mathcal{V}, \pi^{new}\} \leftarrow$ DB-GIP(*extendedPomdp*, br)
4: **for** $j \leftarrow 1$ **to** $\mathcal{V}.size$ **do**
5: $v \leftarrow \mathcal{V}[j]$; $\mathcal{V}' \leftarrow \mathcal{V} - v$
6: *beliefPartition*$[k] \leftarrow$ CALCULATEBELIEFREGION$(v, \mathcal{V}', br)$
7: Π_i.*beliefPartition*$[k] \leftarrow$ *beliefPartition*$[k]$
8: $\Pi_i.\pi$[*beliefPartition*$[k]] \leftarrow \pi^{new}[j]$; $k \stackrel{+}{\leftarrow} 1$
9: **return** $\{\Pi_i,$ *beliefPartition*$\}$

In the following proofs, we use "iteration" to mean one execution of the "while" loop (lines 5-23) of Algorithm 3, n for the number of agents, and "free agent" to denote the ith agent for that iteration.

Algorithm 7 MERGEBELIEFREGIONS(Π_i)

1: **for each** b_1 **in** Π_i.*beliefPartition* **do**
2: **if** Π_i.*count*$(b_1) < n$ **then**
3: **for each** b_2 **in** Π_i.*beliefPartition* **do**
4: **if** Π_i.*count*$(b_2) < n \wedge \Pi_i.\pi[b_1] = \Pi_i.\pi[b_2]$ **then**
5: **if** ISADJACENT(b_1, b_2) **then**
6: $b \leftarrow$MERGEREGIONS(b_1, b_2)
7: ADD$(\Pi_i$.*beliefPartition*$, b, \Pi_i.\pi[b_1])$
8: Π_i.*count*$[b] \leftarrow$ *min*$(\Pi_i$.*count*$[b_1], \Pi_i$.*count*$[b_2])$
9: REMOVE(Π_i, b_1); REMOVE(Π_i, b_2)
10: **return** Π_i

PROPOSITION 1. *In CS-JESP, the joint expected reward for all starting belief points is monotonically increasing with each iteration.*

Proof Sketch. In every iteration, each starting belief point must belong to one of the regions in the belief partition of the free agent. Each such belief region corresponds to one of the value vectors, calculated by a call to OPTIMALBESTRESPONSE(Algorithm 6). Since DB-GIP is optimal, these vectors should either equal or dominate the vectors at the previous iteration, in all belief regions.■

PROPOSITION 2. *CS-JESP will terminate iff the joint policy has converged in all the free agent's belief regions.*

Proof Sketch. By construction, CS-JESP (Algorithm 3) terminates iff *converged* $=$ true, which will happen iff Π_i.*count*$[br] \geq n$, for all belief regions br of the free agent i. Π_i.*count*$[br] \geq n$ iff the joint policy for the region br remains constant for n iterations. In order for the joint *general policy* to remain constant for n iterations, OPTIMALBESTRESPONSE() should return identical *specialized policies* (to those in previous iteration) for all the belief regions , for $n - 1$ free agents. This happens when no one agent can improve the global value by altering its *general policy*, i.e. when local optima is attained. Furthermore, we round off each dimension of a belief region to *precision* decimal spaces, and hence the number of possible belief regions cannot grow indefinitely.■

From Propositions 1 and 2, we can conclude that CS-JESP will always terminate. At termination, the joint policy will be locally optimal as long as none of the belief regions returned by OPTIMALBESTRESPONSE were eliminated by the ROUNDOFF procedure.

4. EXPERIMENTAL RESULTS

This section provides three types of evaluations for CS-JESP using the multiagent tiger domain [11]. The first experiment focuses on run-time evaluations. We provide a comparison of three techniques: (i) CS-JESP+GIP: is the basic version of the combination of the JESP and the value iteration algorithm, GIP of single agent POMDPs. (ii) CS-JESP+DB, is JESP with DB-GIP. (iii)CS-JESP+DBM is CS-JESP+DB with the merging enhancement. Results of this experiment are shown in Figure 3. We experiment with two separate reward structures (presented in [11]). Figure 3(a) and Figure 3(b) focus on reward structure1, while Figure 3(c) and Figure 3(d) focus on reward structure2. In Figure 3(a), x-axis plots varying time horizon while y-axis plots run-time in milliseconds on log-scale[1]. In Figure 3(b), x-axis again plots time horizon, but the y-axis plots run-time in milliseconds (no log-scale is used). Time limit for the problems was set at 7,500,000 ms, after which they

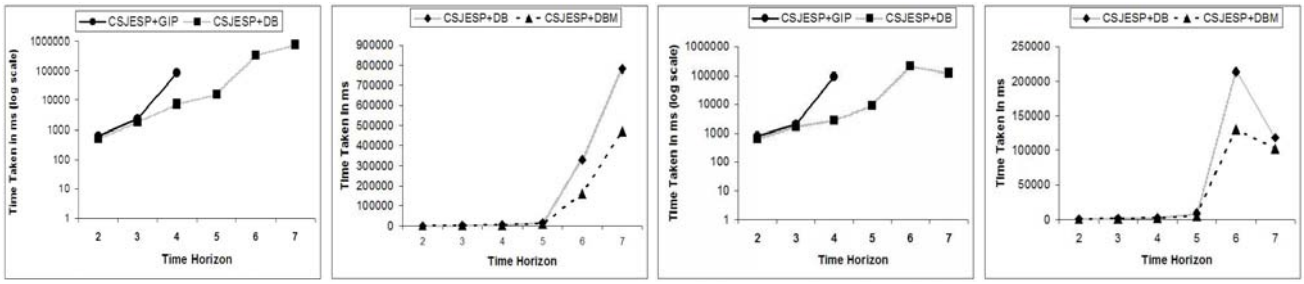

Figure 3: Comparison of (a) CSJESP+GIP, and CSJESP+DB for reward structure 1 (b) CSJESP+DB, and CSJESP+DBM for reward structure 1 (c) CSJESP+GIP, and CSJESP+DB for reward structure 2 (d) CSJESP+DB, and CSJESP+DBM for reward structure 2

were terminated. Figure 3(a) and Figure 3(c) refer to comparisons between CS-JESP+GIP and CS-JESP+DB, while Figure 3(b) and Figure 3(d) refer to comparisons between CS-JESP+DB and CS-JESP+DBM for the two reward structures.

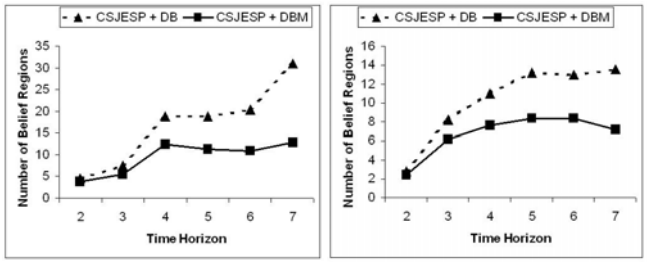

Figure 4: Comparison of the number of belief regions created in CS-JESP+DB and CS-JESP+DBM for reward structures 1 and 2

Figure 3(a) shows that CS-JESP+GIP did not terminate within the specified time limit after T=4. However, CS-JESP+DB converged to the solution even for T = 7, within the specified time limit. Even in cases where CS-JESP+GIP terminates, CS-JESP+DB provides significant speedups. For instance, in Figure 3(a), at T = 4, while CS-JESP+GIP takes in 83717.8 ms, CS-JESP+DB takes only 7345.2 ms leading to a speedup of 11.4 fold. Similar conclusions can be drawn from Figure 3(c). These results illustrate the synergy of JESP and DB-GIP, and the suitability of CS-JESP to take advantage of DB-GIP.

Figure 3(b) shows that CS-JESP+DBM provides further speedups over CS-JESP+DB, as time horizon increases. For instance at T=7 in Figure 3(b), merging in CS-JESP+DBM provided 1.66 fold speedup over CS-JESP+DB. Similar results are obtained with reward structure 2 in Figure 3(d), thus establishing the utility of merging contiguous regions with identical policies. In Figure 3(d) T=7 post merging show a faster execution compared to the T=6 results post merging. This occurs because the number of iterations of CS-JESP required for convergence at T=7 are lower (6) compared with iterations at T=6 (11).

Our second evaluation in Figure 4 focuses on understanding the speedups due to merging in CS-JESP+DBM. The number of belief regions present in the final solution is an indicator of the number of single agent POMDPs getting solved at each iteration. The x-axis in the figures represents the time horizon, while the y-axis is the number of belief regions. Thus in Figure 4, for a time-horizon of 7, using CSJESP+DB led to 31 belief regions, whereas using CSJESP+DBM led to 13 belief regions, a 2.39-fold reduction in the number of belief regions considered. Furthermore, we see that increasing the time horizon leads to increasing reduction in the number of belief regions with CS-JESP+DBM when compared to the number with CS-JESP+DB. Effect of the number of belief regions on the time taken increases with time horizon, because the single agent POMDPs expand in size with the time horizon. This provides the explanation for the timing results for CS-JESP+DBM in Figure 3(b) and Figure 3(d).

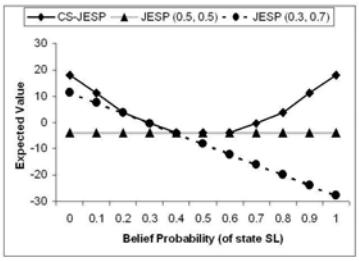

Figure 5: Comparison of the expected values obtained with JESP for specific belief points and CS-JESP

Our third evaluation focused on illustrating that CS-JESP achieves what it set out to do — generating policies over continuous initial belief space as shown in Figure 5. Belief space (in this domain belief probability of SL) is denoted on the x-axis, while the expected value of the policy is depicted on the y-axis. CS-JESP provides a general policy where the expected value is represented by a "CUP"-shape. There are five different policies represented in the cup, each dominant over a single belief region. The figure also indicates that if we were to approximate this entire general policy with a single policy over a single starting belief state, e.g. with JESP, then results may be arbitrarily worse. For instance with JESP (0.3, 0.7), the value at (1, 0) is -27, while the value generated with CS-JESP is 18, a difference of 45. With JESP (0.5, 0.5), the value at (1,0) is -4, where CS-JESP attains a value of 18, a difference of 22.

Of course, we may sample several belief points with JESP and then for a new belief point provide a policy from the nearest sample. Such a proposed heuristic approach naturally leads to our fourth evaluation comparing CS-JESP runtime to an approach that samples the belief space. This evaluation is not meant to be a precise comparison of JESP and CS-JESP, instead the aim is to show that the run-time results for sampled JESP would be comparable to the run times of CS-JESP. In Table 1, we show the run times of JESP and CS-JESP for T = 6, and T=7 for reward structure1. To replicate the policy obtained with CS-JESP, JESP would have to sample atleast as many times as the number of belief regions in the final policy of CS-JESP. For instance, for T=7, the number of samples required for JESP would be thirteen (from Figure 4). Table 1 shows an estimate of such a sampled JESP technique, given runtime re-

sults from [12]. We see that CS-JESP run-times are comparable, yet CS-JESP provides guarantees on these results that are unavailable with sampling.

	CS-JESP	JESP	Sampled Regions	Sampled JESP
T = 6	160336	15000	11	165000
T = 7	470398	73000	13	949000

Table 1: Comparison of run times (in ms) for JESP and CS-JESP

5. SUMMARY AND RELATED WORK

Distributed POMDPs are evolving as a popular approach in modeling multiagent systems, and many different algorithms have been proposed to obtain locally or globally optimal policies. Unfortunately, most of these have either been explicitly designed or experimentally evaluated assuming knowledge of a starting belief, an assumption that often does not hold in complex, uncertain domains. Instead, in such domains, it is important for agents to explicitly plan over continuous belief spaces. This paper provides a novel algorithm, CS-JESP, to explicitly compute finite horizon policies over continuous belief spaces, without restricting the space of policies. By marrying an efficient single-agent POMDP solver with a heuristic distributed POMDP policy-generation algorithm, locally optimal joint policies are obtained, each of which dominates within a different belief region. Key ideas in CS-JESP include: (a) Synergistic interaction between JESP and DB-GIP that enables significant performance improvement in CS-JESP; (b) Calculation of dominanant belief regions for *specialized policies*; (c) Region-based convergence; and (d) Merging of adjacent regions with identical *specialized policies*. To the best of our knowledge, these are the first run-time results for analytically generating policies over continuous belief spaces in distributed POMDPs.

In terms of related work, approaches for solving distributed POMDPs can be broadly classified in two main categories: globally optimal approaches and locally optimal algorithms. Becker *et al.* [2] present an exact globally optimal algorithm – the coverage set algorithm for transition-independent distributed MDPs. However unlike CS-JESP, this algorithm starts from a particular known initial state distribution. Hansen *et al.* [8] present an exact algorithm for partially observable stochastic games (POSGs) based on dynamic programming and iterated elimination of dominant policies. Like our work, they too deal with a continuous belief space and an unknown initial state distribution. This algorithm is important from a theoretical standpoint, but because of the inherent complexity of finding an exact solution for general distributed POMDPs, this algorithm does not scale well.

Among locally optimal approaches, Peshkin *et al.* [16] use gradient descent search to find local optimum finite-controllers with bounded memory. Their algorithm finds locally optimal policies from a limited subset of policies, with an infinite planning horizon. Their work does not consider a continuous belief space and starts from a fixed belief point. We have earlier discussed Nair *et al.* [11]'s JESP algorithm that uses dynamic programming to reach a local optimal. Bernstein *et al.* [7] present a locally optimal bounded policy iteration algorithm for infinite-horizon distributed algorithms. This algorithm has been theoretically shown to work in a continuous belief space from an unknown initial belief distribution. While this is an important contribution, the use of finite-state controllers restricts the policy representation. Also, their experimental results are for a single initial belief. Further, unlike our algorithm they use a *correlation device* in order to ensure coordination among the various agents.

Resource Allocation Among Agents with Preferences Induced by Factored MDPs

ABSTRACT

Distributing scarce resources among agents in a way that maximizes the social welfare of the group is a computationally hard problem when the value of a resource bundle is not linearly decomposable. Furthermore, the problem of determining the value of a resource bundle can be a significant computational challenge in itself, such as for an agent operating in a stochastic environment, where the value of a resource bundle is the expected payoff of the optimal policy realizable given these resources. Recent work has shown that the structure in agents' preferences induced by stochastic policy-optimization problems (modeled as MDPs) can be exploited to solve the resource-allocation and the policy-optimization problems simultaneously, leading to drastic (often exponential) improvements in computational efficiency. However, previous work used a flat MDP model that scales very poorly. In this work, we present and empirically evaluate a resource-allocation mechanism that achieves much better scaling by using factored MDP models, thus exploiting both the structure in agents' MDP-induced preferences, as well as the structure within agents' MDPs.

1. INTRODUCTION

Resource allocation is recognized as an important problem in many research fields, such as computer science, economics, and operations research. The core question of resource allocation is how to distribute a set of scarce resources among a set of agents (either cooperative or self-interested) in the best possible way, with social welfare (sum of agents' utilities) as one of the most popular optimization criteria. This problem is computationally challenging (NP-complete [19]) when agents' utility functions are defined over *bundles* of resources and are not linearly decomposable. Such computational challenges in combinatorial resource-allocation problems have recently precipitated the move towards resource-allocation mechanisms that model the mechanisms underlying agents' resource preferences (e.g., [15]), as opposed to the more-traditional black-box-utility models.

In particular, we have previously proposed a model where an agent's resource preferences are defined by an underlying Markov decision process, where resources are required to enable actions, and the value of a resource bundle is the expected payoff of the optimal policy that is realizable given these resources [8, 9]. In other words, an agent's MDP is parameterized by the available resources, and the agent's utility for resources is defined as the expected value of the best realizable policy. The model assumes that agents' planning problems are *weakly-coupled* [16], i.e., once the resources are distributed, the agents are independent.

Under this model, a naive resource-allocation approach would require each agent to formulate and solve an exponential number of MDPs (one for each resource bundle) just to define its utility function, and then to solve an NP-hard allocation problem on the exponentially-large input. However, a superior method can be implemented that combines the resource-allocation and the policy-optimization problems and formulates them as a single constrained MDP that can then be reduced to a mixed integer program, leading to an exponential reduction in the number of binary decision variables. This approach exploits the structure in agents' preferences that stems from the regularities of the underlying Markov process, which leads to drastic improvements in scalability of the resource-allocation problem.

There is, however, another source of intractability in the model described above that is due to the MDP models themselves. The traditional *flat* way of representing an MDP requires an explicit enumeration of all possible states of the system, which subjects the model to the curse of dimensionality [2] and leads to an exponential blow-up of the state space in terms of the number of *state features* of the problem. This representational challenge is addressed by *factored* MDPs [3] that model the state space as a cross product of state features, represent the transition function as a dy-

namic Bayesian network, and assume the reward function can be additively decomposed into functions with compact domains. Unfortunately, a solution to a well-structured factored MDP does not, in general, maintain the structure and compactness of the problem [14, 7], which forces the need for approximate solutions. One popular family of such methods that is particularly well-suited for our goal is approximate linear programming (ALP) [20, 6], for which there exist several very efficient algorithms [17, 12, 5, 10].

The main contribution of this work is that it extends the line of research on resource-allocation methods for agents with MDP-induced preferences [8, 9] to factored MDP models. It builds on the ALP methodologies of [12] to construct an efficient algorithm that combines resource allocation and approximate policy optimization for factored MDPs. This effectively exploits both the structure in agents' preferences that is *due to the underlying MDPs*, as well as the structure *within the MDPs* themselves, leading to exponential improvements in efficiency both in terms of the size of the resource-allocation problem (as the number of resource types increases) and the size of the policy-optimization problem (as the number of state features in an MDP grows).

2. FACTORED MDP AND ALP

A discrete-time, infinite-horizon, discounted MDP (e.g., [18]) can be described as $\langle \mathcal{S}, \mathcal{A}, P, R, \gamma \rangle$, where $\mathcal{S} = \{s\}$ is the finite set of system states, $\mathcal{A} = \{a\}$ is a finite set of actions, $P : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \mapsto [0, 1]$ is the transition function ($P(\sigma|s, a)$ is the probability of moving into state σ upon executing action a in state s), $R : \mathcal{S} \times \mathcal{A} \mapsto \mathbb{R}$ is the (bounded) reward function ($R(s, a)$ is the reward for executing action a in state s), and $\gamma \in [0, 1)$ is the discount factor (a unit reward at time τ is aggregated into the total reward as γ^τ).

A solution to such an MDP is a stationary, deterministic policy π. We define a policy as a mapping of states to probability distributions over actions: $\pi : \mathcal{S} \times \mathcal{A} \mapsto [0, 1]$, where $\pi(s, a)$ defines the probability that action a is executed in state s (for deterministic policies, only one $\pi(s, a)$ per state is nonzero). One way of solving an MDP is to compute the optimal value function v, which defines, for every state, the total expected discounted reward of the optimal policy. It is then optimal to simply act greedily with respect to v.

The optimal value function can be obtained, for example, using the following minimization linear program (LP), which is often called the *primal LP* of an MDP (e.g., [18]):

$$\begin{aligned} &\min \sum_s \alpha(s) v(s) \qquad \text{s.t.:} \\ &v(s) \geq R(s, a) + \gamma \sum_\sigma P(\sigma|s, a) v(\sigma), \quad \forall s \in \mathcal{S}, a \in \mathcal{A}, \end{aligned} \tag{1}$$

where α is an arbitrary strictly positive distribution over the state space ($\alpha(s) > 0$). This LP has $|\mathcal{S}|$ variables and $|\mathcal{S}||\mathcal{A}|$ constraints. Equivalently, the problem can be formulated as the *dual LP* with $|\mathcal{S}||\mathcal{A}|$ variables and $|\mathcal{S}|$ constraints:

$$\begin{aligned} &\max \sum_{s,a} R(s, a) x(s, a) \qquad \text{s.t.:} \\ &\sum_a x(\sigma, a) - \gamma \sum_{s,a} x(s, a) P(\sigma|s, a) = \alpha(\sigma), \quad \forall s \in \mathcal{S}, \end{aligned} \tag{2}$$

where $x(s, a) \geq 0$ is called the *occupation measure* ($x(s, a)$ is the discounted number of executions of a in s), and the constraints ensure the conservation of flow through each state.

Given a solution to (2), an optimal policy can be computed as: $\pi(s, a) = x(s, a) / \sum_a x(s, a)$. A policy thus obtained is *uniformly-optimal* (optimal for all initial states) when $\alpha(s)$ is strictly positive. The existence of uniformly-optimal policies does not hold for the resource-parameterized MDP models that we use in this work (detailed in Section 3), so for such problems the initial conditions α will be an important part of problem specification.

2.1 Factored MDPs

The standard MDP model defined above requires an enumeration of all system states and thus scales very poorly. This problem is addressed by a compact MDP representation [3, 4] that defines the state space as the cross-product of state features: $\mathcal{S} = z_1 \times z_2 \ldots z_N$, and uses a factored transition function and an additively-separable reward function.

The transition function is specified as a two-layer dynamic Bayesian network (DBN), with the current state features viewed as the parents of the next time-step features:

$$P(\sigma|s, a) = P(\mathbf{z}(\sigma)|\mathbf{z}(s), a) = \prod_{j=1}^{J_P} p_j(\mathbf{z}_j(\sigma)|a, \mathbf{z}_{p_j}(s)), \tag{3}$$

where $\mathbf{z}(\cdot)$ is the instantiation of all $\mathcal{Z}$ features corresponding to a state, $z_j(\cdot)$ denotes the value of the jth state feature of a state, and $\mathbf{z}_{p_j}(\cdot)$ is the instantiation of the DBN-parents $\mathcal{Z}_{p_j}$ of z_j. Likewise, in the rest of this paper, we will use $\mathcal{Z}_\varphi$ to refer to the set of features in the domain of function φ, and $\mathbf{z}_\varphi$ to refer to an instantiation of these features.

The reward function is compactly defined as

$$R(s, a) = \sum_{j=1}^{J_R} r_j(\mathbf{z}_{r_j}(s), a), \tag{4}$$

where $\mathbf{z}_{r_j}(\cdot)$ is an instantiation of the features $\mathcal{Z}_{r_j} \subseteq \mathcal{Z}$ that are in the domain of the jth local reward function r_j.

Clearly, this factored representation is only beneficial if the local transition functions $p_j(z_j(\sigma)|\mathbf{z}_{p_j}, a)$ and local reward functions $r_j(\mathbf{z}_{r_j}, a)$ have small domains: $|\mathcal{Z}_{p_j}| \ll |\mathcal{Z}|$ and $|\mathcal{Z}_{r_j}| \ll |\mathcal{Z}|$, i.e., each reward and transition component depends on a small subset of all state features $\mathcal{Z}$.

2.2 Primal ALP

Approximate linear programming [20, 6] lowers the dimensionality of the primal LP (1) by restricting the optimization to the space of value functions that are linear combinations of a predefined set of K basis functions h:

$$v(s) = v(\mathbf{z}(s)) = \sum_{k=1}^{K} h_k(\mathbf{z}_{h_k}(s)) w_k, \tag{5}$$

where $h_k(\mathbf{z}_{h_k})$ is the kth basis function defined on a small subset of the state features $\mathcal{Z}_{h_k} \subset \mathcal{Z}$, and w are the new optimization variables. This technique is similar to linear regression, where a function is approximated as a linear combination of a given (in general, non-linear) basis. The difference, however, is that here instead of minimizing a measure of error for the given data points, the goal is to minimize the measure to the unknown optimal value function. For the approximation to be computationally effective, the domain of each basis function has to be small ($|\mathcal{Z}_{h_k}| \ll |\mathcal{Z}|$).

As a notational convenience, we can rewrite the above as $v = Hw$, where H is a $|\mathcal{S}| \times |w|$ matrix composed of basis

functions h_k.[1] Thus, the LP (1) becomes:

$$\min \alpha^T Hw \big| AHw \geq r, \tag{6}$$

where the constraint matrix is $A_{sa,\sigma} = \delta(s,\sigma) - \gamma P(\sigma|s,a)$ (where $\delta_{s\sigma}$ is the Kronecker delta, $\delta_{s\sigma} = 1 \Leftrightarrow s = \sigma$).

For this method to be effective, we need to be able to efficiently compute the objective function $\alpha^T H$ and the constraints AH, which can be done as described in [12]. Consider a factored initial distribution:

$$\alpha(s) = \prod_{j=1}^{J_\alpha} \mu_j(\mathbf{z}_{\mu_j}(s)),$$

where, as usual, the domain of each factor μ_j is taken to be small ($|\mathcal{Z}_{\mu_j}| \ll |\mathcal{Z}|$). The objective function is computed as:

$$\begin{aligned}(\alpha^T H)_k &= \sum_s \alpha(s) H_{sk} = \sum_s \prod_i \mu_j(\mathbf{z}_{\mu_j}(s)) h_k(\mathbf{z}_{h_k}(s)) \\ &= \sum_{\mathbf{z}'} \prod_{j'} \mu_{j'}(\mathbf{z}'_{\mu_{j'}}) h_k(\mathbf{z}'_{h_k}),\end{aligned}$$

where $\mathbf{z}'$ iterates over all features in the union of the domain of h_k and the domains of those $\mu_{j'}$ that have a non-zero intersection with the domain of h_k: $\mathbf{z}' = \{\mathbf{z}_{\mu_j} \cup \mathbf{z}_{h_k} : \mathcal{Z}_{\mu_j} \cap \mathcal{Z}_{h_k} \neq \varnothing\}$, because all μ_i that do not have any variables in common with h_k factor out and their sum is 1 (since it is a sum of a probability distribution over its domain).[2]

The constraints in (6) are also computed efficiently:

$$\begin{aligned}(AH)_{sa,k} &= \sum_\sigma A_{sa,\sigma} h_k(\sigma) = \sum_\sigma (\delta_{s\sigma} - \gamma P(\sigma|s,a)) h_k(\sigma) \\ &= \sum_{\mathbf{z}} \delta(\mathbf{z}(s), \mathbf{z}) h_k(\mathbf{z}) - \gamma \sum_{\mathbf{z}} P(\mathbf{z}|\mathbf{z}(s), a) h_k(\mathbf{z}).\end{aligned} \tag{7}$$

The first sum can be computed efficiently, because it is simply $h_k(\mathbf{z}_{h_k}(s))$, since δ is nonzero only at $\mathbf{z}(\sigma) = \mathbf{z}(s)$. The second term can also be computed efficiently, since $P(\mathbf{z}(\sigma)|\mathbf{z}(s), a)$ is a factored probability distribution (just like in the case of α above).

Notice that in the above, the second term in (7) can be precomputed efficiently by performing a backprojection of every basis function h_k:

$$g_k(\mathbf{z}_{g_k}, a) = \sum_{\mathbf{z}} P(\mathbf{z}'|\mathbf{z}(s), a) h_k(\mathbf{z}) \quad \forall k \in [1, K], \tag{8}$$

where the domain of the backprojection g_k is the union of the DBN-parents of all features that are in the domain of the kth basis function: $\mathcal{Z}_{g_k} = \bigcup_{j: z_j \in \mathcal{Z}_{h_k}} \mathcal{Z}_{p_j}$.

The primal ALP described above reduces the number of optimization variables from $|\mathcal{S}|$ to $|w| = K$, and the coefficients of the objective function and every constraint row can be computed efficiently. However, the number of rows in the constraint matrix remains exponential at $|\mathcal{S}||\mathcal{A}|$, so the ALP has to undergo some additional transformation (or approximation) to become feasible. To address this issue, several techniques have been proposed, such as exploiting problem structure [12], sampling [5], and linear approximations [10]. The benefit of the former, compared to the latter two, is that it does not introduce a new source of approximation error, while the downside is that the number of constraints needed to represent the feasible region exactly is exponential in the induced tree width of the associated cluster graph (a graph with a vertex per variable and edges between variables that appear together in the domain of any function).

[1]Note that the exponentially-sized H is never explicitly written out, since each column is a basis function that can be represented compactly.

[2]See [11] or [10] for examples of how the LP coefficients can be computed efficiently.

2.3 Dual ALP

When dealing with constrained MDPs (flat or factored), such as the ones that arise in the resource allocation problem discussed in Section 4, it is more practical to work with the duals of the (A)LPs. Guestrin [11] considers the dual of (6):

$$\max r^T x \Big| H^T A^T x = \alpha. \tag{9}$$

This LP has $|\mathcal{S}||\mathcal{A}|$ variables and $|w| = K$ constraints (approximated flow conservation), where each of the K constraints corresponds to a linear combination of $|\mathcal{Z}_{h_k}|$ real flow constraints, with h_k defining the weights with which they are aggregated into the new approximate constraint. Clearly, (9) is always feasible. Furthermore, as shown in [11], a solution to (9) constitutes a valid density function, summing to $(1-\gamma)^{-1}$, which implies that the LP is bounded.

A problem with the LP (9) is that it has an exponential number of optimization variables. However, as proposed by Guestrin [11], the exact occupation measure x can be represented more compactly by using *marginal occupation measures* (or marginal visitation frequencies) ξ, which define the occupation measure over subsets of the state features. Let us define a marginal occupation measure over each of the following clusters of variables: the domain of every primal basis function $\mathcal{Z}_{h_k}$, the domain of every local reward function $\mathcal{Z}_{r_j}$, and the domains of all backprojections of the basis functions $\mathcal{Z}_{g_k}$. The challenge then becomes in ensuring that the marginal occupation measures ξ are consistent and correspond to a valid global distribution over $\mathcal{Z}$. Fortunately, global consistency (but not necessarily correspondence to a valid flat occupation measure x) can often be achieved via local marginal consistency constraints [11] that ensure that marginal occupation measures ξ_1 and ξ_2 agree on the values of features they share (with non-overlapping features marginalized out):

$$\sum_a \sum_{\widetilde{\mathbf{z}_j}, a} \xi_j(\mathbf{z}_j, a) = \sum_a \sum_{\widetilde{\mathbf{z}_i}, a} \xi_i(\mathbf{z}_i, a), \qquad \forall \mathbf{z}_{ji}, \tag{10}$$

where $\mathcal{Z}_{ji} = \mathcal{Z}_i \bigcup \mathcal{Z}_j$ are the shared features, and $\widetilde{\mathcal{Z}_i} = \mathcal{Z}_j \setminus \mathcal{Z}_i$ and $\widetilde{\mathcal{Z}_j} = \mathcal{Z}_i \setminus \mathcal{Z}_j$ are unique. As is the case in graphical models [13] more generally, and as observed for this particular case in [11], when the cluster graph associated with the domains of the marginal occupation measures ξ forms a *junction tree*[3] local consistency implies global consistency. If the original cluster graph does not form a junction tree, it can be converted to one by applying the widely-used in inference techniques of *moralization* and *triangulation*.[4]

Using the marginal occupation measures, the LP (9) can be represented more compactly as the following LP defined

[3]A junction tree is an undirected tree with clusters of state features as nodes, with the property that if a feature appears in clusters A and B, it also appears in any cluster in the path from A to B.

[4]Note that while the problem of computing the junction tree with the smallest width is an NP-hard problem [1], there are efficient approximations.

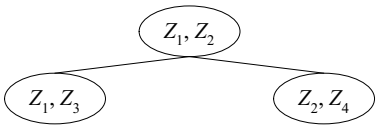

Figure 1: A cluster graph that forms a junction tree.

on marginal occupation measures $\xi_j(\mathbf{z}_j)$, one per each cluster in $\mathcal{Z}_{h_k}$, $\mathcal{Z}_{g_k}$, $\mathcal{Z}_{r_j}$.[5]

$$\begin{aligned}
&\max \sum_{m=1}^{M} \sum_{a} \sum_{\mathbf{z}_{r_j}} r_j(\mathbf{z}_{r_j}, a)\xi_{r_j}(\mathbf{z}_{r_j}, a) \qquad \text{s.t.:} \\
&\sum_{a} \xi_{h_k}(\mathbf{z}_{h_k}, a)h_k(\mathbf{z}_{h_k}) - \gamma \sum_{a} g_k(a)\xi_{g_k}(\mathbf{z}_{h_k}, a) = \\
&\qquad\qquad \sum_{\mathbf{z}_{h_k}} \alpha(\mathbf{z}_{h_k})h_k(\mathbf{z}_{h_k}), \quad \forall k \in [1, K]; \\
&\sum_{\widetilde{\mathbf{z}_j}} \xi_j(\mathbf{z}_j, a) = \sum_{\widetilde{\mathbf{z}_i}} \xi_i(\mathbf{z}_i, a), \\
&\quad \forall a, \xi_j, \xi_i, \mathbf{z}_j, \mathbf{z}_i, \ \widetilde{\mathcal{Z}_i} = \mathcal{Z}_j \setminus \mathcal{Z}_i, \ \widetilde{\mathcal{Z}_j} = \mathcal{Z}_i \setminus \mathcal{Z}_j; \\
&\sum_{a} \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j, a) = (1-\gamma)^{-1}, \qquad \forall j, \ \mathbf{z}_j; \\
&\xi_j(\mathbf{z}_j, a) \geq 0, \qquad \forall a, j, \mathbf{z}_j.
\end{aligned} \tag{11}$$

Given a solution $\xi_j(\mathbf{z}_j)$ to the above LP, the optimal policy for any given state can be computed in the following way, detailed in [12]. Given the dual solution $\xi_j(\mathbf{z}_j)$, compute the primal solution w that defines the value-function approximation. Given the current state, do a one-step lookahead and, for each possible next state, compute the value-function estimate based on w, and greedily select the action that maximizes the sum of the one-step reward and the expected value of the next step (as in the standard MDP).

Another way of obtaining the policy is to calculate it directly from the marginal occupation measures ξ. Each marginal occupation measure forms a valid distribution on its domain, so we can use a variant of the junction-tree inference algorithm for calculating the distribution over actions, given the current state. The procedure is described in Algorithm 1 and works by simply traversing the cluster tree from the root and factoring in the marginal occupation measures along the way, while normalizing appropriately. Note that because the marginal occupation measures (even if globally consistent) do not necessarily correspond to a valid occupation measure, there is not a one-to-one correspondence between the marginals ξ and policy π, as between x and π in the flat case.

EXAMPLE 1. *Consider the cluster graph in Figure 1. The marginal occupation measures are: $\xi(z_1, z_2, a)$, $\xi(z_1, z_3, a)$, and $\xi(z_2, z_4, a)$. This graph forms a junction tree, so global consistency of marginal occupation measures is guaranteed*

[5]Here and below, for simplicity we assume the cluster graph is a junction tree. If not, the LP will have to undergo a preprocessing step, as described above.

Algorithm 1: Policy from occupation measures.

Function PolicyForState
in : $\mathbf{z}$ – current state
out : $\pi(\mathbf{z}, a)$ – policy for current state

$\pi(\mathbf{z}, a) \leftarrow$ PolicyForStateRec($\mathbf{z}$, root-cluster, $\mathbf{1}$, $\varnothing$)
if $\sum_a \pi(\mathbf{z}, a) = 0$ **then**
  /* `use any action supported by marginals` */
  $\pi(\mathbf{z}, a) \leftarrow 1$ for any a, s.t., $\exists j, \mathbf{z}'_j : \ \xi_j(\mathbf{z}'_j, a) > 0$
end

Function PolicyForStateRec
in : $\mathbf{z}$ – current state
: j – cluster id
: $\pi(\mathbf{z}, a)$ – marginal policy
: Ω – features already factored into policy
out : $\pi'(\mathbf{z}, a)$ – marginal policy
: Ω' – features already factored into policy

/* `update features already factored in` */
$\Omega' \leftarrow \Omega \bigcup \mathcal{Z}_{\xi_j}$
/* `factor in` j^{th} `marginal` */
$\pi'(\mathbf{z}, a) \leftarrow \pi(\mathbf{z}, a)\xi(\mathbf{z}_j, a)$
/* `normalize by overlapping features` */
$\mathcal{Z}' \leftarrow \Omega \bigcap \mathcal{Z}_{\xi_j}$
$\pi'(\mathbf{z}, a) \leftarrow \pi'(\mathbf{z}, a)/\xi(z')$
/* `factor in children` */
forall $m \in Children(j)$ **do**
  $\pi'' \leftarrow PolicyForStateRec(j, \pi', \Omega)$
  $\pi'(\mathbf{z}, a) \leftarrow \pi'(\mathbf{z}, a)\pi''(\mathbf{z}, a)$
end

whenever local consistency constraints are satisfied:

$$\sum_{z_2} \xi(z_1, z_2, a) = \sum_{z_3} \xi(z_1, z_3, a), \qquad \forall z_1, a;$$
$$\sum_{z_1} \xi(z_1, z_2, a) = \sum_{z_4} \xi(z_2, z_4, a), \qquad \forall z_2, a.$$

The global distribution for this problem is:

$$x(z_1, z_2, z_3, z_4, a) = \frac{\xi(z_1, z_2, a)\xi(z_1, z_3, a)\xi(z_2, z_4, a)}{\sum_{z_1} \xi(z_1, z_2, a) \sum_{z_2} \xi(z_1, z_2, a)},$$

which is what would be computed by Algorithm 1. □

3. SINGLE-AGENT MODEL

We now briefly describe the model of the capacity-limited agent with an MDP whose action set is parameterized by the resources available to the agent. This is a slight extension of the model described in [8] to factored problems and arbitrary resource requirements.

The justification behind the model described in this section is that often an agent has many capabilities that are all in principle available to it, but not all combinations of these capabilities are realizable within the agent's architectural limitations, because choosing to enable some of the capabilities might seize the resources needed to enable others. In other words, a particular policy might not be feasible

because the agent's architecture does not support the combination of capabilities required for that policy.

We model this constrained policy-optimization problem as follows. The agent has a set of actions that are potentially executable, and each action requires a certain combination of resources. All resources have capacity costs, and each agent has capacity constraints that limit what resources it can make use of. For example, a delivery company needs vehicles and loading equipment (resources) to make its deliveries (execute actions). However, all equipment costs money and requires manpower to operate it (capacity costs). Therefore, the amount of equipment the agent can acquire and successfully utilize is constrained by factors such as its budget and limited manpower (capacity bounds).

Given the above, the goal is to assign to the agent a subset of the available resources that does not violate its capacity constraints, such that the optimal feasible policy under that resource assignment yields the highest expected utility. We can model such an optimization problem as $\langle \mathcal{S}, \mathcal{A}, P, R, \alpha, \mathcal{O}, \rho, \mathcal{C}, \kappa, \widehat{\kappa}, \rangle$, where:

- $\langle \mathcal{S}, \mathcal{A}, P, R, \gamma, \alpha \rangle$ are the components of a factored MDP, represented in a factored manner, as defined in Section 2.1.
- $\mathcal{O} = \{o\}$ is the set of resource types (e.g., $\mathcal{O} = \{$production equipment, vehicle , $\ldots\}$).
- $\rho : \mathcal{A} \times \mathcal{O} \mapsto \mathbb{R}$ is a function that specifies the resource requirements of all actions; $\rho(a, o)$ defines how much of resource o is needed for action a (e.g., $\rho(a, \text{vehicle}) = 1$ means that action a requires one vehicle to be executable).
- $\mathcal{C} = \{c\}$ is the set of capacities of our agent (e.g., $\mathcal{C} =$ space, money, manpower, $\ldots\}$).
- $\kappa : \mathcal{O} \times \mathcal{C} \mapsto \mathbb{R}$ is a function that specifies the capacity costs of resources; $\kappa(o, c)$ defines how much of capacity c a unit of resource o consumes (e.g., $\kappa(\text{vehicle}, \text{money}) = \$50000$ defines the cost of a vehicle).
- $\widehat{\kappa} : \mathcal{C} \mapsto \mathbb{R}$ specifies the upper bounds on capacities; $\widehat{\kappa}(c)$ gives the upper bound on capacity c (e.g., $\widehat{\kappa}(\text{money}) =$ \$1,000,000 defines the agent's budget constraints).

Given the above, the agent's optimization problem is to find the set of resources whose capacity costs satisfy the constraints imposed by $\widehat{\kappa}$, such that the best realizable policy, given these resources (as induced by action resource requirements ρ) yields the highest expected discounted reward. As we have previously shown in [8] (for flat MDPs and binary resource-requirements), this problem is NP-complete.[6] This complexity result still holds for factored MDPs (the models are equivalent in expressiveness and worst-case space requirements), as well as for non-binary resource requirements (binary is a special case). Furthermore, in [8] we presented a reduction of the problem to a mixed integer linear program (MILP). We now develop an analogous reduction for the factored model of the single-agent capacity-constrained MDPs. This factored MILP will serve as the basis for the resource-allocation algorithm in the multiagent setting, discussed in Section 4.

Given a flat occupation measure x, the agent's capacity constraints can be formulated as:

$$\sum_o \kappa(o, c) \max_a \Big\{ \rho(a, o) H\big(\sum_s x(s, a) \big) \Big\} \leq \widehat{\kappa}(c), \qquad \forall c \in \mathcal{C}, \tag{12}$$

[6]It is essentially a multidimensional KNAPSACK problem with item values defined by the MDP.

where H is the Heaviside "step" function of a nonnegative argument, defined as

$$H(z) = \begin{cases} 0 & z = 0; \\ 1 & z > 0. \end{cases}$$

To describe (12) in turns of marginal occupation measures, we use the following Lemma.

LEMMA 1. *Consider a set of marginal occupation measures $\{\xi_j\}$ that are globally consistent and a corresponding policy $\pi(\mathbf{z}, a)$ computer via Algorithm 1. Then*

$$\forall \mathbf{z}, a: \quad \pi(\mathbf{z}, a) > 0 \iff \exists j: \quad \xi_j(\mathbf{z}_j, a) > 0, \tag{13}$$

i.e., the policy prescribes non-zero probability of executing action a in state $\mathbf{z}$ if and only if there is a marginal that prescribes a non-zero probability to that action in same state.

PROOF. The proof is essentially be definition. The " $\Rightarrow$ " direction follows from how policy π is constructed in Algorithm 1: in order for the global distribution to assign a non-zero probability to some event, there must exist a marginal that assigns a non-zero probability to a subset of features corresponding to the same event. The " $\Leftarrow$ " direction follows from global consistency of the marginals. Indeed, assume the opposite: $\xi_j(\mathbf{z}_j, a) > 0$ and $\pi(\mathbf{z}, a) = 0$. This would violate the following consistency constraint:

$$(1 - \gamma)^{-1} \xi_j(\mathbf{z}_j, a) = \sum_{\widetilde{\mathbf{z}_j}} \pi(\mathbf{z}_j, a),$$

where $\widetilde{\mathcal{Z}_j} = \mathcal{Z} \backslash \mathcal{Z}_j$ are the features not in the scope of ξ_j. □

It immediately follows from Lemma 1 that the flat constraints (12) can be equivalently represented on the marginal occupation measures ξ:

$$\sum_o \kappa(o, c) \max_a \Big\{ \rho(a, o) H\big(\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j, a) \big) \Big\} \leq \widehat{\kappa}(c), \forall c \in \mathcal{C}. \tag{14}$$

The difficulty is that these constraints are non-linear due to the maximization over a and the Heaviside function H. To get rid of the first source of nonlinearity, let us observe that a constraint with a single max over a finite set of discrete values can be trivially linearized by expanding out the set over which the maximization is taken:

$$\max_{z \in \mathcal{Z}} f(z) \leq a \iff f(z) \leq a, \quad \forall z \in \mathcal{Z}.$$

In (14), we have a finite sum of max's, but it can also be linearized by observing that the inequality

$$\sum_i^n g(u_i) \max_{z \in \mathcal{Z}} f(z, u_i) = g(u_1) \max_{z \in \mathcal{Z}} f(z, u_1) + \ldots + g(u_n) \max_{z \in \mathcal{Z}} f(z, u_n) \leq a$$

is equivalent to the system of $|\mathcal{Z}|^n$ linear inequalities:

$$g(u_1) f(z_1, u_1) + g(u_2) f(z_2, u_2) + \ldots + g(u_2) f(z_2, u_2) \leq a, \quad \forall z_1, z_2, z_n \in \mathcal{Z}.$$

Applying this to the constraints in (14), we can express the original system of $|\mathcal{C}|$ nonlinear constraints:

$$\sum_o \kappa(o, c) \max_a \Big\{ \rho(a, o) H\big(\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j, a) \big) \Big\} \leq \widehat{\kappa}(c), \forall c \in \mathcal{C},$$

as the following system of $|\mathcal{C}||\mathcal{A}|^{|\mathcal{O}|}$ linear constraints:

$$\sum_o \kappa(o,c)\rho(a_o,o)H\big(\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a_o)\big) \le \widehat{\kappa}(c), \quad \forall c \in \mathcal{C}, a_{o_1}, a_{o_2}, \ldots \in \mathcal{A}. \tag{15}$$

Notice that this straightforward way of eliminating the maximization exponentially increases the number of constraints, because the above expansion enumerates all possible actions for each resource: it enumerates policies where each resource o is used by action a_1, where it is used by action a_2, action a_3, etc. However, in many problems not all resources are used by all actions. In such cases, most of the above constraints become redundant, and the number of constraints can be reduced from $|\mathcal{C}||\mathcal{A}|^{|\mathcal{O}|}$ to $|\mathcal{C}|\prod_o |\mathcal{A}_o|$, where $\mathcal{A}_o$ is the number of actions that use resource o. Furthermore, in a special case, where the resource requirements of actions are binary, the number of constraints can be reduced much more significantly, as discussed in Section 3.1.

To linearize the Heaviside function, we augment the original optimization variables x with a set of $|\mathcal{A}|$ binary variables $\Delta(a) \in \{0,1\}$, where

$$\Delta(a) = H\Big(\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a_o)\Big). \tag{16}$$

In other words, $\Delta(a)$ is an indicator variable that shows whether action a is used in the policy with non-zero probability. Using Δ and expanding the max as above, we can rewrite the resource constraints in (14) as:

$$\sum_o \kappa(o,c)\rho(a_o,o)\Delta(a_o) \le \widehat{\kappa}(c), \quad \forall c \in \mathcal{C}, a_{o_1}, a_{o_2}, \ldots \in \mathcal{A}, \tag{17}$$

which are linear in Δ. We can then synchronize Δ and each of the marginal occupation measures ξ_j via the following linear inequalities:

$$\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a)(1-\gamma) \le \Delta(a), \qquad \forall a \in \mathcal{A}. \tag{18}$$

Indeed, $\xi_j(\mathbf{z}_j,a)(1-\gamma) \le 1$, because $\sum_{\mathbf{z}_j,a} \xi_j(\mathbf{z}_j,a) = (1-\gamma)^{-1}$, which ensures that when any marginal $\xi(\cdot,a)$ assigns a non-zero probability to action a, this drives the corresponding $\Delta(a)$ to be 1. On the other hand, when all $\xi(\cdot,a)$ are 0 for a given a, both $\Delta(a)=0$ and $\Delta(a)=1$ satisfy (18), in which case $\Delta(a)$ will be driven down to $\Delta(a)=0$ by the capacity constraints (if they are binding; if they are not, the value of $\Delta(a)$ is irrelevant).

Putting it all together, the single-agent factored MDP with resources and capacity constraints can be formulated as an MILP by augmenting the LP (11) with binary variables $\Delta(a)$ and constraints (17) and (18).

3.1 Binary Resource Requirements

As a special case of the problem discussed in the previous section, consider a domain where the resource requirements are binary: $\rho(a,o) = \{0,1\}$. Under these conditions the single-agent MILP (11,17,18) can be simplified significantly.

First, observe that, when $\rho(a,o) = \{0,1\}$, the total resource requirements of a policy can be simplified as follows:

$$\max_a \Big\{\rho(a,o)H\big(\sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a)\big)\Big\} = H\Big(\sum_a \rho(a,o) \sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a)\Big).$$

Therefore, instead of introducing $|\mathcal{A}|$ binary variables $\Delta(a)$ that specify whether action a is used in the policy, it suffices to use $|\mathcal{O}|$ variables $\delta(o) \in \{0,1\}$:

$$\delta(o) = H\Big(\sum_a \rho(a,o) \sum_j \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a) \le \widehat{\kappa}(c)\Big), \tag{19}$$

where $\delta(o)$ indicates whether the policy requires resource o.

We can then synchronize the marginals ξ and the binary variables $\delta(o)$ similarly to $\Delta(a)$ above, leading to the following equivalent of (17,18) for binary resources:

$$\begin{aligned} &\sum_o \kappa(o,c)\delta(o) \le \widehat{\kappa}(c), && \forall c \in \mathcal{C}; \\ &\sum_a \rho(a,o) \sum_{j=1} \sum_{\mathbf{z}_j} \xi_j(\mathbf{z}_j,a) \le \delta(o), && \forall o \in \mathcal{O}. \end{aligned} \tag{20}$$

4. RESOURCE ALLOCATION

We now consider the multiagent problem of resource allocation between several agents, where the resource preferences of the agents are defined by factored MDPs with capacity-constraints, as described in the previous section. As mentioned previously, we assume that agents are weakly-coupled [16], i.e., they only interact through the shared resources, and once the resources are allocated, the agents' transitions and rewards are independent. Also, to simplify the following discussion, we assume that agents' resource requirements are binary (as discussed in Section 3.1), but all results directly map to to the non-binary case by making straightforward substitutions from Section 3.

The problem of distributing a set of indivisible resources $\mathcal{O}$ among a set of agents $\Lambda = \{\lambda\}$ is described as follows:

- $\{\langle \mathcal{S}, \mathcal{A}, P^\lambda, R^\lambda, \alpha^\lambda, \rho^\lambda, \widehat{\kappa}^\lambda\rangle\}$ is the collection of single-agent factored weakly-coupled MDPs, as defined in Section 3. For simplicity, but without loss of generality we assume that all agents have the same state and action spaces $\mathcal{S}$ and $\mathcal{A}$, but each has its own transition and reward functions P^λ and R^λ, initial conditions α^λ, as well as its own resource requirements $\rho^\lambda : \mathcal{A} \times \mathcal{O} \mapsto \{0,1\}$ and capacity bounds $\widehat{\kappa}^\lambda : \mathcal{C} \mapsto \mathbb{R}$.
- $\widehat{\rho} : \mathcal{O} \mapsto \mathbb{R}$ specifies the upper bound on the amounts of the shared resources (this defines the additional bound for the multiagent problem).

Given the above model, the goal is to find an allocation of the available resources among the agents that maximizes the sum of the expected discounted rewards of the agents' optimal policies under the resource allocation. This can be achieved via a straightforward combination of the single-agent MILPs from the previous section, augmented with an additional constraint that ensures that the allocation does not exceed the bounds on the total amounts of resources $\widehat{\rho}$.

Putting it all together, we arrive at an MILP that achieves the goal we set forth in this work – an algorithm for simultaneously solving the resource-allocation and the resource-parameterized policy-optimization problem for the factored

Markov model. The following MILP has, for every agent λ, a set of marginal occupation measures ξ^λ and a set of binary variables $\delta^\lambda(o)$. Each agent has its own basis functions h_k^λ, and therefore its own backprojections g_k^λ.

$$\max \sum_\lambda \sum_a \sum_j^{J_R} \sum_{\mathbf{z}_{r_j}^\lambda} r_j^\lambda(\mathbf{z}_{r_j}^\lambda, a)\xi_{r_j}^\lambda(\mathbf{z}_{r_j}^\lambda, a) \qquad \text{s.t.:}$$

$$\sum_a \xi_{h_k}^\lambda(\mathbf{z}_{h_k}^\lambda, a)h_k^\lambda(\mathbf{z}_{h_k}^\lambda) - \gamma \sum_a g_k^\lambda(a)\xi_{g_k}^\lambda(\mathbf{z}_{h_k}^\lambda, a) = \sum_{\mathbf{z}_{h_k}} \alpha^\lambda(\mathbf{z}_{h_k}^\lambda)h_k^\lambda(\mathbf{z}_{h_k}^\lambda), \quad \forall k \in [1, K],\ \lambda \in \Lambda;$$

$$\sum_{\widetilde{\mathbf{z}_j^\lambda}} \xi_j^\lambda(\mathbf{z}_j^\lambda, a) = \sum_{\widetilde{\mathbf{z}_i^\lambda}} \xi_i^\lambda(\mathbf{z}_i^\lambda, a), \quad \forall \lambda \in \Lambda, a \in \mathcal{A}, \xi_j^\lambda, \xi_i^\lambda, \mathbf{z}_j^\lambda, \mathbf{z}_i^\lambda, \widetilde{\mathcal{Z}_i^\lambda} = \mathcal{Z}_j^\lambda \setminus \mathcal{Z}_i^\lambda,\ \widetilde{\mathcal{Z}_j^\lambda} = \mathcal{Z}_i^\lambda \setminus \mathcal{Z}_j^\lambda;$$

$$\sum_a \sum_{\mathbf{z}_j^\lambda} \xi_j^\lambda(\mathbf{z}_j^\lambda, a) = (1-\gamma)^{-1}, \quad \forall j,\ \mathbf{z}_j;$$

$$\sum_o \kappa(o, c)\delta^\lambda(o) \le \widehat{\kappa}^\lambda(c), \quad \forall \lambda \in \Lambda, c \in \mathcal{C};$$

$$\sum_{j=1}^{J_e} \sum_a \sum_{\mathbf{z}_{\rho_j}^\lambda} \rho_j^\lambda(\mathbf{z}_{\rho_j}^\lambda, a)\xi_{\rho_j}^\lambda(\mathbf{z}_{\rho_j}^\lambda, a) \le \delta^\lambda(o), \quad \forall \mathbf{z}_j^\lambda, o; \tag{21}$$

As in the flat-MDP model of [8], this MILP has $|\Lambda||\mathcal{O}|$ binary variables, which is an exponential reduction from a naive resource-allocation scheme that has a decision variable per resource bundle (thus requiring on the order of $|\Lambda|2^{|\mathcal{O}|}$ variables). Furthermore, the number of occupation-measure variables can be drastically reduced in this factored MILP, compared to the flat variant. The actual gains in efficiency and the associated losses in quality depend on what basis functions h_k are used and on how well-structured the MDP is (which ultimately defines the domain sizes of ξ).

5. EXPERIMENTAL RESULTS

We investigated the behavior of the resource-allocation MILP (21) on the factored "SysAdmin" problem [12], which we extended to include resources and capacities.

The problem involves a network of N computers, each of which might fail with probability that depends on the status of the neighboring computers. The job of the decision-maker (the SysAdmin) is to keep the network running. The state of the system is defined by a set of N binary features, each corresponding to the status of a computer. At each time step the SysAdmin can reboot at most one computer and receives a reward for every computer that is functioning properly. We used a network with a unidirectional-ring topology, where each computer influenced and was influenced by the status of a single other computer. The parameters of the transition and reward model are described in detail in [12].

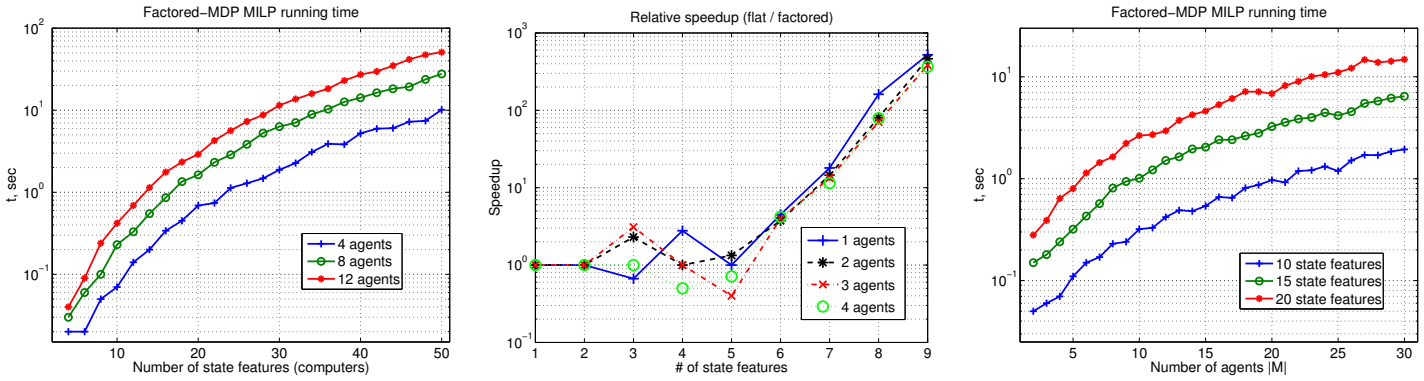
We extended the domain to the multiagent setting with resources as follows. Each SysAdmin agent was in charge of running its own network of N computers. In our domain, computer failures were caused by more serious malfunctions (e.g., a virus infection) that could not be fixed by simply rebooting the computer, and thus performing the recovery actions required resources (e.g., specialized software, hardware, or trained personnel). Further, the computers were heterogeneous (mail servers, web servers, data storage, etc.), and thus the recovery of each computer required a different subset of the resources. The total quantity of the resources was limited, and each SysAdmin also had a limited budget, which constrained the resources it could acquire.

For a local MDP with N computers, there were $|\mathcal{O}| = N$ resources, and each recovery action required two resources, which were randomly selected at the time of problem generation. There was a single capacity cost c (money) and all resources had a unit capacity cost $\kappa(o, c) = 1$.

A thorough empirical analysis of ALP solutions to the SysAdmin problem is presented in [12], and it discusses the quality of solutions and the computational complexity of solving the ALP for various network topologies and different ways of selecting the basis functions. In particular, the experiments in [12] demonstrate that using basis functions over singletons of features leads to high-quality approximations at a very low computational cost. Therefore, we used the same basis functions and focused on evaluating the computational complexity of the resource-allocation MILP (21).

Figure 2a shows the running time of the MILP (21) as a function of the number of state features (computers). As can be seen, the factored MDP approach allows us to easily scale the resource-allocation problem up to MDPs with more than 10^{15} states. Figure 2b demonstrates the corresponding exponential gain in efficiency of the factored MILP (21), compared to the one with a flat-MDP model. Note that the flat MILP [8] in itself commonly achieves exponential speedup over a straightforward resource-allocation mechanism that enumerates all resource bundles [9].

Finally, Figure 2c shows the complexity of the factored MILP as a function of the number of agents. The graph demonstrates that although the number of binary variables in the MILP is proportional to the number of agents, the approach shows promise for scaling to large numbers of agents.



Overall, the trends in these results support the analytical claims about the efficiency gains of using factored models and ALP in the resource-allocation problem.

6. CONCLUSIONS

Recent work on resource-allocation problems has demonstrated that it can be extremely beneficial from the standpoint of computational efficiency to have a good model of the processes that define agents' preferences over resources. For a realistic agent that has to deal with uncertainty, Markov decision processes with action spaces that depend on the resources available to the agent provide a natural model of the agent's utility-formation mechanism. Moreover, resource preferences induced by MDPs are well-structured, which enables the construction of resource-allocation mechanisms that are very computationally efficient[8, 9].

We presented a mechanism that fruitfully exploits the structure in agents' utility functions that is due to the underlying MDPs, as well as the structure within the MDPs themselves (via an approximation). For well-structured MDPs, the latter can lead to another order of exponential speedup over flat MDP methods, as supported by our experiments.

Some interesting directions of our ongoing and future work in this area include exploring factored resource-allocation MILPs on cluster graphs that are not junction trees, as well as looking at other types of structure in agent's MDPs (e.g., context-specific structure [12]).

ABSTRACT

In cooperative peer-to-peer information retrieval systems, each node can be considered an intelligent agent and these agents work collectively to provide an information retrieval service. In order to effectively support multiple and concurrent search sessions in the network, we propose two traffic engineering techniques that minimize processing and communication bottlenecks. One is a novel agent control mechanism whose elements include resource selection, local search scheduling, and feedback-based load control. The other is a new two-phase query routing algorithm based on organizational knowledge. Experimental results show that this framework can reduce congestion situations, increase system throughput, and improve considerably the overall system utility.

1. INTRODUCTION

In recent years, peer-to-peer based information retrieval(IR) systems have begun to receive considerable attention. A peer-to-peer based information retrieval system consists of a set of nodes connected in a peer-to-peer fashion. Each node hosts a document collection to share with other nodes and these nodes work together to provide information retrieval service to users. In this paper, we consider an information retrieval task as a search session during which nodes forward queries to neighbors, perform IR operations and/or return search results. The lack of complete, up-to-date information about the states of other nodes in the network requires sophisticated coordination strategies. In addition, the presence of concurrent search sessions adds another level of complication due to bandwidth and processing capacity limitations: nodes may not be able to complete forwarding and local searches in a timely fashion for all queries they have received. Therefore, nodes have to decide what actions to take for each search session and in what order to execute those actions in order to maximize overall system utility. These local decisions, taking place at each agent, collectively determine the way concurrent queries are distributed and processed in the network.

In this paper, we extend a multi-agent based infrastructure [11, 12] developed for a single search session such that it can handle multiple, concurrent search sessions. These extensions required the development of a new agent control mechanism and a novel coodinated query routing algorithm based on a queueing theory analysis. Both mechanisms control the flow of information from different perspectives in the network to exploit available resources while reducing the occurrence of congestion situations. The purpose of the local control mechanism, based only on the agents' local observations of their neighboring agents, is to improve the average effective propagation speed of search sessions, a concept that will be introduced in later sections. The elements of such a control mechanism include resource selection, local search scheduling and feedback-based load control. The coordinated search algorithm is a modified version of a previously developed two-phase query routing algorithm [12] that exploits static agent organizational knowledge to locate relevant documents quickly while at the same time minimizing hot-spots caused by concurrent search sessions. Experimental results show that this framework can reduce the frequency of congestion situations, increase system throughput, and improve overall system quality.

The contributions of this work include: (1) a novel agent control mechanism based on a queueing theoretical analysis; (2) a simple feedback-based probabilistic load control component to avoid congestion situations while dynamically exploiting available communication and processing bandwidth; (3) a distributed, two-phase query routing algorithm based on a hierarchical structure of agents that balances search traffic in the network.

We make the following assumptions in this paper. First, each agent maintains an independent index and an IR search engine for its local document collection. However, we do not introduce any further restrictions on the local search engines and thus the network can be populated by agents having very different local search engines. Second, the experimental

results presented are based on local search engines that are "perfect" in that they return all relevant documents in the collection for a given query. Third, we assume there is a third-party protocol in place to merge the returned results. Thus, our protocol does not have to deal with the merging of the returned lists. Fourth, we assume that the document collections hosted on agents are disjoint, and therefore the total number of relevant documents for a certain query is the sum of the relevant documents returned from each agent. Lastly, we assume that agents are cooperative in that they all agree to use the same protocols for propagating resource descriptions among each other, accepting queries from peers and finally returning search results to the originators of the queries

The remainder of this paper is organized as follows: Section 2 discusses related research; Sections 3 and 4 introduce the system architecture of a P2P information retrieval system and the individual agent structure respectively. Section 5 presents the local scheduling algorithm in each agent. Section 6 introduces a two-phase search algorithm based on a hierarchical agent organization; Section 7 provides the experimental settings and explains the results; Section 8 discusses future work, and Section 9 summarizes the major contributions of this paper.

2. RELATED WORK

This paper is related to two lines of research: (1) query routing algorithms in peer-to-peer information retrieval systems, and (2) traffic engineering techniques in IP-Level and application-level network research.

The first line of relevant research includes recent studies on pure peer-to-peer information retrieval systems and hierarchical peer-to-peer systems [10, 7, 11, 12]. Lu proposed a framework including resource selection, resource representation and result merging in a hierarchical P2P environment[7]. In particular, a language model based search algorithm is employed in a top-down fashion. Indeed, as a query routing process can be considered as a distributed search process, it is natural to study this system in a multi-agent framework [5, 11, 12]. However, most of these research efforts do not consider situations with multiple, concurrent search sessions which is the focus of this paper.

The second line of relevant research is on network traffic engineering. Traffic engineering, which has mostly concerned IP-level routing problems, involves adapting the routing of traffic to network conditions, with the joint goals of good user performance and efficient use of network resources. The most well studied work along this line is on congestion control which attempts to minimize delays in Internet routing[3]. While query routing in P2P based information retrieval differs considerably from IP level routing problems, there are similarities that can be exploited in query routing algorithms.

3. PROBLEM DESCRIPTION

All agents in a peer-to-peer information retrieval system constitute a graph $G(A, E)$. Set A is the set of all agents in the system while set E includes all connections among agents. A search session s_i starts when an agent A_j receives a query qry_k from a user at time t_l. During the search process, upon receipt of the query qry_k, agents conduct local searches, forward the query to their neighbors and return search results to agent A_j. Agent A_j keeps a set of result tuples $T_m(s_i, A_m, t, Q_{s_i,A_m})$, with each element in the set specifying the fact that an agent contributes a certain amount of quality, Q_{s_i,A_m} in this case, to search session s_i at time t. The search conducted by agent A_m can be evaluated off-line by considering the ratio of the number of relevant documents returned from agent A_m to the total number of relevant documents in the network. Notice that the size of the result tuple set may keep growing with more search results returned from agents. The cumulative quality for a search session at time t is therefore the sum of the quality fields in the result set T_k obtained at time t. Formally, it is defined as:

$$Q_{s_i}(t) = \sum_{A_k} Q_{s_i,A_k} \text{ where } T_k.t < t$$

In the search process, agents discard those queries they have previously processed thereby preventing queries from looping in the system forever. The search session ends when all the agents that receive the query drop it. We define the period from a query entering the system to its leaving the system as the duration of the search session, t^*. Therefore, the maximal quantity for a search session is defined as $Q_{s_i}(t^*)$. The duration of a search session depends on factors including the connectivity of the agent organization, the query routing algorithm and local scheduling algorithms in the agents. In general, a long search session duration indicates the occurrence of hot spots in the network. These hot spots are usually characterized by communication congestion or long query queue length in agents.

In this paper, we focus on open information retrieval systems, meaning that queries can enter the network at any agent from outside users, thereby forming multiple concurrent search sessions in the system. In our model, we define the arrival rate of jobs from outside to the ith node of the network to be λ_{0i}. The distribution of the incoming queries to a single agent conforms to a Poisson distribution, and the overall arrival rate λ from outside to an open network is:

$$\lambda = \sum_{i=1}^{N} \lambda_{0,i}$$

In the presence of multiple concurrent search sessions, we define the overall system utility, GQ, as the sum of the cumulative utility for all the search sessions including both the outstanding search sessions and finished search sessions under the assumption that all search sessions are considered equally important:

$$GQ(t) = \sum_{s_i} Q_{s_i}(t)$$

4. AGENT INTERNAL STRUCTURE

In this section, we describe the internal structure and local scheduling algorithms of each individual agent. Figure 1 illustrates the four components of our agent architecture: a document collection with its associated collection descriptor, a search engine, an agent view structure and a control unit. This section describes the first three components while Section 5 describes the control unit.

The document collection hosted on an agent includes a set of documents to share with other peers. The local search engine allows each agent to conduct local searches and return

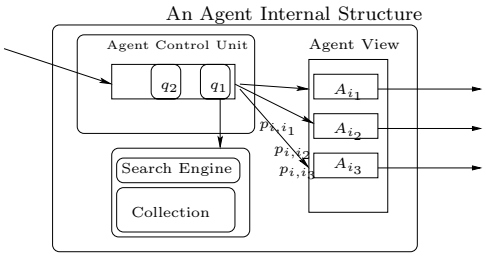

Figure 1: Internal Agent Structure

relevant documents upon receiving user requests. The collection can be described by a collection descriptor, which can be considered as the "signature" of the collection. By distributing collection descriptors, agents can gain knowledge about how content is distributed in the agent network. A collection descriptor characterizes the distribution of the vocabulary in the collection. It is based on the language model concept[9] that has proved effective in various previous studies in the distributed IR field [1, 7, 11]. A language model has many interesting properties which are easily exploitable in the peer-to-peer network system. Most importantly, it is a lightweight, concise and accurate descriptor of the document collection. Additionally, the size of the collection model is almost independent of the size of the document collection.

The agent view structure is an agent's restricted view of the network and determines the underlying topology of the agent "virtual" organization. Each agent's view structure contains the collection descriptors of a set of other agents' collections as well as the addresses of these agents and other related information such as the connection type. The design of the agent view structure depends on the underlying topological agent organization. In a power law based flat agent organization, only one connection type is needed as all agents play the same role. On the other hand, there can be multiple connection types in a hierarchical peer-to-peer agent organization, including links connecting upper level agents to lower level agents, lower level agents to upper level agents and agents at the same level. The specifics of the connection type information can be used in deciding how to route queries. More information about the agent view structure and the role it plays in search process is detailed in [11, 12].

5. AGENT LOCAL CONTROL MECHANISMS

The information retrieval performance, when there are concurrent search sessions, depends on how resources are allocated among these search sessions. The lack of centralized control of these concurrent searches can lead to an uneven distribution of query load among agents; this uneven load can then cause the situation where some agents are flooded with incoming queries while other agents are largely idle. Mitigating this problem requires agents to be able to control the message flow from a local perspective to prevent congestion and speed up the propagation speed of search sessions in the network. In addition to congestion prevention, in order to maximize overall system utility, agents should disseminate queries only to relevant agents so as to exploit bandwidth efficiently and reduce communication and processing load.

In this section, we present an analytical model based on queueing theory for agent control. In particular, the control unit of an agent makes decisions regarding which queries to process locally, in what order to process them (local search), and whether and to whom should the queries be forwarded (resource selection).

5.1 Resource Selection Algorithms

The resource selection algorithm chooses a subset of neighboring agents (that may contain relevant documents or have information about the location of relevant documents) to forward a query for further processing. Resource selection algorithms are characterized by their IR calculation overhead, the communication load they induce and how "focused" the search is. Existing resource selection algorithms include broadcast based routing algorithms, probabilistic based random routing algorithms and language model based algorithms[11, 12, 7]. Each resource selection algorithm incurs a certain amount of cost depending on its specific operations. For instance, a broadcast algorithm needs the least calculation, incurs minimal selection overhead but can easily saturate the network with messages, whereas a probabilistic random approach saves communication load but increases local computation load. A language model based approach has a different trade-off. It requires relatively expensive comparison operations but can significantly reduce the number of messages propagating in the system. Expensive computation operations can reduce agents' throughput which will be described in the next sections. Therefore, in the presence of concurrent search sessions, it is not always preferable to use a resource selection algorithm that generates minimal communication load but requires expensive comparison operations. The trade-off between message number and the amount of computation will be analyzed in the following sections.

5.2 A local scheduling mechanism

Each individual agent control unit maintains several queues including message queues, which contain messages to be forwarded to specific agents, and a local query queue, which contain queries waiting for further local processing. The set of agent control units in the network constitutes a queueing network system. In this section, two approaches for organizing the queueing network are introduced and compared based on their utilization rate and throughput.

Several assumptions are made in order to simplify the analysis.

(1) The service times at each queue including resource selection, local search scheduling and message forwarding are exponentially distributed.

(2) The inter-arrival times of queries are random and have Poisson distribution.

(3) The channel capacity between two arbitrary agents, A_i and A_j, is fixed, denoted as C_{ij}.

(4) The length of queries in the system, L, is considered a constant. This assumption simplifies the calculation of the throughput of communication channels.

Figure 2 shows an agent's control unit and indicates how resource selection, local searches and forwarding for parallel queries are related. This model consists of Q_{rs}, a queue that contains queries to be forwarded to other neighboring agents, Q_{ls}, a queue that contains queries waiting for further local search operations, and message forwarding queues Q_{1j} for each agent A_j in the agent view structure. These queues are considered as M/M/1 queues based on the above assumptions.

The arrival rate λ_i for queue Q_{rs} and Q_{ls} in agent A_i is calculated based on the departure rate, λ_{ji}, from its upstream agent A_j, and the arrival rate, λ_{0i}, from the outside users to agent A_i,

$$\lambda_i = \lambda_{0i} + \sum_{j=1}^{N} \lambda_{ji} \quad (1)$$

for i = 1, .., N

However, in a practical system, agents discard those queries that have been processed previously to ensure loopless communication. We assume the arrival rate of non-redundant queries is $\lambda_i^{'}$.

The resource selection time spent on a query is denoted as t_{rs} and the service time for local search is t_{ls}. Recall that both service times satisfy exponential distribution.

Queue Q_{rs} and Q_{ls} have the same arrival rate as specified in Equation 1. The throughput for Q_{rs} is $\frac{1}{t_{rs}}$ and for Q_{ls} is $\frac{1}{t_{ls}}$. Note that by separating the queue into two queues, the local search operation is no longer the bottleneck. Even when the incoming rate is higher than the service rate of Q_{ls}, an agent can buffer the incoming queries for later processing.

The arrival rate for each message queue Q_{ij}, λ_{ij} is the number of messages departing from Q_s in a time unit, i.e $\lambda_{ij} < \lambda_i^{'}$. The utilization rate for message queue Q_{ij} is $\rho_{Q_{ij}} = \frac{\lambda_{ij}}{\mu_{Q_{ij}}}$ And the throughput for Q_{ij} is

$$\mu_{Q_{ij}} = C_{ij}/L \quad (2)$$

.

Because each agent contributes to the overall system utility for each finished local search, the performance of the scheduling algorithm for the local search queue determines how fast the overall utility is accumulated. Moreover, because the selection of one query is always at the expense of executing other search sessions at a later time, this algorithm also affects the fairness of the network search process. It is worth mentioning that local fairness does not necessarily lead to global fairness.

A simple scheduling algorithm for the local query queue is first come first serve(FCFS) where agents always process queries that enter the system earliest. Although the FCFS algorithm is fair from an agent's local perspective, it can cause significant delay for queries that enter the system at a later time. An alternative scheduling approach is based on a greedy algorithm that aims to maximize the overall utility from an agent's local perspective.

$$GQ(t) = \sum_{s_i} Q_{s_i}(t) = \sum_{A_i} Q_{A_i}(t)$$

$Q_{A_i}(t) = \sum_{s_i} Q_{s_i,A_i}$ is defined as the local accrued utility of agent A_i. Therefore, in order to maximize the overall utility, each agent selects the most relevant subset of queries to process. In order to maximize the local utility, we use a heuristic based sorting algorithm to order the queries queue according to the Kullback-Leibler (KL) distance between the query model and the local collection model. KL distance is a metric to evaluate the distance of two distributions. The calculation detail is introduced in [12].

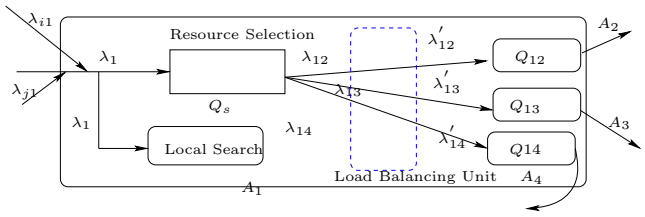

Figure 2: The agent internal structure with a parallel control mechanism

5.3 A Feedback-based, Probabilistic Load Control Unit

The above section analyzed the behavior when the queueing network is stable. However, when the query arrival rate is more than the service rate, the queue length will be ever expanding. In this section, we first analyze the cause of "hot spots" in the above model and then present a feedback based probabilistic load control mechanism in order to avoid or mitigate congestion situations.

5.3.1 The creation of "Hot Spots"

In the above model, there are two cases that would create a congestion situation: (1)The arrival rate for message queues (Q_{12}, Q_{13}, etc) is above the service rate, i.e

$$\lambda_{ij}^{'} > \frac{C_{ij}}{L}$$

(2)The arrival rate for queue Q_{rs} is more than the service rate, i.e:

$$\lambda_i > \frac{1}{t_{rs}}$$

From equation 1, it is equivalent to:

$$\lambda_i = \lambda_{0,i} + \sum_{j=1}^{N} \lambda_{ji} > \frac{1}{t_{rs}}$$

In the following section, we propose a load control mechanism to avoid both situations, thereby improving overall system performance.

5.3.2 A Probabilistic Load Control Algorithm

In order to control the communication load based on limited observations of the network, agents can employ a feedback-based, probabilistic algorithm. Specifically, when an agent forwards queries to its neighboring agents, it not only considers the capacity of its own communication channels, but also takes into account its neighboring agents' service rates, which are acquired dynamically by analyzing the feedback information sent out by its neighboring agents periodically.

Let QS_{ij} be the query set that the resource selection algorithm of agent A_i selects to forward to agent A_j and QS_i

be the query set that agent A_i receives and has not processed previously in a certain time period t. Assume that in a certain period, queue Q_s receives non-redundant query set QS_i and the load control mechanism randomly selects $p_{ij} * |QS_{ij}|$ from the query set QS_{ij} and $q_{ij} * |QS_i - QS_{ij}|$ from the set $QS_i - QS_{ij}$. Notice that $|QS_{ij}| = \lambda_i^{'} * t$ and $|QS_{ij}| = \lambda_{ij} * t$

Agent A_i determines probability p_{ij} and q_{ij} in the following way:

(1) $q_{ij} >= 0$ only if $p_{ij} = 1$.

(2) $p_{ij} = min(p_1, p_2, 1)$ where

$$p_1 = \frac{\frac{C_{ij}}{L}}{|QS_{ij}|}$$

and

$$p_2 = \frac{f_{ij}}{|QS_{ij}|}$$

(3) q_{ij} is determined by:

$$q_{ij} = \frac{min(f_{ij}, \frac{C_{ij}}{L}) * t - |QS_{ij}|}{|QS_i - QS_{ij}|}$$

(4) f_{ij} is determined by agent A_j and forwarded to agent A_i as feedback to control the number of messages to be forwarded to agent A_j from agent A_i. In our work, f_{ij} is determined by

$$f_{ij} = t_{ij} * \lambda_{ij} * t$$

and

$$t_{ij} = \frac{\frac{1}{t_{rs}} - \lambda_{0j}}{\lambda_j - \lambda_{0j}}$$

Recall that λ_{0i} is the arrival rate of queries from outside users instead of other agents. t_{ij} characterizes the overload situation at agent A_j

(1) specifies that agents selected by the resource selection algorithm have higher priority over other agents. Agent A_i would only forward a query to more agents when the utilization rate of communication channel is lower than 1.

(2) prevents the situation where too many queries are scheduled for the communication channel between A_i and A_j. In particular, p_1 is the maximal capacity of the communication channel and p_2 is the maximal number of queries that agent A_j can process in a timely fashion for agent A_i.

(3) decides that when the query arrival rate is low, the load control unit should increase the utilization of the communication channel and attempt to increase the speed that search sessions propagate in the system by forwarding more queries to agent A_j than the set that was selected by the resource selection algorithm.

(4) describes how the feedback information is generated. Agent A_j requests the upstream agents to reduce communication load by t_{ij} in order to prevent congestion situations.

6. A BALANCED TWO-PHASE QUERY ROUTING ALGORITHM

The control mechanism described above engineers traffic flow in a distributed information retrieval system from a local perspective. The effect of this mechanism, however, could be limited by the fact that agents only possess a narrowly defined non-local view of content network traffic. In this section, we introduce a query routing algorithm which exploits a more encompassing but static view of the network topology to route queries. It is the interaction among these two mechanisms that is key to our approach.

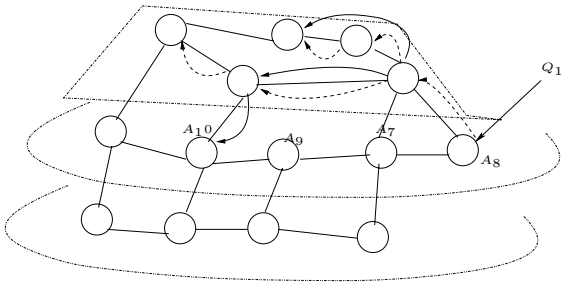

Figure 3: A Two-Phase Query Routing Algorithm In Hierarchical P2P IR System

In our previous work[12], we proposed a hierarchical agent topology and a two-phase search algorithm for use in routing queries. In this section, we extend this work to make it suitable for concurrent query processing in the network. In our hierarchical agent society, agents have two roles: group-mediator and query-processor[12]. All non-leaf agents in the organization take on both roles while leaf agents only take on the role of query-processor. Each mediator manages a group of agents and takes on a central role in group management including decisions on whether a new agent should be added to the group, when to reorganize the group, the selection of group members to handle a query and the propagation of queries to non-group members.

To take advantage of hierarchical agent organization, a two-phase hierarchical search algorithm was developed in [12]. In this protocol, as illustrated in Figure 3, agents in the first phase forward queries to top-level mediators so as to find appropriate starting points for the search. In the second phase, a concurrent search is initiated from these starting points. The intention of this algorithm was to conduct searches in a focused fashion to reduce communication messages. Notice that the load may become unbalanced in such a network. The arrival rate for a top-level mediator A_i is:

$$\lambda_i = \lambda_{0,i} + \sum_{j \in \{A_i^{'}\}} \lambda_{0,j} + \sum_{j=1}^{N} \lambda_j p_{ji}$$

for i = 1, .., N. Here we denote $\{A_i^{'}\}$ as the set of all direct or indirect members of agent A_i. In the above equation, $\lambda_{0,i}$ is the query arrival rate from users, while $\sum_{j \in \{A_i^{'}\}} \lambda_{0,j}$ is the query arrival rate coming from the member set of agent A_i; $\sum_{j=1}^{N} \lambda_j p_{ji}$ is the query arrival rate coming from the neighbors set. This makes the resource selection algorithms very expensive since the selection algorithm at top-level mediators must perform comparisons of query model and collection model of each agent. This algorithm is not a balanced approach since it tends to increase dramatically the burden of top-level mediators, thereby creating hot spots in the network. To resolve this problem, we propose an improved

two-phase search algorithm as demonstrated in Figure 4.

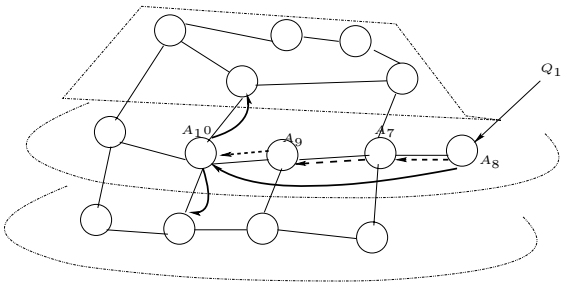

Figure 4: A Balanced Two-Phase Query Routing Algorithm

The first phase of this query routing algorithm is primarily conducted in the horizonal direction. It starts when the initiator of the query, A_8, forwards the query similarity probe messages with a certain TTL (Time To Live) value along the lateral links to the agents at the same level to locate relevant clusters. Upon receipt of these probe messages, agents return back the similarity values of their collections with the queries in question. After the TTL value expires, an agent does not forward the query any further, thus stopping further search along this path. After comparing the similarity returned by the agents, the initiator, $A8$, selects the K most similar agents to proceed to the second phase of the search. The second search phase is primarily conducted inside each group and information flows in the vertical direction. In particular, agents only forward the query along upward links or downward links during the second phase. For evaluation purposes, there is no explicit recognition by individual agents that the query is no longer being processed by any agent in the network. This process continues in the network until all the agents receiving the query drop the message or there are no other agents to forward to. In reality, this phase can also be controlled by a TTL value to limit search efforts. This way, the traffic load is likely to be more evenly distributed among the various levels of the hierarchy given that the entry points of the queries are randomly distributed in the network. Hence, the new search strategy mitigates the hot spot problem encountered in the previous algorithm.

7. EXPERIMENTAL SETTINGS AND RESULTS ANALYSIS

7.1 TRANO Testbed

TRANO(Task Routing on Agent Network Organization) is a multi-agent based information retrieval testbed. TRANO is built on top of the Farm simulator[6] that provides a data dissemination framework for large scale distributed multi-agent organizations. TRANO supports importation and exportation of agent organization profiles including topological connections and other features. Each TRANO agent is composed of an agent view structure and a control unit. In simulation, each agent is pulsed regularly and the agent checks the incoming message queues, performs local operations and then forwards messages to other agents .

7.2 Experimental Settings and Results Analysis

In our experiment, we use TREC-VLC-921 dataset which contains 921 sub-collections to simulate the collections hosted on agents. TREC-VLC-921 was originally split from TREC VLC1 collection by data sources in order to create testbed for distributed information retrieval research[2]. TREC VLC1 is part of the TREC collections which are distributed by the National Institute of Standards and Technology (NIST) for testing and comparing current text retrieval techniques. TREC VLC1 (very large collection) includes documents from 18 different data sources, such as news, patents, and the Web[4]. The formation of hierarchical agent organization can be achieved by a hierarchical clustering algorithm mentioned in [7]. However, this is under the assumption that global information about the content distribution is available during the topology formation. In the absence of global information, [12] proposed a distributed hierarchical clustering algorithm to form a hierarchical organization which is exploited in this paper. During the topology generation process, degree information of each agent is estimated by the algorithm introduced in [8] with parameters $\alpha = 0.5$ and $\beta = 0.6$. In our experiments, we estimate the upward limit and downward degree limit using linear discount factors 0.5, 0.8 and 1.0. Once the topology is built, queries randomly selected from the query set $301 - 350$ on TREC-VLC-921 are injected to the system based on a Poisson distribution

$$P(N(t) = n) = \frac{(\lambda t)^n}{n!} e^{-\lambda}$$

In addition, we assume that all agents have an equal chance of getting queries from the environment, i.e, λ is the same for every agent. In our experiments, λ is set as 0.00543 so that the mean of the incoming queries from the environment to the agent network is 5 per time unit. The service time for communication queue Q_s and Q_{rs}, i.e $t_{Q_{ij}}$ and t_{rs}, is set as 0.2 time unit. The service time for a local search queue, t_{ls} is 3 time units.

We use KL divergence to measure the distance among collection models or between collection models and query models. The formula is:

$$D(p||q) = \sum_i p(i) \log \frac{p(i)}{q(i)}$$

An approximation approach is used to speed up the calculation of KL distance and convert it to a similarity measure. The calculation details can be found in [11].

7.3 Performance Measures

The following measures were used to compare the different search strategies:

Propagation Speed of a search session s_i, $ps_{s_i}(t)$ is defined as the ratio of the number of agents visited at time t, $N(t)$, over the size of the agent society N, i.e $ps_{s_i}(t) = \frac{N(t)}{N}$. Average propagation speed is defined as average of the propagation speed of all the search sessions in the network. Notice that t is the amount of time after a search session starts. The maximal proportion of agents that a message visits is $ps_{s_i}(t^*)$.

Effective Propagation Speed of a search session s_i, $eps_{s_i}(t)$ is defined as the ratio of the number of relevant documents hosted on visited agents at time t,

Table 1: Experimental Results For Various Search Strategies

Name	Topology	RS	LC	λ	t^*	$ps_{s_i}(t^*) * t^*$	$eps_{s_i}(t^*) * t^*$	GU	MsgNumber	$GQ(t^*)$
PBN	**P**owerLaw	**B**roadcast	**N**o	0.00543	32	97%	97%	92%	2603022	77.29
PBY	**P**owerLaw	**B**roadcast	**Y**es	0.00543	31	97%	96%	94%	2563046	78.99

HBY	**H**ierarchical	**B**alanced	**Y**es	0.00543	24	89%	98%	85%	1552011	88.94

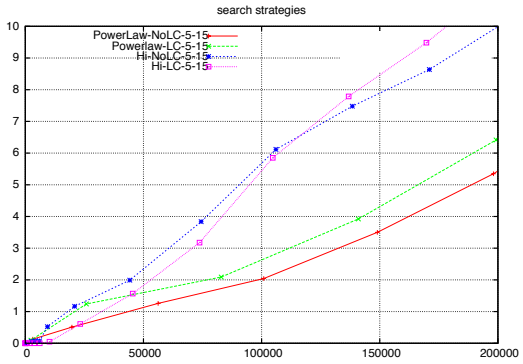

Figure 5: $GQ(t)$ versus the message number

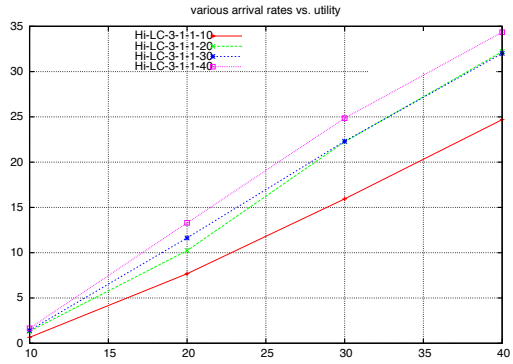

Figure 6: utility increase overtime for various arrival rates

$R(t)$, over the total number of relevant documents in the network R, i.e $eps_{s_i}(t) = \frac{R(t)}{R}$. Note that this ratio is not equal to recall ratio as the local searches may not be scheduled or finished by time t. Average effective propagation speed is defined as the average of the effective propagation speed of all the search sessions in the network. The maximal proportion of agents that a message visits in session s_i is $eps_{s_i}(t^*)$.

Global Utilization Ratio (GU) is defined as the average of the utilization rates of agents in the network. The utilization ratio of an agent is defined as the probability that the agent is busy and its queue is nonempty. A low global utilization ratio can be attributed to either a low query arrival rate or a poorly designed resource selection process and an agent search topology that creates unbalanced data flow in the network, leaving some agents with no queue entries while flooding others.

7.4 Results analysis and evaluation

Table 1 lists the experimental results of 6 different search strategies for 60 time units. These strategies explore the importance of using different topological agent organizations (powerlaw topology and hierarchical topology), search strategies (broadcast, two-phase hierarchical, and a balanced hierarchical search strategy). Fig. 5 depicts the global quality of the system as a function of the number of messages transmitted. *Hi-LC-5-15* is the curve for hierarchical, balanced two-phase search appraoch with local balancing techniques and *Powerlaw-LC-5-15* shows the performance for the broadcast search algorithm running on the powerlaw topology. In the following paragraphs, we analyze these experimental results and results shown in Fig. 6 that indicate how one specific search strategy is affected by the different arrival rates of the external queries.

Whether the load balance mechanism was used or not, the overall results were that the balanced hierarchical(details in Table 1) achieved highest overall utility while limiting the amount of communication relative to the broadcast approach. Additionally, the following findings were also revealed by the experimental results:

First, while the two-phase search algorithm was designed to take advantage of the hierarchical agent organizations, the way queries are forwarded in the system makes it easy to form hot spots that slow down the propagation of queries in the network. Therefore, from Table 1, the two-phase search algorithm produces low search quality. On the other hand, a balanced, hierarchical algorithm taking advantage of lateral links achieves the best search quality among the tested approaches in terms of both the number of communication messages and the overall utility. This is due to the fact that the queries are largely forwarded inside the relevant groups rather than being immediately forwarded to top level mediators in the two-phase search. This avoids the top-level mediators hot spots.

Secondly, a load balancing mechanism tends to improve system performance by reducing the number of messages when query arrival rate increases and congestion situations occur while increasing the number of messages in the network when the service load and utilization of the communication channel is low. From the experimental results, this load balancing mechanism improves the two-phase search algorithm the most. This can be attributed to the fact that the routing in two-phase search algorithm is very unbalanced with the query arrival rate used in these experiments. The preliminary experimental results also demon-

strate that the contribution of load balancing depends on the local computational capacity. Particularly, the traffic engineering techniques contribute to the performance more when local searching is not a bottleneck. When the local search queue size increases to a certain level, optimizing the traffic does not significantly improve search performance. It remains as future work to further discover the correlation between traffic flow and global search performance.

Thirdly, Fig. 6 shows that the overall system performance increases steadily with the increase of query arrival rates. This demonstrates that the system is a stable one.

Finally, the broadcast approach, to our surprise, performs quite well. It generates a lot of extraneous messages which are then filtered out locally by the language model based greedy local search scheduling algorithm. Therefore, this large number of messages did not distract the agents' local searches.

8. DISCUSSION AND FUTURE WORK

One of the directions that we would like to pursue is to provide differentiated service for search sessions by using selectively different search engines and parameters that trade off the likelihood of finding relevant documents to the time required for the search. We also want to be able to specify that some search sessions are more important than others, and expand the model so that the utility function of each search session may not necessarily be linear to the quality accrued over time. Rather, we assume that the utility functions increase faster at the beginning and the increase slows down when a certain amount of quality has been accrued.

$Q_{s_i}(t)$ is an objective measure which reflects the recall ratio at time t for search session s_i. Another measure, user utility, is also defined to capture the preferences that users have on the number of relevant documents returned at different periods during the search process.

$$U_{s_i}(t) = \mu(Q_{s_i}(t), t)$$

The overall system utility, $GU(t)$ is defined as the sum of the utility for each search session in a certain time period:

$$GU(t) = \sum_{s_i} \mu(Q_{s_i}(t), t)$$

By selecting an appropriate μ function, users can specify their preferences for search session s_i, i.e whether they prefer quick response but with a relative low recall ratio or vice versa. In this paper, we take $\mu(x) = x$ and therefore we consider that user satisfaction linearly increases as more relevant documents are returned.

9. CONCLUSIONS

In cooperative peer-to-peer information retrieval systems, each node can be considered as an intelligent agent and these agents work collectively to provide an information retrieval service. In order to effectively support multiple and concurrent search sessions in the network, we propose two traffic engineering techniques that minimize processing and communication bottlenecks. One is a novel agent control mechanism whose elements include resource selection, local search scheduling, and feedback-based load control and the other is a new two-phase query routing algorithm based on organizational knowledge. Experimental results show that this framework can reduce congestion situations, increase system throughput, and improve considerably the overall system utility.

ABSTRACT

Factored representations, model-based learning, and hierarchies are well-studied techniques for improving the learning efficiency of reinforcement-learning algorithms in large-scale state spaces. We bring these three ideas together in a new algorithm. Our algorithm tackles two open problems from the reinforcement-learning literature, and provides a solution to those problems in deterministic domains. First, it shows how models can improve learning speed in the hierarchy-based MaxQ framework without disrupting opportunities for state abstraction. Second, we show how hierarchies can augment existing factored exploration algorithms to achieve not only low sample complexity for learning, but provably efficient planning as well. We illustrate the resulting performance gains in example domains. We prove polynomial bounds on the computational effort needed to attain near optimal performance within the hierarchy.

1. INTRODUCTION

In the Markov decision process (MDP) formalization of the reinforcement-learning (RL) problem (Sutton and Barto 1998), a decision maker interacts with an MDP environment consisting of a finite state space S and action space A. Transitions are controlled by a Markov function where $P(s, a, s') = \Pr(s'|s, a)$ is the probability of reaching state $s' \in S$ after action $a \in A$ in state $s \in S$. The decision maker receives reward value $R(s, a)$ for action a in state s and attempts to maximize the expected cumulative reward.

In the current paper, we treat only MDPs with deterministic transitions, meaning that for each state-action pair there exists a unique s' such that $P(s, a, s') = 1$. We assume they also consist of only negative rewards ($R(s, a) < 0$) except for a set of final states $F \subseteq S$ that end the process when reached. We further assume that there are *short* solutions—policies that terminate after at most T steps for some polynomial size T. These conditions imply that the optimal value function is unique. Even though we present results only for the deterministic case, we stick with the standard notation of MDPs used in the reinforcement-learning community, which assumes stochastic domains.

A number of reinforcement-learning algorithms have been studied (Sutton and Barto 1998), some of which have been shown to find optimal policies under well-understood conditions. In analyzing algorithms, there are two main sources of complexity to be considered. The first, *sample complexity*, defines the amount of real-world experience needed by an algorithm to achieve near optimal results. The second, *computational complexity*, specifies the amount of computational work required per experience (Kakade 2003). We seek algorithms with low sample and computational complexity—both bounded by polynomials in critical parameters of the environment.

The best known reinforcement-learning algorithm is Q-learning. It is a sample-based learning rule with very low computational complexity, but it provably converges (Watkins and Dayan 1992) to the solution to the Bellman equations $Q^*(s, a) = R(s, a) + \gamma \sum_{s'} T(s, a, s') \max_{a'} Q^*(s', a')$, and therefore can be used to find optimal behavior. Unfortunately, Q-learning often exhibits very high sample complexity, making it practical principally in simulated domains in which experience is cheap to generate. To mitigate the high sample complexity of Q-learning, researchers have proposed algorithms that strike other tradeoffs between computational and sample complexity.

DYNA (Sutton 1990) and prioritized sweeping (Moore and Atkeson 1993) showed how learning transition models can empirically decrease sample complexity at increased computational complexity. Recent work (Kearns

and Singh 2002; Brafman and Tennenholtz 2002) has shown how model-based methods can provide formal polynomial-time bounds on both sample and computational complexity in MDPs.

Structure has long been recognized as important in computationally efficient sequential decision making (Boutilier *et al.* 1999). Dynamic Bayes Nets (DBNs) have emerged as a popular formalism for succinctly representing and solving large-scale MDPs (Koller and Parr 2000) and we adopt this factored-state framework in this paper.

In addition to structure in the state space, many researchers have studied algorithms that exploit hierarchical structure in the policy space (Kaelbling 1993; Hengst 2002). These methods have empirically provided relatively modest improvements in sample complexity over baseline RL approaches.

Kearns and Koller (1999) showed how model-based learning can be combined with factored states to provide polynomial sample-complexity bounds. An open problem from this work is achieving a polynomial computational-complexity bound. Dietterich (2000c) showed how factored states and hierarchy could be combined effectively, empirically improving sample complexity and reducing the number of parameters to be learned. Dietterich (2000b) also recognized the importance of combining models, factored states, and hierarchy, but found that the resulting learned hierarchical models no longer benefited from the factored representation.

The contribution of the current work is a novel combination of factored states, hierarchy and models, resulting in progress towards the solution of two important open problems. First, it shows how models can be combined with hierarchy without disrupting the benefits of factored states. The resulting algorithm exhibits greatly reduced sample complexity compared to model-free learning. Second, our combination of methods retains the polynomial sample complexity of existing model-based methods with factored states, with the hierarchy providing an approach to efficient planning in the learned models. Thus, we present the first factored-state reinforcement-learning algorithm with both polynomial sample *and* computational complexity. Section 6 illustrates our algorithm on a class of MDPs.

2. FACTORED-STATE MDPS

A factored-state MDP is one in which the state variables are factored into independently specified components. Let X be the set of state factors and, for all $x \in X$, $D(x)$ is the domain of values that factor x can take on. We write $v = \Phi_x(s)$ as the value of factor x in state s.

For a factored representation to provide a representational advantage over the standard tabular MDP representation, it is important that the transition probabilities and rewards support a structured representation. The assumption we adopt here, which generalizes the standard DBN representation, is that the probability that a factor x takes on a particular value v after a state transition in action a is a function of the *cluster* c of the state s.[1] We write $K(s,a,x)$ as the cluster for state s and factor x under action a and $\bar{P}^x(c,a,v)$ as the probability that a state from cluster c will transition to one that has factor x equal to v, under action a. Using this notation, for each action $a \in A$ and factor $x \in X$, transition probabilities are represented as $\Pr(s'|s,a) = \prod_{x \in X} \Pr(\Phi_x(s')|s,a) = \prod_{x \in X} \Pr(\Phi_x(s')|K(s,a,x),a) = \prod_{x \in X} \bar{P}^x(c_x,a,v)$ where $v = \Phi_x(s')$ and $c_x = K(s,a,x)$.

Similarly, we assume that reward functions are specified using the state clusters: $R(s,a) = \sum_{x \in X} \bar{R}(c_x,a)$ where $c_x = K(s,a,x)$.

2.1 Factored Rmax

Rmax is a reinforcement-learning algorithm introduced by Brafman and Tennenholtz (2002) and shown to have PAC sample complexity by Kakade (2003) (Brafman and Tennenholtz showed it was PAC in a slightly different setting). Factored Rmax is the direct generalization to factored MDPs (Guestrin *et al.* 2002). Factored Rmax is model based in that it maintains a model M' of the underlying factored MDP and, at each step, acts according to some optimal policy of its model. In this section, we'll describe the model used by Factored Rmax.

To motivate the model used by Factored Rmax, we'll describe at a high level the main intuition of the algorithm. Consider a fixed state factor x, action a, and cluster c ($c = K(s,a,x)$ for some state s). There exists an associated distribution $\bar{P}^x(c,a,\cdot)$ and reward $\bar{R}(c,a)$. The agent doesn't have access to these values, so they must be learned.

The trick behind Factored Rmax is to use the agent's experience only when there is enough of it to ensure decent accuracy, with high probability.

Let κ be some user-defined constant that is given to Rmax as input at the beginning of a run. In the determinstic setting $\kappa = 1$. For each distribution $\bar{P}^x(c,a,\cdot)$, Rmax maintains a count $\kappa_a(x,v,c)$ of the number of times it has taken action a from a state s for which $K(s,a,x) = c$ and $v = \Phi_x(s)$. As long as $\kappa_a(x,v,c) < \kappa$, Rmax assumes that any transition from s under a causes state value x to become e, an additional value added to each domain $D(x)$. Once a state value becomes e, a transition under any action cannot change it from being equal to e. Additionally, the reward for any state that has a state variable with value e is equal to $R_{\max}$, the maximum possible reward (zero in our case). On the first timestep such that $\kappa_a(x,v,c) = \kappa$, Rmax updates its model to use the empirical distribution as an approximation of $\bar{P}^x(c,a,\cdot)$, and the empirical reward for $\bar{R}(c,a)$.

3. THE MAXQ VALUE-FUNCTION DECOMPOSITION

One model of a task hierarchy in an MDP is to decompose the main task of maximizing reward en route to a terminal state into subtasks, each with its own terminal states and perhaps subtasks of its own.

Each task $1 \leq i \leq I$ in the hierarchy can be viewed as a self-contained MDP with final states F_i and action set A_i.[2] Actions $j \in A_i$ can be either the primitive actions of the MDP or subtasks $j > i$. The root task $i = 1$ uses $F_i = F$, the final states of the actual MDP.

We also define $T_i \in \mathbb{N}$, for each task i, such that for any given set of fixed polices for subtasks A_i, there exists some (hierarchical) policy for subtask i that terminates within T_i steps from any abstract non-terminal state.

[1] In DBNs, the cluster is determined by the joint assignment of the parents of x.

[2] We view primitive actions as tasks that don't have a set of final states but instead terminate after one timestep.

A *hierarchical policy* $\pi = \langle \pi_1, \ldots, \pi_I \rangle$ is a policy for each task i, $\pi_i : S \to A_i$. Policy π_i is considered locally optimal if it achieves maximum expected reward given subtask policies π_j for $j > i$.

If local optimality holds for all tasks, the corresponding hierarchical policy is called *recursively optimal*.

3.1 Recursive Solution

The state (V) and state-action (Q) forms of the Bellman equations are well known (Sutton and Barto 1998). Dietterich (2000a) implicitly proposes an alternative—the completion-function form:

$$C(s,a) = \sum_{s'} P(s,a,s') \max_{a'}(R(s',a') + C(s',a')).$$

Given a representation for the reward function, the completion function can be used to recover $Q(s,a) = R(s,a) + C(s,a)$, $V(s) = \max_a Q(s,a)$, and $\pi(s) = \text{argmax}_a Q(s,a)$.

Given ϵ-approximate transition and reward functions $\hat{P}$ and $\hat{R}$ and the task hierarchy, we can compute a hierarchically ϵ-optimal policy by defining a hierarchical completion function as follows. We consider the set of tasks i in reverse order from $i = I$ to $i = 1$. For each, we determine a completion function C^i. If i is the task for primitive action a, we define $C^i(s,a) = 0$.

For higher-level tasks i, we solve the MDP with actions A_i, states S, and final states F_i, where the transition function for action $j \in A_i$ is $P^j(s,s')$ and its reward function is $R^j(s)$. In other words, each subtask j is treated like an action that has a reward and a probabilistic transition to some state $s' \in F_j$. The MDP solution produces C^i. Specifically, for $s \in F_i$ we define $C^i(s,j) := 0$. Otherwise, we define the task completion function as follows:

$$C^i(s,j) = \sum_{s' \in F_j} P^j(s,s') \max_{j' \in A_i} (R^{j'}(s') + C^i(s',j')).$$

Computing $R^j(s)$ and $P^j(s,s')$ can be achieved by solving systems of linear equations: if $s \in F_j$, $P^j(s,s) = 1$ and $R^j(s) = 0$; otherwise,

$$\begin{aligned} P^j(s,s') &= \sum_{s_1} P^k(s,s_1) P^j(s_1,s') \quad \text{and} \\ R^j(s) &= R^k(s) + C^j(s,k) \end{aligned} \tag{1}$$

where $k = \pi^j(s)$.

In this construction, each task adopts an optimal policy given the subtasks, so $\pi = \langle \pi_1, \ldots, \pi_I \rangle$ is a recursively optimal policy for the MDP specified by $\hat{P}$ and $\hat{R}$.

3.2 Abstraction

Dietterich (2000c) described how to combine state abstraction with a hierarchical task decomposition. For each task i, define $Z_i \subseteq S$ to be the set of abstract-state representatives, and define an *abstraction function* $\phi_i : S \to Z_i$ mapping states to their abstract representatives. An abstract policy and an abstract completion function differ only for states with different representatives.

Similar to Dietterich (2000c), we say an abstraction is *valid* if the abstract completion function does not incur any approximation under any abstract policy. Define the abstract transition function $\mathbb{P}_i^j : S \times Z_i \to \mathbb{R}$ as $\mathbb{P}_i^j(s,z') = \sum_{s' \in S \text{ s.t. } \phi_i(s') = z'} P^j(s,s')$. We adopt the following concrete assumptions, which imply a valid abstraction:

1. For all $s \in S$, $z' \in Z_i$ and $j \in A_i$, $\mathbb{P}_i^j(s,z') = \mathbb{P}_i^j(\phi_i(s),z')$. That is, the total probability of a transition to states in an abstract class is dependent only on the abstract class of the current state.

2. For all $s, s' \in S$, $j, k \in A_i$, if $P_i^j(s,s') > 0$, then $R^k(s') = R^k(\phi_i(s'))$. That is, for any reachable next state, the reward function depends only on the abstract class.

3. For all $s, s' \in S$ and $k \in A_i$, if $R^k(s) \neq R^k(s')$ and $\phi_i(s) = \phi_i(s')$, then there is no sequence of actions in A_i that takes the agent from s to s'. That is, if two states in the same abstract class have different reward functions then they are not reachable from each other.

These assumptions imply a valid abstraction because the unique solution to the abstract completion function, defined by

$$\mathbb{C}^i(z,j) = \sum_{z' \in Z_i} \mathbb{P}_i^j(z,z') \max_{k \in A_i} (R^k(z') + \mathbb{C}^i(z',k)) \tag{2}$$

matches the completion function for all states $z \in Z_i$. This result follows from the uniqueness of the value function and algebraic substitution using the assumptions above.

The abstract completion function can be used to compute task rewards and policies as follows. First, we extend the abstract completion function to all states in the obvious way: $\mathbb{C}^i(s,j) = \mathbb{C}^i(\phi_i(s),j)$. Next, we can define the reward function recursively by $R^i(s) = \hat{R}(s,a)$ if i is subtask for primitive action a, $R^i(s) = \max_{j \in A_i}(R^j(s) + \mathbb{C}^i(s,j))$ otherwise. Finally, these quantities can be used to define a policy via $\pi_i(s) = \text{argmax}_{j \in A_i}(R^j(s) + \mathbb{C}^i(s,j))$. Note that these computations can be performed in polynomial time in the size of the task hierarchy as long as results are cached (each task should only compute its reward function once for a state).

3.3 An Example Domain

The main MDP environment we used for testing is called *bitflip*. This domain has several qualities that make it suitable for our tests, including an exponential and scalable state space, an exponential set of distinct Q values, linear-size set of completion values, and abstractions that can potentially reduce the size by an exponential factor. For the domain *bitflip*(n), meaning an instance of *bitflip* with n bits, the states are all binary n-bit numbers. There are n actions, with action flip(i) corresponding to "flip the ith bit". The actions don't always succeed. In particular, if action flip(i) is executed, the behavior depends on the bits to the left of i (j such that $j > i$). If any of these bits are set to 1, the action fails and all bits $j \geq i$ are set to 1. Otherwise, the ith bit is flipped. The reward function is deterministic; whenever action i is executed, a reward of -2^i is received. There is one final state, the state where all bits are equal to zero. Note that $V(s) = s$ where s is the state interpreted as an integer in binary. Thus, there are 2^n distinct V and Q values. The optimal policy is to flip the 1 bits, in order, from left to right.

We now describe the hierarchy for *bitflip*. For each i there is a subtask, clear(i), which terminates when the leftmost

i bits are all zero. The subtasks available to clear(i) are flip(i) and clear($i-1$). The subtask clear(n) is the root task. The abstraction function for flip(i) maps all states to four representative states. They correspond to the combinations of bit i being 0 or 1, and all bits to the left of i being 0 or at least one having a 1. This abstraction is valid and results in an abstract completion function with fewer than $8n$ distinct values.

4. DSHP: A DETERMINISTIC SAMPLE-BASED HIERARCHICAL PLANNER

Equation 2 provides an alternative formulation of the completion function based on abstraction that can result in a considerably smaller representation at each task. Solving for the abstract completion function $\mathbb{C}$ requires knowledge of the abstract transition function $\mathbb{P}$ and the reward function R for each of the abstract state representatives. Unfortunately, the analog of Equation 1, which defines MDP models of subtasks, can no longer be formulated in the abstract setting since each task may have its own abstract state space. In this section, we provide a method that overcomes this hurdle in deterministic domains.

Our goal is to develop a planning algorithm that takes as input a model M' of the true MDP M, and produces a hierarchical policy. We make no assumptions on the structure of M' or M, for example they can be factored or flat MDPs. We only require that given a state-action pair (s, a) query, our model M' will either return the correct next state, $T(s, a)$ and reward $R(s, a)$, or a special value $s_{\max}$, which indicates the model is unsure of the behavior resulting from action a in state s. We call such a state-action pair, which leads to $s_{\max}$ in the model M', an "unknown" state-action pair.

Let l be the height (length of the longest root to leaf path) of the MaxQ task hierarchy, and L_i be a list of the tasks on level i ($L_0 = \{1\}$). Let $U_j = \max_{i \in L_j} T_i$ be the maximum of T_i for tasks i on level j. Define $T = \prod_{j=0}^{l} U_j$. With no knowledge of the current MDP M and hierarchy H, we cannot expect any hierarchical policy to take less than T steps (primitive actions) to achieve its goal (whether that be to solve the task or to reach a certain part of the state space). In fact, we may need up to $O(T \cdot l)$ table lookups to execute any such policy for T steps.

At each step, the agent must ensure that it is either executing a recursively near-optimal policy, or it learning something new. Then the goal of the algorithm is to compute a hierarchical policy $\pi_{M'}$ that satisfies one of the following two conditions:

1. The policy $\pi_{M'}$ is recursively optimal in M.
2. By following policy $\pi_{M'}$ for T steps in M, the agent will reach an "unknown" state-action pair (a transition to $s_{\max}$ in M').

The algorithm solves the abstract MDP for the root task. Since doing so requires that the children of the root task have fixed policies, the algorithm first recursively calls itself for each of the root's children (thereby solving them and fixing optimal policies).

One problem with this approach is that the algorithm doesn't have access to the MDP M, but instead a model M'. Thus, for two states s, s' in the same cluster for task i (meaning $\phi_i(s) = \phi_i(s')$), it may be the case that execution of the same abstract action may take one of these states to $s_{\max}$ (in M') but not the other.

Our solution is to solve the MDP in a bottom-up fashion, solving higher level tasks after all lower level subtasks have been solved and to maintain a partially learned recursively optimal policy. In addition, we perform value updates on only those abstract state-action pairs for abstract states that are reachable from the current state. For each task i and for each reachable abstract state $z \in Z_i$, we keep track of the relevant primitive state s, such that $\phi_i(s) = z$, that will be reached if the current learned (partial) policy is performed (from the current state). To do so, we postpone the evaluation of abstract state $z' \in Z_i$ until a path from the current state is found to z', making it vital to know the value of z'. When z' is found, we have the precise primitive state (which abstracts to z') that would be reached on this path. If it is ever the case that a path p to $s_{\max}$ is found, the algorithm immediately halts and returns the policy that generates p. Otherwise, the entire MDP is solved and a recursively optimal policy is found.

Pseudocode for the algorithm is presented below. The core recursive procedure is `Solve`. The `RunTrajectory` routine executes an abstract action from a primitive state in the MDP M' and returns the resulting state and reward.

To simplify the exposition, we assume that every abstract state for subtask i is reachable from every other abstract state for subtask i in T_i steps. We also assume that terminal states of M cannot be reached by any hierarchical policy unless that hierarchical policy also terminates (meaning the root reaches a terminal abstract state). Elimination of these assumptions is straightforward.

4.1 Data Structures

Let H be the set of all tasks in the hierarchy, Z be the set of all abstract states, and $\mathcal{A}$ be the set of all abstract actions.

The model M' is a generative model and can be accessed via the two following functions:

- `NextState` : $S \times A \rightarrow S \cup \{s_{\max}\}$,
- `Reward` : $S \times A \rightarrow \mathbb{R} \cup \{\varnothing\}$.

The model of the hierarchy consists of:

- `Solved` : $H \rightarrow \{True, False\}$: Indicates whether we have solved the task or not. Initialized to $Solved(\cdot) = False$.
- `HAction` : $H \times Z \rightarrow \mathcal{A}$: represents the learned hierarchical policy by giving the next abstract action to take from the given task and abstract state.
- `HNextState` : $H \times Z \times \mathcal{A} \rightarrow Z$: Returns the next abstract state reached by executing the given abstract action in the given task and abstract state.
- `HReward` : $H \times Z \times \mathcal{A} \rightarrow \mathbb{R}$: Returns reward obtained by executing the given abstract action in the given task and abstract state.
- `HValue` : $H \times Z \rightarrow \mathbb{R}$: Returns the total value of the hierarchical policy starting in the given task from the given abstract state.

The input to the algorithm is the model MDP M', the hierarchy $\mathcal{H}$, and the current state s. The output of the algorithm will be a hierarchical policy $\pi_{M'}$.

4.2 Routines

The planning algorithm consists of the following four routines: `Main`, `Solve`, `RunTrajectory`, `HValueIteration`.

`Main`()
1: Set up data structures
2: Call `Solve`(`1`, `s`)
3: Output policy represented by `HAction`.

`Solve`(`i`, `s`)
`Input` : `i` $\in$ `H`, `s` $\in$ `S`
`Output` : `foundSmax` $\in \{$`True`, `False`$\}$
1: Let $\mathcal{Q}$ be the trajectory tree created with root $(s, \phi_i(s))$
2: `KNOWN` $= \{\}$
3: **for** each node N $= (s',\ z' := \phi_i(s'))$ in $\mathcal{Q}$ **do**
4: **for** each action $a_{ij} \in A_i$ **do**
5: **if** a_{ij} is not primitive and `Solved`(`a`$_{ij}$) $=$ `F` **then**
6: Call `foundSmax` $=$ `Solve`(`a`$_{ij}$, `s`$'$)
7: **if** `foundSmax` **then**
8: Set `HAction` to reach a_{ij} from root in $\mathcal{Q}$.
9: return `True` and `HALT`
10: **end if**
11: **end if**
12: (`s`$''$, `r`) $\leftarrow$ `RunTrajectory`(`a`$_{ij}$, `s`$'$)
13: **if** `s`$'' =$ `s`$_{\max}$ **then**
14: Goto line 8
15: **end if**
16: `HNextState`(`i`, `z`$'$, `a`$_{ij}$) $\leftarrow \phi_i$(`s`$''$)
17: `HReward`(`i`, `z`$'$, `a`$_{ij}$) $\leftarrow$ `r`
18: **if** ϕ_i(`s`$''$) $\notin$ `KNOWN` **then**
19: Add node (`s`$''$, ϕ_i(`s`$''$)) to $\mathcal{Q}$ as child to N
20: **end if**
21: **end for**
22: `KNOWN` $=$ `KNOWN` $\cup \{$`z`$'\}$
23: **end for**
24: Call `HValueIteration`(`i`)
25: `Solved`(`i`) $\leftarrow$ `True`
26: Return `False` and `HALT`

`RunTrajectory`(`i`, `s`)
`Input` : `i` $\in$ `H`, `s` $\in$ `S`
`Output` : (`s`$'$, `r`) $\in$ `S` $\times \mathbb{R}$
1: **if** Task i is a leaf task **then**
2: `s`$' \leftarrow$ `NextState`(`s`, `HAction`(`i`, ϕ_i(`s`)))
3: `r` $\leftarrow$ `Reward`(`s`, `HAction`(`i`))
4: return (s', r) and `HALT`
5: **else**
6: `R`$_{total}$ $\leftarrow$ `0`
7: (`s`$_{temp}$, `r`$_{temp}$) $\leftarrow$ `RunTrajectory`(`HAction`(`i`, ϕ_i(`s`)), `s`)
8: `R`$_{total}$ $\leftarrow$ `R`$_{total}$ $+$ `r`$_{temp}$
9: **if** `s`$_{temp} \in$ `F`$_i \cup \{$`s`$_{\max}\}$ (`s`$_{temp}$ is a terminal state) **then**
10: return (`s`$_{temp}$, `R`$_{total}$) and `HALT`
11: **else**
12: `s` $\leftarrow$ `s`$_{temp}$
13: goto line 7
14: **end if**
15: **end if**

`HValueIteration`(`i`)
`Input` : `i` $\in$ `H`
`Output` : updated values

This algorithm simply runs value iteration on the abstract state space Z_i. It uses the functions `HNextState`(`i`, $\cdot$, $\cdot$) and `HReward`(`i`, $\cdot$, $\cdot$), which have already been learned. It then learns the function `HValue`(`i`, $\cdot$) and uses it to compute some optimal policy, which it stores in `HAction`(`i`, $\cdot$).

4.3 Correctness of Algorithm

The `Solve` routine when called with a leaf task (one with only primitive actions), will clearly make no recursive calls. In this case, for each abstract state and action, `RunTrajectory` is used to learn the transition and reward function. If, during any call to `RunTrajectory`, a path to $s_{\max}$ is found the function ends and returns a policy leading to $s_{\max}$. Otherwise, value iteration is used to completely solve the abstract MDP.

If `Solve`(`i`, `s`) is called with a task i that has non-primitive actions (actions that are other tasks), then the correctness follows from a similar argument to the one above. The only difference is that, for each non-primitive action (from each abstract state), a recursive call to `Solve` is made. However, as the tasks called recursively exist below (as the children of) i, we can inductively assume these calls either return `F`, and have learned optimal policies for the subtask, or they return `T` and have learned a policy to reach $s_{\max}$ from s.

4.4 Analysis of DSHP

Our claim is that the runtime of DSHP is polynomial in the relevant input quantities of the reinforcement-learning problem. Specifically, let $VI(i)$ be the time it takes to run value iteration for task i, then DSHP runs in time $O(\sum_{i=1}^{I} (|Z_i| \cdot |A_i| \cdot T + VI(i)))$. To see this result, note that:

- Besides the initial call of `Solve` within `Main`, the only other calls to `Solve` are recursive.
- A call to `Solve`(`i`, $\cdot$) will only make recursive calls `Solve`(`j`, $\cdot$) where task j is below task i in the MaxQ task hierarchy.
- When `Solve`(`i`, $\cdot$) completes (without returning $True$, which halts the entire algorithm), we have that `Solved`(`i`) $=$ `True`.
- Thus, for any task i, `Solve`(`i`, $\cdot$) will never be called more than once during the entire algorithm. Therefore, the number of calls to `Solve` cannot be greater than I, the number of tasks.
- A single call to `Solve`(`i`, $\cdot$) has two main iterations, the outer **for** loop of Line 3 and the inner **for** loop of Line 4. Due to the **if** statement of Line 18, the outer **for** loop will iterate at most $|Z_i|$ times, while the inner **for** loop clearly iterates A_i times. The computation that takes place within the inner **for** loop, not counting the computation within other calls to `Solve` (which we have already counted), is a constant plus the time it takes to call `RunTrajectory`, which happens to be $O(T)$. After the two loops terminate, `Solve`(`i`, $\cdot$) calls `HValueIteration`, which takes time $VI(i)$. Thus, the total complexity of entire algorithm

is $O(\sum_{i=1}^{I}(|Z_i| \cdot |A_i| \cdot T + VI(i)))$. We can make this bound tighter by noting that `RunTrajectory(i,·)` takes less time as the depth in the tree of i increases.

5. USING DSHP TO LEARN AN MDP

Given a solution to the planning problem of Section 4, the learning algorithm is simple: Use experience to generate M', then plan. If DSHP outputs a hierarchical-optimal policy we're done. Otherwise, run the policy until an "unknown" (s, a) is found and repeat. It's clear that the learning algorithm, which we call the **Deterministic Sample-Based Hierarchical Learner (DSHL)** will have sample complexity bounded by $O(T \cdot U(M))$, with $U(M)$ being the number of "unknown" state-actions that can be found, until the model M' is identical to M. For a flat and deterministic MDP M, $U(M) = |S| \cdot |A|$. In factored representations, $U(M)$ is often much smaller. By separating the hierarchy from the underlying representation, DSHL reaps the benefits of both forms of abstraction simultaneously.

6. EMPIRICAL RESULTS

We tested MaxQ, Factored Rmax and DSHL in the *bitflip* and the taxi domain ((Dietterich 2000c)). The results show that, as expected, Rmax has poor computational complexity and MaxQ has poor sample complexity. DSHL achieves both low computational and sample complexity.

6.1 Bitflip domain

Our testing methodology was to evaluate the agent's learned policy after each episode on a number of example states of the environment. The evaluation states were picked to follow a standard structure based on the number of bits n: all 1s (11..11), single 1 in the center (0..010..0), first half 1s (1..10..0), second half 1s (0..01..1), by quarters (1.10.01.10.0) and alternating 1s (101010...). Once an optimal policy is found, the trial stops and we record the cost (number of action choices) and computer time for the trial. Each experiment is repeated for 20 trials and all the results are averaged. We tested each algorithm on *bitflip*(n), where we allowed n to increase until one of two termination conditions were satisfied: when a value of n is reached for which the algorithm took longer than thirty minutes on a single trial, or when the number of action choices reached thirty thousand.

Each algorithm has a number of parameters. For Factored Rmax, the main parameter is the Rmax constant κ. As we are dealing with a deterministic domain, this parameter was set to 1. For MaxQ, one must specify the value of ϵ for exploration and its decay rate. We did a search of these parameters (from 0.1 to 0.3, on 0.05 increments) and chose the setting that gave the best performance for each problem size. DSHL requires no parameter tuning.

As we can see from the Figure 1, the sample complexity of both Factored Rmax and DSHL grows linearly in the number of factors of the domain, whereas the sample complexity of MaxQ grows exponentially. On the other hand, the computational cost for Factored Rmax grows exponentially (Figure 2), while both MaxQ and DSHL show polynomial growth rates. So, DSHL is the only algorithm to show polynomial growth rates in both sample and computational complexities, as predicted by our analyses.

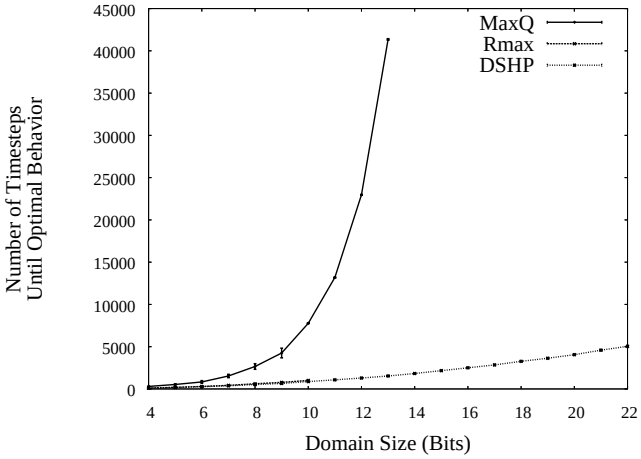

Figure 1: Number of steps per problem size until algorithm reaches optimal policy for the given start states. Rmax can only solve problems upto size 10, given the amount of time allocated.

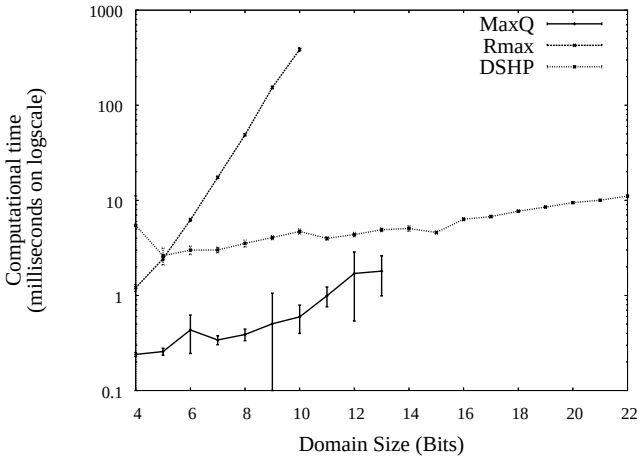

Figure 2: Computational time per step, per problem size. Plotted on a log scale, due to huge disparity between algorithms.

6.2 Taxi domain

We used a similar testing methodology for the taxi domain described by Dietterich (2000c). We used the standard problem (no fuel, no fickle passenger) on a $5x5$ grid. We used the same hierarchical structure and the same kind of abstractions used by MaxQ. The size of the problem in this case is fixed, so we only expose the good performance of DSHL in the two types of complexities.

As in the previous problem, we evaluate the agent's learned policy after each episode on a set of six starting combinations of <taxi (x,y) location, passenger location, passenger destination>. The start states used were: $\{(2,2), Y, R\}$, $\{(2,2), Y, G\}$, $\{(2,2), Y, B\}$, $\{(2,2), R, B\}$, $\{(0,4), Y, R\}$, $\{(0,3), B, G\}$.

The results are shown in the following table:

	Number of steps	Time per step
MaxQ	6298	9.570ms
Factored Rmax	1839	97.780ms
DSHL	319	16.876ms

As can be seen, DSHL significantly improves the sample complexity of both MaxQ and Factored Rmax by combining models, factored state spaces and a hierarchal structure, while attaining low computational complexity comparable to that of MaxQ.

7. CONCLUSION

We have designed a novel algorithm that combines factored representations, model-based learning, and hierarchies to provide a formal guarantee on learning time in many large deterministic reinforcement-learning domains. Empirical results indicate that, for a simple extensible class of MDPs, existing algorithms fail to provide either efficient sample complexity or efficient computational complexity. The results demonstrate, on the other hand, how the theoretical assurances of our hybrid algorithm translate to practical advantages.

ABSTRACT

We propose a formal framework to keyhole plan recognition based on lattice theory and action description logic. This framework minimizes the uncertainty about the prediction of the observed agent's behaviour by dynamically generating new implicit intentions. This approach offers an effective solution to actual recognition of ADL in a smart home, in order to provide assistance to persons suffering from cognitive deficiencies.

Keywords

Description logic, lattice theory, plan recognition, smart home

1. INTRODUCTION

Recent developments in information technology and increasing problems in the health field, including population aging and medical staff shortages, have opened the way to a whole set of new and promising research avenues, most notably, work on smart homes. A growing literature [2][5][9][10] has explored the process by which cognitive assistance, inside a smart home, is provided to occupants suffering from cognitive deficiencies such as Alzheimer's disease and schizophrenia, for the performance of their Activities of Daily Living (ADL). One of the major difficulties inherent to cognitive assistance is to recognize and predict the inhabitant ADL from their basic observed actions and the events produced by these actions. This problem is referred to as plan recognition in the field of artificial intelligence [4]. In the context of cognitive assistance, these predictions are used to identify the various ways a smart home (observer agent) may help its occupants (patients). An important assumption underlying the plan recognition is that the observed agent is rational, i.e., all of his carried actions and intentions are coherent. However, for patients suffering from cognitive deficiencies, rationality might indeed be a strong assumption. The purpose of this paper is then to initiate the development of a generic approach to plan recognition for a smart home, that could be applied to people suffering from cognitive impairments. Hence, we deal with keyhole plan recognition which is, strictly speaking, more general than intended plan recognition, in that it makes no assumption about efforts to cooperate on the part of the observed agent [12]. The literature related to keyhole plan recognition [1][4][8][10], in particular the logical approaches [7][12], share a significant limitation in that they do not take into account intra-dependencies between the possible plans in the recognition process. These intra-dependencies result from the fact that, even if possible plans might seem connected, the intentions concerning two distinct observations are not necessarily related. Our proposal relies on lattice theory and action description logic [3] to define algebraic tools taking into account this problem. These tools also allow us to formalize the inferential process of plan recognition in a model of reasoning by classification through a lattice structure. This interpretation model defines a recognition space. This space will not only serve to characterize the uncertainty in the prediction of a future action. It will also serve to determine the appropriate time when the assisting agent could be brought in to increase his autonomy in order to execute an assistance action in the habitat by taking over the ADL patient control.

2. RECOGNITION SPACE MODEL

A plan recognition process consists, for an observer agent, of interpreting the set of the observed actions, performed by a human or another observed agent in action, with the aim of predicting his future actions and thus the plausible plans that explain his behaviour. Let $A = \{a, b, \ldots\}$ be the set of actions that an observed agent is able to perform and let $P = \{\alpha, \beta, \ldots\}$ be the set of known plans of the observer. Let O be the set of observations such that $O = \{o \mid \exists a \in A \rightarrow a(o)\}$. The assertion $a(o)$ means that observation o corresponds to an a-type action. The set of possible plans that would explain the set of observations O, according to the agent's knowledge, is expressed by $P_s^o = \{\alpha \in P \mid \exists (a,o) \in \alpha \times O \rightarrow a(o)\}$. Starting with this set of possible plans, we can deduce that the agent will at least perform one of them. However, its intentions can go beyond the set of possible plans. In order to generate all agent's intentions, we enhance P_s^o by dynamically generating extra plans (new intentions) based on the composition operation $\alpha \oplus \beta$ between each pair of incomparable possible plans $(\alpha, \beta) \in P_s^o$. We define the set of plausible intentions P_l^o as the union of the composition pairs of possible plans. This set is an interpretation model for O if it forms a lattice structure $< P_l^o, \prec_p, \Delta, \nabla >$ ordered by the subsumption relation of plans $\prec_p$ and each couple of plans admits an upper bound ∇, corresponding to their least common partial subsumer, which is minimally composed of the observed actions. Also, each couple of plans admits a lower bound Δ, corresponding to a variable plan obtained by disunifying the incomparable possible plans using the first-order logic disunification operation [6]. The interest on computing this lower bound is to find a new intention schema. It is defined as a plan that can contain action variables serving to characterize the uncertainty in the prediction of a future action. A plan

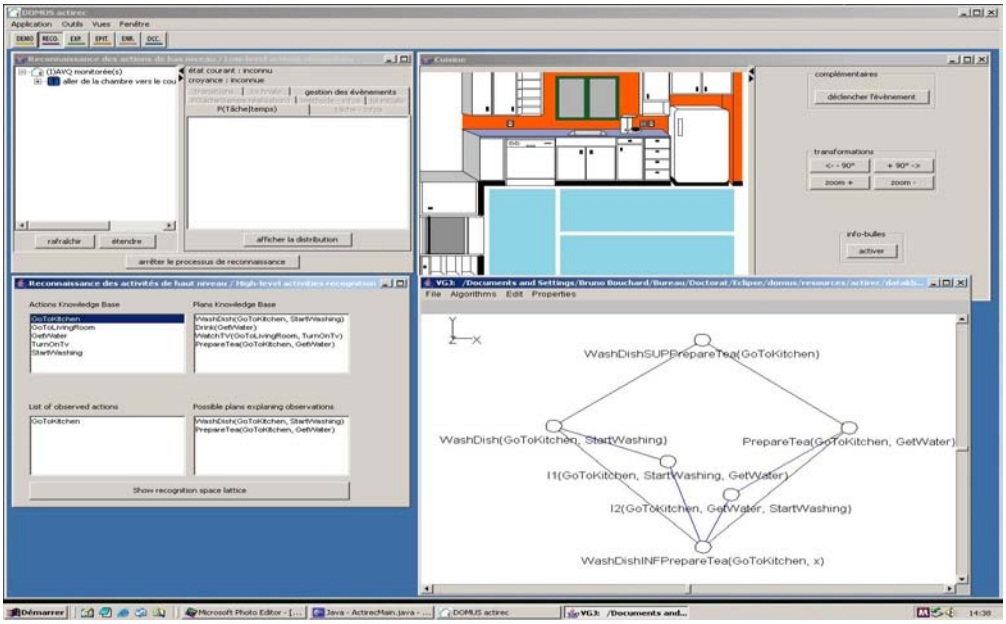

Figure 1. DOMUS application of activities recognition.

$\alpha\Delta\beta$ is defined as a sequence of actions $a_1,\ldots,x,\ldots,a_n$, denoted $\alpha\Delta\beta(a_n \circ a_{n-1} \circ \cdots \circ x \circ \cdots \circ a_1)$, where $\circ$ is a sequence operator and x is an action variable. $\alpha\Delta\beta$ is a variable plan if and only if there exists a substitution $\sigma(x) \in A^+$ such that each new intention $\iota(a_n \circ \cdots \circ \sigma(x) \circ \cdots \circ a_1)$ satisfy the two following consistency properties. The first one is the $\oplus$-stability of ι which means that each intention $\iota \in \alpha \oplus \beta$ is formed by: (i) a set of partial plans included in the knowledge base P of the observer, (ii) at least one action common to plan α and to plan β, and (iii) a composition of actions that are component of α or component of β. There is no possibility of introducing other external actions. The second criteria is the $\oplus$-closure propriety which expresses that each intention ι must admit an upper bound $\alpha\nabla\beta$ and a lower bound $\alpha\Delta\beta$. Hence, the new intentions must be included in the interval $[\alpha\Delta\beta, \alpha\nabla\beta]$. One can ask question regarding the computational complexity of this composition operation. The answer is that the combination of the incomparable possible plans is not done blindly. First, we only consider the consistent possible plans, which satisfy the stability and closure criteria (first filter). Second, the possible plans that we consider are those which are in the lattice structure bounded by the upper and lower bounds (second filter). Finally, for each pair of incomparable possible plans, we combine them by using the disunification operation (third filter). These filters allow us to reduce and control the computational complexity of the composition operation. Therefore, the recognition process can be seen as the generation of all consistent plans, resulting from the substitution of their action variables, which are ordered by the subsumption relation of plans and include between the infinimum and the supremum of the recognition space. Of course, it is assumed that all the observed actions are related. Consequently, we build a lattice structure starting from the first observation that will be refined when new observations will be detected. This refinement will be computed by extracting a sub-lattice (a new refined recognition space) from the initial lattice structure, and so on.

3. RECOGNITION OF ACTIVITIES IN A SMART HOME

The DOMUS[1] lab consists of a standard apartment with a kitchen, living room, dining room, bedroom, and bathroom that are equipped with sensors, smart tags (RFID), location and identification systems for objects and people, audio and video devices, etc. As we can see on the right of the Figure 1, we developed a graphical tool (here showing the kitchen) that allows us to simulate the activation of the various environment sensors by clicking on the corresponding graphical objects, where most of devices are monitored and controlled through a Crestron-based infrastructure. Basic events are generated by sensors as shown on the left of this figure, and are directly sent to low-level activity recognition (LAR) agent which owns a virtual representation of the habitat's environment encoded in a description logic knowledge base described with PowerLoom [11]. When new inputs are received from hardware sensors, the LAR agent updates the state of the habitat and creates an action structure, representing the changes that happened to the environment, according to our model of action described in [3]. Thereafter, the LAR agent notifies the High-Level Recognition (HLR) agent (cognitive assistant) that a new low-level action is detected and it sends the action's type. To be able to plan a future assistance task, the HLR agent must initially understand patient's intentions by building a minimal interpretation model describing his plausible intentions at this specific moment. This model takes the form of a lattice built following a cooking scenario, as shown in the bottom right of Figure 1. The recognition space is composed of all the plans that can be classified between the lattice infinimum and supremum, such as $\{$*WashDish*, *PrepareTea*, *WashDish*∇*PrepareTea*, *WashDish*Δ*PrepareTea*, I_1, $I_2\}$ according to the observed action o_1 detected by LAR agent, in this case, only one action

[1]The DOMUS lab is sponsored by the Natural Sciences and Engineering Research Council of Canada (NSERC) and by the Canadian Foundation for Innovation (CFI).

of the *GoToKitchen* type, such as $O = \{GoToKitchen(o_1)\}$. The lattice infinimum corresponds to $(x \circ GoToKitchen)$, which enables us to generate, by the substitution process of the action variable x and the disunification-composition operations on the incomparable possible plans, two new consistent intentions $I_1(GoToKitchen \circ StartWashing \circ GetWater)$ and $I_2(GoToKitchen \circ GetWater \circ StartWashing)$ that did not exist beforehand in *P*, as shown in the bottom right of Figure 1. In this context, the smart home would be authorized to perform an action of assistance, like reminding the occupant of the procedure to achieve I_1 in the event of a memory lapse (i.e. Alzheimer's disease).

4. RELATED WORKS

Several approaches have been followed to explore solutions to keyhole plan recognition, such as the probabilistic approach of [1][4], the learning approach of [8][10] and the logical approach of [7][12]. The probabilistic methods, primarily based on the Bayesian networks [1] and on the Dempster-Shafer theory [4], use a set of probabilistic rules enabling to update the probability attributed to each plausible hypothesis following an observation. The conclusion drawn from the recognition process by the system is simply the hypothesis having the highest probability. The weakness of the probabilistic approaches stems from the heuristic methods, dependent on the context, used to compute the probability of each competing hypothesis [4]. The learning approaches of [8][10] seek to identify patterns from the observed actions in order to build a probabilistic predictive model of the observed agent behaviour. The main limitation of this kind of approaches is due to the fact that the generalization learned rule might lead to inconsistent behaviour and to a very large amount of training data. The logical approaches of Kautz [7] and Wobke [12] are closer to our work. In these two theories, the observer starts with a collection of plan schemas, forming an interconnected abstraction/decomposition hierarchy expressing the plan library of the observer agent. This hierarchy is represented as axioms in first-order logic and it is supposed to be complete, i.e., it contains the set of all the actions that may be observed. Kautz proposes a set of hypotheses (exhaustiveness, disjointedness, component/use, minimum cardinality), based on McCarty's circumscription theory, for the hierarchy of actions. These hypotheses take the form of inference rules that enable to extract a minimal covering model of interpretation from the hierarchy, for the observed actions. The weakness of Kautz's approach comes from the fact that all plans inferred as possible through the covering model are considered equiprobable. Wobke [12] has proposed a solution to this limitation using situation theory. His proposal, based on Kautz's work, consists of defining a partial order relation between plans and organize the elements of the hierarchy that are defined in terms of situations, by level of plausibility. This classification enables him to draw more refined conclusions than those of Kautz by retaining only the most plausible class among the possible plans. A significant limitation of Wobke's work is created by the situation semantic (a particular case of possible worlds semantic) for which the formal apparatus is complex to make operational in a real context. Finally, these previously explored approaches supposed that the observed actions are induced by the same intention, even if those may be carried out for different purposes.

5. CONCLUSION

This paper has proposed an non-analytical approach, based on lattice theory and action description logic, for re-examining the main issues surrounding the problem of formalizing plan recognition. This combined approach provides a viable solution to plan recognition problems by minimizing uncertainty about the prediction of the observed agent's behaviour. This is achieved by dynamically generating implicit intentions resulting from intra-dependencies existing between possible plans. It should be emphasized that this initial framework is not meant to bring exhaustive answers to the issues raised by the multiple problems related to plan recognition. However, it can be considered as a first step towards developing a complete formal plan recognition theory, based on the classification paradigm. It should bring effective solutions to concrete problems such as the recognition of ADL in a smart home and the problem of completing the plans library, which indeed cannot be complete in any domain.

ABSTRACT

Wireless sensor networks are often difficult to program and unable to adapt to a changing environment. Mobile agent middleware promises to address both concerns by providing higher-level programming abstractions and the ability to inject new agents into a preexisting network. The unique characteristics of wireless sensor networks like resource scarcity and emphasis on spatial locality require new algorithms for controlling agent behavior. This paper presents a procedure for one specific behavior: network exploration. Network exploration is needed by many tasks ranging from simple data collection to network health monitoring. Our proposed procedure uses a genetic algorithm to determine the number of agents and their itineraries, followed by techniques for in-network adaptation to unpredictable situations like node failure. This paper presents a genetic algorithm and its adaptation strategies. The procedure is evaluated using a wireless sensor network consisting of 25 Mica2 motes running Agilla, a mobile agent middleware for wireless sensor networks.

1. INTRODUCTION

Wireless sensor networks (WSNs) have attracted tremendous interest in recent years as embedded systems, microsensors, and batteries improve. A WSN consists of numerous sensors (motes) embedded within the environment that autonomously form wireless ad hoc networks. By increasing the density and scale of traditional sensing systems, a WSN enables users to gain unprecedented levels of context-awareness. Current applications for WSNs include structural and habitat monitoring [6, 5] and fire fighting [2], etc.

Due to the nature of WSNs (nodes are faulty and resource-constraint) developers are confronted with a bewildering set of conflicting requirements, mostly related to software flexibility and efficiency. For example, many WSNs are deployed for long periods of time virtually guaranteeing that the user requirements will change. Unfortunately, most WSNs run statically installed software that is loaded prior to deployment, limiting network adaptivity to the tweaking of predefined parameters. Another conflicting property stems from the fact that WSNs are expected to cover a wide geographic area servicing many users that need to run different programs.

Mobile agents offer a solution to the problems mentioned above. Unlike traditional programs, mobile agents are capable of migrating across the network carrying code and state. As they migrate, they perform application-specific tasks like taking sensor readings, performing in-network data aggregation, and coordinating with other agents to achieve a common goal. This enables the development of fluid applications capable of adapting to the intricacies of WSNs (see an example of a fire tracking scenario in [2]). Mobile agents also allow WSNs to be dynamically reprogrammed by enabling users to inject new agents into the network and allowing old ones to die. Furthermore, they allow multiple applications to co-exist since multiple agents may reside on each node (for an example, see [4]).

Before mobile agents can be effectively used in a WSN, new algorithms must be created for controlling their behavior. One topic of particular interest is *network exploration*. The goal of network exploration is to visit every node and to do so efficiently in terms of time and energy. This paper addresses the specific issue of sensor network exploration using multiple mobile agents. Network exploration is used in many applications including data collection, network diagnostic and health monitoring, residual energy scanning, topology discovery, and global reprogramming. Network exploration requires that every region of the sensor network be visited at least once in a manner that is efficient in terms

of energy consumption and latency. The order and number of visitations does not matter, though redundant visitations in general decrease efficiency and should be limited. The goal of the network exploration procedure is to determine the number of agents and each of their itineraries, and the techniques for dealing with unexpected in-network circumstances, e.g., changes in topology.

2. PROBLEM DEFINITION

Using multiple mobile agents to explore a WSN offers the benefits of flexibility, load distribution, and asynchronous operation. However, since WSNs are large and resource-constrained, these mobile agents must be designed to minimize energy utilization. Furthermore, application requirements dictate that real-time guarantees be met. This section introduces the necessary notation, formulates a minimization problem, and presents a solution.

2.1 WSN Model and Assumptions

A WSN consists of numerous nodes, each containing a set of sensors, microcontroller, external memory, radio transceiver, and power source. Nodes can sense real-world phenomena, perform local computations, store information, receive data, and transmit data. Receiving and transmitting data costs more energy than performing local computations. Moreover, we assume that the WSN is connected to the rest of the world via a single base station called the *collection point*. Finally, we assume that the amount of time an agent spends processing data at each node and the time it takes to migrate is predictable. In practice, such information may be estimated based on empirical measurements (see section 4), where the measured *time per node* includes the processing, migration, and sleeping time. This knowledge is necessary to ensure that the network is explored within a certain time.

2.2 Problem Formulation

Given a sensor network, Ω, with a single collection point, the goal is to explore the entire network by visiting every region within bounded time while minimizing energy consumption. This can be done using multiple mobile agents operating autonomously and in parallel following unique routes. These routes must start and end at the collection point.

Many applications do not need every node to be visited, especially if the nodes are physically close. For example, it may not be necessary to visit two nodes separated by just one meter if the task is to determine the average temperature along a path. To account for this, we introduce a density variable d which specifies how many of the nodes within the network need to be visited for the network to be considered explored. Specifically, a network is considered explored if all nodes $m \in \Omega$ have either been visited, or have a neighbor within d hops that has been visited. Note that if $d = 0$, the exploration problem reduces to one where every node needs to be visited.

The time constraint t is specified by the maximum length of a path, expressed as the number of nodes. We do not use an actual time since the amount of time an agent spends on each node, and the amount of time it takes an agent to migrate, is predictable.

The cost of an agent, a, visiting a node, m, following a certain path, p, is denoted $C_a(m,p)$. It is defined in terms of the weight of the agent, $W_a(m,p)$, and the amount of energy remaining on the node, E_m, as follows:

$$C_a(m,p) = \frac{W_a(m,p)}{E_m} \tag{1}$$

Note that as the amount of energy available on a node increases, the cost decreases and vice-versa. This is necessary to balance the residual energy of the nodes and thereby extend the lifetime of the network.

The weight of agent a, $W_a(m,p)$, is a function that returns the weight, in bytes, of agent a, when visiting node m, following path p. The weight of an agent depends on the size of its code and the amount of data that it carries. The size of its code is fixed, whereas the size of the data varies every hop and depends on what the application does upon visiting each node.

Finally, let P be the set of all paths and P_m be the set of paths that include node m, where $P_m \subseteq P$, we can formulate the following minimization problem:

$$\texttt{min} \left(\sum_{m \in \Omega} \sum_{p \in P_m} \frac{W_a(m,p)}{E_m} \right) \tag{2}$$

such that $\forall p \in P : |p| \leq t$ and the WSN is covered with density d.

3. A GENETIC ALGORITHM SOLUTION

Given the problem's complexity and the size of the search space($O(2^{2^{3t}})$), a heuristic is necessary. In addition, the sensor network's topology may change due to nodes running out of energy, desynchronizing, or being affected by external forces (e.g., being moved by the wind). Continuously monitoring the network topology is energy consuming. Thus, in order to solve the formulated minimization problem defined by equation 2, we propose a procedure containing two phases: an initial route planning phase done by a genetic algorithm and an in-network route adaptation phase that is done by each agent autonomously after it has been injected into the network.

Figure 1 contains the pseudo-code of the genetic algorithm (GA). It takes as input the definition of a sensor network Ω (i.e., the topology), the time constraint t (i.e., the maximum number of nodes of the longest route), the density d, and the specification of the varying size of the agents $W_a(m,p)$. The outcome is the number of agents and their routes, such that the collection is achieved in an energy-aware manner and within a time deadline. The GA can be divided into the following subparts: *Generation of initial population*, *Crossing*, *Mutation*, *Selection*, and *Adding of new individuals*.

```
01: GeneticAlgorithm(Ω,d,t,Wa(m,p))
02:    CreateInitialPopulation(N);
03:     For generation=1 to MaxGenerations
04:        Cross();
05:        Mutate();
06:        NaturalSelection();
07:        AddNewIndividuals(I);
08:     endFor
09:    return AgentRoutes
10: endGeneticAlgorithm
```

Figure 1: The Genetic Algorithm

Generation of initial population and the addition

of new individuals: An initial set, P, of solutions is generated. These solutions are a collection of random paths that cover the network, and are generated by repeatedly calculating paths until the whole network, Ω, has been covered with a density of d. Each path is selected by starting at the collection point and iteratively selecting a random neighbor until the collection point is reached again. Only those neighboring nodes whose minimum distances (in number of hops) to the collection point are not greater than the remaining time will be selected. Since the time constraint is expressed as the maximum number of nodes per path, comparing a nodes distance to the collection point with the deadline is trivial. All feasible neighbors are equally likely to be selected, and the initial size of P, $|P|$, is a design parameter.

Crossing and Mutation: At every iteration, a new generation is added to P by selecting x individuals to be crossed. Two individuals are crossed by taking a portion of each individual's math and combining them to form a new individual. Depending of how those individuals are selected, and which portion of their paths are crossed, new more efficient paths may be formed. Mutation is done by crossing an individual with itself.

Evaluation and Selection: All solutions are evaluated by the function being minimized in 2. Upon evaluation, $k_n\%$ of the worst individuals are randomly selected and removed from the population. Note that to avoid loosing the best solutions generated, the five best solutions are never removed, irrespective of k_n.

3.1 In-Network Route Adaptation

Since the topology of WSNs changes, mobile agents must adapt their routes during runtime. In particular, if an agent cannot successfully migrate from the ith node of its route, to the $(i+1)^{th}$, it incrementally tries to migrate to the jth node such that $j > (i+1)$. Given a dense WSN, it is likely that at least one of the nodes that follow the $(i+1)^{th}$ node on the agent itinerary will be in the ith node's radio range, which allows the agent to resume its exploration. Furthermore, if the underlying mobile agent middleware supports multihop routing (e.g., geographic routing) such as Agilla [3], this solution is even more robust since an agent can migrate to any node in the WSN regardless of distance.

4. EVALUATION

To evaluate our system, we deployed it on an a wireless sensor network consisting of 25 Mica2 motes [1]running Agilla [3], a mobile agent middleware. Having a real implementation allowed us to define realistic $W_a(m,p)$ functions and empirically determine a translation from the deadline expressed in seconds to the maximum number of hops per path.

We measured the actual amount of time agent migration takes. We ran three different experiments with $t = 13$, 22, and 26. The GA generated twenty-five initial solutions, executed for five iterations, and added five new solutions every iteration thereafter. For each experiment, we averaged the three runs and plotted the percent of the network explored versus time. The results are shown in Figure 2.

As expected, Figure 2 shows that the genetic algorithm produces faster results with less variance when the maximum path length is more restrictive (shorter). With a time constraint of $t = 13$, 22, and 26, mobile agents spent an average of 14s, 22.33s, and 24s in the WSN, respectively. The

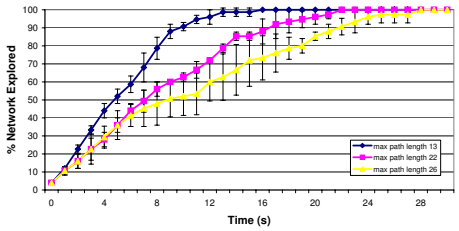

Figure 2: Percent Network Explored vs. Time

average time it takes to move an agent one hop is $1.233s$.

5. CONCLUSIONS

Software for WSNs needs to be more flexible. Mobile agents can provide this flexibility, but new algorithms are needed to control agent behavior. This paper addresses network exploration defined as visiting enough nodes in the network to achieve a certain level of coverage. We present a genetic algorithm that determines the number of agents necessary to explore the network and their paths. It includes contingency plans to account for the dynamic nature of WSNs. We show through experiments on a real WSN that our procedure is effective and that it is able to explore the network within the set deadline, while keeping energy consumption in check.

1. INTRODUCTION

Partially observable stochastic games (POSGs) provide a powerful framework for modeling multi-agent interactions. While elegant and expressive, this framework has been shown to be computationally intractable [1]. An exact dynamic programming algorithm for POSGs has been developed recently, but due to high computational demands, it has only been demonstrated to work on extremely small problems. Several approximate approaches have been developed [3, 5], but they lack strong theoretical guarantees. In light of these theoretical and practical limitations, there is a need to identify special classes of POSGs that can be solved tractably.

One dimension along which computational gain can be leveraged is by exploiting the independence present in the problem dynamics. In this paper, we examine a class of POSGs where the agents only interact loosely by restricting one another's available actions. Specifically, rather than having fixed action sets, each agent's action set is a function of the global state. The agents are independent from one another otherwise, i.e. they have separate transition and reward functions that do not interact. This class of problems arises frequently in practice. Many real world domains are inhabited by self-interested agents that act to achieve their individual goals. They may not affect each other in any way, except for occasionally putting restrictions on what each other can do.

The best-known solution concepts in game theory are that of computing Nash equilibrium and performing strategy elimination. Our work addresses both of these solution concepts. First, we show that finding a Nash equilibrium where each agent achieves reward at least k is NP-hard. Then, we present the MAAE algorithm, an exact algorithm that performs iterated elimination of dominated strategies. It is able to tackle much larger problems than algorithms for the general class by exploiting the independence among agents.

2. FORMAL MODEL

In this section, we will present a formal definition of our model. An n-agent POSG with state-dependent action sets can be defined as $\langle\{S_i\},\{s_i^0\},\{A_i\},\{B_i\},\{P_i\},\{R_i\}\rangle$, where,

- S_i is the state space of agent i. $S = S_1 \times S_2 \times \ldots \times S_n$ denotes the joint state set.
- $s_i^0 \in \Delta(S_i)$ is the initial state distribution of agent i.
- A_i is the action set of agent i. $A = A_1 \times A_2 \times \ldots \times A_n$ denotes the joint action set.
- $B_i : S \rightarrow 2^{A_i}$ is the available action function that maps a joint state to the set of available actions for agent i. $B_i(s) \subset A_i$ for all $s \in S_i$.
- $P_i : S_i \times A_i \times S_i \rightarrow [0,1]$ is the transition function of agent i. The joint transition function is completely factored, where $P((s'_1 \ldots s'_n) \mid (s_1 \ldots s_n),(a_1 \ldots a_n)) = \prod_{i=1}^{n} P_i(s'_i|s_i,a_i)$.
- $R_i : S_i \times A_i \rightarrow \Re$ is the reward function for agent i. This states that the rewards of the agents depend only on the local state and the action taken by agent i.

DEFINITION 1. *A* local policy π_i *of agent i is a mapping from local states and available action sets $\langle s_i, B_i(s)\rangle$ to actions in the available action set $B_i(s)$. The joint state s is a tuple of local states, where s_i denotes the local state of agent i. A* joint policy, $\pi = \langle\pi_1 \ldots \pi_n\rangle$, *is defined to be a tuple of local policies, one for each agent.*

There are several key differences between our model and the general POSG model. First, the power of our model comes from the *available action function*, B, which maps joint states to available actions for each agent. Secondly, our

model does not have an observation function. Each agent has a complete view of its own local state. Partial observability arises as a result of an agent's limited view of the the states of *other* agents but not of its own. Finally, the local policy of each agent is no longer a function of the local state only but a function of the available action set as well.

Here is an example of a POSG with state-dependent action sets. Two autonomous rovers are exploring an unknown terrain and collecting rock samples. There is a river with a narrow bridge on it that only allows one rover to pass at a time. To simplify the illustration, we will assume the rovers have two states {*on land, on bridge*}, and three actions each {*move, get on bridge, pick up rock*}. The rovers receive reward for the number of rocks picked up. The state-dependent action set is used to constrain the rover's actions such that only one is allowed on the bridge at a time. For example, the available actions for rover 1 are specified as follows, $B_1(\langle s_1 = \textit{on land}, s_2 = \textit{on land}\rangle)$ = {*move, get on bridge, pick up rock*}, $B_1(\langle s_1 = \textit{on land}, s_2 = \textit{on bridge}\rangle)$ = {*move, pick up rock*}, and analogously for rover 2.

3. COMPLEXITY

We state our decision problem, denoted as POSG-NE, as follows: given a POSG with state-dependent action sets, $G = \langle \{S_i\}, \{s_i^0\}, \{A_i\}, \{B_i\}, \{P_i\}, \{R_i\}\rangle$, does there exist a Nash equilibrium where all agents have expected utility at least k?

THEOREM 1. *POSG-NE is NP-hard even in problems involving 2 agents and a horizon of 2.*

Proof: We will present a reduction from NFG-NE, a known NP-hard problem [2]. This is the problem of determining the existence of a Nash equilibrium where all agents have expected utility at least k in a 2-agent normal form game, $N = \langle \Sigma_1, \Sigma_2, U_1, U_2\rangle$.

The basis for the reduction rests on the observation that normal form games can be thought of as degenerate POSGs in which each agent only has one state and is allowed to take only one action from that state. When encoding the utility function of the normal form game using constructs in our problem, the challenge lies in the fact that the utility is specified as a function of the actions of *both* agents, whereas, in our model, both the transition and the reward function only have access to the *local* state and action.

To solve this problem, we add auxiliary states to memorize the action taken at each state. We also add composite actions to the action set that corresponds to all possible pairs of actions by each agent. The state-dependent action set restricts the legal actions from the auxiliary states to be the single composite action that corresponds to the pair of actions taken by the agents. The reward for taking the composite action simply corresponds to the utility of the pair of component primitive actions in the normal form game. Therefore, there exists a Nash equilibrium where all agents have expected utility at least k in the POSG if and only if the same is true in the normal form game. □

4. THE MAAE ALGORITHM

We present an algorithm that performs iterated elimination of dominated strategies. The algorithm is able to work directly with the compact representation of a POSG without first converting it to the double exponentially large normal form representation. In this algorithm, first, we first fix the action sets of each agent at each state to the optimistic and pessimistic action sets. The idea behind this is that although an agent cannot predict exactly what actions will be available at each state, it can find out what actions would be available in the best and worst case scenario. In the best case, none of the actions that can be restricted by the state of the other agents are, and in the worst case, all of the actions that can be restricted are in fact unavailable.

For each agent i:

1. For each state s_k, compute the optimistic and pessimistic action sets. Here, $D = \{s \mid s^i = s_k^i\}$.

$$A_{opt}(s_k^i) = \bigcup_{s \in D} B_i(s)$$

$$A_{pes}(s_k^i) = \bigcap_{s \in D} B_i(s)$$

2. Compute the value functions of the 2 MDPs that correspond to alternately fixing the available action sets to the A_{opt} and A_{pes}.

$$U(s) = \max_{a \in A_{opt}(s)} \left[R(s,a) + \sum_{s'} P(s'|s,a) U(s') \right]$$

$$L(s) = \max_{a \in A_{pes}(s)} \left[R(s,a) + \sum_{s'} P(s'|s,a) L(s') \right]$$

3. For each action in each state, derive upper and lower bounds on the action value from the value function bounds $U(s)$ and $L(s)$.

$$Q_U(s,a) = R(s,a) + \sum_{s'} P(s'|s,a) U(s)$$

$$Q_L(s,a) = R(s,a) + \sum_{s'} P(s'|s,a) L(s)$$

4. At each state, eliminate all actions a' whose action value is dominated by another action a, $Q_L(s,a) \geq Q_U(s,a')$.

5. Repeat steps 1 to 4 until no more actions can be eliminated at any state.

Table 1: The iterated action elimination algorithm.

Once we fix the available action sets of each agent at all the states, the agents no longer depend on each other in any way. Our model decomposes to a set of MDPs. For each agent, we solve two MDPs, one using the optimistic action sets and the other using the pessimistic action sets. The solutions will provide us with an upper and a lower bound on the actual value function of each agent. With these upper and lower bounds on the expected values of each state, we can now derive bounds on the expected action values. At each state, dominated actions are pruned. We iterate the action elimination procedure until no more actions can be pruned. Since the number of actions at each state is finite, the procedure will eventually converge.

THEOREM 2. *The iterated action elimination algorithm corresponds to the iterated elimination of very weakly dominated strategies.*

5. EXPERIMENTS

We tested the algorithm on two domains involving machine maintenance and autonomous rover exploration. In manufacturing settings, factories frequently have to make maintenance and repair decisions. The question is how to weigh these two decisions at different stages of the machine life-cycle so as to minimize the likelihood of a machine malfunction.

The detailed specifications for the problem are as follows. There are ten factories, or agents, each owns and operates a machine. Routine maintenance is performed on site. When the machine becomes very old, they need to be serviced by the machine's manufacturer who could only take on one job at a time. This resource constraint is modeled by our state dependent action sets. The state space of each agent is characterized by the current life-cycle of its machine {*new, worn, old, broken*}. Each year, the factory examines the current state of the machine and makes one of the following decisions: *do nothing*, *perform maintenance* or *make repairs*.

Furthermore, each factory has its own reward function. A sample reward function is as follows. There is a high cost, $100,000 associated with a catastrophe (machine breaking while in operation). The factory makes a profit of $5,000 each year when the machine is in operation. Machine maintenance cost $1,000 while repairs cost $10,000. The goal is to maximize the factory's profit.

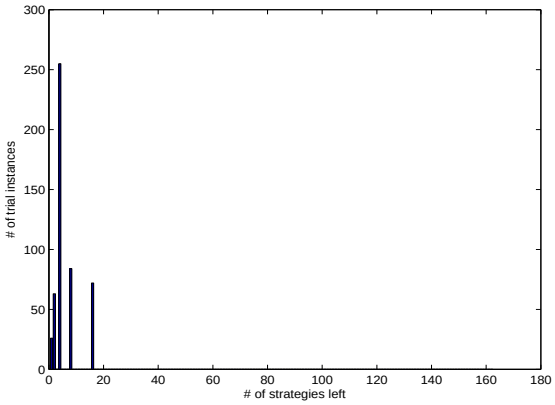

Figure 1: Machine maintenance problem: the distribution of the size of the policy set after the MAAE algorithm is run.

We performed 500 trials by randomly choosing the reward functions of each of the agents. The maintenance costs are chosen in the ranges of $1,000 to $10,000; the cost of a catastrophe ranges from $50,000 to $100,000; finally, the cost of repairs ranges from $10,000 to $50,000. The qualitative trends we found actually correspond well to our intuition. When the machine is relatively new, most of the policies would recommend to do nothing. Unless the penalty for a machine breaking is very high, in which case it adopts a more conservative approach of performing maintenance.

As the machine ages, the algorithm tries to weight the cost of maintenance and repairs. Overall, the MAAE algorithm drastically reduces the size of the policy space. The number of policies before pruning is 162 per agent, while the the number of policies after the algorithm is run, averaged over all trials, is 6. The distribution of the number of policies over all trial runs can be seen in Figure 1 below.

Aside from the large policy space reduction, another key advantage of this algorithm is that it scales well with the number of agents. There are ten agents in this experiment while the general POSG algorithm, due to its high computational demands, has so far only been shown to be effective on 2 agent problems [4]. Next, we tested the MAAE algorithm on a problem with much a larger state space. We examine how the size of the state space and the level of interaction affect the efficiency of the algorithm.

# states	before pruning	after pruning
6	972,000	13
8	34,992,000	168
9	2.1×10^8	69
12	4.5×10^{10}	774
16	5.9×10^{13}	2,198

Table 2: Average size of the policy space before and after action elimination for problems with 3 constrained states.

The second test domain is a simplified 2-agent autonomous rover exploration scenario. The size of each agent's local state space varies from 6 to 16. We introduced up to three constrained states in each agent's state space. 100 trials were run for each size of state space and number of constraints. Table 2 shows detailed results for problems with three constrained states. For problems with one and two constrained states, the final policy space ranges from 3 to 106 and 8 to 252 respectively. In all three cases, the iterated action elimination algorithm is able to reduce the size of the policy space by several orders of magnitude.

ABSTRACT

In multi-agent planning, cooperation is a crucial interaction to reduce plan costs and complexities in order to satisfy non-conflicting goals. However, it is not generally natural to sacrifice from the autonomy of agents by letting agents share all of their local plans. Resource based planning is a planning framework similar to logic based planning based on resources and skills that map to states and actions of world state. Resource based planning is very functional in processing plan elements to find cooperation schemas. In this work we extended the simple resource based plan coordination method proposed by Tonino,et al [2]. Our framework provides not only a basis for modifying plan elements, but also functionality for manipulating plans dynamically. A negotiation algorithm using a resource based perspective provides the necessary ground for forming cooperation among agents. We illustrated the effectiveness of the proposed method on a modified postman domain, where agents try to minimize the cost of delivering the letters they are assigned.

Applications of Autonomous Agents and Multi-agent Systems, Multi-agent Planning, Cooperation and coordination Among Agents

1. INTRODUCTION

Planning is one of the classical, but popular research areas in Artificial Intelligence. If we consider a simple autonomous agent, we desire it to have its own judgement and decision mechanism by the definition of autonomy. Thus a simple autonomous agent should construct her own plan regardless of the framework used or the environment it acts in. Classical AI planners are designed for this sole purpose. However in multi-agent domains individual decisions are rarely enough for producing optimal plans for satisfying all the goals. The global optimum is nearly impossible with pure autonomy, so is individual optimum. Therefore, agents need to cooperate to generate the best multi-agent plan through sharing tentative solutions, exchanging subgoals, or having other agents to satisfy their goals.

The simplest approach to generate a multiagent plan is generating a single plan for all agents. The plan could be generated by a central authority. This perspective might be applicable for agent colonies where a vast number of agents have a single goal, but for autonomous agents with different, possibly conflicting goals, this approach is inadequate.

If the autonomy of the agents is vital for the application, a central planning unit is inappropriate regardless of the success of the plans it produces. It would be more effective if agents generate their plans independently and interact with each other during the execution to revise their plans in case of contingencies, or new goals.

Tonino et al. developed a resource based multi-agent planning method[2] similar to traditional planning. However the representation schema used allows sub-goals and plan elements to be processed as resources that can be exchanged, removed from and inserted into plans.

In this work, we extend the resource based planning framework to handle dynamic goals and complex interaction requirements that exist in many real-life problems. We applied the proposed approach to the modified postman problem where agents (postmen) are required to deliver a predetermined set of letters to some destinations. The domain is dynamic in that, besides the initial letters, agents are required to collect and deliver letters at specified locations in real-time. In order to keep their individual plan costs or total global cost nearly optimal, the agents should cooperate upon new goals by undertaking/exchanging subgoals. We propose a new cooperation mechanism independent of domain properties to handle real-time goals.

2. RESOURCE BASED PLAN FRAMEWORK

The resource based plan framework uses resources and skills instead of states and operators used by traditional planners. A resource is a real or abstract object used or produced by actions of agents. A skill is simply an action of

an agent. A skill instance in a plan represents an application of a skill. Application of a skill consumes some resources and produces new resources. Consumed and produced resources might be identical.

Using these two concepts a plan can be represented by a bipartite directed graph. Resources are represented by resource nodes and skills are represented by skill nodes. Initial world state and the goal state are represented as two sets of resources. Initial resources are consumed by a plan in order to produce goal resources. Figure 1 shows an example plan graph where circles denote the resource nodes, squares denote the skill nodes and directed arcs denote consumption or production of a resource by a skill.

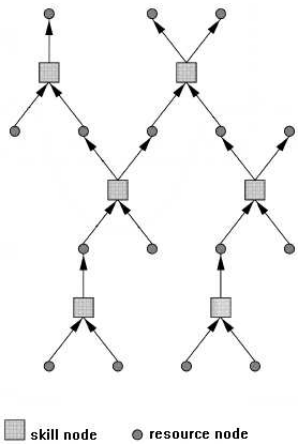

Figure 1: An example single agent Resource Based Plan Graph.

The graph representation is used for determining possibilities of cooperation between agents. Note that each skill produces resources. Some of these resources are goal resources, some are consumed by other skills and some are just side effects of the plan. We can safely remove a skill from a plan graph if we can find a way to generate the same resources that this skill produces.Tonino discusses a plan revision schema based on this principle[2].

They provide a simple protocol for compensation. This framework proves to be successful in establishing cooperation and generating a collaborative plan where total and individual costs of the plan are reduced as much as possible. The framework is applied to a transportation problem where trucks carry goods between cities. In the collaborative plans produced, trucks share routes and goods they carry, thus costs are reduced to minimum for the simple route topologies. However there are some issues that framework is not sufficient.

Although the framework is independent of the problem domain, it is not effective for domains having large state space. The selected application domain (transportation example) possesses a dense and small graph and hence agents produce many side effect resources which can be used by other agents. In most domains, producing extra resources may be cheap, but not trivial. A mechanism to enforce agents producing side effect resources is necessary.

Secondly, the framework mainly transfers the side effect resources of one agent to other relevant agents. There is also a need to finely tune this resource exchange. The simplest form of a collaboration is to transfer a useless resource from the acceptor to the proposer. There are domains in which no useless resource exists and thus it is not possible to simply transfer the resources, which increases the plan cost. The collaboration should allow the exchange of resources whose cost can be assessed by each of the agents participating in the exchange.

Our framework is designed to provide solution to these problems and improve the original framework in technical and theoretical levels. The details of our framework are given in the following sections.

3. DYNAMIC RESOURCE BASED COOPERATION FRAMEWORK

The postman problem is one of the classical example domains for multi-agent research[1, 3]. We changed the classical postman problem as follows. First, agents are required to collect letters from some locations and deliver them to the desired locations. A letter is represented with a source node (possibly the post office) and a destination node. Moreover, the final destination of agents is changed from post office to any node in the graph. It is shown in [1] that if the final destination node is post office, i.e., delivery of all letters is a cycle, then there may be trivial interaction schemas independent of the letter set. By changing the final destination to be any node, we prevent such trivial interactions.

When a new goal is assigned to an agent, possible choices are

- The goal can be already satisfied by the current plan,
- Another agent can satisfy the goal and
- The agent can modify her plan to satisfy the goal.

It is apparent that a rational agent selects one of the feasible alternatives in the order given above. If the new goal is already satisfied by the current plan without additional cost, then the plan is slightly revised to satisfy this new goal. Otherwise the agent computes the cost of modifying the current plan to satisfy the new goal. If the modification is costly, then the agent interacts with others to see whether she can benefit from any cooperation, or not. The cooperation alternative which does not bring additional cost is selected and agents involved in the cooperation revise their plans accordingly.

When an agent asks for another agent to handle one of her goals, the second agent attempts to handle the whole goal alone if it does not bring an extra cost. If this request cannot be satisfied, the proposer agent breaks the goal into subgoals and repeats the same process. In our framework, we have realized only one level decomposition but the this can further be extended to any level easily.

The acceptor agent could simply accept to satisfy the request, deny the request or accept to satisfy only some of the subgoals of the request. Moreover, the agent may satisfy the request because of two reasons; her plan might already satisfy the request with trivial modification or the requested goal might be inserted into her plan with modification which does not increase agent's cost. This structural decomposition of goals in decision making leads to a more interesting and fine tuned cooperation mechanism as we will illustrate in examples.

The acceptor might accept the request with the condition that the proposer handles one or some of the goals of the acceptor. To do this, agents could adopt their plans to partition the total goal set into meaningful subsets. In our system, an acceptor might request from a proposer to deliver one of her letters that contributes most to the cost of her plan.

In the previous section, we mentioned that there is need for a mechanism that is capable of producing side effect resources. We make use of a credibility metric in order to have this effect. Agents have credibility on each other. In case the proposer requests a new task from the acceptor, the acceptor will accept to satisfy this request if the cost of the modification in the acceptors' plan is less than or equal to the credibility of the proposer on the acceptor.

These are the salient features added into the original resource based framework [2]. The following sections describe and exemplify the proposed framework taking into consideration the domain properties.

4. APPLICATION OF DYNAMIC RESOURCE BASED PLANNING TO POSTMAN DOMAIN

Our framework starts with an initial planning phase where each agent constructs a plan for collecting and delivering the letters assigned to her. These plans are constructed independently and hence they do not take into consideration potential cooperations.

The initial plan computation algorithm has exponential complexity in terms of number of letters. The calculation of all pair shortest path and constructing the final path are all polynomial. However, an exhaustive search is necessary to find a minimum hamiltonian path on the constructed graph, which takes exponential time in terms of the number of nodes in the temporal ordering graph which is roughly equal to two times the number of letters.

In the plan graph each skill has a cost. Delivery and collection skills have unit cost, while cost of going from one node to another is naturally the weight of the edge between two nodes. In our framework we used four resources and five skills. Resources are:

- **Connected-Resource** that represents connectivity of graph nodes.
- **Location-Resource** that represents location of an agent.
- **Have-Letter-Resource** that represents having a letter.
- **Delivered-Letter** that represents having delivered a letter.

Skills are:

- **Go-Skill** that represents going from one node to another.
- **Collect-Skill** that represents collecting a letter.
- **Deliver-Skill** that represents delivering a letter.
- **Exchange-From-Skill** that represents getting a letter at rendezvous.
- **Exchange-To-Skill** that represents giving a letter at rendezvous.

Agents have initial credibility on each other. This credibility corresponds to utility concept as we discussed previously. We used a simple scalar credibility measure and set it to an empirical value. If an agent satisfies the request of another agent, she lowers other agent's credibility. The reduction amount is simply the cost of the request for the acceptor agent. The credibility value is chosen such that a given number of trivial deliveries could be handled.

In our work we used a negotiation protocol where agents propose bids for requests. The bids may also include counter proposals and counter requests. By negotiating, agents try to undertake requests for tasks if it is profitable for them. Since negotiation involves counter requests and the agent's utility is based on credibility measure, there are several possible outcomes of the negotiation, some of them increasing cost of a party slightly. For example if the whole task cannot be accepted by any other agent, the agent seeks alternatives to decompose the goal into subgoals .

If the agents agree on cooperation through exchanging letters, a rendezvous should be arranged to transfer the letter. We used an explicit rendezvous concept to build parts of the plan graph to denote that the agents meet at an agreed location and exchange the letter. The negotiation phase includes the arrangement of this rendezvous.

5. CONCLUSION AND FUTURE WORK

We attempted to extend the resource based planning framework of Tonino et.al. Our primary motivation was to extend this framework to allow contingency planning especially for realistic real life problems. The most important feature of this work is to use negotiation to revise plans to handle new goals. Refining the plans in real-time is vital if agents are faced with new goals in real-time. The framework is also designed to be robust, thus more complex interaction schemas can be introduced. For example in an auction based domain, agents might prefer to participate in auctions rather than negotiation. Different interaction mechanisms would result in interesting variations of the framework.

The proposed framework uses a novel representation and modeling schemas for effectively capturing and using distinguished features of more realistic domains. We used a simple utility measure to realize credibility of agents which could be generalized further. This simple measure is sufficiently functional for our example domain. If the agent interactions are more complex, each agent should have better models of others.

ABSTRACT
In this paper we propose a real-time search algorithm called Real-Time Target Evaluation Search (RTTES) for the problem of searching a route in grid worlds from a starting point to a static or dynamic target point in real-time. The algorithm makes use of a new effective heuristic method which utilizes environmental information to successfully find solution paths to the target in dynamic and partially observable environments. The method requires analysis of obstacles to determine closed directions and estimate the goal relevance of open directions in order to identify the most beneficial move. The environment is assumed to be a planar grid and the agent has limited perception. In this paper, we compared RTTES with Real-Time A* (RTA*) and Real-Time Edge Follow (RTEF), and observed a significant improvement.

Categories and Subject Descriptors
I.2 [**Artificial Intelligence**]: Problem Solving, Control Methods, and Search

General Terms
Algorithms, Performance, Experimentation

Keywords
Path planning, Grid world, Real-time search, Heuristic search
