Path planning can be described as finding a path from an initial point to a target point if there exists one. Path planning algorithms are either off-line or on-line. Off-line algorithms find the whole solution in advance before starting. These algorithms suffer from execution time in dynamic or partially observable environments due to frequent re-planning requirements. In on-line case, an agent repeatedly plans its next move in limited time and executes it, but they are not designed to be optimal and usually find poor solutions with respect to path length. Furthermore, there exist some hybrid solutions such as incremental heuristic search algorithms that are more efficient than off-line path planning. However, they are still slow for some real-time applications and are not applicable to moving targets. There are some on-line algorithms trying to overcome these difficulties. For instance, Real-Time Edge Follow (RTEF) [16, 17] uses a powerful heuristic function that can discard some non-promising alternative moving directions in real-time to guide the agent to a static or dynamic target. Although RTEF is able to determine the closed (non-promising) directions successfully, it is weak in selecting the right move from the rest of the alternatives since it uses poor Euclidian distance heuristic. Therefore, we focused on a new method for better selection.

In this paper, we propose a real-time search algorithm, Real-Time Target Evaluation Search (RTTES), and a heuristic method, Real-Time Target Evaluation (RTTE) capable of estimating distance to the target considering the obstacles. The method sends rays away from the agent in four directions, and determines obstacles that the rays hit. For each such obstacle, we extract its border and determine best direction that avoids the obstacle. Finally, by using a resolution mechanism, one of the proposed directions is chosen.

In the next section, the related work is given. In section 3, RTTES is described in brief. The performance analysis is presented in section 4. And finally, the conclusion is given in section 5.

2. RELATED WORK
Optimal [11, 14] and probabilistic [2, 4, 7, 9, 10] off-line path planning algorithms are hard to use for large dynamic environments because of their time requirements. One solution is to make off-line algorithms to be incremental [5, 6, 12, 13] to avoid re-planning from scratch. Although incremental algorithms are efficient in most cases, sometimes a small change in the environment may cause to re-plan almost from scratch. Due to the efficiency problems of off-line techniques, a number of on-line approaches such as Learning Real-Time A* (LRTA*), Real-Time A* (RTA*) [8], Real-Time Horizontal A* (RTHA*) [15], Execution Extended Rapidly Exploring Random Trees [1], and PRM with Kinodynamic Motion Planner [3] are proposed.

Recently, a new on-line path search algorithm (Real-Time Edge Follow - RTEF) [16, 17] is proposed for grid-type environments. RTEF uses a new heuristic (RTEF-ARM) that effectively makes use of global environmental information. With this heuristic, the agent can detect closed directions (directions that cannot reach the target) using perceptual data and tentative map, and determine its next move from open directions. Experimental study shows that RTEF performs better than RTA* and RTA* with n-look-ahead depth in terms of solution path and execution time [17].

3. RTTES & RTTE

We assume that the environment is a planar grid and is partially known by the agent. The agent located at a particular cell is required to reach a target cell avoiding obstacles in real-time. At any step, agent can move north, south, east or west, and is able to maintain a tentative map in its memory while exploration.

RTTES uses the heuristic method RTTE, which analyzes obstacles and proposes moving directions to reach the target through approximately short paths avoiding the obstacles. For this, RTTE geometrically analyzes the obstacles nearby and tries to estimate lengths of paths around obstacles to reach the target. To avoid infinite loops and re-visiting the same locations redundantly, RTTES uses two mechanisms (*visited count grid* & *history*). *Visited count grid* is a 2D matrix storing the number of visits to the cells, and *history* is the set of previously visited marked cells. History cells are assumed to be obstacle. When exploring an unknown environment, the agent may realize that all the ways leading to the target are blocked. In such a case the history should be cleared in order to let the agent backtrack as history cells may cause this. RTTES repeats the following steps until reaching the target or detecting that the target is inaccessible:

1) Use RTTE to compute proposed direction and utilities of neighbor cells
2) If a direction is proposed by RTTE:
   a) Select the neighbor cell with the highest utility from the set of non-obstacle neighbors with the smallest visited count
   b) Move to the selected direction, increment the visited count of the previous cell by one, and insert the cell into the *History*
3) Else if *History* is not empty, clear all the *History*
4) Else destination is unreachable, stop the search with failure.

The RTTE algorithm works as follows:

1) Mark all the moving directions as open
2) Propagate four rays away from the agent to north, south, east and west
2) For each ray hitting an obstacle:
   a) Trace and extract the border of the obstacle
   b) Analyze the border by re-tracing it from left and right sides
   c) Detect closed directions
   d) Evaluate results and determine a direction to avoid obstacle
3) Merge individual results, propose a direction to move, and compute utilities of neighbor cells

As seen above, RTTE propagates four rays from the agent location to north, south, east and west directions, and analyzes the obstacles these rays hit to find out the best direction to move. If a ray hits an obstacle before exceeding the maximum ray distance, the obstacle border is extracted by tracing cells on the border starting from the hit-point. Next the border is re-traced from both left and right sides to determine the geometric features of the obstacle. The closed moving directions are determined similar to RTEF [17]. The obstacle features are evaluated and a moving direction to avoid the obstacle is identified. After all the obstacles are evaluated, the results are merged in order to propose a final moving direction.

4. PEFORMANCE ANALYSIS

In this paper, we compared RTTES with RTA* and RTEF on randomly generated sample grids. We used RTTES and RTEF with two variations: "VC" that only uses visited counts and "VCH" that uses both history and visited counts. Thus, we tested five algorithms: RTTES-VC, RTTES-VCH, RTEF-VC, RTEF-VCH and RTA*. We used grids of three different types: *random*, *maze* and *U-type* with size 200x200. *Random* grids are generated randomly based on different obstacle ratios. *Maze* grids are the ones where every two non-obstacle cells are always connected through a path (usually one path). *U-type* grids are created by randomly putting U-shaped obstacles. We assume that the agent has limited vision (called *visual depth v)* and perceives only the grid cells within the square region *(2v+1)*(2v+1)* centered at agent's location. We take the visual depth as 20 or *infinite* (*full vision*) which means the agent knows the entire grid world in advance.

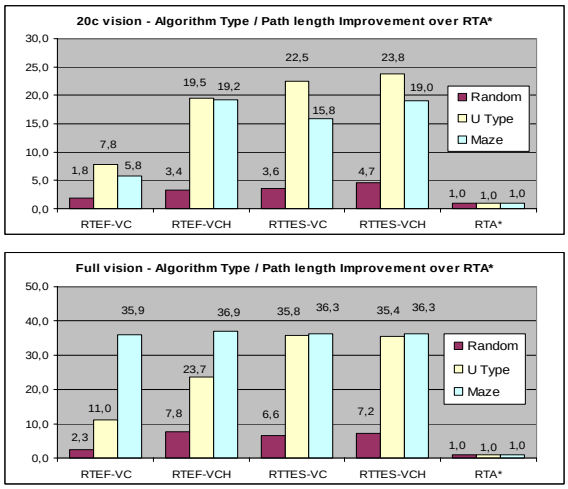

Figure 1. Path Length comparison of 20 cell and full vision

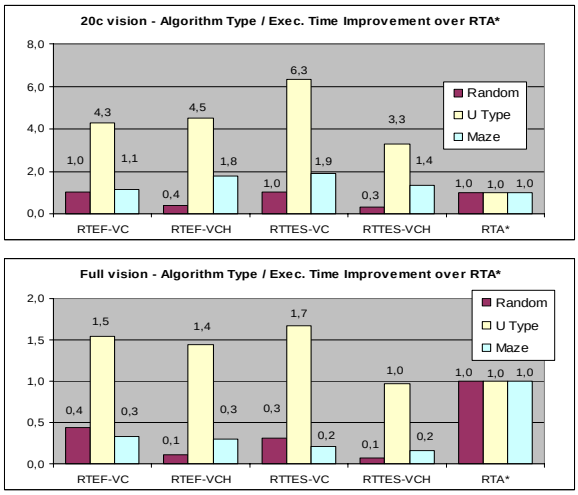

Figure 2. Execution Time comparison of 20 cell and full vision

Figure 1 contains test results that show improvements over RTA* in path length (i.e., path length of RTA* divided by these of compared algorithms) for different grid types. We observed that RTEF and RTTES performed significantly better than RTA* all the time. In random grids, RTEF-VCH and RTTES variations were almost head to head. In maze grids, all the RTEF and RTTES variations performed almost the same with full vision. With 20 cell vision, the results of RTEF-VCH and RTTES-VCH were very close to each other, and they performed better than RTEF-VC and RTTES-VC on the average. In U-type grids, the

results of RTTES variations were almost the same, and they performed better than RTEF variations on the average.

Figure 2 contains comparison of total execution times of previous runs similarly. We report ratios in terms of execution times taking RTA* as basis. In random grids with 20 cell vision RTEF-VC, RTTES-VC and RTA* performed almost the same, and were better than RTEF-VCH and RTTES-VCH. In random grids with full vision, RTA* is better since the efficiency of RTEF and RTTES usually drop in fully known grids. In maze grids, RTEF-VCH and RTTES-VC performed similarly, and were better than the others with 20 cell vision. With full vision, RTA* is better. In U-type grids, RTEF and RTTES usually performed much better than RTA*. The results of RTTES-VC were the best among all.

We also compared the path length of the algorithms with the optimal solutions generated by A* in fully known grids. The ratios of the algorithms' solution path lengths over optimal paths lengths are presented in Tables 1-2. The results show that solutions of both RTTES variations were only 1.14 times longer than the optimal ones on the average, whereas the solutions of RTEF-VC, RTEF-VCH and RTA* were 4.39, 1.5 and 33 times longer respectively. The standard deviations of RTTES algorithms were significantly less than RTEF algorithms. And we see that best improvement was obtained in U-type grids.

Table 1. Average ratios of algorithms' path lengths over optimal path lengths

	RT-VC	RT-VCH	RTTES-VC	RTTES-VCH	RTA*
Average	4,394	1,501	1,142	1,140	33,022
Standart Deviation	8,555	1,068	0,194	0,169	50,417

Table 2. Average ratios of algorithms' path lengths over optimal path lengths in random, U-type, and maze grids

	RT-VC	RT-VCH	RTTES-VC	RTTES-VCH	RTA*
Random Grids	3,577	1,432	1,369	1,339	10,532
Maze Grids	1,967	1,346	1,078	1,081	37,800
U-Type Grids	10,467	1,903	1,113	1,123	39,141

5. CONCLUSION

In this paper, we have focused on real-time search for grid-type problems, and presented an effective heuristic method (RTTE) and a real-time search algorithm (RTTES).

We have compared RTA*, RTEF and RTTES with the help of 1600 test runs. With respect to the path length, experimental results showed that RTTES is able to make use of environmental information very successfully to improve the solutions. In U-type grids, RTTES discovers much shorter paths compared to RTEF and RTA*. In random and maze grids, RTTES and RTEF are almost head to head, and both are much better than RTA*. With respect to execution time, we have observed that RTTES-VC is highly efficient in U-type grids. In random and maze grids, RTEF and RTTES almost perform the same, but it is hard to say about RTA* since the results change much depending on the vision range. With limited vision, the agent knows less about its environment, which increases the efficiency of RTEF and RTTES, and makes them perform usually better than RTA*. The performance decrease in case of unlimited vision is due to the fact that the agent knows more than it requires. We have also seen that RTTES converges to almost optimal solutions in fully known grids with respect to path length.

ABSTRACT

In this paper we propose a run-time approach to organization that is contingent on the task structure of the problem being solved and the environmental conditions under which it is being solved. We use TÆMS as the underlying representation for our problems and describe a framework that uses Organizational Self-Design (OSD) to allocate tasks and resources to the agents and coordinate their activities.

1. INTRODUCTION

In this paper, we are primarily interested in the organizational design of a multiagent system — the roles enacted by the agents, the coordination between the roles and the number and assignment of roles and resources to the individual agents. The organizational design is complicated by the fact that there is no best way to organize and all ways of organizing are not equally effective[1]. Instead, the optimal organizational structure depends both on the problem at hand and the environmental conditions under which the problem needs to be solved. The environmental conditions may not be known *a priori* or may change over time, which would preclude the use of a static organizational structure. On the other hand, all problem instances and environmental conditions are not always unique which would rule out the use of a new, bespoke organizational structure for every problem instance.

In our approach we use Organizational Self-Design (OSD) to dynamically alter the organizational structure of the agents. We define two operators for OSD — agent spawning and composition — when an agent becomes overloaded, it spawns off a new agent to handle part of its task load/responsibility; when an agent lies idle for an extended period of time, it may decide to compose with another (underloaded) agent.

Our work builds on the work by [2]. The primary difference between their work and our work is that we use TÆMS [3] as the underlying representation for our problems. TÆMS is a computational framework that uses annotated hierarchical task networks (HTNs) to allow quantitative reasoning over the task structures. TÆMS allows us to explicitly reason about alternative ways of doing a task, arbitrary ways of combining subtasks, uncertainties, quality/cost tradeoffs, and non-local effects and is hence more general than the approach used by [2].

2. ORGANIZATIONAL SELF DESIGN

2.1 Agent Roles and Relationships

As explained in Section 1, the organizational structure is primarily composed of roles and the relationships between the roles. One or more agents may enact a particular role and one or more roles must be enacted by every agent. The roles may be thought of as the parts played by the agents enacting the roles in the solution to the problem and reflect the long-term commitments made by the agents in question to a certain course of action (that includes task responsibility, authority, and mechanisms for coordination). The relationships between the roles are the coordination relationships that exist between the subparts of a problem.

In our approach, the organizational design is directly contingent on the task structure and the environmental conditions under which the problems need to be solved. We define a role as a TÆMS subtree rooted at a particular node. Note, by definition, a role may consist of one or more other (sub-) roles as a particular TÆMS node may itself be made up of one or more subtrees. Hence, we will use the terms role, task node and task interchangeably.

We, also, differentiate between local and managed (non-local) roles. Local roles are roles that are the sole responsibility of a single agent, that is, the agent concerned is responsible for solving all the subproblems of the tree rooted at that node. For such roles, the agent concerned can do one or more subtasks, solely at its discretion and without consultation with any other agent. Managed roles, on the other hand, must be coordinated between two or more agents

as such roles will have two or more descendent local roles that are the responsibility of two or more separate agents. We achieve this coordination by assigning one of the agents as the manager responsible for enacting the non-local role. This manager is responsible for making the coordination decisions, often in consultation with the agents enacting the descendent sub-roles of that particular non-local role.

2.2 Organization Formation and Adaptation

To form or adapt their organizational structure, the agents use two organizational primitives: agent spawning and composition. These two primitives result in a change in the assignment of roles to the agents. Agent spawning is the generation of a new agent to handle a subset of the roles of the spawning agent. Agent composition, on the other hand, is orthogonal to agent spawning and involves the merging of two or more agents together — the combined agent is responsible for enacting all the roles of the agents being merged. Hence, OSD can be thought of as a search in the space of all the role assignments for a suitable role assignment that minimizes or maximizes a performance measure

In order to participate in the formation and adaption of an organization, the agents need to explicitly represent and reason about the role assignments. Hence, as a part of its organizational knowledge, each agent keeps a list of the local roles that it is enacting and the non-local roles that it is managing. Note that each agent only has limited organizational knowledge and is individually responsible for spawning off or combining with another agent, as needed, based on its estimate of its performance so far.

To see how the organizational primitives work, we first describe four rules that can be thought of as the organizational invariants which will always hold before and after any organizational change:

1. For a local role, all the descendent nodes of that role will be local.
2. Similarly, for a managed (non-local) role, all the ascendent nodes of that role will be managed.
3. If two local roles that are enacted by two different agents share a common ancestor, that ancestor will be a managed role.
4. If all the direct descendants of a role are local and the sole responsibility of a single agent, that role will be a local role.

When a new agent is spawned, the agent doing the spawning will assign one or more of its local roles to the newly spawned agent. To preserve invariant rules 2 and 3, the spawning agent will change the type of all the ascendent roles of the nodes assigned to the newly spawned agent from local to managed. Note that the spawning agent is only changing its local organizational knowledge and not the global organizational knowledge. At the same time, the spawning agent is taking on the task of managing the previously local roles. Similarly, the newly spawned agent will only know of its just assigned local roles.

When an agent (the *composing* agent) decides to compose with another agent (the *composed* agent), the organizational knowledge of the composing agent is merged with the organizational knowledge of the composed agent. To do this, the composed agent takes on the roles of all the local and managed tasks of the composing agent. Care is taken to preserve the organizational invariant rules 1 and 4.

2.3 Reasons for Organizational Change

As organizational change is expensive (requiring clock cycles, allocation/deallocation of resources, etc.) we want a stable organizational structure that is suited to the task and environmental conditions at hand. Hence, we wish to change the organizational structure only if the task structure and/or environmental conditions change. Also to allow temporary changes to the environmental conditions to be overlooked, we want the probability of an organizational change to be inversely proportional to the time since the last organizational change. If this time is relatively short, the agents are still adjusting to the changes in the environment - hence the probability of an agent initiating an organizational change should be high. Similarly, if the time since the last organizational change is relatively large, we wish to have a low probability of organizational change.

To allow this variation in probability of organizational change, we use simulated annealing to determine the probability of keeping an existing organizational structure. This probability is calculated using the annealing formula: $p = e^{-\frac{\Delta E}{kT}}$ where ΔE is the "amount" of overload/underload, T is the time since the last organizational change and k is a constant. The mechanism of computing ΔE is different for agent spawning than for agent composition and is described below. From this formula, if T is large, p, or the probability of keeping the existing organizational structure is large.

Agent spawning only occurs when the agent doing the spawning is too overloaded and cannot complete all the tasks in its task queue by the given deadlines of the tasks. To compute if spawning is necessary, we use the annealing equation with $\Delta E = \frac{1}{\alpha * Slack}$ where α is a constant and *Slack* is the difference between the total time available for completion of the outstanding tasks and the sum of the expected time required for completion of each task on the task queue.

Agent composition, on the other hand, is exactly orthogonal to agent spawning as agent composition only occurs when the agents are underloaded. In such a situation, some of the agents will be sitting idle waiting for tasks to arrive. These idle agents will either be utilizing resources while waiting, or more likely, will have resources allocated to them that could be used elsewhere in the system. In either case, it makes sense to combine some of the idle agents with other agents freeing precious resources.

To calculate if agent composition is necessary, we again use the simulated annealing equation. However, in this case, $\Delta E = \beta * Idle\_Time$, where β is a constant and $Idle\_Time$ is the amount of time for which the agent was idle. If the agent has been sitting idle for a long period of time, ΔE is large, which implies that p, the probability of keeping the existing organizational structure, is low.

3. EVALUATION

To evaluate our approach, we ran a series of experiments that simulated the operation of both the OSD agents and the Contract Net agents on various task structures with varied arrival rates and deadlines. At the start of each experiment, a random TÆMS task structure was generated with a specified depth and branching factor. During the course of the experiment, a series of task instances arrive at the organization and must be completed by the agents before their specified deadlines.

To directly compare the OSD approach with the Contract

Net approach, each experiment was repeated several times — using OSD agents on the first run and a different number of Contract Net agents on each subsequent run. We were careful to use the same task structure, task arrival times, task deadlines and random numbers for each of these trials.

We divided the experiments into two groups: experiments in which the environment was static (fixed task arrival rates and deadlines) and experiments in which the environment was dynamic (varying arrival rates and/or deadlines).

The two graphs in Figure 1, show the average performance of the OSD organization against the Contract Net organizations with 8, 10, 12 and 14 agents. The results shown are the averages of running 40 experiments. 20 of those experiments had a static environment with a fixed task arrival time of 15 cycles and a deadline window of 20 cycles. The remaining 20 experiments had a varying task arrival rate - the task arrival rate was changed from 15 cycles to 30 cycles and back to 15 cycles after every 20 tasks. In all the experiments, the task structures were randomly generated with a maximum depth of 4 and a maximum branching factor of 3. The runtime of all the experiments was 2500 cycles.

We tested several hypotheses relating to the comparative performance of our OSD approach using the *Wilcoxon Matched-Pair Signed-Rank* tests. *Matched-Pair* signifies that we are comparing the performance of each system on precisely the same randomized task set within each separate experiment. The tested hypothesis are:

The OSD organization requires fewer agents to complete an equal or larger number of tasks when compared to the Contract Net organization: To test this hypothesis, we tested the stronger null hypothesis that states that the contract net agents complete more tasks. This null hypothesis is rejected for all contract net organizations with less than 14 agents (static: $p < 0.0003$; dynamic: $p < 0.03$). For large contract net organizations, the number of tasks completed is statistically equivalent to the number completed by the OSD agents, however the *number of agents* used by the OSD organization is *smaller*: 9.59 agents (in the static case) and 7.38 agents (in the dynamic case) versus 14 contract net agents. Thus the original hypothesis, that OSD requires fewer agents to complete an equal or larger number of tasks, is upheld.

The OSD organizations achieve an equal or greater average quality than the Contract Net organizations: The null hypothesis is that the Contract Net agents achieve a greater average quality. We can reject the null hypothesis for contract net organizations with less than 12 agents (static: $p < 0.01$; dynamic: $p < 0.05$). For larger contract net organizations, the average quality is statistically equivalent to that achieved by OSD.

The OSD agents have a lower average response time as compared to the Contract Net agents: The null hypothesis that OSD has the same or higher response time is rejected for all contract net organizations (static: $p < 0.0002$; dynamic: $p < 0.0004$).

The OSD agents send less messages than the Contract Net Agents: The null hypothesis that OSD sends the same or more messages is rejected for all contract net organizations ($p < .0003$ in all cases except 8 contract net agents in a static environment where $p < 0.02$)

Hence, as demonstrated by the above tests, our agents perform better than the contract net agents as they complete a larger number of tasks, achieve a greater quality and also have a lower response time and communication overhead. These results make intuitive sense given our goals for the OSD approach. We expected the OSD organizations to have a faster average response time and to send less messages because the agents in the OSD organization are not wasting time and messages sending bid requests and replying to bids. The quality gained on the tasks is directly dependent on the number of tasks completed, hence the more the number of tasks completed, the greater average quality. The results of testing the first hypothesis were slightly more surprising. It appears that due to the inherent inefficiency of the contract net protocol in bidding for each and every task instance, a greater number of agents are needed to complete an equal number of tasks.

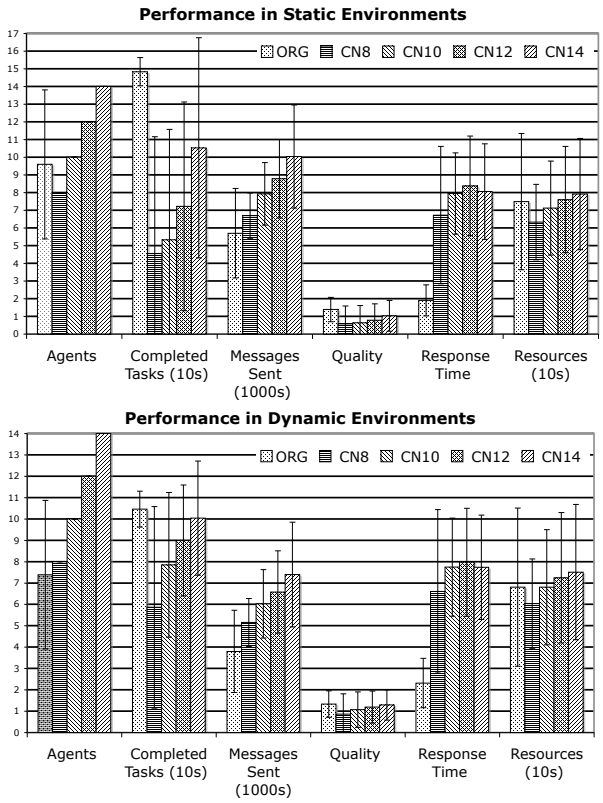

Figure 1: Graph comparing the average performance of the OSD organization with the Contract Net organizations (with 8, 10, 12 and 14 agents). The error bars show the standard deviations.

ABSTRACT

As users interact with an increasing array of personal computing devices, maintaining data consistency across those devices becomes more dif cult. Typical solutions assume access to centralized servers, continual connectivity, or unbounded storage and CPU capacity. In practice, users' devices vary widely in capabilities, use intermittent or sparsely-connected networks and incur (asymmetric) transfer costs. We present a multi-agent system built upon a decision-theoretic approach to constructing and executing multiple plans to achieve consistency in a peer-to-peer, partially observable, non-deterministic environment. We analyze the performance in comparison to a standard epidemic replication algorithm.

1. INTRODUCTION AND MOTIVATION

We consider the problem of transparently ensuring that a user's data remains consistent across all her devices. We construct a *Personal Information Environment* (PIE), a virtual data space not tied to any one physical device. This provides the user the illusion that every le is available on every device all the time.

Users could try to use a single storage unit (such as a USB key or iPod) to store their les, mounting it on any device they are currently using. There are several problems with this approach. First, it requires the user to carry the storage unit and plug it in to every device she uses. If the user forgets to plug it in she will be unable to access her les. Second, these devices often have less than 2GB of storage, so only a subset of the user's les may t.

Alternatively the user could synchronize with a central le server; however, many devices have only intermittent connectivity. Even users with broadband connections can be behind a rewall, making it dif cult for the home (or work) device to be a le server.

When we move toward a decentralized automated solution, several dif cult problems arise. We must know the les the user will need on any particular device. The topology of the device network is not known and may change as devices come and go. Further, devices may not have a xed IP address or may reside behind rewalls. In this situation, the role of limited capacity devices such as PDAs and cell phones frequently on a user's person becomes that of a crucial vessel to transfer data. This turns out to be a problem of propagating information in a resource-constrained, distributed and peer-to-peer non-stationary network that is only locally observable.

Described this way, the problem seems hopeless; however, we have several advantages. First, users are often at least locally predictable. They cannot be in many places at once, allowing time to move data between devices. Second, a limited number of les are touched in a given day and the number of devices is quite small so the problem admits practical computational tractability.

In our approach each device identi es important data it might possess, other devices that need that data, and constructs *plans* to deliver that data (using any intermediaries). Each device adapts and updates the plans of other devices as they become aware of them.

2. RELATED WORK

One of the best-known systems for managing information on mobile devices is Coda [5]. Coda uses manually constructed or heuristically derived hoard pro les that determine which les should be replicated to which devices. Coda does not support multi-hop transfers over resource-constrained devices.

There has also been a large amount of other work on update consistency in disconnected or weakly connected networks. Examples include FICUS [8] and Thor [7] (amongst others). The goal of most of these systems is to manage updates, propagating them to a primary copy or to various clients. Our goal is somewhat different: to place cached copies of les where a user will need them as proactively as possible. Once the replicas are placed, standard techniques can be used or extended to manage consistency.

In the *joint intentions* framework [6], the implied contract between agents requires that each agent, upon obtaining knowledge of another agent's goal, assumes the goal as its own until it is achieved or it becomes irrelevant. Goal existence information and goal status information is communicated via peer-to-peer updates.

We do not explicitly represent goals like some multi-agent systems, but our agents operate in unison to achieve a globally useful if not globally consistent state with an implied contract to make their best effort to complete all multi-plans they receive. In our system, goals are represented as multi-plans . These multi-plans are sent from agent to agent along with whatever data they were constructed for. A multi-plan can become invalidated when a device receives information that there is a newer version of the data

associated with that multi-plan. This is identi ed during a *merge* process that can trigger replanning.

Because the devices that comprise a PIE have varied characteristics, it is important for agents to have some notion of the ability of their peers. [1] presents a set of criteria metrics that indicate characteristics of an agent's abilities and intentions in heterogeneous, complex planning architectures. These metrics consist are *commitment*, *responsibility*, *authority*, and *independence*. Agents in our system are all committed to joint goals; however, different types of devices in a PIE have varying levels of responsibility, authority, and independence. We describe devices using pro les that allow more powerful devices to aid in the operations for less powerful devices.

Our approach exploits the fact that the state space is limited by the number of devices in a typical PIE which allows for a brute force greedy approach. We improve over the limitations suggested by [2] of early decision-theoretic planning systems such as [9]) by de ning innovative utility functions to encode more complex information about the environment.

3. DEFINITIONS

Our goal is to place data (or les) on different devices. A *placement* is an ordered list of *unique* device IDs on which a le is to be located. For example, $l(1,2,3,4)$ is the placement corresponding to a le being located on devices 1, 2, 3, and 4. A *plan*, P_i, is an ordered list of placements: $\{l_{i,1}, l_{i,2}, ..., l_{i,k}\}$ where $l_{i,j}$ denotes the j-th placement of plan P_i. We constrain each plan so that each of its placements is a pre x of the placement that follows. A plan can be abbreviated by its nal placement (*e.g.* $P_i \equiv l_{i,k}$). Each placement has an associated *utility*; that is, there is some value to having a particular le on a particular device or set of devices. We de ne the utility of a plan from those placement utilities: $U(P_i, j)$ is the utility of the plan P_i at position j ($U(P_i, j) = U(l(i_1, i_2, ..., i_j))$)

Let $p_{i,j}$ and $c_{i,j}$ be the probability and cost of transferring some bits successfully from device i to device j respectively. Then we can calculate the *expected utility* of a plan in a straightforward way. For notational convenience, let $L(P_i, j) = \prod_{x=1}^{j-1} p_{i_x, i_{x+1}}$ be the likelihood of data reaching device i_j from device i_1 following plan P_i; let $C(P_i, j) = \sum_{x=1}^{j-1} c_{i_x, i_{x+1}}$ be the cost associated with data reaching device i_j from device i_1 following plan P_i; let $NL(P_i, j)$ be the net loss[1] of the plan P_i at its placement $l_{i,j}$; and let $NV(P_i, j) = U(P_i, j-1) - C(P_i, j-1) - NL(P_i, j)$ be the net value associated with data reaching device i_{j-1} from device i_1 but not reaching device i_j following plan P_i. The expected utility of a plan is:

$$EU(P_k) \equiv \quad EU(l(k_1, k_2, ..., k_n))$$

$$= \quad (1 - p_{k_1,k_2}) * -NL(P_k, 2) \tag{1}$$

$$+ \quad \sum_{i=3}^{n} L(P_k, i-1)(1 - p_{k_{i-1},k_i}) * NV(P_k, i) \tag{2}$$

$$+ \quad L(P_k, n) * (U(P_k, n) - C(P_k, n)) \tag{3}$$

Expression 1 is the cost of failure of the entire plan scaled by the probability of it failing during the rst step. Expression 3 offsets the utility of the success of the plan with the cost of its execution and scales it by the probability of success. Expression 2 is a similar computation to Expression 3 but it considers the effect of the plan failing at each intermediate step.

[1]In our experiments, it is the utility not realized by failing to complete the plan: $NL(P_i, j) = U(\{l_{i,j}, ..., l_{i,n}\}) = U(\{l_{i,1}, ..., l_{i,n}\}) - U(\{l_{i,1}, ..., l_{i,j-1}\})$, where n is the number of placements in a plan.

A *multi-plan* is a (ordered) set of plans: $M_i = \{P_{i,1}, ..., P_{i,n}\}$. Making an assumption about independence, we de ne the expected utility of a multi-plan to be the sum of the expected utilities of the plans it contains: $EU(M_i) = \sum_{P_k \in M_i} EU(P_k)$.

We seek a locally optimal (in expected utility) set of multi-plans to approximate a globally optimal set. Because multi-plans are constructed in a partially observable environment, it would be infeasible to consider all plan interaction. Assuming independence allows concise and computationally tractable plan construction.

We are in the process of integrating multi-plans into the Accord [3] middleware system we are developing which will enable us to derive values and costs from actual user data. Speci cally, the utility of a placement for a le is based on the af nity of that le for each of the devices in the placement, typically implemented as a linear combination of reads and writes for that le. Transfer probability is the empirical probability of the success of transferring bits. Costs are related to the actual bandwidth consumption during a transfer and the amount of a device's resources that would be consumed receiving, storing, and/or sending a le. Regardless of the speci c representation of probabilities, utilities, and costs, our algorithm will select a multi-plan to maximize expected utility.

While each placement must be considered during multi-plan construction, possible placements change very slowly and are enumerated before any connection. Similarly, utility calculation can occur of ine and incrementally. Since the values of the costs and utilities are based on information gathered from other devices, some recalculation must occur in response to new information.

Information obtained during a connection about the location of a le in the system can have two effects. First, it can indicate that the le has arrived at a destination for which there is a pending multi-plan, invalidating the multi-plan. Second, it can indicate that a device previously believed to have a le no longer does, triggering the creation of a new multi-plan. Fortunately, the number of devices tends to be small, so new muli-plans are constructed ef ciently. Additionally, we allow for short circuit evaluation of multi-plans.

Each agent in the system uses the following strategy which can be contracted to a peer device if its processing power is limited: Identify every le it contains that it believes is the most recent version and that is out of sync with other devices.[2] For each such le, construct a multi-plan to transfer the le to any device needing it. When a connection is established with another device, exchange and synchronize le location information and all multi-plans (replanning/merging if necessary). The underlying data is then transfered in decreasing order of associated multi-plan utility.

This ordering allows the agent to make a decision about which les are most important to move to a connected device. As we shall see below, the most bene t is realized when either connectivity between devices or the capacity of any crucial device is limited. When device capacity is limited, a device must decide which les and associated multi-plans to accept or reject during transfers. In our case, a limited capacity device always accepts newer versions of les it already contains, but when faced with a choice, accepts new les only if the multi-plans associated with the new le have higher utility than the lowest utility multi-plans for les already on the device. We later refer to this as the *smart eject/reject policy*.

4. BOOTSTRAPPING

We ran bootstrap simulations using ve devices with 200 and 400 les in total.Initially, les were distributed uniformly across the devices. Connections between devices intermittent not available and were randomly terminated after 3 to 10 seconds. We ran

[2]The Accord middleware provides this information.

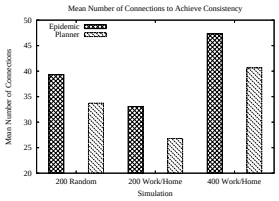

Figure 1: Performance during bootstrapping.

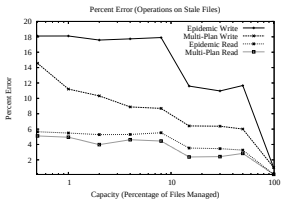

Figure 2: Performance as a function of "go between" capacity.

three sets of trials to determine performance in comparison to the epidemic replication algorithm [4], a popular mechanism for distributing data. In the epidemic model, each device simply transfers any files it has that are missing from any other device it comes in contact with. For each set of trials, the simulations were started from the same initial state and were considered complete when bootstrapping completed. For our experiments, one set of 15 trials was run with 200 files and a randomly generated connection scenario. The second set of 15 trials was run using 200 files and connection probabilities that encode a typical five device scenario: there are two machines in the work place behind a firewall, two machines at home behind a firewall, and one device that is carried between work and home that is the only means of connection between the two sets of machines. We refer to this as the bow tie scenario. The last set of 15 trials was run with 400 files and the bow tie connection scenario.

Figure 1 shows the results. There is a clear advantage to using our method in all cases. The multi-plans completed bootstrapping with an average 14.25% fewer connections for the randomly generated connection scenario, in an average of 14.08% fewer connections with 400 files, and an average of 18.95% fewer connections with 200 files and the bow tie scenario.

5. PERFORMANCE UNDER LOAD

Our simulator allows us to specify reads and writes on specific files over different periods of time.To capture meaningful *error*, we measured *stale* accesses: the number of reads and writes on files that are not the most recently modified version across all devices. In each scenario, a user travels between home and work in the bow tie. As before, the go-between is the only way to transfer data between home and work. Here, scenarios differ in the connectivity and storage characteristics of the go-between: a BlueTooth phone (low capacity, low connectivity); a BlueTooth PDA (low capacity, high connectivity when docked); and a laptop (high capacity, mixed connectivity depending on connection mode). All devices are capable of executing plans and using the smart eject/reject policy. When the epidemic is used, there is no utility data available so the limited capacity device randomly ejects files to accept new incoming files.

Scenario data was gathered over 20 trials using 1000 files. Only 450 of the files were eligible for reads and writes by the user. The capacity of the go-between device was varied from 0.05% to 100% of the number of files in the simulation. For simulations with capacity under 8%, the go-between was modeled as a cell phone; for simulations between 8% and 50%, as a PDA; for 100% capacity, as a laptop. For each test, we simulated eight days worth of user activity with a workload in which the working set of files changed after the first four days.

With the exception of the 100% capacity simulations, the multi-plans (in most cases significantly) outperformed the epidemic algorithm. With severely limited capacity (0.05%), the multi-plans did not reduce the error by as large a margin as with other capacities but still provided some benefit. In the best case (with the go-between cell phone having 8% capacity), the error rate on write operations was less than half of the error rate for the epidemic model.

6. CONCLUSION AND FUTURE WORK

We have described the problem of managing data across an array of resource-constrained devices. Because it is difficult for users to deal with this problem directly, we have argued for building a distributed support system to allow multiple agents to act on the user's behalf. We have presented motivation for the use of decision-theoretic multi-plans for file consistency management in a distributed peer-to-peer device network. We have shown that there is a distinct advantage to intelligently ordering file transfers in the presence of constrained device networks over current algorithms for distributed data replication.

Acknowledgments

We wish to thank Thomas M. Parks and Christopher Nevison for their donation of CPU time to gather data.

1. INTRODUCTION

Since the early 1990's, Markov decision processes (MDPs) and their partially observable counterparts (POMDPs) have been widely used by the AI community for planning under uncertainty. POMDPs offer a rich language to describe situations involving uncertainty about the domain, stochastic actions, noisy observations, and a variety of possible objective functions. Even though an optimal solution may be concise, current exact algorithms that use dynamic programming often require an intractable amount of space. POMDP approximation algorithms can operate with a limited amount of memory, but as a consequence they provide very weak theoretical guarantees. In contrast, we describe a new approach that addresses the space requirement of POMDP algorithms while maintaining well-defined optimality guarantees.

Current methods to find optimal fixed-size controllers rely solely on local information [5, 6], thus can give solutions that are unboundedly below the global optimum. We present a formulation that defines the optimal fixed-size controller, and we employ standard nonlinearly constrained optimization techniques in order to find POMDP policies using this formulation. The quadratic constraints and linear objective function of our formulation belong to a special class of optimization problems for which many robust and efficient algorithms have been developed. While these techniques only guarantee locally optimal solutions, the new formulation facilitates a more efficient search of the solution space and produces high-quality results. Moreover, the algorithms employ more advanced techniques than those previously used [5, 6] to avoid convergence at certain suboptimal points. Using these locally optimal techniques, we demonstrate improved controller quality for a set of large POMDPs while maintaining similar running times when compared with a current state-of-the art approach. This suggests that by using our QCLP, small, high-valued controllers can be efficiently found for a large assortment of POMDPs.

2. BACKGROUND

A POMDP can be defined as a tuple $\langle S, A, P, R, \Omega, O\rangle$, with S, a finite set of states with designated initial state distribution b_0, A, a finite set of actions, $P(s'|s,a)$, the state transition model, $R(s,a)$, the reward model, Ω, a finite set of observations, and $O(o|s',a)$, the observation model. In this paper, we consider the case in which the process unfolds over an infinite sequence of stages. At each stage the agent selects an action, which yields an immediate reward, and receives an observation. The agent must choose an action based on the history of observations seen. Because the state is not directly observed, it may be beneficial for the agent to remember the observation history. The agent's goal is to maximize the expected discounted sum of rewards received. To maintain finite sums, a discount rate, $0 \leq \gamma < 1$ is used.

Finite-state controllers are an elegant way of representing POMDP policies using a finite amount of memory. The controller can formally be defined by the tuple $\langle Q, \psi, \eta\rangle$, where Q is the finite set of controller nodes, $\psi : Q \rightarrow \Delta A$ is the action selection model for each node, and $\eta : Q \times A \times O \rightarrow \Delta Q$ represents the node transition model for each node, given an action was taken and an observation seen. We allow for stochastic transitions and action selection, as this can help to make up for limited memory [8]. The value of a node q at state s, given action selection and node transition probabilities, is provided by: $V(q,s) = \sum_a P(a|q)\big[R(s,a) + \gamma \sum_{s'} P(s'|s,a) \sum_o O(o|s',a) \sum_{q'} P(q'|q,a,o)V(q',s')\big]$ This equation is referred to as the Bellman equation.

Two previous POMDP solution techniques have sought to optimize fixed-size controllers. Poupart and Boutilier [6] have developed a method called bounded policy iteration (BPI). This approach alternates between policy improvement and evaluation, iterating through the nodes in the controller and using a linear program to examine the value of probabilistically taking an action and then transitioning into the old controller. If an improvement can be found, the action selection and node transition probabilities are updated

For variables: $x(q', a, q, o)$ and $y(q, s)$
Maximize $\sum_s b_0(s)y(q_0, s)$
Given the Bellman constraints:
$$\forall q, s \; y(q,s) = \sum_a \left[\left(\sum_{q'} x(q', a, q, o) \right) R(s,a) + \gamma \sum_{s'} P(s'|s,a) \sum_o O(o|s',a) \sum_{q'} x(q', a, q, o) y(q', s') \right]$$
And probability constraints:
$$\forall q, o \; \sum_{q',a} x(q', a, q, o) = 1, \; \forall q, o, a \; \sum_{q'} x(q', a, q, o) = \sum_{q'} x(q', a, q, o_k) \text{ and } \forall q', a, q, o \; x(q', a, q, o) \geq 0$$

Table 1: The QCLP for finding the optimal fixed-size controller. Variable $x(q', a, q, o)$ represents $P(q', a|q, o)$, $y(q, s)$ represents $V(q, s)$, q_0 is the initial controller node and o_k is an arbitrary fixed observation.

accordingly. This approach guarantees to at least maintain the value of a provided controller, but it is not likely to find a concise optimal controller. Also, while heuristics can be used to incorporate start state knowledge [7], they may be difficult to adjust and are not be applicable in all domains. Meuleau et al. [5] use gradient ascent based on a cross-product MDP created from the controller and the POMDP. Due to the complex and incomplete gradient calculation, this method can be time consuming and error prone.

3. OPTIMAL FIXED-SIZE CONTROLLERS

The linear program used by BPI may allow for controller improvement, but can easily get stuck in local maxima. While Poupart and Boutilier suggest heuristics for becoming unstuck, a nonlinear approach can allow these local solutions to be avoided. Also, since BPI requires that value is increased for all states, possible improvements are not always made. We believe that many POMDPs have small optimal controllers or can be approximated concisely. Optimization techniques permit these controllers to be found while maintaining moderate resource usage.

Unlike BPI and Meuleau et al.'s gradient ascent, our formulation defines the optimal controller for a given size. This is done by considering the values of each node and state pair variables. To ensure that these values are correct given the action selection and node transition probabilities, quadratic constraints must be added. This results in a quadratically constrained linear program (QCLP). QCLPs may contain quadratic terms in the constraints, but have a linear objective function. They are a subclass of general nonlinear programs that has structure which algorithms can exploit. Although it is often difficult to solve a QCLP exactly, many robust and efficient algorithms can be applied. Our QCLP has a simple gradient calculation and an intuitive representation that matches well with common optimization models.

Contrary to BPI, which alternates between policy improvement and evaluation, our QCLP improves and evaluates the controller in one phase. As seen in Table 1, the value of an initial node is maximized at an initial state distribution using parameters for the action selection and node transition probabilities at each node, $P(q', a|q, o)$, and the values of each node in each state, $V(q, s)$. To ensure that the values are correct given the action and node transition probabilities, nonlinear constraints representing the corresponding Bellman equations must be added to the optimization. The second and last constraints in the table ensure that the variables represent proper probabilities, and the third constraint guarantees that action selection does not depend on the observation that has not yet been seen.

THEOREM 1. *An optimal solution of the QCLP results in an optimal stochastic controller for the given size and initial state distribution.*

PROOF. The optimality of the controller follows from the Bellman equation constraints and maximization of a given node at the initial state distribution. The Bellman equation constraints restrict the value variables to valid amounts based on the chosen probabilities, while the maximum value is found for the initial node and state. Hence, this produces an optimal controller. □

4. EXPERIMENTS

For this paper, we used a freely available nonlinearly constrained optimization solver *snopt* [3] on the NEOS server. BPI was implemented in a manner very similar to the original techniques in [6]. Meuleau et al.'s gradient ascent was also implemented, but produced significantly worse results in substantially more time than the other techniques.

In our experiments, we used BPI and snopt to optimize a range of fixed-size controllers. Each method was initialized with the same ten random deterministic controllers and we report mean values and times. While the experiments were conducted on different computers, we expect solution times to only differ by a small constant factor in our experiments.

4.1 Hallway benchmark

The hallway domain introduced by Littman, Cassandra and Kaelbling [4], is a frequently used benchmark for POMDP algorithms. A robot must navigate a grid world with 57 states, 21 observations and 5 actions.

The results for this domain are shown in Table 2 and Figure 1. We see that for all controller sizes the mean value produced by the QCLP is more than twice that of BPI. Also, the time taken to produce these controllers remains similar, but the difference increases as controller size grows. It can be noted that much higher values can be produced by the

10	9.1 mins	4 mins	130.8 mins	62.8 mins

Table 2: Mean running times for the QCLP and BPI on the hallway and machine problems

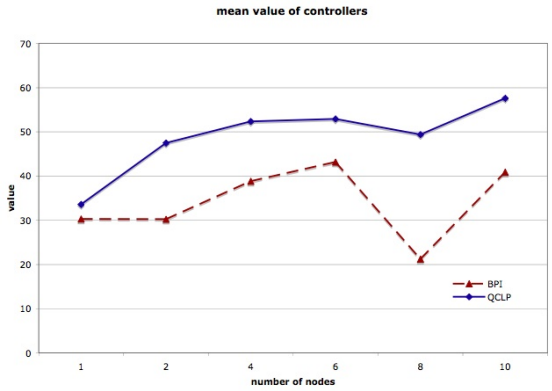

Figure 2: Machine domain: the mean values using BPI and the QCLP for increasing controller size

QCLP with markedly smaller controllers, thus reducing the time required.

Poupart and Boutilier also report results for BPI on a 1500 node controller. In their implementation, an escape technique that attempts to avoid local maxima was also used. After 69 hours, BPI produced a controller with a value of 0.51. Our QCLP formulation generates a controller with 65% higher value in 0.22% of the time with 0.67% of the representation size.

4.2 Machine maintenance

In order to test performance on a larger problem, we consider a machine maintenance domain with 256 states, 4 actions and 16 observations. For more details, see [2].

For this problem, the optimal policy for the underlying MDP is known to be 66.236. We see in Table 2 and Figure 2 that very small controllers produce solutions which are close to this upper bound. The techniques using the QCLP show higher mean values for all controller sizes than those produced by BPI. While the differences are less dramatic than the previous example, they are no less consistent. And although we again notice a disparity in running time as the number of nodes increases, we also notice that the mean value of the 10 node controller produced by BPI has lesser value and longer running time than the 2 node controller for the QCLP. This suggests that smaller controllers could replace those produced by BPI.

5. CONCLUSIONS

We introduced a new approach for solving POMDPs using a nonlinear programming formulation of the problem, which defines an optimal fixed-size stochastic controller. Near-optimal controllers can be found using standard nonlinear optimization techniques. This provides a promising new way for solving POMDPs and approximating optimal solutions with concise controllers. We showed that by using nonlinear optimization algorithms, we can produce higher valued controllers than those found by BPI, the existing state-of-the-art approach. We demonstrated empirically a consistent improvement over a range of controller sizes. We also showed that higher quality solutions can be found with significantly smaller controllers and similar running times. These results suggest that optimal or near-optimal controllers could be found for large POMDPs, making our approach very useful in a range of practical application domains.

In the future, we plan to examine the relationship between the nonlinear formulation and the performance of various optimization algorithms. Different representations may better match current nonlinearly constrained optimization methods and may thus produce better solutions. We also plan to study the applicability of the QCLP approach to problems involving multiple agents modeled as decentralized POMDPs. The BPI technique has already been generalized successfully to the multi-agent case [1]. In future work, we expect to be able to demonstrate similar performance gains in optimizing fixed-size controllers for a set of agents in large multi-agent domains.

ABSTRACT

We build on recent work on argumentation frameworks for generating desires and plans. We provide a rich instantiation of Dung's abstract argumentation framework for (i) generating consistent desires; and (ii) generating consistent plans for achieving these desires. This is done through three distinct argumentation frameworks: one (now standard) for arguing about beliefs, one for arguing about what desires the agent should adopt, and one for arguing about what plans to intend in order to achieve the agent's desires. More specifically, we refine and extend existing approaches by providing means for comparing arguments based on decision-theoretic notions (cf. utility). Thus, the *worth* of desires and the *cost* of resources are integrated into the argumentation frameworks and taken into account when comparing arguments.

1. INTRODUCTION

Various frameworks have been proposed for formalising and mechanising the reasoning of autonomous software agents based on *mental attitudes* such as beliefs, desires and intentions (BDI). These range from theoretical models of mental attitudes using modal logics [13], to operational agent architectures such as AgentSpeak [5] and 3APL [8]. A central feature of reasoning with mental attitudes is that *conflict* may arise between various attitudes.

Argumentation is a promising approach for reasoning with inconsistent information, based on the construction and the comparison of arguments [6]. The basic idea is that it should be possible to say more about the certainty of a particular fact than just assessing a probabilistic certainty degree in the interval $[0, 1]$. In particular, it should be possible to assess the reasons (i.e. *arguments*) why a fact holds, and to combine and compare these arguments in order to reach a conclusion. The process of *argumentation* may be viewed as a kind of reasoning about arguments (considering attacks and conflicts among them, comparing their strengths etc.) in order to determine the most *acceptable* of them. Various argument-based frameworks have been developed in defeasible reasoning [12] for generating and evaluating arguments.

Classicaly, argumentation has been mainly concerned with *theoretical reasoning*: reasoning about *propositional* attitudes such as knowledge and belief. Recently, a number of attempts have been made to use argumentation to capture *practical reasoning*: reasoning about what to do. This requires capturing arguments about non-propositional attitudes, such as desires and goals. Some argument-based frameworks for practical reasoning are instantiations of Dung's abstract framework [6] (e.g. [1, 3, 9]). Others are operational and grounded in logic programming (e.g. [10, 14]).

In this paper, we build on recent work on argumentation frameworks for generating desires and plans [1, 3, 9]. We provide a rich, argumentation-based framework for (i) generating consistent desires; and (ii) generating consistent plans for achieving these desires. This is done through three distinct argumentation frameworks: one (now standard) for arguing about beliefs, one for arguing about what desires the agent should adopt, and one for arguing about what plans to intend in order to achieve the agent's desires. More specifically, we refine and extend existing approaches by providing means for comparing arguments based on decision-theoretic notions (cf. utility). Thus, the *worth* of desires and the *cost* of resources are integrated into the argumentation frameworks and taken into account when comparing arguments.

The paper is organised as follows. After some formal preliminaries in the next section, we present our three integrated argumentation frameworks in Section 3. We discuss related work in Section 4 and conclude in Section 5.

2. PRELIMINARIES

In this section we start by presenting the logical language which will be used throughout this paper, as well as the different mental states of the agents (their bases).

Let $\mathcal{L}$ be a propositional language, $\vdash$ stands for classical

inference and $\equiv$ for logical equivalence. From $\mathcal{L}$ we can distinguish the three following sets of formulas:

- The set $\mathcal{D}$ which gathers all possible desires of agents.
- The set $\mathcal{K}$ which represents the knowledge.
- The set RES which contains all the available resources in a system.

From the above sets, two kinds of rules can be defined: *desire-generation* rules and *planning* rules.

DEFINITION 1. **(Desire-Generation Rules)** *A* desire-generation rule *(or a* desire rule*) is an expression of the form*

$$\varphi_1 \wedge \cdots \wedge \varphi_n \wedge \psi_1 \wedge \cdots \wedge \psi_m \Rightarrow \psi$$

where $\forall\ \varphi_i \in \mathcal{K}$ *and* $\forall\ \psi_i,\ \psi \in \mathcal{D}$.

The meaning of the rule is "if the agent *believes* $\varphi_1, \ldots, \varphi_n$ and *desires* $\psi_1, \ldots, \psi_m$, then the agent will *desire* ψ as well". And let $\texttt{head}(\varphi_1 \wedge \cdots \wedge \varphi_n \wedge \psi_1 \wedge \cdots \wedge \psi_m \Rightarrow \psi) = \psi$.

Let's now define the notion of *planning rule*, which is the basic building block for specifying plans.

DEFINITION 2. **(Planning Rules)** *A* planning *rule is an expression of the form*

$$\varphi_1 \wedge \cdots \wedge \varphi_n \wedge r_1 \cdots \wedge r_m \rightarrowtail \varphi$$

where $\forall\ \varphi_i \in \mathcal{D},\ \varphi \in \mathcal{D}$ *and* $\forall r_i \in RES$.

A planning rule expresses that if $\varphi_1, \ldots, \varphi_n$ are achieved and the resources $r_1, \ldots, r_m$ are used then φ is achieved.[1]

Let DGR and PR be the set of all possible desire generation rules and planning rules, respectively. Each agent is equipped with four bases: a base $\mathcal{B}_b$ containing its *basic beliefs*, a base $\mathcal{B}_d$ containing its desire-generation rules, a base $\mathcal{B}_p$ containing its planning rules and finally a base $\mathcal{R}$ which will gather all the resources possessed by that agent. Beliefs can be uncertain, desires may not have equal priority and resources may have different costs.

DEFINITION 3. **(Agent's bases)** *An agent is equipped with four bases* $\langle \mathcal{B}_b, \mathcal{B}_d, \mathcal{B}_p, \mathcal{R} \rangle$*:*

- $\mathcal{B}_b = \{(\beta_i, b_i) : \beta_i \in \mathcal{K}, b_i \in [0,1], i = 1, \ldots, n\}$. *Pair* (β_i, b_i) *means belief* β_i *is certain at least to degree* b_i.[2]
- $\mathcal{B}_d = \{(dgr_i, w_i) : dgr_i \in DGR, w_i \in \mathbb{R}, i = 1, \ldots, m\}$. *Symbol* w_i *denotes the* worth *of the desire* $\texttt{head}(dgr)$. *Let* $Worth(\psi) = w_i$.
- $\mathcal{B}_p = \{pr_i : pr_i \in PR, i = 1, \ldots, l\}$.
- $\mathcal{R} = \{(r_i, c_i), i = 1, \ldots, n\}$ *where* $r_i \in RES$ *and* $c_i \in \mathbb{R}$ *is the cost of consuming* r_i. *Let* $Cost(r_i) = c_i$ *be a function which returns the cost of a given resource.*

In what follows, $\mathcal{B}_b^*$, $\mathcal{B}_d^*$, $\mathcal{B}_p^*$, $\mathcal{R}^*$ will denote the sets of formulas when the weights are ignored. Using desire-generation rules, we can characterise *potential desires.*[3]

[1]Note that the implications defined in desire-generation rules and planning rules are not material. So for example, from $\neg y$ and $x \rightarrowtail y$, we cannot deduce $\neg x$.

[2]The certainty degree can be seen as a necessity measure of possibility theory.

[3]Amgoud and Kaci [3] call them "potential initial goals."

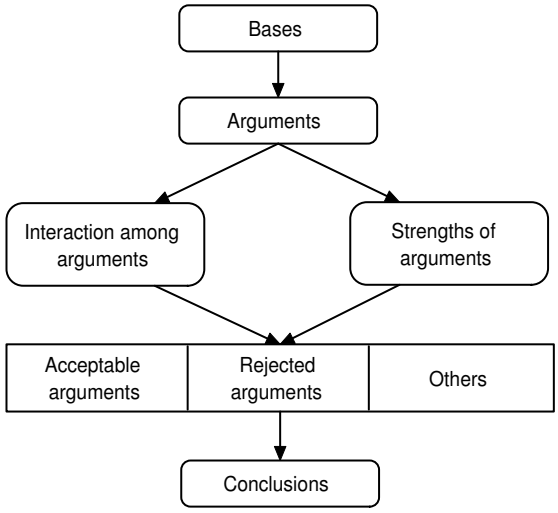

Figure 1: General view of argument-based decision making

DEFINITION 4. **(Potential Desire)** *The set of* potential desires *of an agent is* $\mathcal{PD} = \{\psi : \exists \varphi_1 \wedge \cdots \wedge \varphi_n \wedge \psi_1 \wedge \cdots \wedge \psi_m \Rightarrow \psi \in \mathcal{B}_d^*\}$.

These are "potential" desires because the agent does not know yet whether the antecedents (i.e. bodies) of the corresponding rules are true.

3. ARGUMENTATION FRAMEWORKS

The conceptual sketch of an argumentation framework is illustrated in Figure 1. It is essential to distinguish between arguing over beliefs and arguing over goals or desires. A proposition is believed because it is *true* and *relevant*. Desires, on the other hand, are adopted because they are *justified* and *achievable*. A desire is justified because the world is in a particular state that warrants its adoption. For example, one might desire to go for a walk because she believes it is a sunny day and may drop that desire if it started raining. A desire is *achievable*, on the other hand, if the agent has a plan that achieves that desire.

As a consequence of the different nature of beliefs and desires, they are supported by two different types of arguments. These arguments need to be treated differently, taking into account the different way they relate to one another. For example, a belief argument can be attacked by arguing that it is not consistent with observation, or because there is a reason to believe the contrary. Arguments for desires, on the other hand, could be attacked by demonstrating that the justification of that desire does not hold, or that the plan intended for achieving it is itself not achievable.

To deal with the different nature of the arguments involved, we present three distinct argumentation frameworks: one for reasoning about beliefs, another for arguing about what desires are justified and should be pursued, and a third for arguing about the best plan to intend in order to achieve these desires. The first framework is based on existing literature on argumentation over beliefs, originally proposed by Dung [6] and later extended by Amgoud and Cayrol [2]. For arguing about desires and plans, we draw on and extend

work on argumentation-based desire-generation and planning [1, 3, 9].

3.1 Arguing over beliefs

Using beliefs, an agent can construct *belief arguments*, which have a deductive form. Indeed, from a set of beliefs, another belief is deduced as follows:

DEFINITION 5. **(Belief Argument)** *A* belief argument *A is a pair $A = \langle H, h\rangle$ such that:*

1. *$H \subseteq \mathcal{B}_b^*$;*
2. *H is consistent;*
3. *$H \vdash h$;*
4. *H is minimal (for set $\subseteq$) among the sets satisfying conditions 1, 2, 3.*

The support *of the argument is denoted by $\texttt{SUPP}(A) = H$. The* conclusion *of the argument is denoted by $\texttt{CONC}(A) = h$. $\mathcal{A}_b$ stands for the set of all possible belief arguments that can be generated from a belief base $\mathcal{B}_b$.*

In [2, 11], it has been argued that arguments may have forces of various strengths, and consequently different definitions of the force of an argument have been proposed. Generally, the force of an argument can rely on the information from which it is constructed. Belief arguments involve only one kind of information: *the beliefs*. Thus, the arguments using more certain beliefs are found stronger than arguments using less certain beliefs. A certainty level is then associated with each argument. That level corresponds to the less entrenched belief used in the argument. This definition is also used in belief revision [7].

DEFINITION 6. **(Certainty level)** *Let $A = \langle H, h\rangle \in \mathcal{A}_b$. The* certainty level *of A is $Level(A) = min\{a_i : \varphi_i \in H$ and $(\varphi_i, a_i) \in \mathcal{B}_b\}$.*

The different forces of arguments make it possible to compare pairs of arguments. Indeed, the higher the certainty level of an argument is, the stronger that argument is. Formally:

DEFINITION 7. **(Comparing arguments)** *Let $A_1, A_2 \in \mathcal{A}_b$. The argument A_1 is* preferred *to A_2, denoted $A_1 \succeq_b A_2$, if and only if $Level(A_1) \geq Level(A_2)$.*

Preference relations between belief arguments are used not only to compare arguments in order to determine the "best" ones, but also in order to refine the notion of *acceptability* of arguments. Since a belief base may be inconsistent, then arguments may be conflicting.

DEFINITION 8. **(Conflicts between Belief Arguments)** *Let $A_1 = \langle H_1, h_1\rangle, A_2 = \langle H_2, h_2\rangle \in \mathcal{A}_b$.*

- *A_1* undercuts *A_2 if $\exists h_2' \in H_2$ such that $h_1 \equiv \neg h_2'$.*
- *A_1* attacks$_b$ *A_2 iff A_1 undercuts A_2 and not ($A_2 \succeq_b A_1$).*

Having defined the basic concepts, we are now ready to define the argumentation system for handling belief arguments.

DEFINITION 9. **(Belief Argumentation framework)** *An* argumentation framework *AF_b for handling belief arguments is a pair $AF_b = \langle \mathcal{A}_b, Attack_b\rangle$ where $\mathcal{A}_b$ is the set of belief arguments and $attack_b$ is the defeasibility relation between arguments in $\mathcal{A}_b$.*

Since arguments are conflicting, it is important to know what are the "good" ones, generally called *acceptable*. Beliefs supported by such arguments will be inferred from the base $\mathcal{B}_b$. Before defining the notion of acceptable arguments, let's first introduce a crucial notion of defence.

DEFINITION 10. **(Defence)** *Let $S \subseteq \mathcal{A}_b$ and $A_1 \in \mathcal{A}_b$. S* defends *A_1 iff for every belief argument A_2 where A_2 $attacks_b$ A_1, there is some argument $A_3 \in S$ such that A_3 $attacks_b$ A_2.*

An argument is acceptable either if it is not attacked, or if it is defended by acceptable arguments.

DEFINITION 11. **(Acceptable Belief Argument)** *A belief argument $A \in \mathcal{A}_b$ is* acceptable *with respect to a set of arguments $S \subseteq \mathcal{A}_b$ if either:*

- *$\nexists A' \in S$ such that A' $attacks_b$ A; or*
- *$\forall A' \in S$ such that A' $attacks_b$ A, we have an acceptable argument $A'' \in S$ such that A'' $attacks_b$ A'.*

This recursive definition enables us to characterise the set of acceptable arguments using a fixed-point definition.

PROPOSITION 1. *Let $AF_b = \langle \mathcal{A}_b, Attack_b\rangle$ be an argumentation framework. And let $\mathcal{F}$ be a function such that $\mathcal{F}(S) = \{A \in \mathcal{A}_b : S$ defends $A\}$. The set $Acc(\mathcal{A}_b)$ of* acceptable belief arguments *is defined as: $Acc(\mathcal{A}_b) = \bigcup \mathcal{F}_{i\geq 0}(\emptyset)$*

PROOF. Due to the use of propositional language and finite bases, the argumentation system is finitary, i.e each argument is attacked by a finite number of arguments. Since the argumentation system is finitary then the function $\mathcal{F}$ is continuous. Consequently, the least fixpoint of $\mathcal{F}$ is $\bigcup \mathcal{F}_{i\geq 0}(\emptyset)$. □

The set $Acc(\mathcal{A}_b)$ contains non-attacked arguments as well as arguments defended directly or indirectly by non-attacked ones.

3.2 Arguing over desires

Amgoud and Kaci have introduced *explanatory arguments* as a means for generating desires from beliefs [3]. We extend this framework in this section and refine it in order to resolve some problematic features caused by the fact that they combine belief argumentation with desire argumentation in a single framework. Moreover, we consider more general desire generation rules in the sense that a desire may not only be generated from beliefs as in [3], but it can also be generated from other desires.

In what follows, the functions $\texttt{BELIEFS}(A)$, $\texttt{DESIRES}(A)$ and $\texttt{CONC}(A)$ return respectively, for a given argument A, the beliefs used in A, the desires supported by A and the conclusion of the argument A.

DEFINITION 12. **(Explanatory Argument)** *Let $\langle \mathcal{B}_b, \mathcal{B}_d\rangle$ two bases.*

- *If* $\exists(\Rightarrow \phi) \in \mathcal{B}_d^*$ *then* $\Rightarrow \phi$ *is an* explanatory argument *(A) with:*
  $\texttt{BELIEFS}(A) = \emptyset$
  $\texttt{DESIRES}(A) = \{\phi\}$
  $\texttt{CONC}(A) = \phi$

- *If* $B_1, \ldots, B_n$ *are belief arguments, and* $E_1, \ldots, E_m$ *are explanatory arguments, and* $\exists$ $\texttt{CONC}(B_1) \wedge \ldots \wedge \texttt{CONC}(B_n) \wedge \texttt{CONC}(E_1) \wedge \ldots \wedge \texttt{CONC}(E_m) \Rightarrow \psi \in \mathcal{B}_d^*$ *then* $B_1, \ldots B_n, E_1, \ldots E_m \Rightarrow \psi$ *is an* explanatory argument *(A) with:*[4]
  $\texttt{BELIEFS}(A) = \texttt{SUPP}(B_1) \cup \ldots \cup \texttt{SUPP}(B_n) \cup \texttt{BELIEFS}(E_1) \cup \ldots \cup \texttt{BELIEFS}(E_m)$
  $\texttt{DESIRES}(A) = \texttt{DESIRES}(E_1) \cup \ldots \cup \texttt{DESIRES}(E_m) \cup \{\psi\}$
  $\texttt{CONC}(A) = \psi$

$TOP(A) = \texttt{CONC}(B_1) \wedge \ldots \texttt{CONC}(B_n) \wedge \texttt{CONC}(E_1) \wedge \ldots \wedge \texttt{CONC}(E_m) \Rightarrow \psi$ *is the* TOP rule *of the argument.*
Let $\mathcal{A}_d$ *denote the set of all explanatory arguments that can be generated from* $\langle \mathcal{B}_b, \mathcal{B}_d \rangle$*, and* $\mathcal{A} = \mathcal{A}_d \cup \mathcal{A}_b$*.*

EXAMPLE 1. *Let* $waic \in \mathcal{K}$, $aic \in \mathcal{D}$*; waic denotes "there is a relevant workshop at the Sydney AI conference;" aic denotes "attend the Sydney AI conference." Suppose we have:*
$\mathcal{B}_b = \{(waic, 0.8)\}$
$\mathcal{B}_d = \{(waic \Rightarrow aic, 6)\}$
$\mathcal{B}_p = \emptyset$
$\mathcal{R} = \emptyset$
The agent can construct the explanatory argument A_1 *in favour of its desire to attend the Sydney AI conference:*
B_1*:* $\langle \{waic\}, waic \rangle$
A_1*:* $B_1 \Rightarrow aic$
with $\texttt{BELIEFS}(A_1) = \{waic\}$, $\texttt{DESIRES}(A_1) = \{aic\}$, $\texttt{CONC}(A_1) = \{aic\}$.

Note that the above example involves a desire-generation rule that contains beliefs only in its body. The following extended example shows how a desire can follow from another, already generated desire.

EXAMPLE 2. *Extending example 1, let: keynote denote "interesting key note speech"; attendkey denote "attend the key note speech". Suppose we have the following additional desire-generation rule, which states that if there is an interesting keynote speech at a conference I already desire to attend, then I would also desire to attend that speech:* $(keynote \wedge aic \Rightarrow attendkey, 8)$*. Suppose also that the agent believes that there is an interesting key note speech. Thus, we have the following new bases:*
$\mathcal{B}_b = \{(waic, 0.8), (keynote, 0.7)\}$
$\mathcal{B}_d = \{(waic \Rightarrow aic, 6), (keynote \wedge aic \Rightarrow attendkey, 8)\}$
$\mathcal{B}_p = \emptyset$
$\mathcal{R} = \emptyset$.
The agent can construct the explanatory argument A_2 *for the desire to attend the keynote speech:* B_1*:* $\langle \{waic\}, waic \rangle$
B_2*:* $\langle \{keynote\}, keynote \rangle$
A_1*:* $B_1 \Rightarrow aic$
A_2*:* $B_2, A_1 \Rightarrow attendkey$
with $\texttt{BELIEFS}(A_1) = \{waic\}$, $\texttt{BELIEFS}(A_2) = \{waic, keynote\}$, $\texttt{DESIRES}(A_1) = \{aic\}$, $\texttt{DESIRES}(A_2) = \{aic, attendkey\}$, $\texttt{CONC}(A_1) = \{aic\}$ *and* $\texttt{CONC}(A_2) = \{attendkey\}$.

[4]Note that B_i and E_i are comma-separated argument labels, not a conjunction of formulae (as in desire generation rules).

As with belief arguments, explanatory arguments may have different forces. However, since explanatory arguments involve two kinds of information: *beliefs* and *desires*, their strengths depend on both the quality of beliefs (using the notion of certainty level) and the importance of the supported desire. Formally:

DEFINITION 13. **(The force of explanatory arguments)** *Let* $A \in \mathcal{A}_d$ *be an explanatory argument. The* force *of A is* $Force(A) = <Level(A), Weight(A)>$ *where:*

- $Level(A) = \min\{a_i : \varphi_i \in \texttt{BELIEFS}(A)$ *and* $(\varphi_i, a_i) \in \mathcal{B}_b\}$*. If* $\texttt{BELIEFS}(A) = \emptyset$ *then* $Level(A) = 1$*;*
- $Weight(A) = w_i$ *such that* $(TOP(A), w_i) \in \mathcal{B}_d$*.*

In order to avoid any kind of wishful thinking, belief arguments are supposed to take precedence over explanatory ones. Formally:

DEFINITION 14. **(Comparing mixed arguments)** $\forall A_1 \in \mathcal{A}_b$ *and* $\forall A_2 \in \mathcal{A}_d$*, it holds that* A_1 *is* preferred *to* A_2*, denoted* $A_1 \succeq_d A_2$*.*

Concerning explanatory arguments, one may prefer an argument which will, for sure, justify an important desire. This suggests the use of a conjunctive combination of the certainty level of the argument and its weight. However, a simple conjunctive combination is open to discussion since it gives an equal weight to the importance of the desire and to the certainty of the set of beliefs that establishes that the desire takes place. Indeed, since beliefs verify the validity and the feasibility of desires, it is important that beliefs take precedence over the desires. This is translated by the fact that the certainty level of the argument is more important than the priority of the desire. Formally:

DEFINITION 15. **(Comparing explanatory arguments)** *Let* $A_1, A_2 \in \mathcal{A}_d$*.* A_1 *is* preferred *to* A_2*, denoted by* $A_1 \succeq_d A_2$*, iff*

- $Level(A_1) > Level(A_2)$*, or*
- $Level(A_1) = Level(A_2)$ *and* $Weight(A_1) > Weight(A_2)$*.*

An explanatory argument for some desire can be defeated either by a belief argument (which undermines the truth of the underlying belief justification), or by another explanatory argument (which undermines one of the existing desires the new desire is based on). Figure 2 summaries this notion of attack.

DEFINITION 16. **(Attack among Explanatory and Belief Arguments)**
Let $A_1, A_2 \in \mathcal{A}_d$ *and* $A_3 \in \mathcal{A}_b$*.*

- A_3 b-undercuts A_2 *iff* $\exists h' \in \texttt{BELIEFS}(A_2)$ *such that* $\texttt{CONC}(A_3) = \equiv \neg h'$*;*
- A_1 d-undercuts A_2 *iff* $\exists h' \in \texttt{DESIRES}(A_2)$ *such that* $\texttt{CONC}(A_1) \equiv \neg h'$*;*
- *An argument* $A' \in \mathcal{A}$ attacks_d $A_2 \in \mathcal{A}_d$ *iff* A' *b-undercuts or d-undercuts* A_2 *and not* $(A_2 \succeq_d A')$*.*

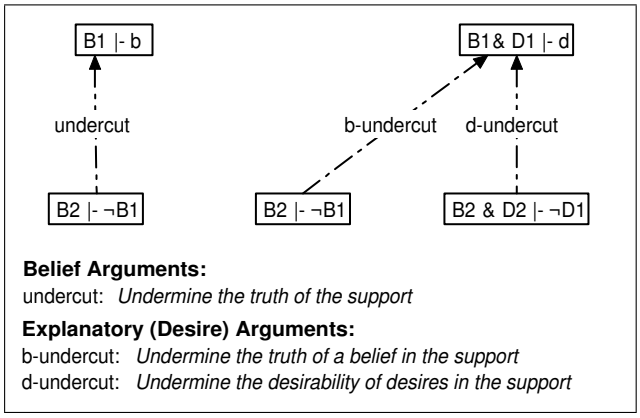

Figure 2: Summary of attacks involving belief and explanatory arguments

The following example illustrates the above concepts.

EXAMPLE 3. *(Builds on example 1) The agent finds out that the workshop has been cancelled (wcancel). That agent does not desire to go to the AI conference if it is not of international standing (int). Unfortunately the Sydney AI conference is not a good one. So the new bases are:*
$\mathcal{B}_b = \{(waic, 0.8), (wcancel, 1), (wcancel \rightarrow \neg waic, 0.8), (\neg int, 1)\}$
$\mathcal{B}_d = \{(waic \Rightarrow aic, 6), (\neg int \Rightarrow \neg aic, 9)\}$
$\mathcal{B}_p = \emptyset$
$\mathcal{R} = \emptyset$.
The following arguments can be built:
B_1: $\langle\{waic\}, waic\rangle$
B_2: $\langle\{wcancel, wcancel \rightarrow \neg waic\}, \neg waic\rangle$
B_3: $\langle\{\neg int\}, \neg int\rangle$
A_1: $B_1 \Rightarrow aic$
A_2: $B_3 \Rightarrow \neg aic$
It is clear that the argument B_2 b-undercuts the argument A_1 since $waic \in$ BELIEFS(A_1) and CONC$(B_2) = \neg waic$. *The argument A_2 d-undercuts the argument A_1 since* CONC$(A_2) = \neg aic$ *and $aic \in$* DESIRES(A_1).

Now that we have defined the notions of argument and defeasibility relation, we are ready to define the argumentation framework that should return the justified/valid desires.

DEFINITION 17. **(Argumentation framework)** *An* argumentation framework *AF_d for handling explanatory arguments is a tuple $AF_d = \langle \mathcal{A}_b, \mathcal{A}_d, Attack_b, Attack_d\rangle$ where $\mathcal{A}_b$ is the set of belief arguments, $\mathcal{A}_d$ the set of explanatory arguments, and $attack_d$ is the defeasibility relation between arguments in $\mathcal{A}$ and $attack_b$ is the defeasibility relation between arguments in $\mathcal{A}_b$.*

The definition of acceptable explanatory arguments is based on the notion of defence. Unlike belief arguments, an explanatory argument can be defended by either a belief argument or an explanatory argument. Formally:

DEFINITION 18. **(Defence among Explanatory and Belief Arguments)**
Let $S \subseteq \mathcal{A}$ and $A \in \mathcal{A}$. S defends *A iff $\forall A' \in \mathcal{A}$ where A' $attacks_b$ (or $attacks_d$) A, there is some argument $A'' \in S$ which $attacks_b$ (or $attacks_d$) A'.*

$\mathcal{F}'$ is a function such that $\mathcal{F}'(S) = \{A \in \mathcal{A}$ such that S defends $A\}$.

One can show easily that the function $\mathcal{F}$ is monotonic. Thus, it admits a least fixpoint. This last captures the acceptable arguments of AF_d.

PROPOSITION 2. *Let $AF_d = \langle \mathcal{A}_b, \mathcal{A}_d, Attack_b, Attack_d\rangle$ be an argumentation framework. The set $Acc(\mathcal{A}_d)$ of* acceptable explanatory arguments *is defined as*

$$Acc(\mathcal{A}_d) = (\bigcup \mathcal{F}'_{i\geq 0}(\emptyset)) \cap \mathcal{A}_d$$

PROOF. Due to the use of propositional language and finite bases, the argumentation system is finitary, i.e each argument is attacked by a finite number of arguments. Since the argumentation system is finitary then the function $\mathcal{F}'$ is continuous. Consequently, the least fixpoint of $\mathcal{F}'$ is $\bigcup \mathcal{F}'_{i\geq 0}(\emptyset)$. □

One can show that the above argumentation framework captures the results of the first framework which handles belief arguments.

PROPOSITION 3. *Let $AF_d = \langle \mathcal{A}_b, \mathcal{A}_d, Attack_b, Attack_d\rangle$ be an argumentation framework. $\bigcup \mathcal{F}'_{i\geq 0}(\emptyset) = Acc(\mathcal{A}_b) \cup Acc(\mathcal{A}_d)$*

PROOF. This follows directly from the definitions of $\mathcal{F}$ and $\mathcal{F}'$, and the fact that belief arguments are not attacked by explanatory arguments since we suppose that belief arguments are preferred to explanatory ones. □

DEFINITION 19. **(Justified desire)** *A desire ψ is* justified *iff $\exists$ $A \in \mathcal{A}_d$ such that* CONC$(A) = \psi$, *and $A \in Acc(\mathcal{A}_d)$.*

Desires supported by acceptable explanatory arguments are justified and hence the agent will pursue them (if they are achievable).

3.3 Arguing over plans

In the previous section, we have presented a framework for arguing about desires and producing a set of *justified* desires. In what follows we will show, among these justified desires, which ones will be pursued and with which plan.
The basic building block of a plan is the notion of "partial plan," which corresponds to a planning rule.

DEFINITION 20. **(Partial Plan)** *A* partial plan *is a pair $[H, \varphi]$ where*

- *$\varphi \in \mathcal{R}$ and $H = \emptyset$, or*
- *$\varphi \in \mathcal{D}$ and $H = \{\varphi_1, \ldots, \varphi_n, r_1 \ldots, r_m\}$ such that $\exists \varphi_1 \wedge \cdots \wedge \varphi_n \wedge r_1 \cdots \wedge r_m \rightarrowtail \varphi \in \mathcal{B}_p$.*

A partial plan $[H, \varphi]$ is elementary *iff $H = \emptyset$.*

DEFINITION 21. **(Instrumental Argument, or Complete Plan)** *An* instrumental argument *is a pair $\langle G, d\rangle$ such that $d \in \mathcal{D}$, and G is a finite tree such that:*

- *the root of the tree is a partial plan $[H, d]$;*
- *a node $[\{\varphi_1, \ldots, \varphi_n, r_1 \ldots, r_m\}, h']$ has exactly $n + m$ children $[H'_1, \varphi_1], \ldots [H'_n, \varphi_n]$, $[\emptyset, r_1], \ldots [\emptyset, r_m]$ where each $[H'_i, \varphi_i]$, $[\emptyset, r_k]$ is a partial plan;*
- *the leaves of the tree are elementary partial plans.*

Nodes(G) *is a function which returns the set of all partial plans of tree* G, *Des*(G) *is a function which returns the set of desires that plan* G *achieves, and Resources*(G) *is a function which returns the set of all resources needed to execute* G.

Let $\mathcal{A}_p$ *denotes the set of all instrumental arguments that can be built from agent's bases.*

An instrumental argument may achieve one or several desires of different worths with a certain cost. So the strength of that argument is the "benefit" or "utility" which is the difference between the worths of the desires and the cost of the plan. Formally:

DEFINITION 22. **(Strength of Instrumental Arguments)** *Let* $A = \langle G, g\rangle$ *be an instrumental argument. The* utility *of* A *is*

$$\texttt{Utility}(A) = \sum_{d_i \in Des(G)} Worth(d_i) - \sum_{r_j \in Resources(G)} Cost(r_j).$$

In [3], the strength of an instrumental argument is defined only on the basis of the weight of the corresponding desire. That definition does not account for the cost of executing the plan.

EXAMPLE 4. *A customer requires a car hire (a resource) in order to go to Sydney (a goal), which in turn achieves the agent's wish to attend an Artificial Intelligence conference (a desire). The customer desires to attend the AI conference because he believes it includes a workshop related to his research (a belief that justifies the desire). Let:*
aic = "attend the Sydney AI conference";
syd = "go to Sydney";
reg = "pay conference registration";
rent = "rent a car";
ford = "get a particular car of make Ford";
pay\$100 = "pay \$100";
pay\$200 = "pay \$200";[5]
We can now specify the following, for the buyer agent B *and seller agent* S:

1. $\mathcal{B}_b^B = \{(waic, 1)\}$
2. $\mathcal{B}_d^B = \{(waic \Rightarrow aic, 6)\}$
3. $\mathcal{B}_p^B = \begin{cases} syd \wedge reg \rightarrowtail aic \\ rent \rightarrowtail syd \\ ford \wedge pay\$200 \rightarrowtail rent \\ pay\$100 \rightarrowtail reg \end{cases}$
4. $RES = \{pay\$100, pay\$200, ford\}$
5. $\mathcal{R}^B = \{pay\$100, pay\$200\}$
6. $\mathcal{R}^S = \{ford\}$

Figure 3 shows an instrumental argument, for attending the Sydney AI conference, that agent B *can construct using the above information. Note that this plan involves the execution of action ford by agent* S, *because* B *does not have "ford" as one of its resources. Without getting the car from* S, B *cannot make it to Sydney using this plan.*

[5]Realistically, one requires a more elaborate treatment of actions, e.g. the agent must also be able to pay \$300, or pay \$50 six times. For simplicity, we suffice with these illustrative unique actions.

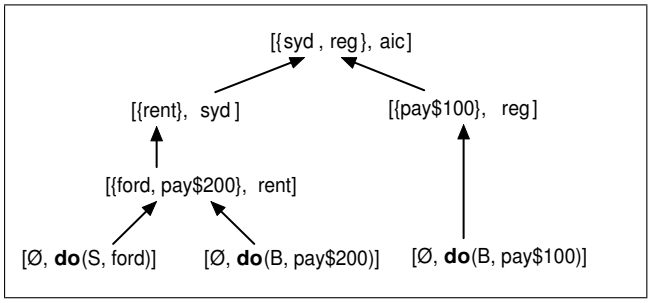

Figure 3: Complete plan for example 4

In [1], it has been shown that there are four great families of conflicts between partial plans. In fact, two partial plans $[H_1, h_1]$ and $[H_2, h_2]$ may be conflicting for one of the following reasons:

- *desire-desire* conflict, *ie* $\{h_1\} \cup \{h_2\} \vdash \bot$
- *plan-plan* conflict, *ie* $H_1 \cup H_2 \vdash \bot$.
- *consequence-consequence* conflict, *ie* the consequences of achieving the two desires h_1 and h_2 are conflicting.
- *plan-consequence* conflict, *ie* the plan H_1 conflicts with the consequences of achieving h_2.

The above conflicts are captured when defining the notion of *conflict-free* sets of instrumental arguments.

DEFINITION 23. **(Conflict-free sets of instrumental arguments)** *Let* $S \subseteq \mathcal{A}_p$. S *is* conflict-free, *with respect to the agent's beliefs* $\mathcal{B}_b^*$, *iff* $\nexists\ \mathcal{B}' \subseteq \mathcal{B}_b^*$ *such that:*

1. $\mathcal{B}'$ *is consistent, and*
2. $\bigcup_{\langle G,d\rangle \in S}[\bigcup_{[H,h]\in Nodes(G)}(H \cup \{h\})] \cup \mathcal{B}' \vdash \bot$

As with belief and explanatory arguments, we now present the notion of an *acceptable set of instrumental arguments.*

DEFINITION 24. **(Acceptable Set of Instrumental Arguments)** *Let* $S \subseteq \mathcal{A}_p$. S *is* acceptable *iff:*

- S *is conflict-free.*
- S *is maximal for set inclusion among the sets verifying the above condition.*

Let $S_1, \ldots, S_n$ *be the different acceptable sets of instrumental arguments.*

DEFINITION 25. **(Achievable desire)** *Let* $S_1, \ldots, S_n$ *be the different acceptable sets of instrumental arguments. A desire* ψ *is* achievable *iff* $\exists S' \in \{S_1, \ldots, S_n\}$, *such that* $\langle G, \psi\rangle \in S'$

DEFINITION 26. **(Utility of Set of Instrumental Arguments)** *For an acceptable set of instrumental arguments* $S = \{\langle G_1, d_1\rangle, \ldots, \langle G_m, d_m\rangle\}$, *the set of all desires achieved by* S *and all resources consumed by* S *as follows:*
$DE(S) = \{g_l : g_l \in Des(G_k), l = 1, \ldots, h, k = 1, \ldots, m\}$
$RE(S) = \{r_l : r_l \in Res(G_k), l = 1, \ldots, h, k = 1, \ldots, m\}$
The utility of a set of arguments S *is:*

$$\texttt{Utility}(S) = \sum_{g_i \in DE(S)} Worth(g_i) - \sum_{r_j \in Resources(S)} Cost(r_j).$$

We can now construct a complete pre-ordering on the set $\{S_1, \ldots, S_n\}$ of acceptable sets of instrumental arguments. The basic idea is to prefer the set with a maximal total utility: a maximal set of consistent plans.

DEFINITION 27. **(Preferred set)**
Let $S_1, \ldots, S_n$ be the acceptable sets of instrumental arguments. S_i is preferred *to S_j iff* $\texttt{Utility}(S_i) \geq \texttt{Utility}(S_j)$

Note that the above definition allows for cases where a set with a single desire/plan pair is preferred to another set with two or more desire/plan pairs (because the utility achieved by this desire is higher than the other two). This is more flexible than the frameworks of Amgoud and of Hustijn and van der Torre [1, 9], where sets with maximal *number* of desires are privileged, with no regard to their priority or the cost of different plans.

In order to be pursued, a desire should be both justified (i.e supported by an acceptable explanatory argument) and also achievable. Such desires will form the intentions of the agent.

DEFINITION 28. **(Intention set)**
Let $T \subseteq \mathcal{PD}$. T is an intention set iff:

1. *$\forall d_i \in T$, d_i is justified and achievable.*
2. *$\exists S_l \in \{S_1, \ldots, S_n\}$ such that $\forall d_i \in T$, $\exists \langle G_i, d_i \rangle \in S_l$.*
3. *$\forall\ S_k \neq S_l$ with S_k satisfying condition 2, then S_l is preferred to S_k.*
4. *T is maximal for set inclusion among the subsets of $\mathcal{PD}$ satisfying the above conditions.*

The second condition ensures that the desires are achievable together. If there is more than one intention set, a single one must be selected (e.g. at random) to become the agent's *intention*. The chosen set is denoted by $\mathcal{I}$. Finally, the *intended resources*, denoted $\mathcal{IR} \subseteq RES$ denote the resources needed by plans in S_l for achieving $\mathcal{I}$. The example below, depicted in Figure 4, puts the above concepts together.

EXAMPLE 5. *(Extends example 4) Suppose the buyer also would like to go on holiday to New Zealand and must reason with a limited budget. Let:*
nz = "take a holiday in New Zealand";
flynz = "fly to New Zealand";
hotel = "book a hotel accommodation";
friend = "stay at a friend's place";
call = "call a friend";
Suppose the agent has the following new desire generation knowledge base: $\mathcal{B}_d^B = \{(waic \Rightarrow aic, 0.6), \Rightarrow nz, 0.5)\}$ and that desires aic and nz are justified.

Finally, suppose costs are assigned as follows: $Cost(pay\$200) = 0.2$, $Cost(pay\$100) = 0.1$, $Cost(pay\$200) = 0.2$, $Cost(call) = 0$, $Cost(ford) = 0$).[6]

Suppose the buyer has two instrumental arguments for going to New Zealand: one requires booking a hotel (and paying \$200), while the other involves calling a friend to arrange a stay at his place. There are no conflicts between the arguments A_1, A_2 and A_3. Thus, there exists a unique acceptable set of instrumental arguments $\{A_1, A_2, A_3\}$. Since the desires aic and nz are supposed justifies, then there is a unique intention set $I = \{aic, nz\}$.

[6]The cost of "*ford*" to the buyer is zero because this resource is possessed by the seller and hence would only incur a cost to the seller.

4. RELATED WORKS

Recently, a number of attempts have been made to use formal models of argumentation as a basis for practical reasoning. Some of these models (e.g. [1, 3, 9]) are instantiations of the *abstract* argumentation framework of Dung [6], and our work is a contribution to this approach. Other approaches are based on an encoding of argumentative reasoning in logic programs (e.g. [10, 14]) or on completely new theories of practical reasoning and persuasion (e.g. [4, 15]).

Amgoud [1] presented an argumentation framework for generating consistent plans from a given set of desires and planning rules. This was later extended with argumentation frameworks that generate the desires themselves (see below).

Amgoud and Kaci [3] have a notion of "conditional rule," which is meant to generate desires from beliefs. Our desire generation rules are more general. In particular, we allow the generation of desires not only from beliefs, but also on the basis of other desires. Hence, our desire generation rules are more general.

Another problem arises because Amgoud and Kaci's definition does not distinguish between desires and beliefs in the antecedent and consequent of these rules. This may lead to incorrect inferences where an agent may conclude beliefs on the basis of yet-unachieved desires, hence exhibiting a form of wishful thinking. Our approach resolves this by distinguishing between beliefs and desires in the rule antecedents, allowing desires only in the consequent, and refining the notion of attack among explanatory arguments accordingly.

Hulstijn and van der Torre [9], on the other hand, have a notion of "desire rule," which contains only desires in the consequent. But their approach is still problematic. It requires that the selected goals[7] are supported by goal trees[8] which contain both desire rules and belief rules that are deductively consistent. This consistent deductive closure again does not distinguish between desire literals and belief literals (see Proposition 2 in [9]). This means that one cannot both believe $\neg p$ and desire p. In our framework, on the other hand, the distinction enables us to have an acceptable belief argument for believing $\neg p$ and, at the same time, an acceptable explanatory argument for desiring p.

Another advantage of our framework is that it derives preferences among explanatory and instrumental arguments using both worth and cost measures. This contrasts with Amgoud's and Hulstijn and van der Torre's frameworks, which privilege extensions with maximal number of desires without regard to desire priorities and resource cost. And while [3] does incorporate the weight of desires when calculating the strength of an instrumental argument, the cost of executing plans is not taken into account.

5. CONCLUSIONS

We presented a formal model for reasoning about desires (generating desires and plans for achieving them) based on argumentation theory. We adapted the notions of attack and preference among arguments in order to capture the differences in arguing about beliefs, desires and plans. We incorporated both the worth of desires and cost of resources in order to produce intentions that maximise utility.

One of the main advantages of our framework is that, being grounded in argumentation, it lends itself naturally

[7]Similar to our justified desires
[8]Similar to our explanatory arguments.

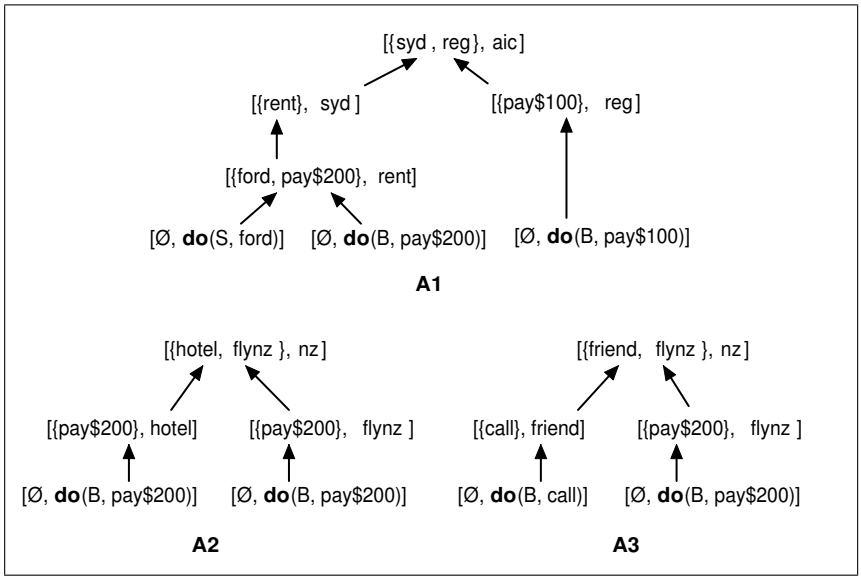

Figure 4: Plans for example 5

to facilitating dialogues about desires and plans. Indeed, we are currently extending our framework with dialogue game protocols in order to facilitate negotiation and persuasion among agents. Another interesting area of future work is investigating the relationship between our framework and axiomatic approaches to BDI agents.

ABSTRACT

We propose an improved approach for modeling behaviours of negotiation partners and predictive decision-making based on this modelling. Our prediction is based only on the history of the offers during the current negotiation. The mechanism estimates an influence of different factors contributing to partner's behaviour during negotiation and uses this information to construct a prediction about agent's future behaviour. The optimal sequence of offers is determined according to the prediction. The approach is tested in simple scenarios and the results comparing our approach to random strategy selection are illustrated.

negotiation and conflict handling in agent systems

1. INTRODUCTION

Negotiation is a process of searching a space of potential agreements in order to find a solution that satisfies the preferences and requirements of all interested parties [5]. The problem of negotiation has been studied from various perspectives in many fields. These fields include: decision and game theory, management and social sciences, artificial intelligence and agent technology [9]. The essential problems of the negotiating parties are the limited or uncertain knowledge and conflicting preferences. The agent technology provides tools for solving this kind of problems. However, decision-making paradigms of the negotiation agents still need to be developed and improved. A successful agent needs to learn and adapt to complex behaviour of its negotiation partner and changing environment. An approach proposed by Faratin [4] allows for limited adaptation to partners behaviour by using so called behaviour-dependant tactics. These tactics imitate opponent's behaviour and can be mixed with other types of tactic such as time-dependant. However, it is difficult to decide which type of tactics to use and to what extent in terms of weights mixing various factors such as: time and behaviour imitation. Therefore, some approaches based on machine learning have been proposed to predict the negotiation partner's behaviour.

Most of the learning approaches supporting the negotiation such as Bayesian learning [12], Q-learning [3], case-based-reasoning [1] and evolutionary computation [11][10] focus on learning from previous negotiations. Some work [7][6] studies the negotiation scenarios by taking into account the parameters of negotiation such as: deadline and reservation value but assuming a simplified type of negotiation strategies, namely only time-dependant. The work proposing learning from current negotiation is quite rare. One of the approaches was proposed by Hou [8]. In this paper a nonlinear regression was proposed to model the negotiation opponent's behaviour based only on the previous offers. However, the approach copes only with single tactics but negotiation agent may encounter an opponent with more complex behaviour involving a mixture of different tactics.

In this paper we propose to treat the negotiation as an optimization problem because too small concessions may discourage the partner from making significant concessions and to large concession will obviously lead to a low level of utility at the end of an encounter. Our predictive decision-making mechanism allows for high adaptation to negotiation partner's behaviour based only on the history of offers in the current negotiation.

It extends the predictive decision-making mechanism described in [2]. The approach is based on difference method and is therefore computationally efficient. In the future work we will propose other prediction approach based on nonlinear multivariate regression analysis. Our extended approach allows for additional gain of efficiency compared to the previous paper [2] because instead of a brute force search of the optimal sequence of actions we propose a more efficient search based on a solution of optimization equation that reduces significantly the time of modelling.

The second section recalls an idea of estimation of different factors influencing negotiation partner's behaviour. The

third section presents a method of constructing a prediction. In the fourth section an idea of assessing the whole sequence of offers is described. In the fifth section we describe a way of calculating values of concession. Sixth section presents the results of experiments. Conclusions and future work are presented in the 6 section.

2. THE ESTIMATION OF DEGREES OF VARIOUS FACTORS DEPENDENCY

Typically, there are two main factors that influence the negotiation agent behaviour: time and imitation. The agents behaviour depends to some extent on time and it depends to some extent on imitation. In order to be able to assess the degrees of this dependency appropriate criteria will be introduced in a form of functions mapping the sequences of previous actions of both parties in the current encounter into interval $[0, 1]$. These two criteria should state to what extent our partner responds to its time constraint and to what extent does it respond to our actions. We propose to define these criteria as necessary conditions for using pure tactics by our negotiation partner (either behaviour-dependant or time-dependant). In order to do it we have to know what is characteristic for an agent using time-dependant tactic (necessary condition) or behaviour-dependant tactic. This feature will be used as the factor dependency criterion.

2.1 Time-dependency

The time-dependant tactic may be modelled by the use of polynomial or exponential function. As mentioned before we have to determine the characteristic feature of these type of functions. The whole family of polynomial or exponential functions has a constant sign of all derivatives and this feature is treated as a necessary condition for being time-dependant. The given information is the sequence of previous offers of both parties. Based on it we want to determine the extent to which the sequence of our partner's offers is generated by a particular decision function corresponding to a pure tactic. In other words we want to determine how good the partner's behaviour fits to a particular decision function. Assuming that a decision function used to generate a sequence of offers had a constant sign of all its derivatives the differences of all orders calculated for the given sequence must also have a constant sign. This is because of a correspondence of the difference of n-th order and the n-th derivative. Having a sequence of partner offers: b_i of a length m the differences of different orders can be calculated as follows:

$$\begin{aligned}
\Delta^1 b_i &= b_{i+1} - b_i \qquad i \in \{1, 2, \ldots, m-1\} \\
\Delta^2 b_i &= \Delta b_{i+1} - \Delta b_i \qquad i \in \{1, 2, \ldots, m-2\} \\
\Delta^3 b_i &= \Delta^2 b_{i+1} - \Delta^2 b_i \qquad i \in \{1, 2, \ldots, m-3\} \\
&\ldots \\
\Delta^{m-1} b_i &= \Delta^{m-2} b_{i+1} - \Delta^{m-2} b_i \qquad i \in \{1\}
\end{aligned}$$

If all the differences for each particular order k have the same sign then the necessary condition of being time-dependant is fully satisifed:

$$\forall k \in \{1, 2, \ldots, m-1\} \quad \forall i, j \in \{1, 2, \ldots, m-k\} \quad sgn(\Delta^k b_i) = sgn(\Delta^k b_j)$$

In order to evaluate a degree to which time-dependency is satisfied we formulate a criterion. For the difference of each order k we introduce a subcriterion D^k. The subcriterion must be defined in such a way that it gives full level of satisfaction if all the differences are either negative or positive. If the means of the positive and negative values counterbalance each other then the criterion should give the full level of violation what corresponds to the lowest level of satisfaction. In other words the full violation means that the contributions of positive and negative values are the same. Partial degree of criterion satisfaction will be obtained if we observe a dominance of one sign over other and the higher is this dominance the higher the degree of satisfaction. Therefore, we introduce the partial degree of subcriterion satisfaction D^k of the difference of an order k as an aggregate of the means of the positive values of differences and the negative values of the differences as follows:

$$D_k = \frac{|\frac{\sigma_p^k}{m_p^k} + \frac{\sigma_n^k}{m_n^k}|}{Max\{|\frac{\sigma_p^k}{m_p^k}|, |\frac{\sigma_n^k}{m_n^k}|\}} \tag{1}$$

where $\sigma_p^k = \sum_{\Delta_k b_i > 0} \Delta_k b_i$, $\sigma_n^k = \sum_{\Delta_k b_i < 0} \Delta_k b_i$. m_p^k and m_n^k are the amounts of the positive and negative values of $\Delta^k b_i$, respectively. If the absolute values of the averages $|\frac{\sigma_p^k}{m_p^k}|$, $|\frac{\sigma_n^k}{m_n^k}|$ are close then the value of D^k is small, what means that the criterion is highly violated. The values of all given D^k are then aggregated to the overall value of criterion satisfaction. This value is obtained by the use of weighted sum where the weights are proportional to the extent of contribution of the differences $\Delta^k b_i$:

$$D_t = \sum_{k \leq m-1} w_k D_k$$

where w_k is calculated as follows:

$$w_k = \frac{Max\{|\sigma_p^k|, |\sigma_n^k|\}}{\sum_{j=1}^{m-1} Max\{|\sigma_p^j|, |\sigma_n^j|\}}$$

2.2 Behaviour-dependency

The responsiveness to partner's behaviour may be realized by behaviour-dependant tactic. We propose to use the sequence of relative first order difference as a basis for measuring the extent to which our partner is imitating our behaviour. Having the sequences of the last m concessions of our agent s_i and the sequence of the last m concessions b_i of the negotiation partner we can calculate the sequence $r_i = \frac{\Delta^1 b_i}{\Delta^1 s_i}$ describing the change of behaviour of the modelled agent in relation to the change of our agent's behaviour. We define two subcreteria allowing for the assessment of the imitative-behaviour of our negotiation partner. First subcreterion assesses how positive are the responses of the modelled agent to our offers (the values of r_i are higher then one). We aggregate all values of r_i by the use of weighted sum:

$$r = \sum_{i=1}^{m} w_i r_i$$

The weights w_i may increase with the value of index i which means that the later offers reflect better the current state of our partner's behaviour and therefore, the higher the values of indices i the more important is the quotient r_i. If the

calculated value of r is greater than 1 then our negotiation partner is responding with higher concessions than ours and therefore it may be called relatively cooperative. The value of r equal to 1 means that the agent makes the same concessions as ours and can therefore be called neutral. The values of r smaller than 1 tell us that our partner is not relatively cooperative because its concessions are smaller than ours. The first subcreterion may be defined as a function $h : r \mapsto [0, 1]$ mapping the value of r into a degree of responsiveness in the following way:

$$D_1 = h(r) = Max[1, Min[0, 0.5r]]$$

The neutral value of r ($r = 1$) is assigned the value of 0.5 by function h what in terms of fuzzy logic means that the extent of condition satisfaction and dissatisfaction is the same. If the value of r is greater than 1 then the degree of subcreterion satisfaction is higher than 0.5 (more true than false) and in the opposite case ($r < 1$) the degree of satisfaction is lower than 0.5 (more false than true).

Additional subcreterion can asses the degree of relational trend in the agent's behaviour in terms of monotonicity of sequence r_i. The degree of monotinicity D_2 may be measured as a sign consistency for the differences Δr_i what can be done analogously as in previous subsection (formula 1). We calculate the average D_b of the obtained values of D_1 and D_2 and treat this value as a degree of the overall responsiveness:

$$D_b = \frac{D_1 + D_2}{2}$$

3. THE AGENT'S BEHAVIOUR PREDICTION BASED ON DIFFERENCE METHOD

As mentioned in previous sections there are two main factors contributing to the overall behaviour of negotiation agent: time and imitation. We propose to construct separate predictions of these two factors first. Then prediction can be build by mixing the time-depending and the behaviour-depending predictions together using the weights obtained in the previous section. Our prediction constitutes a function mapping a history of the previous m offers of both negotiating parties H_m and a potential offer s_{m+1} of our agent into a value of the predicted response $\hat{b}_{m+1}$ of our partner:

$$f : (H_m, s_{m+1}) \rightarrow \hat{b}_{m+1}$$

As mentioned in Introduction in the future work we will conisder other type of prediction based on the multivariate regression analysis. The two predictions, namely time-depending f_t and imitation-depending f_b that will be combined together to the overall prediction f map the history of the current encounter to the value of the predicted offer in the following way:

$$\hat{b}^t_{m+1} = f_t(H_m) \quad (2)$$

$$\hat{b}^b_{m+1} = f_b(H_m, s_{m+1}) \quad (3)$$

As stated before these mappings are combined to obtain the overall prediction as follows:

$$\begin{aligned} \hat{b}_{m+1} &= f(H_m, s_{m+1}) = \\ &= \frac{D_t}{D_t + D_b} \times \hat{b}^t_{m+1} + \frac{D_b}{D_t + D_b} \times \hat{b}^b_{m+1} \end{aligned} \quad (4)$$

The predictor f may be applied multiple l times in a recursive way. In order to reuse the predictor second time we store the time-depending prediction $\hat{H}^t_{m+1} = H^t_m \cup \{s_{m+1}, \hat{b}^t_{m+1}\}$ ($H^t_m = H_m$). We also store separately the overall prediction $\hat{H}_{m+1} = H_m \cup \{s_{m+1}, \hat{b}_{m+1}\}$. Based on this information the prediction for the second step can be obtained as follows:

$$\hat{b}^t_{m+2} = f_t(\hat{H}^t_{m+1}) \quad (5)$$

$$\hat{b}^b_{m+2} = f_b(\hat{H}_{m+1}, s_{m+2}) \quad (6)$$

where s_{m+2} is a potential offer of our agent in the next step of negotiation. The overall second step prediction is calculated as follows:

$$\begin{aligned} \hat{b}_{m+2} &= f(\hat{H}_{m+1}, s_{m+2}) = \\ &= w_t \times \hat{b}^t_{m+2} + w_b \times \hat{b}^b_{m+2} \end{aligned} \quad (7)$$

where w_t and w_b are the normalized values of D_t and D_b:

$$w_t = \frac{D_t}{D_t + D_b} \qquad w_b = \frac{D_b}{D_t + D_b}$$

As stated before we can repeat this procedure multiple l times.

3.1 Time-depending prediction

The time-dependant behaviour may be realized by the use of decision functions from the polynomial or exponential family of functions. We used this information in the previous section to determine the degree of time-dependency and in this section we want to determine a level of the particular time-dependant tactic in order to predict this type of behaviour. We propose to measure a trend in agent's behaviour in terms of a degree of concavity or convexity of the concession curve. In other words we want to determine what a kind of tactics (conceder, linear or boulware) our partner is using, and how strong is the tactic in terms of a value of the parameter β. Our time-depending prediction is based on a difference method that requires to determine the maximal order of differences that should be taken into account. In a case of linear and conceder tactics it is sufficient to consider only the first order difference because for the curve generated by the linear tactic all higher order differences are equal to zero and the curve generated by the conceder tactic is close to linear after a number of offers. The most crucial is the successful prediction of the boulware tactic because the most drastic changes of the behaviour of an agent using this kind of tactic occur when it is approaching its deadline. All the differences up to k-th order having the same sign are taken into consideration as follows:

$$sgn(\Delta^1 b_i) = sgn(\Delta^2 b_i) = \cdots = sgn(\Delta^k b_i) \neq sgn(\Delta^{k+1} b_i)$$

The more differences are consistent in a sign the stronger boulware tactic on the side of opponent agent was applied. We calculate the time-dependent prediction for the next step as follows (Figure 1):

$$\hat{b}_{m+1} = f_t(H_m) = b_m + \sum_{j=1}^{k} \Delta^j b_{m-j} \quad (8)$$

where $\hat{b}_{m+1}$ is the prediction of the $m+1$ offer and k is an index of the last difference consistent in sign. It can be proved that the difference based method is a good approximation of any function from the polynomial family of functions. The

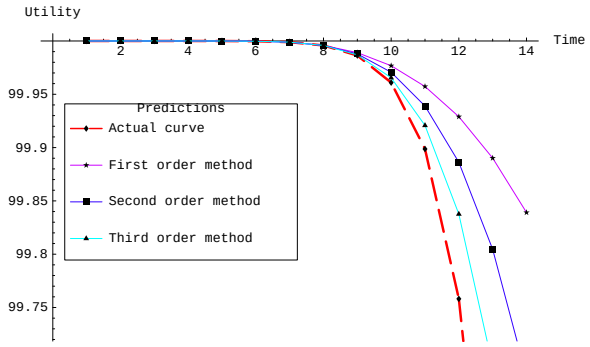

Figure 1: Examples of different order predictions for boulware tactic

recursive application of the formula (8) allows for the prediction in the next steps.

3.2 Imitation-depending prediction

The imitation-depending prediction constitutes a function that maps the history H_m of offers of the current encounter and a potential future offer s_{m+1} of our agent into the prediction about our opponent's next move $\hat{b}_{m+1}$:

$$\hat{b}_{m+1} = f_b(H_m, s_{m+1})$$

The purpose of the function f_b is to predict how the negotiation partner will respond to the potential offer s_{m+1} of our agent. In terms of control theory the history of the negotiation H_m up to an offer m describes the current state of the encounter. The variable s_{m+1} is a potential control with which we may influence partners behaviour. The updated history $\hat{H}_{m+1}$ after the step of control s_{m+1} is the next state of negotiation. In order to construct the function f_b we apply the Taylor's formula of first order as follows:

$$f_b(H_m, s_{m+1}) \quad = \quad b_m + \frac{\Delta b_{m-1}}{\Delta s_{m-1}}(s_{m+1} - s_m)$$

where the value of a relational difference $\frac{\Delta b_{m-1}}{\Delta s_{m-1}}$ is treated as an approximation of the first order derivative of the function f_b in a point s_m.

4. SEMI-STRATEGIC REASONING

The predictor described in previous sections can be regarded as a transition function that maps a state (history of previous offers) and a potential control (our potential offer) into the next state. In these terms the negotiation may be treated as a multi-stage control process and our task is to determine the sequence of optimal controls (our potential future offers) $s_{m+1}, s_{m+2}, \ldots, s_{m+l}$ knowing the sequence of our opponent's respones $\hat{b}_{m+1}, \hat{b}_{m+2}, \ldots, \hat{b}_{m+l}$. The multi-stage control process constitutes the combination of prediction with decision-making about the next offers. The mechanism described in [2] involves discretization of the space of each potential offer in each negotiation step. All possible sequences of offers in the discrete space are considered and the optimal sequence is determined. However, such an approach is a kind of brute force, and therefore is quite time consuming. We propose to determine a sequence of the optimal

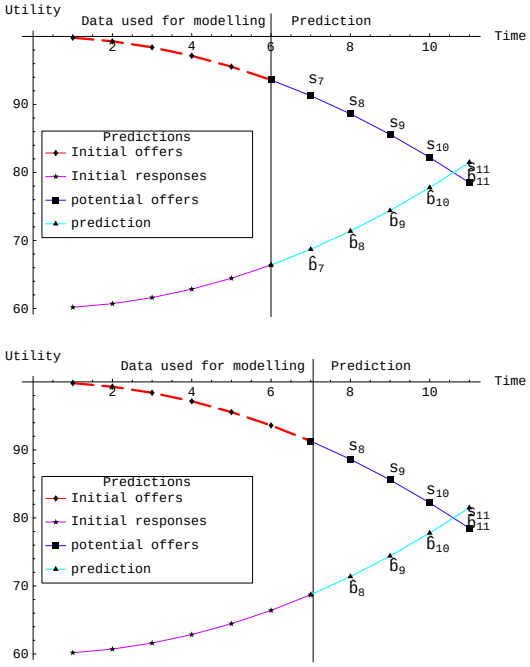

Figure 2: An example of prediction as a response to sequence of potential offers in steps 7 and 8

controls in a different way. In order to avoid the inefficiency of searching the whole space of solutions we propose to predict a small amount of k opponent's steps forward. Then we assume that we make the same average concession up to the terminal state l and determine this concession by solving optimization equation (9). In other words we want to determine the sequence of a form: $s_{m+1}, s_{m+2}, \ldots, s_{m+k}, s_{m+k} + c, s_{m+k} + 2c, \ldots, s_{m+k} + (l-k)c$. In order to determine the concession c of the second part of the sequence we solve the following optimization problem:

$$c : min\{|\hat{b}_{m+l} - (s_{m+k} + (l-k)c)|\} \qquad (9)$$

It states that we have to find a value of c for which we meet with the opponent (ia. reach an agreement) in terminal state $m+l$. After the counterpart has responded, the whole mechanism can be reused for further decision making in the next steps of negotiation.

5. CONCESSION DETERMINATION

The previous section described a way we asses a sequence of offers. Assuming that we determined the optimal sequence of concessions we have to determine the value of the next offer based on this information. It turns out that various sequences of offers may result (in terms of prediction) in similar final utility. Therefore, the decision-making process should take into account all sequences with various first concessions satisfying the optimization constraint (9). Assume we have all the optimal sequences $\{s^j\}$ with the various first

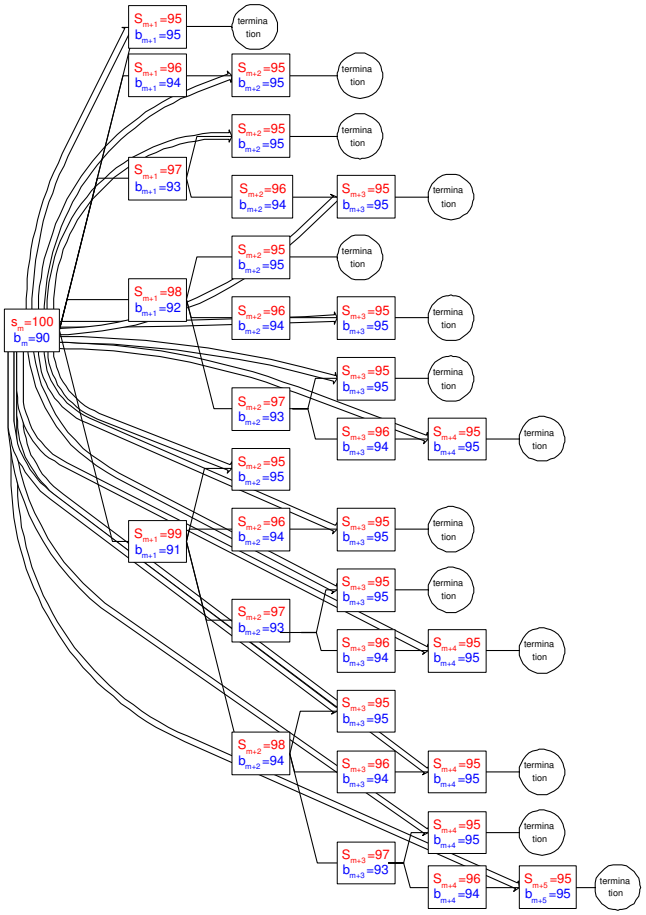

Figure 3: Simplified example of negotiation prediction. The thick arrows indicate the optimal sequences with various first concessions

concessions:

$$\begin{array}{ccc} s^1_{m+1} & , & s^1_{m+2}, \ldots, s^1_{m+l} \\ s^2_{m+1} & , & s^2_{m+2}, \ldots, s^2_{m+l} \\ \ldots & , & \ldots \\ s^n_{m+1} & , & s^n_{m+2}, \ldots, s^n_{m+l} \end{array}$$

To determine the value of a concession based on the predicted sequence we use two values: the first concession in the sequence $s^j_{m+1} - s^j_m$ and the average of all concessions in the sequence $\frac{s^j_{m+l} - s^j_m}{l}$. The less responsive an agent is the less important the first concession is. It means that in the case of time-dependant behaviour the opponent agent does not respond to our behaviour and it is not important what concession we make in what rounds. What is important is the average concession in all rounds. Therefore, the average concession should be taken into account in a case of time-dependant behaviour and the first concession should be taken into account in a case of the responsive agent. Because the extents to which the two factors influence agent's behaviour are fuzzy we have to aggregate the two types of concession taking into consideration the level of imitative behaviour and the level of time-depending behaviour. The experiments presented in the next section show that the following type of aggregation is appropriate:

$$\begin{aligned} offer^j &= s_m + sgn(s^j_{m+1} - s^j_m)(|s^j_{m+1} - s^j_m|)^{w_t} \times \\ &\times sgn\left(\frac{s^j_{m+l} - s^j_m}{l}\right)\left|\frac{s^j_{m+l} - s^j_m}{l}\right|^{w_b} \end{aligned}$$

The offers $offer^j$ are then averaged over all the optimal sequences with the various first concessions in order to calculate the final value of an offer:

$$offer = offer^1 w_1 + offer^2 w_2 + \cdots + offer^n w_n$$

where the weights w_j are proportional to the utility that can be gained by applying j-th sequence of actions $\{s^j\}$ according to our prediction.

6. RESULTS

The enhanced mechanism has been tested in a simulated experimental negotiations with more advanced settings than in [4] (the same settings as in [2]). On a side of our negotiation agent the predictive mechanism is used and the negotiation partner uses the static strategies being a mixture of a time-dependant tactic and a behaviour-dependant tactic with various weights assigned to these two tactics. In order to make experiments feasible we choose seven time-dependant tactics and divide them into three subsets:

- Conceder: $C = \{\beta \quad | \quad \beta \in \{2, 5, 8\}\}$
- Linear: $L = \{\beta \quad | \quad \beta \in \{1\}\}$
- Boulware: $B = \{\beta \quad | \quad \beta \in \{0, 3, 0.5, 0.7\}\}$

We consider two behaviour-dependant tactics:

- Absolute Tit-For-Tat: a: $\delta \in \{1\}$ and $R(M) = 0$ (without a random factor)
- Relative Tit-For-Tat: r: $\delta \in \{1\}$

The space of weights assigned to the tactics consists of 9 values obtained through discretization. Analogously as for the set of β values we decompose the set of all weights into three subsets:

- Small: $S = \{0.1, 0.2, 0.3\}$
- Medium: $M = \{0.4, 0.5, 0.6\}$
- Large: $L = \{0.7, 0.8, 0.9\}$

The cartesian product of the sets of the time-dependant tactics, the behaviour-dependant tactics and the weights results in a set of 126 static strategies:

$$ST = (C \cup L \cup B) \times \{a, r\} \times (S \cup M \cup L)$$

The whole set of the static strategies ST is divided into 18 groups of strategies in order to illustrate the performance of our approach:

$$\begin{aligned} ST = &(C \times \{a\} \times S) \cup (L \times \{a\} \times S) \cup (B \times \{a\} \times S) \cup \\ &\cup (C \times \{a\} \times M) \cup (L \times \{a\} \times M) \cup (B \times \{a\} \times M) \cup \\ &\cup (C \times \{a\} \times L) \cup (L \times \{a\} \times L) \cup (B \times \{a\} \times L) \cup \\ &\cup (C \times \{r\} \times S) \cup (L \times \{r\} \times S) \cup (B \times \{r\} \times S) \cup \\ &\cup (C \times \{r\} \times M) \cup (L \times \{r\} \times M) \cup (B \times \{r\} \times M) \cup \\ &\cup (C \times \{r\} \times L) \cup (L \times \{r\} \times L) \cup (B \times \{r\} \times L) \end{aligned} \quad (10)$$

Each group will be shortly denoted using only the first letters. For example:

$$CAS = C \times \{a\} \times S$$

A simple scenario involving a buyer agent and a seller agent

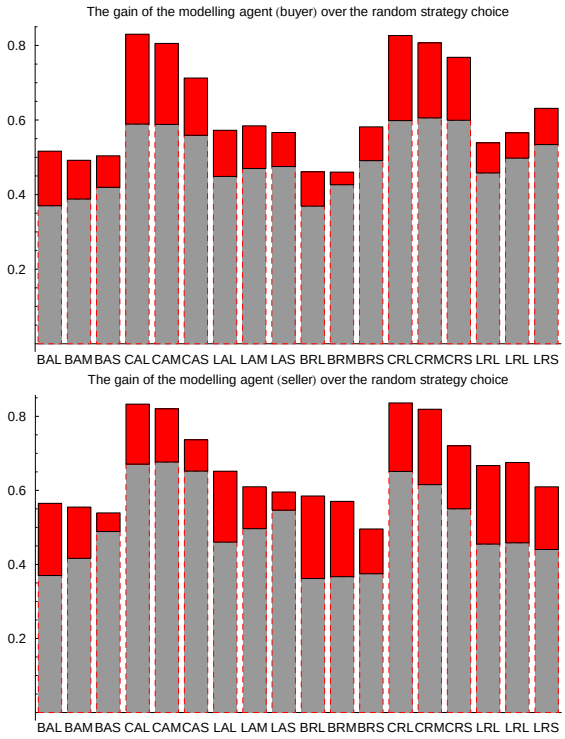

Figure 4: The performance of prediction mechanism applied for the buyer and the seller agents

is presented below. We consider following settings for the buyer: $min^b \in \{10\}$, $max^b \in \{50\}$, $k^b \in \{0\}$, and the consistent deadline for both players $t^b_{max} = 15$. The agreement ranges of both parties are assumed to be fully overlapping ($\Phi = 0$). Analogously as in [4], $max^b - min^b = max^s = min^s$ and $k^s = k^b$. $min^s = min^b + \Phi * (max^b - min^b)$, $max^s = min^s + (max^b - min^b)$. In the experiments we apply the prediction mechanism up to 9 steps forward, ie in the case of deadline $t^b_{max} = 15$ it makes prediction after the first six offers have been generated by the use of time-dependant tactic. This provides also initial data for the modelling. For the initial offers generation we use medium tough tactic ($\beta = 0.5$) with additional perturbations in order to better explore the initial responses of negotiation partner. We carry out the simulations without a communication cost and with low communication cost ($comm \in \{0.01\}$) separately (cost $\tau(t) = tanh(t * comm)$). More advanced scenarios considering different behaviour-dependant tactics and different values of communication cost will be described in further work. The performance of our enhanced modelling approach is illustrated in Figures (4) and (5). The grey parts of bars in the chart represent an average value of utility of a negotiation agent using all the strategies from particular subset of static strategies (for instance: CSA) against all the strategies from the set ST. This corresponds to playing with a random strategy from a particular subset against a random strategy selected from the whole ST according to an uni-

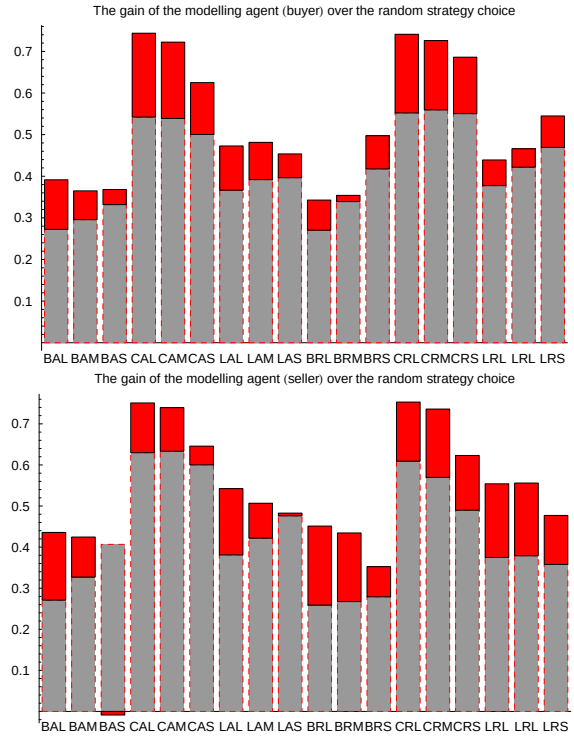

Figure 5: The performance of prediction mechanism taking into account the communication cost applied for the buyer and the seller agents

form probability distribution. The red (dark) surplus in the bar chart illustrates a gain in terms of the utility obtained by the use of our approach instead of the random static strategy choice. In cases of a gain the red (dark) surplus is above the grey part of a bar and in a case of loss it is under the grey part. The bar charts (Figure 4) clearly show that the gain of our predictive mechanism is significant, i.e. on average in comparison with the classical approach without prediction. Although, the reasoning was simplified in comparison to [2] the proposed mechanism still outperforms the random strategy choice and in terms of the gained utility the results are similar to [2]. It should be noted that in the cases of strategies with high contribution of behaviour-dependant tactics (BAS, BRS, etc.) the utility gain is smaller compared to other strategies which is caused by a specific nature of behaviour-dependant tactics. If an opponent uses the time-dependant tactic we can take advantage of it to finish negotiation earlier with a good level of utility. However, very high values of utilities are not possible because the imitation of our behaviour on the side of our partner means that roughly its concessions can not be much bigger than ours. As far as the communication cost is concerned the results are better than in [2]. The figure 5 shows that the utility gain is significant and positive in most of the cases. Another thing worth noticing is that the results are not symmetric for the buyer and for the seller because of the use of Relative Tit For Tat tactic that does not work symmetrically for both roles of an agent. The reason for it is that the value of quotient that is used in this tyoe of tactic is usually higher for the buyer than for the seller. Compared to [2] we obtained high gain in efficiency of the approach.

The simulation for the same scenario took just 20% of the time of the simulation presented in [2].

7. CONCLUSIONS AND FUTURE WORK

The paper proposes an improved approach for reasoning from the history of offers of current negotiation and decision-making based on this reasoning. The predictive mechanism allows an agent to adapt to negotiation partner's behaviour that results in better agreements. The presented results of simulated experiments show that our agent equipped with the enhanced predictive mechanism outperforms the classical approach by achieving substantial gains in terms of utility. In the future the regression analysis will be applied for partner's behaviour prediction and the approach will be tested in more complex scenarios including not consistent deadlines of negotiation parties, partial degrees of overlap of the ranges and different values of communication cost.

ABSTRACT

Multiagent resource allocation is a timely and exciting area of research at the interface of Computer Science and Economics. One of the main challenges in this area is the high complexity of negotiation. In particular, the complexity of the task of identifying rational deals, *i.e.* deals that are beneficial for all participants, often hinders the successful transfer of theoretical results to practical applications. To address this issue, we propose several protocols designed to tame the complexity of negotiation by exploiting structural properties of the utility functions used by agents to model their preferences over alternative bundles of resources. In particular, we consider domains where utility functions are *k-additive* (that is, synergies between different resources are restricted to bundles of at most k items) and *tree-structured* in the sense that the bundles for which there are synergies do not overlap. We show how protocols exploiting these properties can allow for drastically simplified negotiation processes.

1. INTRODUCTION

Multiagent resource allocation is a timely and exciting area of research at the interface of Computer Science and Economics. Applications range from electronic commerce [19], over logistics [12], to the exploitation of earth observation satellites [13]. In this paper, we are going to be concerned with a framework where agents negotiate over a finite number of indivisible resources in a distributed manner [9, 18]. Agents are assumed to only negotiate deals that are beneficial for each of the parties involved (which may be more than two). We are interested in negotiation histories that lead to allocations that are optimal from a social point of view; and we consider an allocation optimal if it maximises the sum of utilities of the agents in the system, *i.e.* if it maximises (utilitarian) social welfare [1].

Unfortunately, the complexity associated with the task of identifying rational deals, *i.e.* deals that are beneficial for all participants, is typically very high and often hinders the successful transfer of theoretical results to practical applications. Common approaches to tame this type of complexity are to restrict the range of utility functions agents can use to model their preferences and to exploit the structure of utility functions during negotiation [4, 15, 17]. This is also the approach we are going to follow in this paper. Concretely, we are going to discuss so-called *tree-structured domains*, where the utility functions of agents are subject to certain structural restrictions. We use a compact representation of utility functions based on the notion of *k-additivity*, which restricts the synergies between different resources to bundles of at most k items each [11]. Tree-structured domains are sets of k-additive utility functions where the bundles for which there are synergies do not overlap.

We then propose two protocols that restrict negotiation to deals involving only the smallest bundles first, and then incrementally bigger bundles. However, these guided negotiation processes are not guaranteed to converge to an allocation with maximal social welfare, *i.e.* the protocols need to be enhanced further. The first protocol we propose is made *intrusive* in the sense that it modifies the structure of agents' utility functions. The second protocol has a centralised flavour and introduces a *system agent* that can *compensate* for a temporary loss in utility. This combination of *guidance* and *social compensation* allows us to restore the convergence properties of the negotiation framework.

Paper Overview

In the remainder of this introduction we briefly review the multilateral negotiation framework we take as the basis for our work [9, 18]. We then exemplify the high complexity of the framework, in Section 2, by analysing the number of deals that agents need to consider at each stage during a negotiation process. The class of tree-structured utilities is introduced in Section 3. Section 4 then presents a number of protocols exploiting these structural properties of util-

ity functions, and shows how they reduce the complexity of the negotiation process. Our theoretical results are complemented by a brief experimental analysis of the protocols. Section 5 concludes with a discussion of the benefits and drawbacks of the approach advocated in this paper.

Multilateral Negotiation over Indivisible Resources

We briefly review the negotiation framework originally introduced by Sandholm [18], albeit in the context of task allocation problems (see [9] for a detailed introduction). Let $\mathcal{A}$ be a finite set of *agents* and let $\mathcal{R}$ be a finite set of indivisible *resources* that cannot be shared. An *allocation* A is a partitioning of the resources in $\mathcal{R}$ amongst the agents in $\mathcal{A}$. Each agent $i \in \mathcal{A}$ is equipped with a *utility function* $u_i : 2^{\mathcal{R}} \rightarrow \mathbb{R}$. We write $u_i(A) = u_i(A(i))$ for the utility assigned by agent i to the bundle it receives in allocation A. A *deal* may involve the reallocation of any number of resources between any number of agents. We therefore specify deals $\delta = (A, A')$ simply as pairs of allocations (with $A \neq A'$). A deal may be accompanied by a monetary *side payment*. We write p_i for the amount paid by agent i (negative in case i receives money). The sum of side payments associated with any given deal has to add up to 0. A deal $\delta = (A, A')$ with side payments p is called *individually rational* iff $u_i(A') - u_i(A) - p_i > 0$ for each agent i involved in the deal (and $p_i = 0$ otherwise). Agents are assumed to only negotiate such individually rational deals.

To assess the overall quality of an allocation, we use the concept of (utilitarian) *social welfare* [1]: $sw(A) = \sum_{i \in \mathcal{A}} u_i(A)$. It is well-known that a deal is individually rational iff it increases social welfare [9]. It is also known that any sequence of individually rational deals will eventually result in an allocation with maximal social welfare [18]. However, this *convergence result* only applies in case agents can negotiate deals involving any number of agents and resources. A recent result has identified the class of *k-deals* (involving at most k resources each) as sufficient to guarantee convergence to an optimal allocation in case all agents use *additively k-separable* utility functions to model their preferences, *i.e.* in case $\mathcal{R}$ can be divided into several preferentially independent bundles of at most k items each [4].

2. NUMBER OF BOUNDED DEALS

Results that identify conditions under which the convergence to a socially optimal allocation remains possible when agents only negotiate deals involving at most k items each significantly reduce the complexity of negotiation (at least in cases where k is small). In particular, the restriction to k-deals significantly reduces the number of deals to be considered at any given stage. In this sense, the quoted result on additively k-separable domains [4] is a first step towards a realistic multilateral negotiation system. However, even in such favourable cases it may be infeasible for agents to identify a k-deal that is acceptable to all parties involved. In this section, we are going to demonstrate this problem by analysing the number of bounded deals that could be implemented in a given allocation.

Recall that $|\mathcal{A}|$ is the number of agents and $|\mathcal{R}|$ is the number of resources in the system. This means that there are $|\mathcal{A}|^{|\mathcal{R}|}$ possible allocations overall (for each resource, we can choose which agent to give it to). Hence, in any given situation there are $|\mathcal{A}|^{|\mathcal{R}|} - 1$ potential deals to consider (we could move to any alternative allocation). This number can, of course, be somewhat reduced, for instance by discounting any previous allocations, but the remaining number of potential deals that need to be checked for their mutual acceptability would still be prohibitively high.

Bounded Number of Resources

The situation improves significantly if we restrict ourselves to bounded deals involving at most k distinct resources. There are $\binom{|\mathcal{R}|}{k}$ ways of selecting k items from the full set $\mathcal{R}$. Then each of the chosen k items can be moved to any of the $|\mathcal{A}|$ agents in the system. If the agent receiving a given item is the same agent where that item resided before the deal, then we take this as an encoding for the item not being moved at all, *i.e.* we are also capturing those deals that involve fewer than k resources. Only one of these cases needs to be excluded, namely the case where not a single of the k chosen resources gets moved (as this would not count as a valid deal). Hence, we end up with the following overall number of possible k-deals for any given allocation A:

$$\binom{|\mathcal{R}|}{k} \cdot (|\mathcal{A}|^k - 1) \tag{1}$$

This is polynomial in both the number of agents and the number of resources, while it has been exponential in the number of resources for deals without structural restrictions. In the case of $k = 1$, for instance, we only have to consider $|\mathcal{R}| \cdot (|\mathcal{A}| - 1)$ potential deals from any given allocation.

Bounded Number of Agents

In case we restrict the *number of agents* involved in a deal, the number of possible deals is not constant anymore, but varies depending on the current distribution of goods. To see this, we first compute the number of deals that are possible within a subgroup $S \subseteq \mathcal{A}$ of agents for a given allocation A. For any given agent $i \in S$, and any resource $r \in A(i)$ currently held by i, i can choose to which agent within the group S the item r should go (or whether it should remain with i). This makes $|S|^{|A(i)|}$ choices for agent i. The same is true for every agent in S (and in the end we still need to subtract 1 to account for the case were not a single resource is moving). We end up with the following formula:

$$|S|^{\sum_{i \in S} |A(i)|} - 1 \tag{2}$$

This number is constant as long as we do not change the overall number of resources held by the agents in S. For a group of two agents $S = \{i, j\}$, for instance, the above formula simplifies to $2^{|A(i)|+|A(j)|} - 1$. Hence, the number of *bilateral* deals (involving only two agents) that are implementable given allocation A can be computed as follows:

$$\sum_{i \neq j \in \mathcal{A}} (2^{|A(i)|+|A(j)|} - 1) \tag{3}$$

Now this number is not constant anymore; it depends on the distribution of resources in allocation A. Take a scenario with 3 agents and 9 resources. If each agent holds 3 resources, then the above formula shows that there are $3 \cdot (2^{3+3} - 1) = 189$ potential bilateral deals. If, on the other hand, we start with an allocation where one of the agents holds all 9 resources to begin with, then there are $2 \cdot (2^{9+0} - 1) + (2^{0+0} - 1) = 1022$ bilateral deals. Indeed, formula (3) shows that the number of possible deals increases as

resources become less evenly distributed amongst the agents in the system. It also shows that, even if we only allow for bilateral deals, the number of deals to be considered is exponential in $|\mathcal{R}|$, the overall number of resources, in case the distribution of resources is highly unbalanced. If the distribution of resources is reasonably well balanced, on the other hand, then the number of possible bilateral deals is "only" exponential in $\frac{|\mathcal{R}|}{|\mathcal{A}|}$, which may be manageable in cases where the number of resources is of a similar order of magnitude as the number of agents.

In conclusion, our discussion in this section has given some insight into the factors that determine the number of deals to be considered in each negotiation round and we have seen that the restriction to deals involving only a limited number of resources can result in a significant reduction in complexity. If we restrict deals to those between a bounded number of agents, the positive effect is considerably less significant. In either case, the number of deals to be considered typically remains very high and makes the design of general strategies for multilateral negotiation particularly challenging.

3. TREE-STRUCTURED DOMAINS

In this section, we are going to introduce a restriction on utility functions which we call *tree-structured* utilities. This is a natural restriction for many applications, which will allow us to drastically reduce the search space without losing the convergence properties.

The k-additive Form

An important parameter in the specification of any multiagent resource allocation problem is the way we represent the preferences of individual agents over alternative bundles of resources. A natural and compact language is the so-called *k-additive form* of representing utility functions. A utility function u_i is k-additive iff there exists a set of *coefficients* $\{\alpha_i^T \mid T \subseteq \mathcal{R}\}$ such that $\alpha_i^T = 0$ whenever $|T| > k$, and the following equality holds for all bundles $R \subseteq \mathcal{R}$:

$$u_i(R) = \sum_{T \subseteq R} \alpha_i^T \quad (4)$$

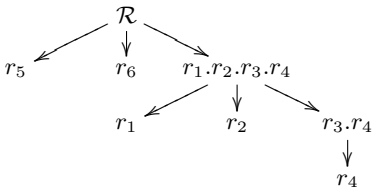
That is, agent i enjoys an increase in utility of α_i^T when it owns all the items in T together, *i.e.* α_i^T represents the synergetic value of this bundle. If a utility function is defined in terms of such coefficients, we say that it is given in k-additive form. When describing examples, we are going to use a simplified notation. For instance, $u_i = 5.r_1 + 3.r_2.r_3$ represents a 2-additive utility function with two non-zero coefficients: $\alpha_i^{\{r_1\}} = 5$ and $\alpha_i^{\{r_2,r_3\}} = 3$.

The k-additive form goes back to the work of Grabisch [11] in fuzzy measure theory and has recently been advocated as a useful preference representation language in the context of both combinatorial auctions [5] and distributed negotiation schemes [3]. Similar preference languages have been used in Artificial Intelligence for some time [2]; what is special about the k-additive form is that it parametrises the degree of synergies in a natural manner. If k can be chosen freely, then *any* utility function can be written in k-additive form, and the k-additive form is typically significantly more *concise* than simply enumerating the utilities for all bundles [3]. For ease of presentation, we are going to assume that the coefficient for the empty bundle $\alpha_i^{\{\}} = 0$ for all agents $i \in \mathcal{A}$ (but the applicability of our results is not affected by this assumption).

Terms and Trees

To define tree-structured domains, we require utilities to be represented in k-additive form. The set of *terms* of a utility function u_i is the set of bundles T with a non-zero coefficient α_i^T in the k-additive form. For instance, the utility function $u_i = 16.r_2 + 5.r_1.r_2.r_4 - 2.r_1.r_3$ uses the terms r_2, $r_1.r_2.r_4$, and $r_1.r_3$. Let $\{u_1, \ldots, u_n\}$ be the set of utility functions of the agents in the system. $\mathcal{T}$ will denote the set of all terms appearing in the representation of any of the utility functions $u_1, \ldots, u_n$, and α_i^T will denote the coefficient of term T in u_i. Finally, $\mathcal{T}^l$ denotes the set of terms in $\mathcal{T}$ consisting of exactly l resources, while $\mathcal{T}^{\leq l}$ denotes the set of terms in $\mathcal{T}$ with at most l resources each.

Intuitively, tree-structured utilities are k-additive functions in which there are no "overlapping" terms.



DEFINITION 1. *A set of utility functions $\{u_1, \ldots, u_n\}$ is called tree-structured iff, when represented in k-additive form, it is the case that for all terms $T_1, T_2 \in \mathcal{T}$ we have either $T_1 \subseteq T_2$, or $T_1 \supseteq T_2$, or $T_1 \cap T_2 = \{\}$.*

It is also helpful to note that a set of utility functions is tree-structured iff the terms of $\mathcal{T}$ can be represented by a tree, in which $\mathcal{R}$ is the root, and each term is a node. Branches of the tree represent the $\subset$ relation. The following example illustrates this representation.

EXAMPLE 1. *Consider the set $\{u_1, u_2, u_3\}$ of utility functions defined as follows:*

$$\begin{aligned} u_1 &= r_2 + 3.r_5 \\ u_2 &= 3.r_1 + 10.r_1.r_2.r_3.r_4 + 8.r_5 + 4.r_6 \\ u_3 &= r_6 - r_4 + 8.r_3.r_4 \end{aligned}$$

These functions are 4-additive as well as tree-structured. The set of terms $\mathcal{T} = \{r_1, r_2, r_4, r_5, r_6, r_3.r_4, r_1.r_2.r_3.r_4\}$ can also be represented by the following tree:

The idea of tree-structured domains has also been used by Rothkopf *et al.* [17] in the context of combinatorial auctions. In their work, bids are restricted to bundles that belong to a given tree structure. They show that this restriction makes the winner determination problem tractable. We are going to exploit this reduced level of complexity as well, although by designing a negotiation protocol rather than an optimisation algorithm.

We note here that any set of k-additive tree-structured utilities is also additively k-separable. Hence, the convergence towards an allocation with maximal social welfare in case agents only negotiate individually rational k-deals is guaranteed by the aforementioned result [4].

$\mathcal{T}$-deals

Still, as argued in Section 2, even finding a rational k-deal can often be computationally infeasible. Our aim is therefore to exploit this new restriction on utility functions to

come up with a new type of deal that is less complex, while still ensuring the same convergence properties.

DEFINITION 2. *Let $\mathcal{T}$ be a set of terms. A $\mathcal{T}$-deal is a deal involving the reallocation of the resources of a single term in $\mathcal{T}$ from any number of senders to a single receiver.*

For our example above, for instance, moving all of r_1, r_2, r_3 and r_4 from whichever agent currently holds them to, say, agent 1 would be a valid $\mathcal{T}$-deal. Only moving r_3, on the other hand, would not constitute a $\mathcal{T}$-deal (because r_3 does not occur as a term in the representation of the utility function any of our three agents).

How many $\mathcal{T}$-deals are possible from a given allocation? The exact number will depend on the particular allocation in question, but $|\mathcal{T}| \cdot |\mathcal{A}|$ will certainly be an upper bound: for any term in $\mathcal{T}$ we can choose which of the agents in $\mathcal{A}$ should receive that term in its entirety. How many terms can we have in $\mathcal{T}$ in the worst case? Firstly, the number of non-overlapping terms of size k is bound by $\lceil \frac{|\mathcal{R}|}{k} \rceil$. Secondly, given a set of k resources, we can use these to construct a subtree with at most $2k-1$ nodes (to see this, consider that splitting each term/node into two balanced subnodes will give a tree exhibiting the maximal number of nodes). Hence, we end up with the following upper bound for the number of terms in $\mathcal{T}$ for any set of k-additive tree-structured utility functions:

$$|\mathcal{T}| \quad \leq \quad (2k-1) \cdot \left\lceil \frac{|\mathcal{R}|}{k} \right\rceil \tag{5}$$

Hence, even if we do not put any restrictions on k (*i.e.* in case $k = |\mathcal{R}|$), we end up with an upper bound for the number of possible $\mathcal{T}$-deals of $(2 \cdot |\mathcal{R}| - 1) \cdot |\mathcal{A}|$. This number is of the same order of magnitude as the number of 1-deals available from any given allocation, and significantly lower than the number of possible k-deals for any $k > 1$. In other words, the complexity of finding rational $\mathcal{T}$-deals is also very low compared to that of finding rational k-deals.

However, as illustrated by our next example, simply restricting negotiation to individually rational $\mathcal{T}$-deals will not be sufficient to guarantee that an allocation with maximal social welfare will be reached eventually in all cases.

EXAMPLE 2. *Consider the following utility functions:*

$$\begin{aligned} u_1 &= 10.r_1 \\ u_2 &= 10.r_2 \\ u_3 &= 11.r_1.r_2 \end{aligned}$$

Furthermore, let the initial allocation be the allocation assigning all items to agent 3. Then the (only) optimal allocation gives r_1 to agent 1 and r_2 to agent 2. Clearly, there are no rational $\mathcal{T}$-deals allowing the system to reach this optimal allocation. For any of these deals, the utility of agent 3 would drop from 11 to 0, while the receiving agent (either 1 or 2) would only gain 10 utility points. Hence, it would not be possible to arrange for suitable side payments making such a deal beneficial for everyone involved.

In order to restore the desired convergence properties of the framework, we will need to investigate more complex protocols restricting the negotiation process and exploiting, through $\mathcal{T}$-deals, the properties of tree-structured utilities.

4. TREE-CLIMBING PROTOCOLS

The basic idea of *tree-climbing protocols* is to allow $\mathcal{T}$-deals involving only the smallest bundles first, then to incrementally allow bigger bundles, until all possible $\mathcal{T}$-deals have been tried. The *Naive Tree-Climbing Protocol* is a simple implementation of this principle.

Algorithm 1 Naive Tree-Climbing Protocol

Require: n agents with tree-structured utilities $u_1, \ldots, u_n$ (with $\mathcal{T}$ the set of all terms)
1: $l \leftarrow 1$.
2: **repeat**
3: Restrict allowed deals to $\mathcal{T}^l$-deals.
4: Let agents negotiate individually rational $\mathcal{T}^l$-deals.
5: **if** no more deal can be conducted **then**
6: $l \leftarrow l + 1$
7: **end if**
8: **until** $l > |\mathcal{R}|$

Clearly, this protocol is more restrictive than the liberal "protocol" consisting of allowing any $\mathcal{T}$-deals, *i.e.* it cannot guarantee an optimal outcome either (see Example 2). By inspecting more carefully the scenario described in Example 2, however, we find clues indicating possible improvements of this protocol: During the first step of the protocol (where $l = 1$, and only $\mathcal{T}^1$-deals are allowed), the term $r_1.r_2$ in u_3 prevents the resources from moving away from agent 3. If, during this first step, terms containing more than one resource were to be *removed* from the utility functions, then the resources would be able to move towards agents 1 and 2.

4.1 An Intrusive Tree-Climbing Protocol

Based on this idea, we design a new protocol which, during round l, removes from all utility functions any terms involving more than l resources. This protocol is called the *Intrusive Tree-Climbing Protocol* (ITCP). It is intrusive in the sense that it modifies the utility functions of each agent during each round of the protocol. In the specification of the ITCP, $u_i^{\leq l}$ denotes the utility function u_i with all terms of size greater than l having been removed. For instance, if $u_i = 12.r_1 + 3.r_1.r_2 + r_1.r_3 - 2.r_1.r_2.r_4$, then $u_i^{\leq 1} = 12.r_1$, $u_i^{\leq 2} = 12.r_1 + 3.r_1.r_2 + r_1.r_3$, and $u_i^{\leq 3} = u_i$.

Algorithm 2 Intrusive Tree-Climbing Protocol (ITCP)

Require: n agents with tree-structured utilities $u_1, \ldots, u_n$ (with $\mathcal{T}$ the set of all terms)
1: $l \leftarrow 1$.
2: **repeat**
3: Restrict allowed deals to $\mathcal{T}^l$-deals,
4: Enforce all agents i to change their utilities to $u_i^{\leq l}$.
5: Let agents negotiate individually rational $\mathcal{T}^l$-deals.
6: **if** no more deal can be conducted **then**
7: $l \leftarrow l + 1$
8: **end if**
9: **until** $l > |\mathcal{R}|$

Convergence

As we shall see, the ITCP guarantees convergence to an allocation with maximal social welfare, provided the utility functions of all agents are tree-structured with *positive* coefficients. We are first going to show that each round of the

protocol will lead to an allocation deemed optimal wrt. the truncated utility functions of agents populating the system. The social welfare of an allocation A wrt. truncated utility functions in round l is denoted by $sw^{\leq l}(A) = \sum_{i \in \mathcal{A}} u_i^{\leq l}(A)$.

LEMMA 1. *For any set of tree-structured utilities with positive coefficients, if at the end of round l of the ITCP an optimal allocation wrt. $sw^{\leq l}$ has been reached, then at the end of round $l+1$ an optimal allocation wrt. $sw^{\leq l+1}$ will be reached.*

PROOF. Assume after round l the allocation A^l has been reached and that allocation is optimal wrt. $sw^{\leq l}$. Let A^{l+1} be (any of) the allocation(s) that are optimal wrt. $sw^{\leq l+1}$. Because of the tree structure, we can consider the optimal allocation of resources belonging to distinct terms in $\mathcal{T}^{l+1}$ separately. Let $T \in \mathcal{T}^{l+1}$. We can distinguish three cases: (1) If T is owned by a single agent in A^{l+1}, then we are done, because this can be achieved using a $\mathcal{T}^{l+1}$-deal. (2) If not, and if T is also not owned by a single agent in A^l, then we are done, because the optimal allocation will be the same as in A^l. (3) If it were the case that T is owned by a single agent in A^l but not in A^{l+1}, then that would pose a problem, because the necessary reallocation would not be a $\mathcal{T}^{l+1}$-deal. However, this situation is impossible due to our restriction to positive coefficients. □

We are now in a position to prove that the ITCP does indeed guarantee the intended convergence property.

THEOREM 1. *For any set of tree-structured utilities with positive coefficients, following the ITCP will result in an allocation of resources with maximal social welfare.*

PROOF. The proof is by induction over the number of rounds. In the first round, all agents have additive utility functions, and it has been shown elsewhere that negotiation with individually rational deals involving only a single resource each will converge to an optimal allocation in additive domains [9]. Lemma 1 shows that the property of having maximal social welfare wrt. truncated utility functions persists from one round to the next. Hence, after the final round, the allocation reached will have maximal social welfare wrt. the full utility functions. □

Negative Coefficients

Observe that our proof of Lemma 1 shows why we need to restrict ourselves to k-additive functions with *positive* coefficients. If there are negative coefficients, then also deals that "destroy" an existing term can increase utility. This is also demonstrated by the following example.

EXAMPLE 3. *Consider the following utilities:*

$$u_1 = 2.r_1.r_2 + 10.r_3 - 100.r_1.r_2.r_3$$
$$u_2 = 5.r_3$$

After round 2 of the ITCP, agent 1 would own all three resources, and the social welfare relative to terms of length ≤ 2 would be 12. In round 3, the only individually rational deal involving a term with exactly 3 resources would be to move $r_1.r_2.r_3$ from agent 1 to agent 2 (increasing social welfare from -88 to 5). But then the deal of moving r_3 back to agent 1 would increase social welfare even further, namely from 5 to 10 (which is the maximal social welfare attainable for this resource allocation problem). However, this deal would not be admissible in the ITCP during round 3.

A potential way around this problem would be to widen the class of $\mathcal{T}$-deals, and to also allow for deals that involve a term from $\mathcal{T}$ being removed from a *single sender* (while our actual definition of $\mathcal{T}$-deal foresees a single receiver). With that extension, the ITCP could be proved to converge to an allocation with maximal social welfare also for tree-structured utilities with arbitrary coefficients, although it would also lose much of its appeal by increasing the range of available deals at each stage significantly.

Note that in the work of Rothkopf *et al.* [17] this problem does not occur, because the standard bidding language for combinatorial auctions (the so-called "OR language") can only express superadditive preferences in the first place [14].

Communication Complexity

The *communication complexity* of a negotiation scheme assesses the length of negotiation processes and the amount of information that agents exchange. The "first level" of communication complexity is concerned with the *number of deals* required to reach an optimal allocation [8]. Here we can distinguish two types of upper bounds, namely the length of the longest and that of the shortest path to the optimum. For the ITCP we obtain the following bounds:

- The ITCP requires agents to implement a maximum of $|\mathcal{T}| \cdot (|\mathcal{A}| - 1)$ deals (*longest path*), after which the optimal allocation will be reached.
- In the ITCP, agents can always reach an optimal allocation by negotiating at most $|\mathcal{T}|$ deals (*shortest path*).

The shortest path applies if agents always implement the "ideal" deal for every term in $\mathcal{T}$. The longest path applies if utility functions are such that we can move each term to every agent before it finally reaches its eventual owner.

Discussion

A possible interpretation of the ITCP would be that it works with a sequence of progressively more fine-grained *approximations* to the real utility functions in such a way that structurally simple deals become individually rational (wrt. these approximations). Of course, these are approximations wrt. the *representation* of utility functions (in k-additive form), but not necessarily wrt. the values that utility functions assign to bundles of resources.

These two dimensions may, however, coincide in many practical cases. If we assume that the synergetic effect of a bundle of resources reduces as the cardinality of that bundle increases, then the sequence of auxiliary utility functions used in the ITCP will indeed be progressively more accurate in terms of the values they assign to bundles as negotiation develops. In other words, if the coefficients in the k-additive form are high for single resources, and if they get smaller as the size of the respective term increases, then the utility functions used in the ITCP become more accurate in each round. This is a very reasonable assumption to make: the larger a bundle of resources is, the more difficult would it be for an agent to estimate the additional benefit incurred by owning all the resources in that bundle *together* (beyond the benefit incurred by the relevant subsets). Indeed, the very same (cognitive) argument is one of the main reasons why k-additive utilities with low values of k are not only computationally attractive but also highly relevant in practice.

Nevertheless, the ITCP *does* violate the postulate of full individual rationality for all stages of a negotiation process.

Also, because of its "intrusive" aspect, this protocol is not completely satisfactory: it cannot be applied when agents are not under the control of the designer or when they are not willing to temporarily manipulate their own preferences in order to implement the protocol correctly. Clearly, such a protocol would be of little use when agents are humans, or simply when privacy issues prevent the designer from directly accessing the agents' preferences.

4.2 A Non-Intrusive Protocol

To overcome the drawbacks of our intrusive protocol, we design a third protocol in which utilities are not modified, but where a special payment function influences the rationality considerations of each agent. In addition, the system itself also participates in the side payments, by giving money to or taking money from the negotiating agents. For this purpose, we introduce a so-called *system agent*. The trick here is that these side payments have exactly the same effect as truncating the utility functions, but without being intrusive (as shown in Theorem 2). Thus, this protocol could be used in real applications, even with human agents as long as utilities have been elicited.

This new protocol is called the *Omniscient ϵ-Altruistic Tree-Climbing Protocol* (OATCP). In this protocol the system actively mediates the negotiation process. The protocol is called *omniscient*, because the system needs to know the utility functions of all agents. It is called *ϵ-altruistic*, because the system must be prepared to share its money with the agents in order to reach an allocation with maximal social welfare, and because the amount of money it shares depends on a parameter ϵ. For the specification of the OATCP, we define $\Delta^{\leq l}_{(A,A')} = sw^{\leq l}(A') - sw^{\leq l}(A)$. This is the increase in social welfare for the deal $\delta = (A, A')$ wrt. truncated utilities considering only terms of size $\leq l$.

Algorithm 3 Omniscient-Altruistic Tree-Cl. Pr. (OATCP)

Require: n agents with tree-structured utilities $u_1, \ldots, u_n$ and a parameter $\epsilon \in (0, 1]$ (with $\mathcal{T}$ the set of all terms)

1: All agents transmit their utility functions to the *system agent*.
2: $l \leftarrow 1$.
3: **repeat**
4: Restrict allowed deals to $\mathcal{T}^l$-deals.
The side payment for agent i for a $\mathcal{T}^l$-deal $\delta = (A, A')$ involving n' agents is computed as follows:
$p_i = u_i(A') - u_i(A) - \frac{\epsilon}{n'} \cdot \Delta^{\leq l}_{(A',A)}$.
For the system agent, $p_{sys} = -\sum p_i$.
5: Let agents negotiate individually rational deals.
6: **if** no more deal can be conducted **then**
7: $l \leftarrow l + 1$
8: **end if**
9: **until** $l >\mid \mathcal{R} \mid$

Role of the System Agent

Note that in the OATCP the *system agent* could be viewed as a kind of bank giving or receiving money from agents. The amount of money shared with other agents depends on the difference of satisfaction enjoyed by the whole society before and after the deal and on the value of the parameter ϵ.

- When ϵ is close to 1, the system agent in not guaranteed to earn any money in the long run. In that case, the system agent is said to be *altruistic*, because the other agents will benefit from this by earning a lot.
- When ϵ is close to 0, then during each deal, the system agent takes from the other agents as much money as possible. Thus, the negotiating agents will earn the minimum amount of money necessary to reach the optimal allocation, and the system agent will earn a lot more (not altruistic at all in that case).

The protocol could be extended in such a way that the money earned by the system agent would later be redistributed. One option would be to simply divide the money equally amongst all agents, but how to best set up this redistribution in view of both fairness considerations and strategic issues is a question that warrants further investigation.

Convergence

The following results show that this protocol also converges to an allocation with maximal social welfare, just as the ITCP does. We first establish that a deal is "rational" with the special payment function (*i.e.* utility gains outweigh payments for each of the agents except the system agent) iff it increases social welfare wrt. truncated utilities.

LEMMA 2. *During round l of the OATCP, a given deal $\delta = (A, A')$ is rational iff $sw^{\leq l}(A) < sw^{\leq l}(A')$.*

PROOF. '$\Rightarrow$': Suppose the deal is rational. That is, for each agent i involved, $u_i(A') - u_i(A) - p_i > 0$. Thus,

$$sw^{\leq l}(A') - sw^{\leq l}(A) \;=\; \frac{1}{\epsilon} \cdot \sum (u_i(A') - u_i(A) - p_i) \;>\; 0$$

'$\Leftarrow$': Now suppose $sw^{\leq l}(A') > sw^{\leq l}(A)$. Then for each agent i involved in the deal, the rationality criterion is met:

$$u_i(A') - u_i(A) - p_i \;=\; \frac{\epsilon}{n'} \cdot \Delta^{\leq l}_{(A',A)} \;>\; 0$$

This completes our proof of Lemma 2. □

This directly leads to the convergence result.

THEOREM 2. *For any set of tree-structured utilities with positive coefficients, following the OATCP will result in an allocation of resources with maximal social welfare.*

PROOF. We show that the deals accepted in this protocol are the same as those accepted in the ITCP protocol. Clearly, during round l, a deal $\delta = (A, A')$ is accepted in the ITCP iff $sw^{\leq l}(A) < sw^{\leq l}(A')$. Lemma 2 shows that the OATCP behaves in exactly the same way. The claim then follows from Theorem 1. □

Given this operational equivalence between the two protocols, the communication complexity of the OATCP (*i.e.* the number of deals required to reach an optimal allocation following the protocol) is the same as for the ITCP.

Money Earned by the System Agent

A critical point of the OATCP is that it requires an external provider of money. However, the following result shows that the system agent will actually *earn* money over the entire duration of the protocol, as long as we choose a sufficiently small value for ϵ.

THEOREM 3. *If ϵ is sufficiently small, then the system agent will have earned a positive amount of money by the end of any OATCP negotiation.*

PROOF. Let us first compute how much is earned by the system agent each time a deal is conducted. Suppose at step l, a deal $\delta = (A, A')$ is conducted by n' agents. The system agent makes the following payment:

$$\begin{aligned} p_{sys} &= -\sum \left(u_i(A') - u_i(A) - \frac{\epsilon}{n'} \cdot \Delta^{\leq l}_{(A',A)} \right) \\ &= -(sw(A') - sw(A)) + \epsilon \cdot \Delta^{\leq l}_{(A',A)} \end{aligned}$$

Now let d be the number of deals conducted during the whole of the negotiation process. Furthermore, let A_{init} be the initial allocation and let A_{fin} be the final allocation If p^{total}_{sys} denotes the total amount of money the system agent pays out during the whole negotiation process, then $-p^{total}_{sys}$ is the money earned by the system. We get:

$$\begin{aligned} -p^{total}_{sys} &= \sum_{\delta=(A,A')} \left(sw(A') - sw(A) - \epsilon \cdot \Delta^{\leq l}_{(A',A)} \right) \\ &\geq sw(A_{fin}) - sw(A_{init}) - \epsilon \cdot d \cdot \max_{A,A',l} \Delta^{\leq l}_{(A',A)} \end{aligned}$$

Clearly, we can see that $-p^{total}_{sys}$ converges to the overall social surplus as ϵ decreases:

$$\lim_{\epsilon \to 0}(-p^{total}_{sys}) = sw(A_{fin}) - sw(A_{init})$$

Hence, as long ϵ is chosen small enough, the system agent can always earn during negotiation. □

The central idea in the OATCP is that the system agent (*i.e.* the mechanism) can give a "loan" to agents to allow them to accept otherwise disadvantageous deals, but that these agents repay this loan later on when they arrange deals that are overly beneficial for themselves. This general idea would also be applicable in other scenarios than we have considered here, where agents do not necessarily have tree-structured utility functions. As long a the final allocation has higher utilitarian social welfare than the initial allocation and as long as the system agent has sufficient funds to temporarily sustain allocations with very low social welfare, *any* sequence of deals can be made individually rational from the viewpoint of the negotiating agents and would still result in an eventual surplus for the system agent.

4.3 Experimental Analysis

We have shown that both the ITCP and the OATCP perform optimally in case all agents model their preferences using tree-structured utilities with positive coefficients. While this is a reasonably wide class of utility functions that are relevant to real application domains, it is also clear that it will not always be possible to meet these constraints. Still, the ideas implemented in our protocols seem to have a general appeal and may also be useful (albeit not to the degree of guaranteeing optimal outcomes in all cases) in domains that are not tree-structured.

To test this intuition, we have carried out a number of experiments with agents that do not have tree-structured utilities. Figure 1 shows an example. The graph relates the performance of the ITCP/OATCP and of a protocol only implementing 1-deals to the maximal social welfare attainable. In each run, we have generated the utility functions of 4 agents over 10 resources in k-additive form by randomly choosing 8 terms and coefficients each. The size of terms is drawn from $\{1..k_{max}\}$ and the size of coefficients is drawn from {1..100} (uniform distribution). The horizontal axis shows the value of k_{max} and the vertical shows the social welfare of the final allocation (averaged over 20 runs). The experiment shows that the ITCP/OATCP clearly outperforms the 1-deal protocol for larger values of k_{max}, and that it typically manages to reach an allocation with over 95% of the maximal social welfare. We have run similar experiments with other distributions (not reported here for lack of space). The ITCP/OATCP generally performs well and is preferable to a 1-deal protocol whenever the agents' utilities include a significant number of terms of size greater than 1.

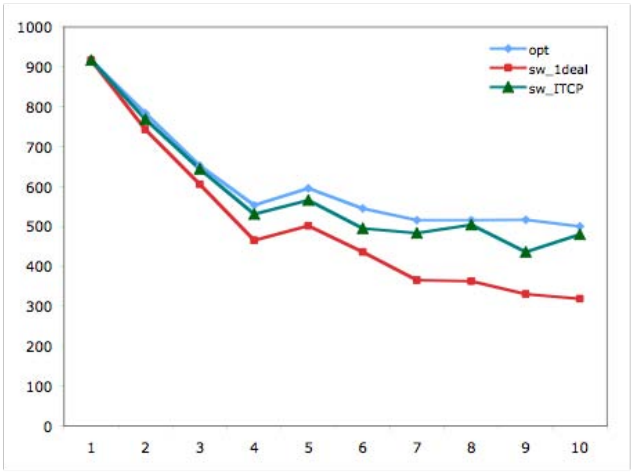


Figure 1: Performance of different protocols

5. CONCLUSION

We have further analysed a negotiation framework previously studied by several authors [7, 8, 9, 18]. While most work on negotiation in multiagent systems has addressed either bilateral negotiation [16] or auctions [6], this framework is multilateral, *i.e.* deals may involve any number of agents and any number of resources. The requirement for full multilateral negotiation stems from the fact that agents are assumed to be both rational and myopic. Recent results have identified situations in which deals involving only a limited number of resources each are required to reach allocations that are optimal from a social point of view [4].

However, the task of identifying rational deals, *i.e.* deals that are beneficial for all participants remains highly complex. In this paper, we have shown that if all agents model their preferences by means of *tree-structured* utility functions, then finding an allocation with maximal social welfare does become feasible by implementing adequate protocols. Two protocols, clearly designed to exploit the specific structure of these functions, have been proposed in this paper. The crucial contribution in our proposal, we believe, is the *combination of two ideas:*

- The central idea in the ITCP has been to provide a protocol that *guides* negotiation. In each round, there are only a relatively small number of options as to which deal to choose (and the complexity of these deals increases stepwise, from round to round). The particular choices made in the definition of the ITCP mean that deals are not too far from truly rational deals (certainly if we make some additional assumptions on the nature of utility functions, as discussed earlier).

- The additional idea in the OATCP has been to introduce a system agent that can *compensate* for a temporary loss in social welfare (provided that such a loss is due to a deal sanctioned by the guidelines implemented in the ITCP). It thereby allows for a wider range of deal sequences leading to the optimal allocation, including sequences of structurally simple deals.

This combination of *guidance* and *social compensation* makes our approach work. While our formal results are restricted to tree-structured domains, we believe that the central ideas are general enough to be applied to other scenarios as well. This view is supported by our experimental results with utility functions that are not tree-structured.

Our proposal may be considered a hybrid between distributed and centralised approaches to resource allocation. On the one hand, allocations emerge in a distributed manner as a result of a sequence of local negotiation steps. On the other hand, the concept of the system agent introduces a centralised element. One of the main arguments usually given in favour of distributed approaches over centralised ones (such as combinatorial auctions), is that it may not always be possible to find an agent that could act as the central authority (the auctioneer) executing the allocation procedure.[1] To some degree, the same reservations may be made against our proposal. However, we believe that there is at least one important difference. In a combinatorial auction, the auctioneer is endowed with the (significant) computational burden of deciding the final allocation (the so-called winner determination problem [6]). In our approach, on the other hand, there are no computationally hard tasks associated with the role of the system agent. Of course, in the context of the tree-structured domains studied here, the centralised task is not prohibitively hard in itself. Still, our work shows that it can also be distributed safely amongst agents by employing our protocols. Importantly, our experiments suggest that the ideas underlying the design of these protocols also have a more general appeal.

A potential problem with our approach is that agents could stop participating in negotiation before the optimal allocation has been reached. Indeed, it may be rational for them to do so, because our protocols allow certain agents to temporarily enjoy higher utility than they would enjoy in the socially optimal allocation. In this sense, the framework loses the "anytime character" of the original system [18], where every new allocation would be guaranteed to have higher social welfare than its predecessor. This anytime character is particularly important because of the prohibitively high complexity of the general framework [3, 7, 8]. If optimal allocations cannot be guaranteed to be found within a reasonable amount of time, then the original framework does at least guarantee some improvement over the initial allocation when time runs out. In our proposal, the anytime character of the framework is far less important, because it dramatically reduces the complexity of negotiation and thereby makes convergence to an optimal allocation within a reasonable amount of time a realistic option. Nevertheless, the issue of incentive compatibility in the OATCP protocol remains an interesting topic for future work.

[1]Such arguments for distributed negotiation schemes are similar to those often given to motivate the interest in *distributed constraint optimisation problems* [10]. It would be interesting to explore whether algorithms developed in this area could be applied to our negotiation setting as well.

ABSTRACT

This paper presents a statistical learning approach to predicting people's bidding behavior in negotiation. Our study consists of multiple 2-player negotiation scenarios where bids of multi-valued goods can be accepted or rejected. The bidding task is formalized as a selection process in which a proposer player chooses a single bid to offer to a responder player from a set of candidate proposals. Each candidate is associated with features that affect whether or not it is the chosen bid. These features represent social factors that affect people's play. We present and compare several algorithms for predicting the chosen bid and for learning a model from data. Data collection and evaluation of these algorithms is performed on both human and synthetic data sets. Results on both data sets show that an algorithm that reasons about dependencies between the features of candidate proposals is significantly more successful than an algorithm which assumes that candidates are independent. In the synthetic data set, this algorithm achieved near optimal performance. We also study the problem of inferring the features of a proposal given the fact that it was the chosen bid. A baseline importance sampling algorithm is first presented, and then compared with several approximations that attain much better performance.

1. INTRODUCTION

Recent developments in automated decision-making are making it possible for agents to negotiate with each other in environments of increasing complexity, such as supply chains and market-based scheduling [16, 1]. At the same time, computer systems are becoming commonplace in our every day lives, and settings in which computers and people make decisions together are increasingly prevalent [4]. One area in which both of these trends interleave is electronic commerce, where computers acting as autonomous agents, or as proxies for individual people, are changing the way goods and services are traded on the Internet [21].

One of the main challenges for agents that negotiate in strategic environments is reasoning about the bidding strategies of others. For example, in the Supply Chain domain of the Trading Agent Competition [1] (TAC SCM), agents bid competing offers for supplying a series of multi-valued contracts, each satisfying a minimal configuration of computer hardware resources. The agent with the lowest offer is selected to supply each contract after procuring the necessary resources. Agents cannot observe each others' bids, resources or the winning bid configuration. For agents to out-bid their opponents without sacrificing future revenue, they must be able to predict their opponents' bids for current and future contracts.

Although much work has been done on predicting the bidding and pricing behavior of automatic agents in negotiation [16, 20, 19], modeling people's bidding behavior presents several new challenges. First, social factors such as altruism, self-interest and fairness affect people's negotiation strategies [3]. Second, people's behavior is diverse – the extent to which social factors affect behavior varies greatly among people [12]. Third, people's play does not generally adhere to traditional game-theoretic equilibria [13, 3]. Fourth, humans often make mistakes with regard to their reported utility function[2].

To explain these findings, researchers in behavioral economics have suggested that people's preferences in settings that include other decision-makers are affected by others' outcome as well as their own [15]. For example, in particular contexts, some buyers reject proposals that are highly beneficial to the sellers, even though they are beneficial to the buyers, because they see them as unfair. To be able to interact successfully with individuals, artificial agents must be able to learn how these social preferences affect the bidding behavior of different people.

This work presents a machine learning approach for meeting these challenges. Our study uses a series of take-it-or-leave-it negotiation scenarios in which one agent proposes a trade consisting of multiple goods to a responder agent who must accept or reject the trade. In previous work, we showed that a computer player that used a decision theoretic model to reason about the responder's social preferences outperformed other computer players that used standard game theoretic equilibria [10]. This work formalizes the task of bidding from the proposer's perspective without using a decision-theoretic model. It defines a *selection process* where a number of candidate proposals are available to the proposer and

one of them is selected as the chosen bid. Previously we were only concerned with predicting whether or not the proposer's offer was accepted by the responder. In this work, we need to predict the outcome of a multi-way decision process where there are many possible offers for the proposer to choose from.

Each candidate is associated with features, that affect whether or not the candidate is chosen. In general, these features can represent anything about the decision-making that is salient to agents' models. In this work, these features are players' social preferences, defined in terms of functions over their payoffs.

In this work we address the following three tasks. First, we show how to predict the chosen bid given the features of all the candidate proposals. Second, we present and evaluate two algorithms for learning a selection process from data. One of the algorithms uses supervised learning, where an instance consists of the attributes of each proposal and the classification is whether or not the proposal was the chosen bid. In this approach, the probability of a particular candidate offer being selected does not depend on the quality of the attributes of other candidates. The other algorithm learns from each *pair* of candidate proposals, where one was the chosen bid and one was not. In this way, it learns from individual candidates, but also takes into account the quality of other candidates.

To capture the behavior of different types of people, both algorithms use a mixture model of belief networks, each associated with a separate utility function that is a weighted summation of its social preferences. In this way, each network predicts how likely a particular type of person is to bid any given proposal. The feature weights for each type are updated by using standard gradient descent. Because the type of a person is not observed, we estimate a probability distribution over the type space using a technique that is inspired by the Expectation Maximization algorithm [8].

These algorithms are evaluated on real data that was obtained by observing people negotiate with each other in laboratory settings as well as synthetic data that was designed by the researchers by sampling from pre-generated selection models. We expected the second algorithm to be better suited for learning selection processes because it learns from candidate proposals that are *not* chosen as well the chosen bid. This gives us vital information to use in the learning process. For example, if there are many candidate proposals with feature values that are similar to those of the chosen bid, their likelihood should be higher than that of a proposal whose feature values are *less* similar to the chosen bid. The results confirm our hypothesis, in that they show that the algorithm that learns from pairs of candidates performs much better for both data sets. In particular, the second algorithm achieved near optimal performance on the synthetic data set.

The third task is to infer the features of a proposal given the fact that it was the chosen bid. For example, suppose that the contracts in the TAC SCM domain specified minimal hardware configurations. Given a winning bid and a prior distribution over the possible configuration values, it might be possible for agents to infer that the RAM size feature of the winning bid was significantly larger than the minimal required RAM size. They could then tailor their future bids to include larger RAM components.

As a baseline, we present an importance sampling algorithm that weights the features of a candidate proposal by the probability that the object is the winner. We then discuss several alternative approximation algorithms that are much quicker than the baseline algorithm. As a result, many more samples may be generated in the same amount of time, leading to great increases in accuracy over the baseline.

While this paper focuses on the application of selection processes to negotiation, many domains in which a chosen element is selected out of a set of candidates can be modeled as selection processes. For example, the winner of a racing match can be modeled as the chosen candidate out of a set of participants. The features in this example might be skill, age and years of training. Another example might be choosing a spokesperson for a large company where the skills of the spokesperson are the features. We can thus infer that the chosen individual had good communication skills. Lastly, selection processes can also be of use to behavioral economists who wish to describe and predict how behavior differs across cultures and social contexts. The mixture models we present in this work can be used to capture how societies differ in their negotiation behavior.

2. RELATED WORK

Several works provided models for predicting the probability of acceptance of proposals in negotiation. Most of these studied automatic agents. Pardoe and Stone [19] used data obtained from past trading agent competitions to learn the probability that a customer will accept a given bid price. They estimated a separate probability distribution for each range within the possible bid prices and then converted these probabilities to a density function that was biased towards assigning a higher probability of acceptance to lower bids. Lawrence [14] used a naive Bayes classifier to learn the winning probability of seller bids given features relating to buyer characteristics (type of company, past profitability, etc...) The optimal seller price maximized its expected profit given the winning probabilities. All of these works learned a two-way decision process – whether to accept or reject a bid based on past history. We consider a different problem of choosing between multiple candidates where the likelihood of different candidates depends on the relationship between their features.

Das *et al*. [7] showed that computer agents playing stochastic strategies that are based on observed market data could outperform humans in a continuous double auction. This work compared between the performance of automatic agents with the collective performance of people and did not consider social factors. Our criteria of performance is not whether a computer agent can beat humans on average, but the predictive accuracy of a computer model that uses social preferences to predict *individual* bids of people. Also we use a different domain, in which multi-valued goods can be traded by players.

Because we represent social preferences in agents' utility functions, Our work is related to recent approaches for learning agents' utility functions. Ng and Russell [18] defined the inverse reinforcement learning problem as to infer an agent's utility function by observing its behavior. The main technique was to view the agent's decisions as defining a set of linear constraints on the utility functions. This approach relied explicitly on the assumption that the agent is fully rational, and therefore any decision constrains its utility function. Chajewska *et al.* [6], like Ng and Russell, learned a utility function by observing past decisions, but they also allowed a prior probability distribution over the space of utility functions. They also made the assumption that the agent is rational.

In contrast, we do not assume that a decision maker is rational, for two reasons. First, as stated in Section 1, people may choose actions that are contrary to their perceived utility functions [2]. We wish to model the behavior of real agents, so we need to allow for the possibility of mistakes. Second, choosing an action is only one kind of selection process, and we wish are approach to apply to selection processes in general, including those not resulting from a decision-making problem.

Lastly, Chajewska and Koller [5] used a probabilistic approach to learn the structure of utility functions from a database of partially

elicited utility functions of individuals. This is a different problem from the one we study, as we are not given any explicit information about the utility function, we are only told which action is selected.

3. SELECTION PROCESSES

We begin by presenting notation. There is a set of N data instances $d^{(1)}, \ldots, d^{(N)}$. Each instance $d^{(k)}$ represents one selection process, consisting of a set $m^{(k)}$ of candidate proposals $c_1^{(k)}, \ldots, c_{m^{(k)}}^{(k)}$ and a chosen bid that that is denoted as $c_*^{(k)}$. We usually drop the superscript (k) where unambiguous and write $c_1, \ldots, c_m$ for the set of candidates. Each candidate proposal c_j has a set of n features $\mathbf{x}_j = x_{j:1}, \ldots, x_{j:n}$, where each feature $x_{j:i}$ is a real number. Following our convention, we use $\mathbf{x}_*$ to denote the features of the chosen bid. In general, i will be used to index features, j will be used to index candidates within an instance, and k will be used to index instances.

Our task is to develop a model for selecting the chosen bid c_* from the set of candidate proposals in each instance. For any candidate, we let $S(c_j)$ denote the decision made for candidate proposal c_j according to the model. This decision can be to select or not to select the candidate as the chosen bid. Given the features of all the candidates, we assume that one of several types is used for making each decision. A type represents a particular way of making a selection, and there may be more than one way of deciding a particular selection process. For example, two types of agents in the TAC SCM domain can make different bids for supplying the same hardware configuration because they weigh the configuration features in different way.

One approach for representing this diversity in the model is to define a separate type for every instance. This captures the fact that each instance is a separate negotiation process that is independent from the other instances. In this case the number of types would have to equal the size of the training set, making it impossible to learn. Instead, we say that agents fall into a finite number of types. There is a prior probability distribution over types, denoted by $P(\tau)$. Once a type is selected according to $P(\tau)$ it is used to select the chosen bid. According to our model, the same type is used for making the decision for all candidate proposal in an instance. This is because it is the same agent that picks the chosen bid and at the same time rejects all the other proposals in that instance.

Associated with each type is a set of weights. The weight w_i^τ is the weight associated with feature i according to type τ. Given the candidate features, and the type, we compute a score for each candidate offer, which is a weighted sum of its feature values. Formally, we write u^τ for the scoring function associated with each type τ, and define

$$u_j^\tau = u^\tau(\mathbf{x}_j) = \sum_{i=1}^{n} w_i^\tau x_{j:i}$$

Now, consider first a simple selection process in which there are only two candidate proposals. For a fully rational decision maker, the chosen bid will be the proposal associated with the higher utility. To capture the fact that people sometimes make mistakes with respect to their utility function, we can allow noise to exist in the selection process, by making the probability of the chosen bid depend on the sigmoid function. That is

$$P(S(c) = \text{chosen}|\mathbf{x}, \tau) = \frac{1}{1 + e^{-u^\tau(\mathbf{x})}} \quad (1)$$

This function makes sense, because when the score is large and positive, the probability that a particular proposals is the chosen bid tends towards 1; when it is large and negative this probability tends towards 0. At 0, the proposer is completely indifferent between the two possibilities and has a probability of $\frac{1}{2}$ of choosing either. The closer the score is to 0, the more likely the proposer will make a mistake and choose the proposal with lower expected utility.

However, we need to generalize this to a selection process which involves more than two candidate proposals. To this end, we turn the scores of proposals into probabilities by making the probability that candidate c_j is selected to be the chosen offer be proportional to $e^{u_j^\tau}$. That is

$$P(S(c_j) = \text{chosen}|\mathbf{x}_1, \ldots, \mathbf{x}_m, \tau) = \frac{e^{u^\tau(\mathbf{x}_j)}}{\sum_{j=1}^{m} e^{u^\tau(\mathbf{x}_j)}} \quad (2)$$

This soft-max function is helpful in two ways. First, it is a generalization of the sigmoid model for the simpler model. Indeed, if the decision comes down to two candidates, we have

$$\begin{aligned} P(S(c_1) = \text{chosen}|S(c_1)\text{or}S(c_2) = \text{chosen}, \mathbf{x}_1, \mathbf{x}_2, \tau) &= \frac{e^{u_1^\tau}}{e^{u_1^\tau} + e^{u_2^\tau}} \\ &= \frac{1}{1 + e^{-(u_1^\tau - u_2^\tau)}} \end{aligned} \quad (3)$$

which is just the sigmoid function using the difference between scores of c_1 and c_2.

Second, by using the soft-max function, we make the probability of each candidate offer to depend not only on its own features, but also on the features of the other candidates which were not chosen.

4. LEARNING TO CHOOSE BIDS

The learning task is to simultaneously learn the prior distribution over type $P(\tau)$, as well as the feature weights $\mathbf{w}^\tau$ associated each type. We are given the features of each candidate, and a classification representing whether the candidate proposal was the chosen bid. We define mixture model over types, where each type is associated with a single-layer sigmoid belief network [17], but the type that generates each data instance is not observed. We present two algorithms for providing a mapping from the candidate features to a classification.

The first algorithm, called LEARN-SUPERVISED is shown in Figure 1. It uses supervised learning where each candidate offer is viewed as a separate training instance. The sigmoid function of Equation 1 is used to compute the predicted output $P(S(c_j))$, which is the likelihood that a particular candidate proposal is selected as the chosen bid. To learn the feature weights of the utility function associated with each type we use gradient descent. We make the true output 1 if the candidate was selected as the chosen bid and 0 if candidate was not selected. The error function to minimize for each candidate c_j is the absolute difference between the true output and the predicted output $P(S(c_j))$.

For each type, we compute the posterior probability $P(\tau \mid S(c_j))$ of generating the candidate c_j using Bayes rule. This probability is then used to adjust the learning rate for the gradient descent step. Intuitively, if a type is more likely to have been used for rejecting or selecting a candidate, that candidate should have more influence in learning the feature weights of that type. Similarly, if a type is unlikely to have been used for a candidate, the candidate should have little impact on the features weights. Therefore the learning rate is made proportional to the probability that the type was used to make this decision. Once the learning rate has been determined, a standard gradient descent update is performed.

The second algorithm views each data instance as consisting of *all* the possible candidate proposals, together with the identity of the selected candidate. The algorithm, called LEARN-PAIRS, is presented in Figure 2. It compares the features of the selected candidate c_* with those of every other candidate c_j, and treats the choice

Repeat until convergence of parameters:
  For each instance $d^{(k)}$:
    For each type τ:
      For each candidate $c_j \in d^{(k)}$, let $u_j^\tau = \sum_{i=1}^n w_i^\tau x_{j:i}$
      $P(c_*\text{chosen} \mid \tau, \mathbf{x}_1, \ldots, \mathbf{x}_m) = e^{u_*^\tau} / \sum_{j=1}^m e^{u_j^\tau}$
    For each type τ:
      $P(\tau \mid S(c_*) = \text{chosen}, \mathbf{x}_1, \ldots, \mathbf{x}_m) = \frac{P(S(c_*)=\text{chosen}|\tau,\mathbf{x}_1,\ldots,\mathbf{x}_m)P(\tau)}{\sum_\tau P(S(c_*)=\text{chosen}|\tau,\mathbf{x}_1,\ldots,\mathbf{x}_m)P(\tau)}$
      Let learning rate $\alpha_\tau = \alpha * P(\tau \mid S(c_*) = \text{chosen}, \mathbf{x}_1, \ldots, \mathbf{x}_m)$
      For each $c_j \in d^{(k)}$ where $c_j \neq c_*$:
        For each feature i, let $d_i = x_{*:i} - x_{j:i}$
        Let $u_{diff} = \sum_i w_i^\tau d_i = u_*^\tau - u_j^\tau$
        Let $p = P(S(c_*) = \text{chosen} \mid S(c_*)\text{or } S(c_j) = \text{chosen}, \mathbf{x}_*, \mathbf{x}_j)$
          $= 1/(1+e^{-u_{diff}})$
        $p' = p * (1-p)$
        For each feature w_i^τ:
          $w_i^\tau = w_i^\tau + \alpha_\tau * d_i * (1-p) * p'$
  Reestimate
    $P(\tau) = \frac{1}{N} \sum_{k=1}^N P(\tau \mid S(c_*^{(k)}) = \text{chosen}, \mathbf{x}_1^{(k)}, \ldots, \mathbf{x}_{m^{(k)}}^{(k)})$

Figure 2: Algorithm LEARN-PAIRS

between them as a two-way decision. The utility to use in making the decision is the difference between the individual utilities u_*^τ and u_j^τ. Because the score is a linear function of the features, this difference is equal to the result of applying the scoring function u^τ to the differences between the features. Therefore, the predicted output is simply the probability of c_* being the chosen candidate, given that c_j is not chosen, which can be computed as

$$P(S(c_*) = \text{chosen} \mid c_* \text{ or } S(c_j) = \text{chosen}, \mathbf{x}_*, \mathbf{x}_j) = \frac{1}{1+e^{-(u_*^\tau - u_j^\tau)}}$$

The error function to minimize is always 1 minus this quantity, which is just applying Equation 3 to two decisions. The learning rate for the gradient descent step is computed in a similar fashion to algorithm LEARN-PAIRS.

Both algorithms need to compute the distribution over the type space. Because the actual type that generates each instance is unknown, we compute a new distribution over the type space by aggregating the likelihood of each and every data instance, and then normalizing. This process is similar in fashion to the Expectation Maximization algorithm. After all candidates for all instances have been processed, new values of $P(\tau)$ are estimated by the Bayes rule using the previously computed $P(\tau|S(c_j), \mathbf{x}_j)$.

4.1 Experimental Results

We evaluated the algorithms using data originating from the Colored Trails (CT) framework [11], in which two players must exchange resources in order to achieve their goals. Each game consists of a one-shot deal, in which one of the players, deemed the allocator, must make an offer to the other player, deemed the deliberator, which can in turn accept or reject the offer. The deliberator is not allowed to counter the allocator's offer with another proposal. The score that each player receives if no offer is made is identical to the score each player receives if the offer is rejected by the deliberator. We refer to this event as the *no negotiation alternative*. The score that each player receives if the offer is accepted by the deliberator is referred to as the *proposed outcome* score. The outcome of the game is determined by an offer-response pair, and each player's score in the game depends solely on his or her own performance. Games can differ in the resource players hold and the dependency relationships that hold between the players.

Each instance in our data set consisted of a CT game, in which the candidates were the set of possible proposals for the allocator in the game, and the chosen bid. There were about 30 candidates in each instance. Let NN_A and NN_D be the no-negotiation alternative scores for the allocator and deliberator, and PO_A and PO_D, the proposed outcome scores The properties of each proposal represents four social preferences that were computed as a function of players' scores: the individual benefit to the allocator if the proposal is accepted $PO_D - NN_D$; the joint benefit for both players $(PO_D + PO_A) - (NN_D + NN_A)$; the degree to which the outcome benefits the allocator more than the deliberator $PO_D - PO_A$; and the advantageousness of the trade to the allocator $(PO_D - NN_D) - (PO_A - NN_A)$.

We evaluated the algorithms using real data, generated by people playing CT games in a lab setting, and synthetic data, where each instance was generated by sampling a CT game, generating the set of candidate proposals for the game and choosing a bid according to a predetermined model. There were 169 instances in the real data set, whereas the synthetic data set included 1,000 instances. In both cases, we trained and tested the algorithms separately, using ten-fold cross validation. We evaluated the algorithms on a held-out data set using two metrics. First, "Likelihood" measures the average probability specified by the learned model that the chosen bid wins (the average is the geometric mean over all instances in the test set). Second, "Accuracy" measures the frequency with which the predicted bid, i.e. the candidate proposal with highest probability of winning, was actually the chosen candidate in the test set. With 30 candidates to choose from, we would expect both numbers to be quite small, but the relative sizes of the numbers indicate which algorithm performs better.

Table 1 compares the performance of LEARN-PAIRS to LEARN-SUPERVISED on real data, when using one, two and three types to learn a selection process. It also includes a naive predictor as a baseline that assumes a uniform probability distribution over all candidates for each instance. The relative sizes of the numbers indicate which algorithm performs better.

As shown in the table, while both algorithms performed better than the baseline, the performance of LEARN-PAIRS was consistently better than that of LEARN-SUPERVISED for both evaluation metrics. In addition, both algorithms improved in one metric as the number of types increased.

	Algorithm	Likelihood	Accuracy
	UNIFORM	0.0318	0.0375
One type	LEARN-SUPERVISED	0.0345	0.0562
	LEARN-PAIRS	0.0483	0.0812
Two types	LEARN-SUPERVISED	0.0344	0.0625
	LEARN-PAIRS	0.0591	0.0812
Three types	LEARN-SUPERVISED	0.0341	0.0688
	LEARN-PAIRS	0.0609	0.0812

Table 1: Performance comparison on real data

Table 2 evaluates performance of both algorithms on synthetic data. Here, we ran in an experiment in which a model of 3 types was used to generate the data and 3 types were used by the learning algorithms. We also report the performance of the actual model used to generate the data, which constitutes a gold standard. We ran experiments with many different numbers of types, both for the actual model and the learning algorithm, with comparable results. Results show that the likelihood of LEARN-PAIRS is much better than that of LEARN-SUPERVISED, and is close to the performance represented by the gold standard. Interestingly, both algorithms have the same accuracy as the gold standard. This suggests that simply predicting the chosen bid is an easier task than determining the probability of selecting each candidate as the chosen bid.

One possible explanation about this difference in performance of the algorithms in the CT domain is that LEARN-SUPERVISED ignores the dependencies between candidate proposals. It assumes that the probability a candidate is accepted depends only on its own features and not on the features of all the other candidates. In reality, if the other candidate proposals are exceptionally good, this candidate should be less likely to be the chosen bid, and conversely if they are bad. By ignoring this fact, LEARN-SUPERVISED is missing crucial information relevant to the selection of the chosen bid. Furthermore, the probabilities of acceptance for all candidates in an instance will in general not sum to 1, and a further drawback of LEARN-SUPERVISED is that a different type may be used for the decision for each candidate. In contrast, LEARN-SUPERVISED models the dependencies between candidates, and assumes the same type makes the decision for each instance.

Algorithm	Likelihood	Accuracy
UNIFORM	0.0320	0.0374
LEARN-SUPERVISED	0.0346	0.2212
LEARN-PAIRS	0.0603	0.2212
ACTUAL MODEL	0.0620	0.2212

Table 2: Performance comparison on synthetic data

5. INFERRING THE PROPERTIES OF A CHOSEN BID

In this section we consider the problem of inferring the properties of a proposal from the fact that it was the chosen bid. We assume now that the model is known, and that we have a prior probability distribution over the properties of any candidate proposal. For now, we do not assume that different candidates have the same prior. If a given proposal happens to be the chosen bid, it means that those property values that lead to a higher score are more likely. The task is to obtain the posterior distribution over the properties of a target proposal, given that it is the chosen bid.

As a baseline, we propose a simple importance sampling method to achieve this task. Let the target candidate be c_1. We begin by sampling from the prior distribution for each candidate including the target, to obtain features $\mathbf{x}_1$ for the target and $\mathbf{x}_j$ for each of the other candidates c_j. We also sample the type τ used to make the decision from the probability distribution $P(\tau)$. We compute the score for each candidate $u_j^\tau = \sum_i w_i^\tau x_{j:i}$. We then compute the probability $p = \frac{e^{u_1^\tau}}{\sum_{j=1}^m e^{u_j^\tau}}$ that the target candidate was chosen. We then weight the sample consisting of the features $\mathbf{x}_1$ by the probability p. We thus obtain a set of weighted samples that is an approximation to the posterior distribution over features of the target candidate. This set of samples can be used to obtain expectations of the features we are interested in.

This method, which we call IMPORTANCE-SAMPLE, requires sampling all the candidate proposals. We can do better by making the observation that the probability that a candidate is the chosen bid depend most heavily on its own score. Once the type has been fixed, and the score of the target candidate has been determined, we can attempt to estimate the probability that the target is the chosen bid without sampling the other candidates. This approach has the advantage that because only one candidate proposals needs to be sampled, many more samples can be taken for the same running time. On the other hand, because this approach uses an estimate of the probability that the target candidate is the winner, rather than sampling, it is biased. The degree of the bias depends on the quality of the estimates.

There are several ways to estimate the probability that the target proposal is the chosen bid, given its features. We wish to estimate

$$P(c_1 \text{ wins}|\mathbf{x}_1, \tau) = E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[\frac{e^{u^\tau(\mathbf{x}_1)}}{e^{u^\tau(\mathbf{x}_1)} + \sum_{j=2}^m e^{u^\tau(\mathbf{x}_j)}}] \quad (4)$$

where $E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[f]$ denotes the expectation of f with respect to $\mathbf{x}_2, ..., \mathbf{x}_m$. This probability is hard to estimate directly without sampling $\mathbf{x}_2, \ldots, \mathbf{x}_m$ many times for each $\mathbf{x}_1$, which is precisely what we wish to avoid. However, we can hope to approximate it, either with a method that does not sample $\mathbf{x}_2, \ldots, \mathbf{x}_m$ at all, or with a method that only samples $\mathbf{x}_2, \ldots, \mathbf{x}_m$ a fixed number of times, and amortizes that sampling over all samples of $\mathbf{x}_1$. Our first approximation comes from the consideration that in the case where c_1 is unlikely to be the winner, $e^{u^\tau(\mathbf{x}_1)}$ will usually be small compared to $\sum_{j=2}^m e^{u^\tau(\mathbf{x}_j)}$. Therefore the ratio $\frac{P(c_1^{(1)} \text{ wins}|\mathbf{x}_1^{(1)},\tau)}{P(c_1^{(2)} \text{ wins}|\mathbf{x}_1^{(2)},\tau)}$ of the probability the target candidate wins for two different samples $\mathbf{x}_1^{(1)}$ and $\mathbf{x}_1^{(2)}$ will usually be approximately equal to

$$\frac{E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[\frac{e^{u^\tau(\mathbf{x}_1^{(1)})}}{\sum_{j=2}^m e^{u^\tau(\mathbf{x}_j)}}]}{E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[\frac{e^{u^\tau(\mathbf{x}_1^{(2)})}}{\sum_{j=2}^m e^{u^\tau(\mathbf{x}_j)}}]} = \frac{e^{u(\mathbf{x}_1^{(1)})}}{e^{u(\mathbf{x}_1^{(2)})}} \quad (5)$$

Since the only thing that is required to get good weighted samples is that the ratios between the weights be correct, we can simply use $e^{u^\tau(\mathbf{x}_1^{(k)})}$ as the weight of the kth sample. The scheme that uses these weights is called SAMPLE-SIMPLE.

However, this is a very crude approximation. In particular, the approximation is inaccurate in the cases where $e^{u^\tau(\mathbf{x}_1)}$ is large. In such cases, the weights will be biased upwards, because we are ignoring the $e^{u^\tau(\mathbf{x}_1)}$ term in the denominator of Equation 4 which

is no longer negligible. A better approximation can be obtained by not ignoring the $e^{u^\tau(\mathbf{x}_1)}$ term in the denominator. Instead, we approximate Equation 4 by

$$\frac{e^{u^\tau(\mathbf{x}_1)}}{e^{u^\tau(\mathbf{x}_1)} + E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}]} \quad (6)$$

This scheme, called SAMPLE-EXPECT, uses a preprocessing step in which a number of samples of $\mathbf{x}_2, ...\mathbf{x}_m$ are taken to estimate $E_{\mathbf{x}_2,\ldots,\mathbf{x}_m}[\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}]$ for each type τ. The estimate for the selected type is then substituted in Formula 6 to obtain the approximate weight for sample $\mathbf{x}_1$.

Of course, simply moving the expectation inwards is likely to produce an inaccurate approximation. In particular, the expectation of Equation 4 is likely to be dominated by cases where $\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}$ is small, not by the expected value of $\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}$. This suggests a different approximation scheme, where we use small values of $\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}$. In this scheme, called SAMPLE-MIN, we take a certain number of samples of $\mathbf{x}_2, ..., \mathbf{x}_m$ in a preprocessing step. From those samples we take the minimum value of $\sum_{j=2}^{m} e^{u^\tau(\mathbf{x}_j)}$ for each type. We use that value for the selected type instead of the expectation in Equation 6 to compute the weight for sample $\mathbf{x}_1$. An interesting question in this scheme is how many samples of $\mathbf{x}_2, ...\mathbf{x}_m$ to take in the preprocessing step. Even if we had infinite time, taking more samples would not necessarily be a good thing, because the minimum may become too small, yielding a less accurate approximation.

Thus far, we have assumed there is a particular target proposal whose features we want to infer. But another kind of inference problem is to infer the features of a generic proposal, given the fact that it was chosen. For example, the runners in a race might include three runners whom we know by name and who have a reputation, as well as fifteen other anonymous, generic runners. Suppose now that we want to infer the posterior probability distribution over the properties of an anonymous candidate. One approach would be simply to choose one of the anonymous candidates to be our target candidate, and proceed using one of the methods described earlier. But this would be unnecessarily wasteful — it would ignore the probability that one of the other anonymous candidates is chosen as the winner. In the extreme case, all the candidates have the same prior distribution over features. In that case the probability that one of the anonymous candidates is selected is 1, and every sample should have a weight of 1.

A better approach, assuming there is a reasonable number of anonymous candidates, is to use a rejection sampling method, which we call SAMPLE-GENERIC . We sample a type from $P(\tau)$, and features for each of the candidates, as in the baseline IMPORTANCE-SAMPLE method. We then select a winning candidate using the model. If the winner is an anonymous candidate with the prior we are interested in, we keep its features as a sample. If not, we reject the sample.

It is worth examining the advantage of this approach more closely. The advantage over IMPORTANCE-SAMPLE is indeed what we have stated, that each sample can be expected to have a much higher weight. The advantage of this approach over the estimated schemes SAMPLE-SIMPLE, SAMPLE-EXPECT and SAMPLE-MIN is not that the samples taken have higher weight, since with those schemes more samples could be taken, enough so that their total weight is equal to that of SAMPLE-GENERIC. Rather, it comes from the fact that SAMPLE-GENERIC does not use a biased approximation of the probability that the target candidate wins.

5.1 Experimental Results

We first tested the algorithms for inferring the properties of a winning candidate using synthetic data, where there is only one feature x, one type, and the scoring function is simply $u = x$. The prior over the feature is a Gaussian.

		Probability that c_1 wins		
		0.001	0.01	0.1
Algorithm	Samples	Error	Error	Error
IMPORTANCE-SAMPLE	100	0.1770	0.1689	0.1454
SAMPLE-SIMPLE	1000	0.0576	0.0610	0.2412
SAMPLE-EXPECT	900	0.0828	0.0586	0.0554
SAMPLE-MIN	900	0.0680	0.0577	0.0806

Figure 3: Relative error rates for the different algorithms on three experiments, varying the probability that c_1 wins

We considered three cases, varying the probability that the target candidate c_1 will be the winning candidate from 0.001 to 0.1. Figure 3 shows the results for an experiment in which the number of samples was chosen to ensure that each algorithm had the same running time. We report the relative error of the estimated expected value of the feature x of c_1 compared to an estimate of ground truth obtained by taking 1,000,000 samples and keeping the ones where c_1 wins. The results are averaged over 10,000 runs. Also shown is the number of samples used by each algorithm.

We see that in the first case, where there is a very low probability of c_1 winning, algorithm SAMPLE-SIMPLE is a very good approximation and has the best performance. On the other hand, in the third case where the probability is quite high, SAMPLE-SIMPLE performs very poorly indeed. These results are as one would expect, because the approximation of Equation 5 assumes that the score of the target candidate is very small relative to the scores of the other candidates. Meanwhile, algorithms SAMPLE-EXPECT and SAMPLE-MIN, which do not make this assumption, significantly outperform IMPORTANCE-SAMPLE in all three cases. SAMPLE-MIN is slightly better for low probabilities of c_1 winning and SAMPLE-EXPECT is better for high probabilities.

Algorithm	Signed Error	Absolute Error
IMPORTANCE-SAMPLE	-0.0069	0.0232
SAMPLE-SIMPLE	0.0242	0.0277
SAMPLE-EXPECT	0.0257	0.0259
SAMPLE-MIN	0.0239	0.0239
SAMPLE-GENERIC	-0.0062	0.0212

Figure 4: Signed and absolute errors for the five algorithms on the Colored Trails model

Finally, we compare the algorithms, and also SAMPLE-GENERIC, on a richer model learned from the Colored Trails data. Each instance now consisted of the candidate proposals for a Colored Trails game. Because all proposals have the same prior, we can use SAMPLE-GENERIC here. Note that now the candidates are correlated with each other — if a game has one high-scoring proposal it is likely to have more. This fact will hurt the algorithms that only sample c_1, because they will not discover the correlations between candidates. The results are shown in Figure 4. The figure shows both the average signed errors, and the average absolute errors, of the estimate of the individual utility feature of the winning proposal, taken over 100 runs. SAMPLE-GENERIC is the best performer. Examining the signed errors, we see that they are very high and positive for all three algorithms that only sample c_1. These three algorithms are consistently overestimating, and are suffering from an upward bias

which causes them to underperform the other two algorithms even though they use many more samples.

6. CONCLUSION AND FUTURE WORK

We presented a model used to predict selection processes, and two learning algorithms for learning the parameters of a selection process from data. We showed that a model which reasons about dependencies between candidates is superior to one that does not. We also presented several methods for inferring the properties of a candidate from the fact that it won, and showed that algorithms that only sample the target candidate perform much better than an algorithm that samples all candidates.

In other domains, it is possible for zero or more than one candidates to be chosen but the choice of one candidate does have a bearing on whether other candidates are chosen. For example, consider hiring a candidate to fill a faculty position. If the search turns up more than one outstanding candidate, more than one offer will be made. If the committee feels that there are no good candidates, no offer will be made. But in general the candidates are in competition with each other, and if an offer is made to one candidate that reduces the probability that one will be made to another candidate. In future, we intend to model these types of processes.

Selection processes can naturally be accommodated in probabilistic models. There is a close relationship between selection processes and probabilistic relational models (PRMs) [9]. In a PRM, an object X may be related to another object Y via a complex attribute. We may have uncertainty as to which other object Y the object X is related to. This is known as reference uncertainty. In a PRM, this uncertainty has been traditionally modeled by specifying an explicit probability distribution over the possible objects Y. The distribution over possible objects traditionally does not depend on the attributes of the possible objects. However, it is natural to make the choice of possible object Y a selection process, which depends on the attributes of the possible objects. For example, we may have a *Job* object. This object will have a complex attribute *Candidate*, which is a multi-valued attribute. The *Job* will be related to a number of *Person* objects via the *Candidate* attribute. In addition, the *Job* object will have an *Occupant* attribute, which is single-valued. We have reference uncertainty with regards to the value of the *Occupant* attribute. Modeling *Occupant* as a selection process, will make the candidates the values of the *Candidate* attribute, and the winner depends on the features of the candidates.

ABSTRACT

Distributed Constraint Satisfaction Problems provide a natural mechanism for multiagent coordination and agreement. To date, algorithms for Distributed Constraint Satisfaction Problems have tended to mirror existing non-distributed global-search or local-search algorithms. Unfortunately, existing distributed global-search algorithms derive from classical backtracking search methods and require a total ordering over agents for completeness. Distributed variants of local-search algorithms (such as distributed breakout) inherit the incompleteness properties of their predecessors, or depend on the creation of new communication links between agents. This paper presents an algorithm in which a global ordering is not required, while avoiding the problems of existing local-search algorithms.

1. INTRODUCTION

Constraint Satisfaction Problems (CSPs) have proven applicable in a wide variety of domains. A CSP is classically defined by a set of variables $\mathcal{V}$, a domain for each variable $\mathcal{D}_v$, and a set of constraints $\mathcal{C}$. A *solution* to a CSP is a complete assignment of values to variables which satisfies every constraint.

A Distributed CSP (DisCSP) is formed when the description and solution procedure of a CSP are separated amongst multiple agents. The distributed environment extends the applicability of CSPs to domains such as distributed scheduling and resource contention. Of particular interest is the use of DisCSPs as models for solving other multiagent problems, with DisCSP algorithms defining a protocol for agent communication. Common examples of such problems include scheduling, task assignment, and limited forms of negotiation where simple decision(s) must be made per agent. A DisCSP can be constructed by representing each of the agents decisions as a variable, with constraints describing any inter-agent relationships.

A DisCSP can be solved by distributed variants of existing global-search or local-search algorithms. However, local-search algorithms [7] are incomplete in both the distributed and non-distributed case. Distributed variants of global-search [1, 3, 5, 6] presented to date make use of a total order over variables.

We argue that any total order impacts the characteristics of backtracking-style search in undesirable ways for use in many multiagent problems. For example, an agent which has a 'higher' rank in the ordering has more 'authority' and is therefore less likely to change its value than a 'lower' ranking agent. In an anytime environment this results in higher-ranked agents being granted more stable answers. While some problems may desire such behaviour our concern lies with those problems which do not.

We also argue that, when using a total order, it is difficult to add constraints between two previously independent DisCSPs. To do so would require a re-computation of the variable ordering and/or an arbitrary decision that one DisCSP ranks higher than the other. If a problem is frequently altered by the addition of groups of variables, as is likely to occur in large DisCSP networks, global re-computation will become increasingly difficult. If variable ordering is instead made arbitrarily (for example, ordering by variable identifier) the problem of stability is exacerbated.

These arguments can be demonstrated in an example large-scale meeting scheduling problem described below.

Example. The universities of Pluto and Saturn each use an automated system for scheduling meetings amongst their own staff. The staff give constraints of the form 'Alice needs to meet with Bob for 2 hours this Wednesday or Thursday' to agents on their own computers. Individual universities contain a large number of staff with generally sparse connections, so a distributed algorithm is used in which agents communicate directly with each other. Agents are assigned comparable identifiers using finely-tuned schemes specific to each university. These identifiers are chosen to permit backtracking in a distributed global-search algorithm within the university.
Despite best efforts at fairness, a static ordering creates problems between research peers. If the ordering states 'Alice ranks higher than Bob' then any trivial change in Alice's meeting times must always be accepted by Bob. Inversely, Bob may request a change to Alice's meetings only after exhausting all possible meeting schedules and detecting infeasibility. This problem is distinct from that of preference orderings, and instead relates to stability (ie. Alice's schedules are more stable than Bob's).

To worsen matters, Bob from Pluto wishes to arrange a meeting with Carla from Saturn. Their identifiers, while still possibly unique, are not meaningfully comparable for the purpose of a backtracking search. To continue using any existing distributed algorithm, we must be able to compare identifiers between agents operating at Pluto's and Saturn's universities. An example solution is to decide that all Saturn's identifiers are 'greater' than Pluto's identifiers. Unfortunately this would have the same impact on the behaviour of the algorithm as outlined above - meeting schedules for researchers from Pluto would become subservient to those from Saturn. Any changes in meeting times for Saturn's researchers, no matter how trivial, must be accepted by Pluto's researchers.
Furthermore, any decision for resolving the variable order would require intervention by authorities at each university or the use of a heuristic method such as DisAO [1, 3]. While these decisions can be made for pairs or sets of universities, it does not scale well computationally. For example, if Dennis was an independent researcher he must establish 'comparability' with each university and all other researchers. The addition of new researchers frequently raises the possibility of frequent re-computation of variable ordering.

The above example highlights problems that arise from using a total order to establish 'authority' or 'importance' between agents, and maintaining a total order subject to merging of previously independent DisCSPs. The computational disadvantages of a total order were also noted and addressed within the development of Asynchronous Weak-Commitment Search (AWCS) [5, 6]. However, AWCS creates additional links between variables, which we believe is undesirable in large-scale meeting scheduling. The specific difficulties of large-scale distributed meeting scheduling motivated us to develop an algorithm which:

- has no need for 'authority' between variables, effectively avoiding the need for a total order on variables.
- provides fairness in the level of stability for variables.
- does not add links between variables, avoiding the eventual need for 'broadcasting' assignments.
- addresses the risk of cyclic behaviour exhibited by local search algorithms.

Section 2 will present a model of a simple meeting scheduling problem as a DisCSP, and present how *arguments* can form the basis of communication between agents. Section 3 will describe the internal decision processes of each agent to handle arguments in an appropriate manner. Section 4 will present analysis of the algorithm.

2. MODELLING ARGUMENTS

We begin with a simple example demonstrating how a distributed constraint satisfaction problem can be solved through arguments. We will then describe a formal model of this problem with corresponding notation able to represent the dialogue. This transformation serves as inspiration for a new distributed constraint satisfaction algorithm.

Example. Alice, Bob, Carla and Dennis are attending a conference and must organise meeting times for themselves:

- Bob must meet with Carla.
- Bob must meet with Alice before meeting with Carla.
- Dennis must meet with Alice.
- Bob, Carla and Dennis must have a separate group meeting.
- Available times are 1pm, 2pm and 3pm.
- Double-booking for meeting time-slots is not allowed.
- Each person knows only those meetings that they need to attend.
- No person has any 'authority' over any other.
- Communication can only occur between people who already know each other.

To find the solution they state arguments (proposals and rejections) in turn, providing further detail if two arguments are contradictory or if they alter a previous argument:

Alice to Dennis	$\Rightarrow$	I propose a 1pm meeting
Dennis to Carla	$\Rightarrow$	I propose a 2pm group meeting
Dennis to Bob	$\Rightarrow$	I propose a 2pm group meeting
Carla to Bob	$\Rightarrow$	I propose a 1pm meeting
Alice to Bob	$\Rightarrow$	I propose a 2pm meeting
Bob to Alice	$\Rightarrow$	I have a group meeting at 2pm, so I propose a 1pm meeting instead
Bob to Carla	$\Rightarrow$	I completely reject your proposal, so I propose a 3pm meeting instead
Alice to Dennis	$\Rightarrow$	I now have another meeting at 1pm, so I propose a 3pm meeting instead

2.1 Constraint Model

To construct a distributed constraint satisfaction problem we translate the time of attending a meeting for each person into a variable. Equality constraints are used to ensure meeting times are agreed to by all users. For example, a pair of variables a and b may represent the scheduled time of the meeting between Alice and Dennis. The constraint $a = b$ is interpreted as 'the time Alice decides to meet with Dennis must be the same as the time that Dennis decides to meet with Alice'. Inequality constraints ensure that meetings occur at distinct times.

Note that there is significant redundancy in the constraints and variables as presented in Figure 1. This occurs as the constraints upon one person are not automatically known to others. Relaxing this requirement would generate a simpler constraint graph, but would conflict with our aim to solve in a distributed manner. Using this constraint model as an example, we will now define suitable notation for representing the dialogue.

$$\mathcal{V} = \{a, b, c, d, e, f, g, h, i\}$$

$$\mathcal{D} = \{1\text{pm}, 2\text{pm}, 3\text{pm}\}$$

$$\mathcal{C} = \left\{ \begin{array}{ll} a = b & a \neq i \\ b \neq c & c = d \\ c = g & d \neq e \\ d = g & e = f \\ f \neq g & f > h \\ g \neq h & h = i \end{array} \right\}$$

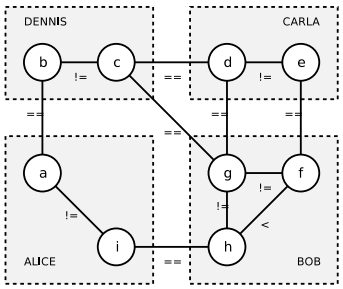

Figure 1: Example of a constraint model and graph

2.2 Argument Model

To represent proposals and rejections as outlined above, we require two distinct message types; isgoods and nogoods. These will be the only message types required to construct our algorithm.

An **isgood** is an ordered partial assignment for a sequence of connected variables, and so represents a 'proposal'. Consider the argument in our example where Bob says to Alice: "I already have a group meeting at 2pm, so I propose a 1pm meeting for us instead". This is a proposal, and so can be written as an ordered partial assignment or 'isgood':

$$\langle (g, 2\text{pm}), (h, 1\text{pm}) \rangle$$

This isgood is read as "variable g took on value 2pm, and so h took on value 1pm". Note that variables in an isgood must be connected to their immediate predecessor, and therefore $\langle (d, 2\text{pm}), (h, 1\text{pm}) \rangle$ is *not* an isgood. Also note that we use the operator $+$ to represent the appending of a variable assignment to an isgood. For example, $\langle (g, 2\text{pm}), (h, 1\text{pm}) \rangle + (i, 1\text{pm}) = \langle (g, 2\text{pm}), (h, 1\text{pm}), (i, 1\text{pm}) \rangle$.

A **nogood** is an unordered partial assignment which is provably not part of a solution, and so represents a 'rejection'. Consider the argument in our example where Bob says to Carla: "I reject your proposal, and I propose a 3pm meeting for us instead" This is a rejection (he must meet Carla before Alice, so 1pm is not a possible meeting time) followed by a proposal, which written in sequence are:

$$\{(e, 1\text{pm})\} \text{ and } \langle (f, 3\text{pm}) \rangle$$

They are read as "variable e cannot take value 1pm" and "variable f took on value 3pm" respectively. As demonstrated in our example, a nogood is usually accompanied by an isgood.

We say that a constraint is **satisfied** by an isgood I if the constraint is explicitly not violated by the assignments in I. Testing whether a constraint is satisfied is therefore only possible if all variables appearing in the constraint also appear in I. Similarly, a nogood is satisfied if it is not a subset of the assignments in I. For example, given an isgood $I = \langle (g, 2\text{pm}), (h, 1\text{pm}) \rangle$, we know:

- $I + (i, 2\text{pm})$ does not satisfy the constraint $h = i$
- $I + (i, 1\text{pm})$ does satisfy the constraint $h = i$
- I does not satisfy the nogood $\{(h, 1\text{pm})\}$
- I does satisfy the nogood $\{(h, 1\text{pm}), (i, 1\text{pm})\}$

Thus, given a set of constraints and a set of nogoods, we say that an assignment (v, d) is **consistent** with respect to an isgood I iff each constraint on v and each nogood is satisfied by $I + (v, d)$.

By the notation $|I|$ we indicate the number of tuples in I. Finally, we will write $I \sqsubseteq I'$ to indicate that I is a **sub-isgood** of I'. A sub-isgood is the tail (or entirety) of another isgood. For example:

$$\begin{aligned} \langle (i, 1\text{pm}) \rangle &\sqsubseteq \langle (h, 1\text{pm}), (i, 1\text{pm}) \rangle \\ &\sqsubseteq \langle (g, 2\text{pm}), (h, 1\text{pm}), (i, 1\text{pm}) \rangle \\ \langle (i, 2\text{pm}) \rangle &\not\sqsubseteq \langle (h, 1\text{pm}), (i, 1\text{pm}) \rangle \\ \langle (h, 2\text{pm}) \rangle &\not\sqsubseteq \langle (h, 1\text{pm}), (i, 1\text{pm}) \rangle \end{aligned}$$

3. SOLVING WITH ARGUMENTS

Using the above notation, and the dialogue of our example as a guide, it is possible to construct a distributed search algorithm in which agents will:

- send and receive proposals (isgoods) and rejections (nogoods)
- convince neighbours to change their value by sending progressively longer proposals
- reject a proposal from a neighbour if it is inconsistent
- justify their variable assignment by the proposal of just one neighbour
- communicate only with agents for which they share a constraint

To achieve this, each agent records the most recent proposals sent/received by neighbouring agents and an unbounded nogood store. Unlike other distributed algorithms, SBDS does not regard all information from neighbours as a consistent 'agent view'. Instead, the isgood received from just one neighbour is chosen as justification for our current assignment and combines to form our 'agent view'. Formally, the information stored by each agent is:

- *sent*(v) - last isgood sent to each neighbour v
- *recv*(v) - last isgood received from each neighbour v
- *nogoods* - set of all nogoods ever received
- *support* - the neighbour chosen for our 'agent view'
- *view* - current agent view (*recv*(*support*) extended by an assignment to our own variable)

Procedure 1 *main* ()

```
1: while true do
2:    for all received nogoods N (in fifo order) do
3:       receive-nogood(N)
4:    for all received isgoods I (in fifo order) do
5:       receive-isgood(I)
6:    select-support()
7:    for all neighbours v do
8:       send-isgood(v)
9:    wait until at least one message in the queue
```

Procedure 2 *receive-isgood* (I)

```
1: let v be the variable which sent I
2: set recv(v) to I
3: if no choice of value is consistent wrt recv(v) then
4:    send-nogood(v)
```

Procedure 3 *receive-nogood* (N)

```
1: if N in nogoods then
2:    break, as this nogood was already known
3: add N to nogoods
4: if no value is consistent then
5:    terminate algorithm
6: for all neighbours v do
7:    if no choice of value is consistent wrt recv(v) then
8:       send-nogood(v)
```

Procedure 4 *select-support* ()

1: *update-view* ()
2: **if** our current value is inconsistent wrt some $recv(v)$ and $|recv(v)| \geq |view|$ **then**
3: **set** *support* to a neighbour u, maximising $|recv(u)|$
4: *update-view* ()

Procedure 5 *update-view* ()

1: **let** $view'$ be $recv(support)$ extended by a consistent assignment to self, and maximal with respect to $\prec$
2: **let** v be the first variable assigned in $view'$
3: **if** $scope(view) \neq scope(view')$ **or** $view \prec view'$ **or** the assignment of v is equal in $view'$ and $recv(v)$ **or** the assignment of v is unequal in $view$ and $recv(v)$ **then**
4: **set** $view$ to $view'$

Procedure 6 *send-nogood* (v)

1: **let** N be an inconsistent subset of $recv(v)$
2: **send** N to v
3: **set** $recv(v)$ to $\langle\,\rangle$
4: **if** $support = v$ **then set** *support* to *self*

Procedure 7 *send-isgood* (v)

1: **if** our current value is consistent wrt $recv(v)$ **and** $sent(v) \sqsubseteq view$ **then**
2: **break**, as a new isgood is not necessary
3: **lock** communication channel with v
4: **if** there are no unprocessed isgoods from v **then**
5: **let** L be $\min(\max(|recv(v)|, |sent(v) + 1|), |view|)$
6: **let** I be an isgood such that $I \sqsubseteq view$ and $|I| = L$
7: **send** I to v
8: **set** $sent(v)$ to I
9: **unlock** communication channel with v

The *main* loop of our algorithm processes all messages before choosing *support* and *view* and sending new isgoods. Incoming isgoods are stored in $recv(v)$ by the *receive-isgood* procedure. If no assignment to our own variable is consistent with respect to the new isgood and current known nogoods, the procedure *send-nogood* is called to derive and send a nogood. Similarly the *receive-nogood* procedure handles an incoming nogood; each $recv(v)$ is re-tested for consistency, and *send-nogood* is called if appropriate.

The *select-support* procedure determines which neighbouring variable will be considered as our support for this iteration. A new support must be chosen if a received isgood from a neighbour is longer than our current *view* and conflicts with our current value.

The *update-view* procedure refreshes the current *view* according to the isgood $recv(support)$. In most cases *update-view* will replace *view* by selecting and appending a consistent assignment for our variable to the tail of $recv(support)$. As our algorithm is asynchronous, and agents can determine their assignments simultaneously, there is the possibility of cyclic behaviour. This is corrected in existing distributed search algorithms by the use of a total order on agents; a change by a lower ranked agent cannot induce a change in a higher ranked agent. In place of a total order on agents, we use orderings for isgoods defined over the same set of variables. These orderings are only used in a situation where a cycle is deemed likely. Being independent they can contain no bias towards any agent or value.

Formally, let $scope(I)$ be the sequence of variables in the isgood I. For example, with $I = \langle(c, 1\text{pm}), (b, 2\text{pm})\rangle$ we have $scope(I) = \langle c, b\rangle$. We assume an ordering $\prec$ is known to all agents and is total for isgoods of the same *unordered* scope.[1] We will not replace a *view* with $view'$ if each of the following is true:

- *view* is not out-of-date (ie. the most recently received assignment for v is the same as that presented in *view*)
- $view'$ is out-of-date (ie. the most recently received assignment for v is different from that presented in $view'$)
- $view'$ may be part of a cycle (ie. the ordered scopes of *view* and $view'$ are identical, and the first assignment is to a neighbour v)
- $view'$ is lower in the ordering (ie. $view' \prec view$)

This scheme causes an agent to postpone changing its value if its new view would be out-of-date, would propagate a cycle, and the old view is regarded as 'superior' by the ordering. As the definition of the ordering is uniform across all agents, any cyclic behaviour will quickly resolve in favour of a single view. Theorem 1 contains a formal statement and proof of this result.

The *send-nogood* procedure generates and sends an appropriate nogood when a received isgood is found to be inconsistent. The nogood may be any inconsistent subset of the assignments in the isgood. An interesting effect of this procedure is that nogoods are formed only from variables in a sequence, rather than 'all neighbours' as occurs in AWCS.

The *send-isgood* procedure constructs the strongest possible isgood to send to agent v while satisfying certain 'minimality' requirements. If there is no need to send an isgood (ie. we have already established agreement with our neighbour) then we need not counter its argument. An isgood is not sent to a neighbour v if there are unprocessed isgoods in the communication channel.

We ensure that individual pairs of agents do not communicate simultaneously by using a mutex on individual communication channels. If an argument from a neighbour v has arrived between the last call to *receive-isgood* and the activation of the lock then we skip sending an argument on this iteration. The result is half-duplex communication with all agents able to operate asynchronously.

To avoid cycles of oscillating agent values in inconsistent problems, we increase the length of successive arguments which are sent. This is achieved by recording the last isgood sent and attempting to increase the length of subsequent isgoods. As any cycle must be finite, eventually the arguments (isgoods) being transmitted will contain the cycle itself. If the cycle is formed from inconsistent values it will generate a nogood and break the cycle; otherwise the cycle-breaking mechanism of *update-view* will take effect.

[1] Cryptographic hash functions can be used to provide a suitably unbiased ordering for sets of assignments written in a canonical form.

From	To	Argument
a	b, i	$\langle(a, 1\text{pm})\rangle$
c	b, d, g	$\langle(c, 1\text{pm})\rangle$
e	d, f	$\langle(e, 1\text{pm})\rangle$
b	a	$\langle(b, 1\text{pm})\rangle$
b	c	$\langle(a, 1\text{pm}), (b, 1\text{pm})\rangle$
d	c, g	$\langle(d, 1\text{pm})\rangle$
d	e	$\langle(c, 1\text{pm}), (d, 1\text{pm})\rangle$
f	e	$\{(e, 1\text{pm})\}$
f	e, g, h	$\langle(f, 3\text{pm})\rangle$
e	f	$\langle(e, 3\text{pm})\rangle$
e	d	$\langle(f, 3\text{pm}), (e, 3\text{pm})\rangle$
c	b	$\langle(c, 2\text{pm})\rangle$
c	d, g	$\langle(b, 1\text{pm}), (c, 2\text{pm})\rangle$
g	c, d, f, h	$\langle(g, 2\text{pm})\rangle$
i	a, h	$\langle(i, 2\text{pm})\rangle$
d	c	$\langle(d, 2\text{pm})\rangle$
d	g	$\langle(c, 2\text{pm}), (d, 2\text{pm})\rangle$
d	e	$\langle(b, 1\text{pm}), (c, 2\text{pm}), (d, 2\text{pm})\rangle$
h	g	$\langle(h, 1\text{pm})\rangle$
h	i	$\langle(g, 2\text{pm}), (h, 1\text{pm})\rangle$
i	h	$\langle(i, 1\text{pm})\rangle$
i	a	$\langle(h, 1\text{pm}), (i, 1\text{pm})\rangle$
a	i	$\langle(a, 3\text{pm})\rangle$
a	b	$\langle(i, 1\text{pm}), (a, 3\text{pm})\rangle$
b	a	$\langle(b, 3\text{pm})\rangle$
b	c	$\langle(a, 3\text{pm}), (b, 3\text{pm})\rangle$
c	d, g	$\langle(b, 3\text{pm}), (c, 2\text{pm})\rangle$

Solved: $a, b, e, f = 3\text{pm}$; $c, d, g = 2\text{pm}$; $h, i = 1\text{pm}$

In the first iteration, a, c and e announce their initial values (all chose 1pm). Note that other agents could communicate at the same time (eg. g and h) but to simplify the explanation we have limited the presentation of arguments.

In the second iteration, b, d and f respond to these proposals. In the first case, b accepts the proposed time of 1pm from a and communicates an agreeable value to a. As c proposed a contradictory value, b provides a longer isgood as a counter-proposal. At the same time, d accepts the proposed time of 1pm from c and communicates that to its neighbours. Finally, f rejects the proposal from e outright with a nogood, and proposes instead a time of 3pm.

In the third iteration, e and c respond to the counter-proposals. Given the longer proposal from f, e must change its current value. When updating its neighbour d, e must provide a longer argument. Similarly, c provides longer proposals to d and g.

In the fourth iteration g and i announce their values for the first time, choosing values supported by c and a respectively.

In the fifth iteration, d accepts the proposed time of 2pm from c. Note the increasing (and varying) lengths of isgoods as d communicates with different neighbours. Similarly, h accepts the proposed time of 2pm from g and chooses its first assignment accordingly.

In the sixth iteration, i changes its *support* from a to h, and changes its value accordingly. This change is then communicated to a. Note that this is the first communication from i to a.

In the seventh iteration, a is forced to choose between b and i as *support*. As a had no previous support it is free to choose either (if it previously had used b as *support* it would have retained it). In this instance, a chooses to use i as *support* and change value accordingly.

The final iterations consist of propagating this change to b (which changes its value), and then to c. Note that c does not change value, but still must communicate the change of b's value to d and g.

Table 1: Example algorithm execution on the problem in Figure 1

4. RESULTS

We have described desirable properties of an algorithm for distributed constraint satisfaction. Specifically, we have attempted to construct an algorithm which:

- has no need for 'authority' between variables, effectively avoiding the need for a total order on variables.
- provides fairness in the level of stability for variables.
- does not add links between variables, avoiding the eventual need for 'broadcasting' assignments.
- addresses the risk of cyclic behaviour exhibited by local search algorithms.

The fact that we do not add links between variables is evident from the algorithm itself. Similarly, we note the absence of any total ordering over the variables, which avoids any notion of 'authority'. Each isgood establishes an order over variables within a local context in the form of a sequence in which assignments were made. This is necessary for the introduction of nogoods in the style of Dynamic Backtracking [2, 1]. However, the combination of these local orders does not necessarily end in the construction of a total order over variables. We have also provided a novel method to address cyclic behaviour which plagues distributed local search algorithms [7]. Each of these results can be observed in the detailed algorithm execution shown in Table 1.

Key to the success of SBDS is the elimination of cyclic behaviour in what is otherwise a local search algorithm. Below we will present formal proof that cyclic behaviour has been eliminated:

LEMMA 1. *Eventually no new nogoods will be generated, and the length of view will become stable (bounded above) for each agent.*

PROOF. Each agent maintains an unbounded store of nogoods, and each isgood is constructed in a way that is consistent with all nogoods known at the time. Therefore, if the algorithm were to never terminate, eventually no new nogoods will be generated.

If no new nogoods are generated, then the method of selection for *support* and *view* ensures that *support* will stabilise. As a result, the length of *view* will also stabilise as it is monotonic increasing over time, but bounded above by either the depth of the 'support tree' or the length of a cycle. □

THEOREM 1. *The algorithm is sound, and will terminate.*

PROOF. The algorithm uses sound nogood derivation techniques and will terminate with 'no solution' only if the empty nogood is derived. Inversely, each agent ensures that its neighbours know its current value, and will continue to communicate if an inconsistency exists. The algorithm will not terminate unless it has a correct answer, and therefore is sound.

By Lemma 1 we know that eventually no new nogoods will be generated and the length of *view* will become stable for each agent. Therefore the *support* for each agent will also become stable, and so value selection for each variable will become dependant only upon information from its *support*. In such a situation the algorithm will only fail to terminate if there exists some directed tour of agents $v_1, \ldots, v_n$ which are 'supporting' each other and oscillating between candidate solutions. However, each candidate solution has the same unordered scope, and so we can utilise the postponement scheme outlined in Section 3. By this scheme, solutions ranked lower by $\prec$ will be removed until the oscillating stops and the algorithm terminates. □

Finally, we provide empirical evidence that no variables change value significantly more often than any other. Figure 2 presents the number of value changes per variable while using our algorithm to solve a randomly constructed feasible problem. Observe that the frequency of value change is fairly evenly distributed amongst variables, with none forced to change significantly more than another. Identical results are seen for other problem sizes and constraint tightness. This particular result also provides further evidence that no significant 'authority' is exerted by one variable over another. If authority was exerted we would expect an exponential (or at least polynomial) increasing curve, as some variables are forced to change by others.

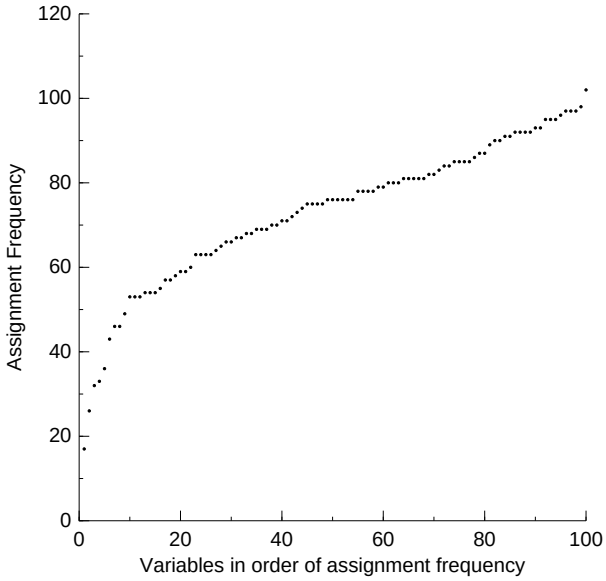

Figure 2: Frequency of assignment changes per variable for a random problem of 100 variables, 300 constraints, domain size of 5, and constraint tightness of 0.325

5. PERFORMANCE

In previous work [4] we used a complicated definition of isgood involving a measure of 'strength' that allowed SBDS to approximate chronological backtracking search. The aim of that measure of strength was to minimise the rate of growth of L in *send-isgood*, and so reduce the amount of information being transmitted in each iteration. However, this measure significantly complicated the proof of completeness. To minimise the rate of growth of L, and to increase performance, we replace this measure with a simple heuristic carefully constructed to maintain completeness.

First note that the completeness of SBDS depends upon lines 1 of *update-view* and line 5 of *send-isgood*. We risk cyclic behaviour if we do not choose a $view'$ which is maximal with respect to $\prec$ or forcibly increase the length sent to neighbours. However, these items incur significant performance penalties. For example, by choosing a $view'$ that is maximal with respect to $\prec$, we are unable to use min-conflict or similar value selection heuristics. Similarly, by consistently increasing the length of isgoods, we discourage local-search behaviour and impact performance accordingly.

However, we are not required to select the maximal $view'$ or increase the length of isgoods with *every* iteration of the algorithm. We may instead perform either action after a finite number of iterations, by:

- forcing an increase in $|sent(v)|$ only after a bounded number of iterations of the algorithm;
- permitting heuristic selection of $view'$ until $|sent(v)|$ cannot be increased further;
- permitting a decrease in $|sent(v)|$ when the ordered scope of *view* changes.

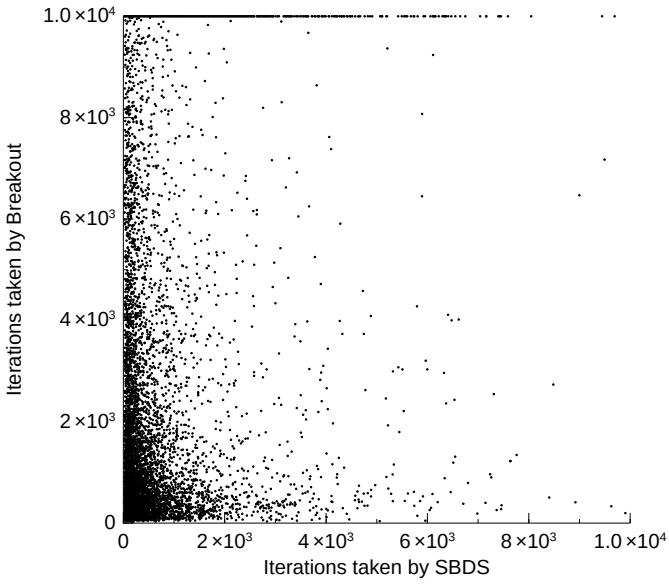

Figure 3: Comparison of SBDS and Distributed Breakout for feasible random problems with 200 variables and 400 constraints, domain size of 5, and constraint tightness of 0.4

These simple techniques significantly improve the performance of SBDS by permitting the use of min-conflict heuristics in value selection. Figures 3 and 4 present comparisons of SBDS and Distributed Breakout. We compare with Distributed Breakout as it is simple to implement, and is often very fast on feasible problem instances. We ran each on approximately 13000 feasible random binary problem instances, with an upper limit of 10000 iterations per instance. We also ran SBDS on approximately 350 infeasible random problem instances generated in the same way.

Figure 3 plots each random problem instance found feasible by SBDS, comparing the number of iterations taken for each algorithm. For the majority of instances where the algorithms completed, both took less than 2000 iterations. However, Distributed Breakout still had a large proportion of instances which took more than 2000 iterations, and a significant proportion were not completed. Particularly important is that there were few problems found 'easy' for Distributed Breakout but hard for SBDS.

Figure 4 graphs the percentage of completed problems for Distributed Breakout and SBDS. As Distributed Breakout is unable to solve infeasible problem instances we have not presented those. As can be seen, of the problem instances found feasible by SBDS, 98% were solved within a 4000-iteration limit. In contrast Distributed Breakout was able to complete only 50% of the same problems within 4000 iterations, and 55% within 10000 iterations. We also present the percentage of problem instances found to be infeasible by SBDS, and the iterations required to find them. While performance is worse on infeasible problems, it is still reasonable.

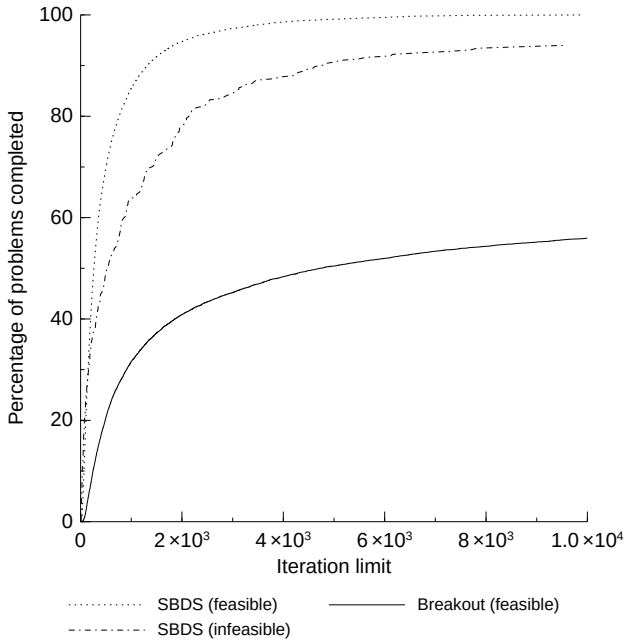

Figure 4: Comparison of SBDS on feasible and infeasible random problems with 200 variables and 400 constraints, domain size of 5, and constraint tightness of 0.4.

6. CONCLUSION

Distributed Constraint Satisfaction Problems provide a natural mechanism for multiagent coordination and agreement. To date, algorithms for Distributed Constraint Satisfaction Problems have tended to mirror existing non-distributed global-search or local-search algorithms. However, there exist natural examples of DisCSPs for which a total variable ordering and/or linking variables is not desired. If we are to solve such DisCSPs we must develop new algorithms designed specifically for distributed environments.

In this paper we have presented one such algorithm. Key to the success of the algorithm is the use of argumentation as a model for agent operation. This technique avoids fixed ranks for agents and the resultant behaviour which is undesirable in natural problems such as meeting scheduling. The placing of a total order over solutions for subsets of variables also provides a novel approach to solving the issue of cyclic behaviour in local search algorithms. This paper also represents a significant simplification, with formal proof results and better performance, of the algorithm presented in [4].

Note that SBDS has been developed with specific goals in mind; it is designed to solve problems for which existing algorithms are unsuitable. It is therefore difficult to compare performance characteristics with other algorithms, in much the same way as comparisons between centralised and distributed algorithms are difficult. The above performance results are promising, but further testing against other distributed search algorithms is required.

ABSTRACT

In this paper, we study how argumentation can be used as a basis for negotiation between autonomous agents, where negotiation strategies of the different parties are represented as argumentation theories within their knowledge. We propose an argumentation based negotiation protocol in which offers by the negotiating parties are linked to different arguments that they can build according to their individual negotiation strategy. This protocol is able to take into account the different roles of agents and context of interaction, where the strength of the arguments supporting an offer can depend on these factors. The agents can adapt their negotiation strategies and offers, as their environment changes, in particular during the course of the negotiation as they exchange information. In addition, using abduction alongside with argumentation, agents can find negotiating conditions to support an argument for an offer, thus extending the negotiation object in order to help find an agreement. To illustrate further the advantages of the approach we also study how we can capture and extend negotiation strategies within another negotiation mechanism, in particular the well-known mechanism of bargaining with multiple parties. This exposes further the main advantages of modularity and flexibility of our argumentation based representation of negotiation strategies and the adaptability that this offers in a changing environment of negotiation.

1. INTRODUCTION

Negotiation is an important problem in multi-agent systems where autonomous agents need to be able to develop their own high-level strategy of operation. The diversity of strategies that different agents set can raise conflicts between them requiring a negotiation procedure to resolve these. Typically, negotiation aims to modify the local decisions of agents in order to avoid negative interactions and to emphasize the situations where positive or helpful interactions are possible.

The design of computational agents needs automated negotiation for various reasons [18]: 1) Agents interact in an open environment and may pursue different goals; 2) Several new applications such as electronic-business require an operational decision making level; and 3) The development of virtual enterprises requires negotiation and dynamic alliances. In all these cases, automated negotiation should provide a great help to save labor time in the sense that it may replace, at least partially, human negotiators. Automated negotiation has long been studied in the multi-agent systems field and different negotiation mechanisms have been proposed. These are based on game theoretic models (see e.g. [17]), heuristic approaches (see e.g. [6]) and some of them on argumentation (see e.g. [2, 14, 19]).

According to [8, 16] the approaches based on argumentation remove many of the limitations of the other approaches. These limitations stem from the facts that (a) the proposals made by the negotiating agents denote single points in the space of the negotiation agreements, (b) the only feedback that can be made to a proposal is a counter proposal, which itself is another point in the space, or an acceptance or withdrawal and (c) it is hard to change the set of issues under negotiation in the course of a negotiation. The added value of the approaches based on argumentation is that they provide additional information, over and above proposals. The arguments that agents can give to support their offers allow them to explicitly express their needs and rational of proposal. Agents have the possibility to question the arguments used by the other agents and to state their specific preferences for supporting their proposals. This gives the possibility to alter, during the negotiation process, the basic position of a negotiating party and its offers, e.g. by extending the negotiation space, or by offering treats or rewards in order to achieve an agreement.

In this paper, we study negotiation using as a basis an argumentation framework [9, 10] that is able to express in a simple and direct way policies and negotiation strategies that can vary according to the particular circumstances in which these are applied. Based on this we propose a negotiation protocol where the decision making for negotiation is done through argumentative self-deliberation of the agents with their own theory. This is able to take into account the different roles that agents can have and specific contexts that describe particular or exceptional situations that agents could find themselves during the course of negotiation. Roles and context define in a natural way dynamic preferences on the decisions implied by the negotiation strategies of the agents as their environment (that includes the other negotiating agents) changes. In addition, aiming to provide agents with a level of robustness in the face of incomplete information from the negotiation environment, we integrate abduction within the argumentation framework. Agents are then able to deliberate on alternative choices and take decisions which are conditional on assumptions about the environment of the negotiation, e.g. assumptions on the preferences of other agents, the specific conditions in the current negotiation context, etc.

In order to illustrate further how argumentation can be used to enhance negotiation we will also study how we can capture and extend negotiation strategies within the traditional negotiation mechanism of bargaining with multiple parties. We show that their formulation within argumentation provides a representation that is more flexible in accommodating special or new requirements and allows us to enhance these negotiation strategies.

The rest of the paper is organized as follows. Section 2 presents briefly the background argumentation framework that we will use. Section 3 describes a new negotiation protocol based on argumentation. Section 4 develops a buying-selling scenario illustrating the main features of our protocol. It also studies representations of negotiation strategies within the negotiation mechanism of bargaining with multiple parties. Section 5 discusses related work and concludes.

2. BACKGROUND

2.1 Argumentation with Dynamic Preferences

In this section, we present the basic concepts of the argumentation framework on which our study of negotiation model will be based. This framework is presented in detail in [9, 10]. Each party in the negotiation will represent its own negotiation strategy (and background knowledge) within this framework.

Our aim is to use the declarative nature of the framework to allow the representation of flexible policies of negotiation strategies that can be sensitive to different circumstances as the negotiation process evolves. In particular, we will assume that negotiating agents are always associated with an (social) environment of interaction. We call this the *context of interaction* (i.e. market, enterprise, etc.). This determines the relationship between the possible roles the different agents can have within this environment and can influence the negotiation strategies used by the agents. Generally, roles are associated to a *default context* that defines shared social relations of different forms (e.g. authority, friendship, relationship, etc.) and specifies the interaction between different roles. For instance in the army context an officer gives orders that are obeyed by a soldier, or in the market a regular customer has benefits over a normal customer.

Consequently, a default context can be understood via priorities between the different roles. However, a default context determining the basic roles filled by the agents is not the only environment where they could interact and negotiate. For example two friends can also be colleagues, an officer and a soldier can be family friends in civil life. Therefore we consider a second level of context, called *specific context,* which can overturn the pre-imposed, by the default context, ordering between roles and establish a different relation between them. For instance, the authority relationship between an officer and a soldier would change under the specific context of a social meeting or regular and normal customers may have an equivalent consideration during the high season.

The argumentation framework that we will use was originally proposed in [11] and extended further in [9, 10] in order to deal with the dynamic nature of interaction of autonomous agents. It has been also adapted to model communication theories and dialogues (see e.g. [4, 12]). This framework uses a priority relation between arguments in the theory which is not a static relation but context dependent that captures the non-static preferences associated to roles and specific context of interaction. We define an agent's argumentation theory for describing a preference policy, e.g. a negotiation strategy, in an environment with roles and context as follows. The full presentation of the argumentation framework can be found in (e.g. [10]).

Definition 1. An agent's argumentative **policy theory, T**, is a theory $\mathbf{T}= ((\mathcal{T}, \mathcal{T}_\circ), \mathcal{P}_R, \mathcal{P}_C)$ where $\mathcal{T}$ contains the **argument** rules in the form of definite Horn logic rules, $\mathcal{P}_R$ contains **priority** rules which are also definite Horn rules with head h-p(r_1, r_2), s.t. $r_1, r_2 \in \mathcal{T}$ (h-p standing for higher priority) and all rules in $\mathcal{P}_C$ are also priority rules with head h-p(R_1, R_2) s.t. $R_1, R_2 \in \mathcal{P}_R \cup \mathcal{P}_C$. $\mathcal{T}_\circ$ contains auxiliary rules of the agent's background knowledge

We therefore have three levels in an agent's theory. In the first level we have the rules $\mathcal{T}$ that refer directly to the subject domain of the agent. We call these the **Object-level Decision Rules** of the agent. In the other two levels we have rules that relate to the policy under which the agent uses his object-level decision rules according to roles and context. We call the rules in $\mathcal{P}_R$ and $\mathcal{P}_C$, **Role (or Default Context) Priorities and Specific Context Priorities** respectively.

In a more general setting, we can associate the dynamic preferences expressed through the rules of the two later levels, to *normal situations* (related to a default context) and *specific situations* (related to specific contexts).

Definition 2. Let $(\mathcal{T}, \mathcal{P})$ be a theory, $T \subseteq \mathcal{T}$ and $P \subseteq \mathcal{P}$. Then (T, P) is **admissible** iff $(T \cup P)$ is consistent and for any (T', P') if (T', P') attacks (T, P) then (T, P) attacks (T', P').

We remind that the notion of attack between arguments in a theory is based on the possible conflicts between a literal L and its negation and on the priority relation given by *h-p* in the theory.

Given a ground literal L then L is a **credulous** (respectively **skeptical**) **consequence** of the theory iff L holds in a (respectively every) maximal, w.r.t. set inclusion, admissible subset of the theory.

Hence for an object-level argument (from $\mathcal{T}$) to be admissible it needs to take along with its priority arguments (from $\mathcal{P}$ where $\mathcal{P} = \mathcal{P}_R \cup \mathcal{P}_C$) to make itself at least "as strong" as the opposing counter-arguments. This need for priority rules can repeat itself when the initially chosen ones can themselves be attacked by opposing priority rules and again we would need to make now the priority rules themselves at least as strong as their opposing ones.

In several cases the admissibility of an argument depends on whether we have or not some background information about the specific case in which we are reasoning. Sometimes this information maybe just unknown and agents can reason further to find *assumptions* related to the unknown information under which they can build an admissible argument. We can formalize this conditional form of argumentative reasoning by defining the notion of *supporting information* and extending argumentation with *abduction* on this missing information. This, as we will see later, is very useful for negotiation.

Definition 3. Let T= $((\mathcal{T}_\circ, \mathcal{T}), \mathcal{P})$ be a theory, and, $\mathcal{A}$, a distinguished set of predicates in the language of the theory, called **abducible** predicates[1]. Given a goal G, a set S of ground abducible literals consistent with the *non-defeasible* part of the background theory $\mathcal{T}_\circ$, is called a **strong (**respectively **weak) supporting information** for G iff G is a **skeptical** (respectively **credulous**) consequence of $((\mathcal{T}_\circ \cup S, \mathcal{T}), \mathcal{P})$ and S is a minimal (w.r.t. set inclusion) such set that has this property.

An argument can then be generalized as follows.

Definition 4. Let T = $((\mathcal{T}_\circ, \mathcal{T}), \mathcal{P})$ be a theory, and $\mathcal{A}$ its *abducible* predicates. A **supported argument** in T is a tuple (Δ, S), where S is a set of abducible literals consistent with $\mathcal{T}_\circ$ and Δ is a set of argument rules, which is not admissible in $((\mathcal{T}_\circ, \mathcal{T}), \mathcal{P})$, but is admissible in the theory $((\mathcal{T}_\circ \cup S, \mathcal{T}), \mathcal{P})$. We say that S **supports** the argument Δ and that Δ is **conditional** on S.

The supporting information refers to the incomplete and evolving information of the external environment of interaction. Typically, this information pertains to the context of the environment, the roles between agents or any other dynamic aspect of the agent's knowledge.

Given the above framework the **argumentative deliberation** of an agent can be formalized via the following basic reasoning functions that will be useful in our study of negotiation.

Definition 5. Let *Ag* be an agent, T his argumentation theory, G a goal and S a set of abducibles consistent with the background part, $\mathcal{T}_\circ$, of its theory. Then we say that *Ag* **deliberates** on G, under S, to produce S^{ag}, denoted by **deliberate**(*Ag*, G, S; S^{ag}), iff S^{ag} is a strong supporting information for G in the theory T and $s^{ag} = S^{ag} - S$. If S^{ag} is a subset of S then we say that *Ag* accepts G under T and S and is denoted by **accept(*Ag*, G, S)**.

[1] For simplicity, we will assume that abducible predicates are a subset of the background predicates.

3. THE NEGOTIATON PROTOCOL

In this section, we will set up a negotiation protocol for intelligent agents by exploiting the internal argumentative deliberation that each agent can perform. The negotiation object(s), e.g. the price of a product, decided by the involved agents are associated to a class of goals for each agent, e.g. sell at high prices for a seller and buy at low prices for a buyer. During the negotiation the agents accumulate extra information about the external environment via supporting information conditions that each agent generates to support, in its own theory, the argument for its offer (see definition 3). This supporting information is then associated with the offer and in some cases it can be seen as extending the negotiation object. The various items of supporting information are collected together and build gradually during the negotiation allowing thus a form of incremental deliberation of the agents as they acquire more information. We note that in this paper, we are not interested in the communication protocol supporting the negotiation. The main elements of the negotiation protocol we propose are as follows:

1. Each agent insists in making proposals corresponding to its own high-level goal as long as its deliberation within its theory and the accumulated supporting information (agreed by the two agents so far) produces new supporting information (see definitions 3, 4) for this goal. A proposal contains an offer corresponding to the negotiation object (e.g. a specific price), together with supporting information representing conditions under which this offer is made. Different offers will typically have different supporting information, e.g. a goal to buy at a low price may contain several prices as possible offers, each of them being supported by the appropriate information. Thus the negotiation object can be extended and may cover several issues related to the initial issue, e.g. terms and conditions under which an agent could accept a specific price.

2. The first of the two negotiating agents who is unable to produce a new offer with supporting information for his goal, abandons it and searches for supporting information, if any, under which it can accept the (counter) proposal of the other agent. For example, a seller agent unable to find another way to support offers with high prices considers selling at a low price and looks for supporting information under which it may be able to do so.

3. In such a case, the negotiation enters a conciliation phase and if the receiver agent can endorse the proposed supporting information the negotiation ends with agreement on this offer and the supporting information accumulated so far. Otherwise, the sender takes this into account and tries again to find another way to support the goal (offer) of the other agent. If this is not possible, then the negotiation ends in failure.

Besides the argumentative functions *deliberate* and *accept* (see definition 5) we use three other functions of an agent, external to his argumentative reasoning, that are needed in the negotiation process. The function *propose(Offer, e_j, s_i)* is used by a sender agent to determine what information to send to the other agent: *Offer* is an offer drawn from an agent's goal and proposed

as an alternative on which negotiating agents could agree; e_j is the evaluation (see below) by the sender of the supporting information s_j sent to it in the previous step by the other agent; and s_i is the new supporting information produced by the deliberation of the sender for its *Offer*.

The function *evaluate(Ag, s_i)* produces an evaluation e_i, where for each (abducible) literal in the supporting information s_i this is either accepted or rejected (i.e. negated) according to some process of evaluation by a receiving agent *Ag.* This can therefore be considered as a *critique* (see e.g. [16]) of s_i by *Ag*. This function can vary in complexity from a simple check in the agent's database to an argumentative deliberation on s_i and a new subsidiary negotiation process on this.

The function *update(S,e)* updates, through an external mechanism, the store of accumulated supporting information *S* with the new information *e* produced by the agent's evaluation of the supporting information sent by the other agent. Part of the task of this function is also to maintain the consistency of the store *S*. We require that conflicts are resolved in favour of the latest information i.e. in favour of the information in *e*. In this paper we will not be concerned with the details of this mechanism as they are not important for the specification of the protocol. Thus *S* is related to the concept of *commitment store* (see [7, 13]) adopted by the agent literature (see e.g. [1]). A commitment store holds all the statements to which an agent has committed during the negotiation. In our case *S* corresponds to the union of the commitment stores and contains all the additional information produced in the course of the negotiation and accepted by each negotiating agent.

The negotiation protocol we are proposing operates via the alternate application by each one of the two negotiating agents of the algorithm given below. This defines formally the steps of the negotiation process. Note that in the presentation of this algorithm, we assume that it is agent X who is applying it. Agent Y applies exactly the same algorithm, and therefore the reader has only to replace X with Y in order to see how a negotiation process between two agents would evolve (see Section 4 for a buying-selling scenario).

Below we will denote by G^X the argumentation goal corresponding to an offer O^X and by $e_n^{X\to Y}$ the evaluation by agent X of the supporting information sent by agent Y. Also we will denote by $s^{I,J}$ the supporting information generated by agent, I, for the goal of agent, J, (I, J can take the values X or Y).

Each agent (agent X here) can receive three types of proposals. In the first one, denoted by *propose(O^Y, $e^{Y\to X}$, $s_n^{Y,Y}$)*, another agent, Y, sends to X an offer, O^Y, with a new alternative supporting information, $s_n^{Y,Y}$. This proposal also includes, $e^{Y\to X}$ (empty in the initial proposal), which is the evaluation by Y of the supporting information sent to it in the previous step by X for its offer O^X. In the second type of proposal, denoted by *propose(O^Y, $e_m^{Y\to X}$, ⊗)*, the other agent, Y, sends to X (via step 4.4 for agent Y) its answer to an offer made previously by X to consider the offer O^Y of Y, i.e. X has entered the conciliation phase and Y is responding to this. This answer contains the evaluation, $e_n^{Y\to X}$, by Y of the terms (or conditions) proposed by X in order to accept an offer O^Y satisfying the goal of Y. Finally, in the third type of proposal, denoted by *propose(O^X, ⊗, $s_n^{Y,X}$)* another agent, Y, sends to X an answer where it proposes the conditions, $s_n^{Y,X}$, under which it could accept the offer O^X of X, i.e. Y has previously entered the conciliation phase.

Begin
S={}; n=0
1. agent X receives a proposal O from an agent Y

2. **if** O is of the form propose(O^Y, $e_{n-1}^{Y\to X}$, $s_n^{Y,Y}$) **then**
2.1. $e_n^{X\to Y}$←evaluate(X, $s_n^{Y,Y}$);
2.2. S←update(S, $e_{n-1}^{Y\to X} \cup e_n^{X\to Y}$)
2.3. **if** $e_n^{X\to Y} = s_n^{Y,Y}$ and accept(X, G^Y, S) **then** END(agreement, O^Y)
else
2.4. n←n+1; find $s_n^{X,X}$ s.t. deliberate(X, G^X, S; $s_n^{X,X}$) and $s_n^{X,X} \neq s_i^{X,X}$ ∀ i < n
2.5 **if** s_n^X exists **then** propose(O^X, $e_{n-1}^{X\to Y}$, $s_n^{X,X}$) to Y
else (*Enter Conciliation Phase*) m = 0
2.6. S←update(S, $e_n^{Y\to X}$)
2.7. m←m+1; find $s_m^{X,Y}$ s.t. deliberate(X, G^Y, S; $s_m^{X,Y}$) and $s_m^{X,Y} \neq s_j^{X,Y}$ ∀ j < m
2.8. **if** $s_m^{X,Y}$ exists **then** propose(O^Y, ⊗, $s_m^{X,Y}$) to Y
else END(Failure)
2.9. endif
2.10. endif
2.11. endif
2.12. endif

3. **if** O is of the form propose(O^Y, $e_m^{Y\to X}$,⊗) **then**
3.1. goto 2.6; endif

4. **if** O is of the form propose(O^X, ⊗, $s_k^{Y,X}$) **then**
4.1. $e_k^{X\to Y}$←evaluate(X, $s_k^{Y,X}$)
4.2. S←update(S, $e_k^{X\to Y}$)
4.3. **if** $e_k^{X\to Y} = s_k^{Y,X}$ and accept(X,G^X,S) **then** END(agreement, O^X)
4.4. **else** propose(O^X, $e_k^{X\to Y}$, ⊗)
4.5. endif
4.6. endif
end

We can show the following formal properties for the above negotiation protocol.

Proposition 1. Let X, Y be two agents and T_X, T_Y their respective argumentation policy theories which contain a finite number of sentences. Then,
(1) any negotiation process will terminate.
(2) if a negotiation process terminates with agreement on an offer O and S is the final set of supporting information accumulated during the negotiation then the corresponding goal, G(O), is a skeptical conclusion of both $T_X \cup S$ and $T_Y \cup S$.

Proof
(1) Termination follows directly from the fact that, when an agent deliberates again, either on its own goal or the goal of the other agent, the algorithm requires that it produces new supporting information and the fact, that there can only be a finite number of different supporting information generated by the theories of the agents.
(2) There are two cases for the process to terminate in agreement. In the first case (step 2.3) agent X agrees on the offer G^Y of the other agent (agent Y) when accept(X, G^Y, S) holds. By the definition of accept(X, G^Y, S) this means that G^Y is a skeptical conclusion of $T_X \cup S$. This is also a skeptical conclusion of $T_Y \cup S$ since agent Y has produced this offer for its own goal G^Y (at its step 2.4) and its supporting information has been accepted by agent X and updated in S at step 2.2. Similarly, we show that the result holds also in the second case where agreement can be reached, at step 4.3.

4. EXAMPLES OF NEGOTIATON

In this section, we will present two examples of negotiation in order to illustrate how our argumentation-based approach to negotiation works in practice. First we will present a bargaining example of buying-selling transactions that illustrates how the specific negotiation protocol that we have proposed in the previous section applies and how the argumentative deliberation of the agents is performed within this protocol. Then we will investigate how our argumentation framework can be used for representing and extending negotiation strategies within another negotiation mechanism, in particular the well-known mechanism of bargaining with multiple parties.

4.1 A Buying-Selling Scenario

Let us consider a buying-selling scenario between a seller agent, called X, who has the goal, G^X, to sell a product at a high price and a buyer agent, called Y, who has the (opposing) goal, G^Y, to buy this product at a low price. These goals generate corresponding offers and counter-offers containing different values for the negotiation object, namely the price for the product. Therefore agents are trying to find an agreement on a specific price by agreeing either on an offered selling price O^X or on an offered buying price O^Y. We assume that the seller has the following simplified (where only two prices high and low exist) argumentation policy for selling products. We present only a part of this theory[2].

[2] Here and below we will use Logic Programming notation where any term starting with a capital letter represents a variable. Abusing this notation we will denote the constant names of the priority rules in the role part, $\mathcal{P}_R$, of the theory with capital R letters (subscripted) and the priority rules in the specific context part, $\mathcal{P}_C$, of the theory with subscripted capital C letters. All variables are universally quantified over the whole rule in which they appear. Each rule represents the collection of ground rules that we obtain by grounding its variables over the Herbrand universe of the theory.

The goal G^X of the seller is G^X=sell(prd,buyer,high_price). There are two ways or methods to get this "high_price", either through a normal payment method or through payment via installements. The object-level theory $\mathcal{T}^X$ contains the rules:
r_1: sell(Prd, Ag, high_price, method1)← pay_normal(Ag,Prd)
r_2: sell(Prd, Ag, high_price, method2)← pay_install(Ag,Prd)
r_3: sell(Prd, Ag, low_price)← pay_cash(Ag,Prd)
r_4: sell(Prd, Ag, Price)← sell(Prd, Ag, Price, Method)
r_5: ¬sell(Prd, Ag, P_2)← sell(Prd, Ag, P_1), $P_2 \neq P_1$
r_6: ¬sell(Prd, Ag, P, M_2)← sell(Prd, Ag, P, M_1), $M_2 \neq M_1$

Its role and context priority theories, $\mathcal{P}^X_R$ and $\mathcal{P}^X_C$, are given below. They contain the policy of the seller under which it should treat or negotiation with the various types of customers. For example, it should prefer to sell with normal paying conditions (e.g. cash or visa) over payment by installments when the buyer is a normal customer (see R_1). Also that there is always a preference to sell at high price (see R_2, R_3) but for regular customers there are conditions under which the seller would sell at low price (see R_4, R_5). This low price offer to a regular customer applies during a sales season (see C_3, C_4) and not during a high season (see C_1, C_2) where the preference of a high price is stronger.

R_1: h-p(r_1(Prd, A), r_2(Prd, A)) ← normal(A)
R_2: h-p(r_1(Prd, A), r_3(Prd, A))
R_3: h-p(r_2(Prd, A), r_3(Prd, A))
R_4: h-p(r_3(Prd, A), r_1(Prd, A)) ←regular(A), buy_2(A, Prd)
R_5: h-p(r_3(Prd, A),r_1(Prd,A))←regular(A), late_del(A, Prd)

C_1: h-p(R_2(Prd, A), R_4(Prd, A)) ← high_season
C_2: h-p(R_2(Prd, A), R_5(Prd, A)) ← high_season
C_3: h-p(R_4(Prd, A), R_2(Prd, A)) ← sales_season
C_4: h-p(R_5(Prd, A), R_2(Prd, A)) ← sales_season
C_5: h-p(R_4(Prd, A), R_5(Prd, A))

Lets us consider the particular negotiation scenario given below as it evolves through the application of our proposed negotiation protocol and study how the seller uses its own argumentative reasoning, with the above theory, in this scenario. For simplicity of presentation we will show the *update* function simply as union. We would also like to note that in the following example we only present the reasoning made by each agent during the negotiation process. The presentation of the communication protocol (e.g. structure of exchanged locutions, performatives used, etc.) implementing this negotiation dialogue is out of the scope of this paper. This is part of our future work and it will be based on the work we proposed in [4, 12].

Seller X (step 1)
-propose(high_price, {}, $s_0^{X,X}$)
-$s_0^{X,X}$={ pay_normal, normal(Y)})

Buyer Y (step 2)
-$e_0^{Y\to X}$={ pay_normal, ¬normal(Y)}
-S= $e_0^{Y\to X}$
-deliberate(Y, buy(prd, X, low_price),S; $s_1^{Y,Y}$)
-$s_1^{Y,Y}$={expensive(Y, high_price)}
-propose(low_price,$e_1^{X\to Y}$, $s_1^{Y,Y}$)

Seller X (step 3)
-$e_1^{X\to Y}=s_1^{Y,Y}$
-$S\leftarrow S\cup e_1^{X\to Y}$
-Cannot Accept
-deliberate(X, sell(prd, Y, high_price), S; $s_1^{X,X}$)
-$s_1^{X,X}$={pay_install}
-propose(high_price, $e_1^{X\to Y}$, $s_1^{X,X}$)

Buyer Y (step 4)
-$e_2^{Y\to X}=\neg s_1^{X,X}$
-$S\leftarrow S\cup e_2^{Y\to X}$
-deliberate(Y, buy(prd, X, low_price), S; $s_2^{Y,Y}$)
-$s_2^{Y,Y}$={pay_cash}
-propose(low_price, $e_2^{Y\to X}$, $s_2^{Y,Y}$)

Seller X (step 5)
-$e_3^{X\to Y}=s_2^{Y,Y}$
-$S\leftarrow S\cup e_3^{X\to Y}$
-Cannot Accept
-deliberate(X, sell(prd, Y, high_price), S; s)
-fails to find new s.

Seller X (step 6): ***X Enters Conciliation Phase***
-deliberate(X, sell(prd,Y,low_price), S; $s_1^{X,Y}$)
-$s_1^{X,Y}$={regular(Y), buy_2(Y,prd)}
-propose(low_price, ⊗, $s_1^{X,Y}$)

Buyer Y (step 7)
-$e_4^{Y\to X}$={regular(Y), ¬buy_2(Y, prd)}
-propose(low_price, $e_4^{Y\to X}$, ⊗)

Seller X (step 8)
-$S\leftarrow S\cup e_4^{Y\to X}$
-deliberate(X, sell(prd, Y, low_price), S; $s_2^{X,Y}$)
-$s_2^{X,Y}$={later_del(Y,prd)}
-propose(low_price, ⊗, $s_2^{X,Y}$)

Buyer Y (step 9)
-$e_5^{Y\to X}= s_2^{X,Y}$
-$S\leftarrow S\cup e_5^{Y\to X}$
-accept offer; END(agreement, low_price)

At step 1 the seller agent proposes to the buyer agent to buy the product at a high price (which is the preferred price for the seller according to his theory). Step 2 of the example corresponds to the second step of the negotiation algorithm. At this stage the buyer agent cannot accept the offer. He thus deliberates on his own goal and proposes a low price. At step 3 the seller cannot accept the proposal for low price: his theory even under the fact that this is not a normal customer contains admissible arguments for the contrary of this proposal to sell low. He now needs to find a new argument for his goal of selling high. Deliberating on his goal, he finds such an argument, using the object-level rule r_2. This new argument needs the support (or is conditional on) *pay_install(buyer, prd)* and the seller offers this information to the buyer insisting on his offer of a high_price.

At step 5 the seller deliberates again on his own goal (to sell high) but cannot find a new solution anymore. It therefore initiates at step 6 a conciliation phase of the negotiation where he considers the offer made by the buyer, i.e. to sell at *low_price*. He deliberates on this goal and finds (an admissible argument using r_3 and R_4) that it is possible to do so if the customer can pay cash (which is already in the store S), is a *regular* one and he accepts to buy two of the products. In this way the seller agent extends the negotiation object by submitting for negotiation these latter two conditions. Note that for this to skeptically derive the offer to sell low, we need to be at a sales season and that the context C_1 rule must not apply i.e. that we are not in high season, facts that the seller knows in its background theory. The buyer confirms that he is a regular one but refuses to buy two (i.e. it generates a critique to the extended offer). The seller then has another solution to sell low to a regular customer conditional on late delivery, which is accepted by the buyer agent and the process ends in agreement on "low price with a late delivery".

Note that the late delivery condition has been generated dynamically in the particular scenario extending the negotiation object of the price in order to reach agreement. In some other scenario it could happen that this will not enter at all the process.

As we have already remarked, the evaluation function *evaluate(Ag, s_i),* can take, in its more complex case the form of a new subsidiary argumentative deliberation of *Ag* on s_i. This could lead to a nested negotiation process, where the negotiation object is extended further and covers additional issues related to the original (or parent) object. Let us illustrate this subsidiary argumentative deliberation, along with the possible nested negotiation steps, by considering that the buyer agent in the above example has the following argumentation theory for his general policy with regards to methods of payment and how he uses this to evaluate proposals from the seller.

r_1: pay(Prd, Price, install)← reasonable(Prd, Price)
r_2: pay(Prd, Price, cash)← ¬expensive(Prd, Price)
r_3: ¬pay(Prd, P, M_2)←pay(Prd, P, M_1), $M_2 \neq M_1$
R_1:h-p(r_1(Prd, P), r_2(Prd, P))
R_2:h-p(r_2(Prd, P_1), r_1(Prd, P_2)) ←¬cash_flow_problems, $P_1 \leq P_2$
cash_bonus(Prd, Bonus)
C_1:h-p(R_2(Prd,P_1,P_2),R_1(Prd,P_2))←discount(Prd,P_1,D), D>30%

According to this policy buyer prefers to pay by installments rather than cash. When he has no cash flow problems and there is a cash bonus he prefers to pay in cash (provided also that the cash price is not higher than the installments price). In the specific case where the price is at a discount of more than 30% then this preference to pay cash is stronger than the preference to pay by installments.

At the fourth step of the example above the buyer evaluates the proposal of the seller to pay by installments via an argumentative deliberation on *pay(prd, high_price,install).* The negotiation object is extended from <Price> to <Price, MethodOfPayment>. Despite the fact that *high_price* is a reasonable price for the buyer *pay(prd,high_price,install)* it is not a skeptical conclusion of his theory as he has an admissible argument for *pay(prd, low_price, install).* The buyer would then make this counter offer (in a new subsidiary step) to pay by installments but at a low price. If the seller rejects this offer the buyer could then re-evaluate and, assuming that there is a cash

bonus at a discount of over 30% for *low_price*, the above theory of the buyer would then give the skeptical conclusion *pay(prd, low_price, cash)*. Hence the buyer would then offer to pay cash for a low price.

4.2 Bargaining with Multiple Parties

In a bargaining setting, the negotiation process starts with an initial offer formulated by one of the participating parties and then proceeds with an alternate exchange of offers. This process stops either when an agreement is found or one of the involved parties decides to terminate the negotiation with a specific party (or all the parties) without any agreement. Normally, in many realistic scenarios a member participates in several bargaining processes simultaneously, e.g. a buyer contacts several merchants in search for the best terms for buying a given product.

We will study an example type of bargaining considered in [5]. According to this scenario an agent is responsible for negotiating a price with several potential sellers on behalf of a buyer. The offers sent by the sellers are arranged in a queue and then are taken from the queue and evaluated. A buyer agent can accept an offer, propose a counter-offer or terminate the negotiation with the corresponding party. If the offer is accepted, the negotiating agent asks the other party to confirm the agreement, and upon receiving the confirmation, he terminates all the negotiation processes in which he is involved. In the contrary case where a confirmation refusal message arrives or the confirmation message is not received after an agreed delay, an occurrence of the event "no_confirmation" is generated and the agent continues to negotiate with the other remaining parties. In the case where there are no more potential sellers remaining, the overall negotiation process is terminated with a failure.

Below we will show how this evaluation strategy of the buyer agent for each offer it receives can be captured in a natural and direct way within our argumentation framework[3]. We will use the term "offer" to designate the prices proposed by the sellers, and the term "counter-offer" to designate the prices proposed by the buyer. We will also use the following predicates and constants in the representation of the buyer's theory:

- *offer(P,X):* the current offer of the party P is X
- *first_offer(P,X)*: indicates the first offer X of the party P
- *previous_offer(P,X)*: the previous offer of the party P was X
- *counter_offer(P,X)*: X is a counter offer suggested as a reply to P's most recent offer reception
- *previous_counter_offer(P,X)*: X is a counter offer suggested as a reply to the P's second most recent offer reception
- *accept(P, X)*: indicates that the most recent offer X of P can be accepted
- *terminate(P)*: indicates that the negotiation with the party P must be terminated
- *good_price*: indicates a price that can be accepted
- *increment*: indicates an acceptable amount of raising the price
- *acceptable_price*: it is the top price that can be accepted
- *best_offer(X)*: X is the current best offer
- *time_remaining(T)*: indicates the time before the deadline of the bargaining

In the theory that we will present here we will also extend the standard bargaining scenario in order to illustrate further the flexibility of our direct and modular representation of the problem. For example, we can allow for a price greater to "good_price" to be acceptable under some specific circumstances, e.g. when we have only a few remaining sellers or little time remaining before the deadline of the bargaining, provided that the buyer has a big urgency for buying a specific product.

We will represent one by one the policy rules of the evaluation strategy of the buyer directly from their natural specification. Note that "counter_offer", "accept" and "terminate" are all contrary to each other, i.e. each one implies the negation of all others. Similarly, different prices for "accept" and "counter_offer" are contrary to each other.

"If the first offer of P is greater than the "good_price" then ask for the "good_price"."
r_1:counter_offer(P,good_price)←first_offer(P,X), X>good_price.

"If P has not improved his offer terminate the negotiation with him."
r_2: terminate(P) ← offer(P,Y), previous_offer(P,Z), Y≥ Z.

"If P has improved his offer with respect to the previous one, then concede a small amount with respect to the previous counter-offer but do not counter-propose a price below the current best offer."
r_3: counter_offer(P, min(X+increment, W)) ← offer(P,Y), previous_offer(P,Z), Y<Z, previous_counter_offer(P,X), best_offer(W)

"If the offer of P is below the acceptable price and it is the best one that has been received then you can accept it"
r_4: accept(P,Y) ←best_offer(Z), offer(P,Y), Y≤Z, Y≤ acceptable_price

"If somebody offers the "good_price" then this offer can be accepted."
r_5: accept(P,Y) ← offer(P,Y), Y≤good_price

"A good price has preference over any other response and over other prices below the acceptable price"

R_1: h-p(r_5(P,Y), r_2(P))
R_2: h-p(r_5(P,Y), r_3(P,Z))
R_3: h-p(r_5(P,Y), r_4(P,Y1)) ← Y < Y1

"Prefer to accept a price below the acceptable price over terminating the process"
R_4: h-p(r_4(P,Y), r_2(P))

"Prefer to counter offer asking for a better price over accepting a price below the acceptable price"
R_5: h-p(r_3(P,H), r_4(P,Y))

"When we are in a critical situation, i.e. there are only a few sellers left and time is running out, then prefer to accept an offer over making a counter offer. This applies only when there is a big urgency to acquire the product."

[3] Note that we will not be concerned here with the issue of how the buyer selects the next offer to be evaluated. This can be done using another modularly separated preference policy written analogously in the theory of the buyer.

R_6: h-p(r_4(P,Y), r_3(P,H)) ← few_sellers_remaining, time_remaining(T), T≤time_threshold
C_1: h-p(R_5(P,H), R_6(P,Y))
C_2: h-p(R_6(P,Y), R_5(P,H)) ← big_urgency

5. RELATED WORK AND CONCLUSIONS

We have presented an argumentation-based negotiation framework, which like other approaches that use argumentation (see e.g. [8, 16]), removes many of the limitations of the alternative approaches. Our approach confirms the advantages of an argumentation-based approach to negotiation and covers the requirements defined in [8] for an effective argumentation-based negotiation. Comparing with other argumentation-based approaches (see e.g. [2, 14, 19]), the integration of roles (or default context) and contexts (or specific contexts) within the deliberation process of the agents facilitates agents to dynamically adapt their strategies, offers and counter-offers as the environment of negotiation changes. In addition, integrating abduction within the argumentative reasoning of the agents we allow them to extend, during the process of negotiation, the negotiation object with other objects pertaining to conditions under which an agent could accept an offer. In most current approaches (see e.g. [14]), agents generate proposals and counter-proposals until an agreement or a failure is reached, by reasoning only on their own goals or objectives. In our framework we have proposed a negotiation protocol where an agent, when he cannot satisfy his own goal, can consider in a conciliation phase, the other agent's goal and search for conditions under which he could accept it. This can lead again to the extension of the negotiation object helping to reach an agreement. We have shown that our argumentation framework is well suited for modeling this negotiation protocol. However, the negotiation protocol itself, is not crucially dependent on the specific underlying logical framework for argumentation and it could be built similarly on top of other such frameworks (e.g. [3, 15]) provided also that they are extended with abduction so that they can have supported arguments. We also have investigated through the extension of a case study, originally presented in [5], the application of our argumentation framework for representing negotiation strategies within another negotiation mechanism, in particular the well-known mechanism of bargaining with multiple parties. Other negotiation problems, e.g. the resource allocation problem, can also be captured and extended in the same way. This framework and the presented examples have been implemented using the Gorgias [20] system.

Our future work concerns the introduction of multi-criteria techniques from decision theory in the evaluation, by the agents, of the exchanged offers and counter-offers and the development of an associated communication protocol to support the negotiation protocol, based on the work we proposed in [4, 12]. We wish also to investigate how to integrate within the same framework a "personality" component for each one of the negotiating agents, expressed also as an argumentation theory, and study how this can influence the negotiation process between different types (e.g. cooperative or self-interested) of agents.

Monotonic Concession Protocols for Multilateral Negotiation

Ulle Endriss

ulle@illc.uva.nl

ABSTRACT

The most natural way of thinking about negotiation is probably a situation whereby each of the parties involved initially make a proposal that is particularly beneficial to themselves and then incrementally revise their earlier proposals in order to come to an agreement. This idea has been formalised in the so-called monotonic concession protocol, a set of rules defining the range of acceptable moves during a negotiation process intended to follow this general scheme. In the case of negotiation between just two agents, the monotonic concession protocol has become a textbook example and its formal properties are well-understood. In the case of multilateral negotiation, where more than two agents need to come to an agreement, on the other hand, it is not at all clear how to set up a monotonic concession protocol. As it turns out, the design of such a protocol boils down to the question of what constitutes a multilateral concession. In this paper, we make several proposals as to what might be an appropriate definition and analyse the properties of the proposed concession criteria.

1. INTRODUCTION

Negotiation between self-interested agents is a blossoming research area at the heart of multiagent systems, incorporating many ideas and models originally developed in different branches of economics (notably game theory), and at the same time benefiting significantly from the adoption of computational methods [6, 7, 10]. Much work on negotiation is either concerned with *bilateral* ("one-to-one") negotiation [10] or with *auctions* [2]. The latter are highly structured forms of negotiation between several agents.[1] Truly *multilateral* negotiation, on the contrary, where groups of more than just two agents can freely come together and agree on a deal between them has received far less attention. This is very much due to the significant technical challenges posed by such rich negotiation models (and certainly not because they would not be considered important).

For instance, in the context of distributed task and resource allocation, it is well-known that protocols only permitting two agents at a time to negotiate agreements are usually not expressive enough to reach optimal allocations [3, 11]. A typical example would be a scenario with three agents and three resources. Think of the agents as being arranged in a circle. Suppose the agents all differ in their assessment of the respective values of the three items and also suppose that, initially, each agent holds their second-most preferred item, their lefthand neighbour holds their favourite item, and their righthand neighbour holds their least-preferred item. Now any potential deal between two agents would either involve one of them losing all resources, or having to exchange their second-best item for the worst one. Neither would be considered beneficial by that agent, *i.e.* a *rational* agent would have to refuse any such deal.[2] Hence, using bilateral deals alone, it is not possible for rational agents to move away from the initial allocation and reach the ideal situation where each agent gets their preferred resource. Such limitations can be overcome by negotiation mechanisms that allow for more than just two agents to make a deal. In our example, for instance, it is clear that there is a multilateral deal between all three agents that would be considered rational by all of them.

Other examples for the need for multilateral negotiation abound (international politics being just one of them). Clearly, there are many situations where the options to agree on deals between more than just two parties at a time can greatly enrich the opportunities available to the negotiators

[1] But note that the *outcome* of an auction is usually also just a collection of separate bilateral deals between the auctioneer and different bidders.

[2] Even with monetary side payments, it is not difficult to set up an example where any bilateral deal would be considered irrational by at least one of the agents concerned [3, 11].

and can lead to much better negotiation outcomes. On the downside, of course, such multilateral negotiation models are a lot more complex than bilateral negotiation (and typically also more complex than the highly structured negotiation schemes between several agents given by auctions). Acknowledging these difficulties, this paper aims at clarifying some of the more fundamental issues at stake.

Specifically, in this paper we are interested in *monotonic concession protocols* for multilateral negotiation. A negotiation *protocol* is a set of rules specifying the range of "legal" moves available to each agent at any stage of a negotiation process (in contrast to this, an agent's negotiation *strategy* is a function from the negotiation history to a follow-up move respecting the protocol). Monotonic concession protocols, in particular, formalise what might be considered the most natural way of thinking about negotiations: Initially, each of the parties involved make a proposal that is particularly beneficial to themselves, and then they incrementally revise their earlier proposals in order to eventually come to an agreement. In the case of negotiation between two agents, the monotonic concession protocol has become a textbook example for negotiation mechanisms [10, 13] and its formal properties are well-understood. In the multilateral case, as we shall see, there appear to be many different ways of generalising the (single) definition for the two-agent case. Crucially, the design of multilateral monotonic concession protocols boils down to the question of what constitutes a concession to a group of agents, rather than to a single opponent. This paper identifies (at least some of) the available options, and analyses their formal properties. We also include a preliminary discussion of the question of how to design suitable negotiation strategies for these protocols.

Paper Overview

Section 2 reviews the monotonic concession protocol for the *two-agent case* and an associated negotiation strategy, as developed in the work of Zeuthen [15], Harsanyi [4], and Rosenschein and Zlotkin [10]. Following this, Section 3 sets out the general framework of generalising the protocol to the multilateral case. Such a generalisation requires us to decide what constitutes an *agreement* between several agents and, crucially, how to characterise a *concession* to more than one opponent. These concepts are discussed in Section 4. In particular, Section 4 presents seven alternative definitions of the term *multilateral concession*. Each of these gives rise to a different variant of the monotonic concession protocol. The *properties* of these variants of the basic protocol, in particular *termination* and *deadlock-freedom*, are then analysed in Section 5. Some of the issues pertaining to the definition of a suitable *strategy* in a multilateral negotiation context are discussed in Section 6. Section 7 concludes.

2. THE TWO-AGENT CASE

In this section, we are going to describe the monotonic concession protocol for *two* agents, as presented by Rosenschein and Zlotkin [10]. We are also going to discuss a particular negotiation strategy, originally introduced by Zeuthen [15] and shown to be based on sound game-theoretical foundations by Harsanyi [4], that agents may adopt during an interaction regulated by the protocol.

Notation and Assumptions

Let $\mathcal{A} = \{1, 2\}$ be a set of two agents and let $\mathcal{X}$ be a finite set of *potential agreements* (which we are also going to refer to as *deals* or *proposals*). Each of the agents $i \in \mathcal{A}$ is equipped with a *utility function* $u_i : \mathcal{X} \rightarrow \mathbb{R}_0^+$ mapping agreements to non-negative reals. That is, we exclude any potential agreements that would yield negative utility for either one of the agents *a priori*. $\mathcal{X}$ includes a specific agreement, called the *conflict deal*, that yields utility 0 for both agents. This will be the agreement chosen in case negotiation breaks down and is assumed to be the worst possible outcome.

Monotonic Concession Protocol

The monotonic concession protocol proceeds in *rounds*. In each round, both agents make simultaneous *proposals*, *i.e.* they each propose one of the potential agreements from $\mathcal{X}$. In the first round, each agent is free to make any proposal. In any subsequent round, each agent $i \in \mathcal{A}$ has got two options (let $x_i \in \mathcal{X}$ be the most recent proposal made by i):

(1) Make a *concession* and propose a new deal x_i' that is preferable to the other agent j: $u_j(x_i) < u_j(x_i')$.

(2) Refuse to make a concession and stick to proposal x_i.

An *agreement* is found when one agent makes a proposal that its opponent rates at least as high as its own current proposal, *i.e.* when $u_1(x_1) \leq u_1(x_2)$ or $u_2(x_2) \leq u_2(x_1)$ or both. *Conflict*, on the the hand, arises when both agents refuse to make a concession during a given round. The protocol runs until either an agreement is found or conflict occurs. In case of agreement, the proposal satisfying both agents is chosen (in case both proposals are satisfiable, we flip a coin to pick one). In case of conflict, the conflict deal is the outcome of the negotiation.

The monotonic concession protocol is known to always *terminate* [10], *i.e.* there can be no infinite sequence of rounds.

Zeuthen Strategy

What would be a suitable strategy for agents to adopt when following the monotonic concession protocol? Zeuthen [15] proposed that agents should evaluate their respective *willingness to risk conflict*, and that the agent with the lower value for this measure should make the next concession (and both agents should concede in case their risk values are equal). Furthermore, a concession should be *sufficient* to ensure that the other agent will have to concede in the following round.

Zeuthen proposed to calculate an agent's willingness to risk conflict as the quotient of the loss in utility incurred in case the other agent's proposal is being adopted and the loss incurred by causing conflict (both with respect to the utility of the agent's own current proposal). As the utility of the conflict deal is 0, the willingness of agent i to risk conflict (with j being the other agent) is given by the following formula (we assume $u_i(x_i) \neq 0$ for ease of presentation):

$$Z_i \quad = \quad \frac{u_i(x_i) - u_i(x_j)}{u_i(x_i)}$$

Zeuthen's intuitive justification for this strategy has been complemented by Harsanyi's work [4], who showed how the same strategy can be derived from a small number of *fundamental postulates*. The most important of these is the

postulate of *utility maximisation*. Harsanyi argues as follows: Suppose the two agents are playing a single-round game; each agent can either accept or reject the other's proposal. Let p_2 be the probability that agent 2 will reject x_1. Then the expected payoff for agent 1 of rejecting x_2 is $(1 - p_2) \cdot u_1(x_1)$. On the other hand, Harsanyi argues, the *certain* payoff associated with accepting x_2 is $u_1(x_2)$. Hence, agent 1 should accept iff $u_1(x_2) \geq (1 - p_2) \cdot u_1(x_1)$. This is equivalent to $\frac{u_1(x_1) - u_1(x_2)}{u_1(x_1)} \leq p_2$. Together with a *symmetry* and a *monotonicity* postulate, this leads to the Zeuthen criterion: agent 1 should concede whenever $Z_1 \leq Z_2$.[3]

The Zeuthen strategy is *efficient* in the sense of leading to a final agreement maximising the product of utilities [4, 10].[4] This follows from the fact that $Z_1 \leq Z_2$ is equivalent to $u_1(x_1) \cdot u_2(x_1) \leq u_1(x_2) \cdot u_2(x_2)$, *i.e.* in each round the agent whose current proposal yields the lower product of utilities makes a concession.

The strategy is also "almost" *stable* (*i.e.* in Nash equilibrium [9]). The only critical case is when both agents have the same willingness to risk conflict after the penultimate round. In that case, an agent could benefit from deviating and sticking to their latest proposal. This problem can be overcome by extending the Zeuthen strategy with a mixed equilibrium strategy for the two-person game induced by this "last step situation", albeit at the cost of giving up on efficiency [9, 10].

3. NEGOTIATION PROTOCOLS

In this section, we are going to discuss the design of negotiation protocols that can be used by more than just two agents.

Notation and Assumptions

Again, let $\mathcal{X}$ be a finite set of potential agreements and let $\mathcal{A}$ be a finite set of agents. Each agent $i \in \mathcal{A}$ is equipped with a utility function $u_i : \mathcal{X} \to \mathbb{R}_0^+$, *i.e.* we only admit non-negative utilities, and $\mathcal{X}$ includes the so-called conflict deal to which every agent assigns utility 0. In one case we are going to comment on the effects of only allowing strictly positive utilities (for anything but the conflict deal).

A Multilateral One-Step Protocol

We should stress that, in this paper, we are not interested in finding the "best" protocol for multilateral negotiation. Instead, we are only interested in generalising the ideas present in the two-agent monotonic concession protocol. Also in the two-agent case, it is well-known that the monotonic concession protocol is not the "best" protocol. Indeed, there is a simple alternative, termed the *one-step protocol* by Rosenschein and Zlotkin [10], that is much simpler than the monotonic concession protocol and permits a negotiation strategy that is both stable and efficient. Recall that the Zeuthen strategy cannot guarantee both stability *and* efficiency (depending on how the "last step situation" is handled, either stability or efficiency need to be sacrificed). The idea of the one-step protocol is to simply ask both agents for a proposal and to adopt the proposal that yields the higher product of utilities (and to flip a coin in case the products are the same). The best strategy that agents can follow in this protocol is to propose the agreement that is best for themselves amongst those with maximal product of utilities. This is clearly both stable and efficient.

The one-step protocol can easily be extended to the multilateral case: Collect a proposal from each agent and randomly choose an outcome amongst those proposals that maximise the product of utilities. The obvious strategy, which is the same as for the two-agent case, is also both stable and efficient. This simplistic solution not withstanding, we still remain interested in the monotonic concession protocol, because —unlike the one-step protocol— it is a direct formalisation of natural negotiation behaviour.

Multilateral Monotonic Concession Protocols

How can we generalise the monotonic concession protocol to cases where more than two agents need to come to an agreement? The general structure of the negotiation protocol will stay the same:

(1) In the first round, each agent makes an initial proposal.

(2) In each subsequent round, each agent either makes a *concession* or sticks with their current proposal.

(3) The above is being iterated until either a conflict situation arises (no agent makes a concession) or *agreement* is reached.

The two critical terms here, which we have as yet left undefined, are *concession* and *agreement*.

4. AGREEMENT AND CONCESSION

In this section, we are going to discuss the meaning of the terms *agreement* and *concession* in the context of multilateral negotiation.

Multilateral Agreements

In the case of agreement, the generalisation from the two-agent case to the general multilateral case is straightforward:

> *Agreement is reached iff one agent makes a proposal that is at least as good for each other agent as their own current proposal.*

To put it more formally, agreement is reached iff there exists an agent $i \in \mathcal{A}$ such that $u_j(x_i) \geq u_j(x_j)$ for all agents $j \in \mathcal{A}$.

Options for Defining Multilateral Concessions

In the case of concession, however, it is not at all clear what would be the "correct" way of generalising to the multilateral case. Indeed, what does it mean to make a concession to a group of opponents? Do we have to make our new proposal more palatable to everyone else, to just one of them, or do we have to propose something that would somehow increase the utility of the group as a whole (and what would that actually mean)?

[3] What may be considered questionable in Harsanyi's argument is that he implicitly assumes that x_2 will be selected as soon as agent 1 accepts it. This disregards the possibility that both agents accept each others proposal, in which case the choice should be random. However, interestingly, this more complex assumption leads to the same solution. In this case, the expected payoff for accepting x_2 is $p_2 \cdot u_1(x_2) + (1 - p_2) \cdot \frac{1}{2}(u_1(x_1) + u_1(x_2))$. Using this in place of $u_1(x_2)$ eventually leads to the same inequation $Z_1 \leq Z_2$

[4] This also implies that the final agreement will be *Pareto optimal* (no alternative agreement would be better for one agent without decreasing utility for the other [8]).

All of the following interpretations of the term *concession* seem to have some merit:

(1) *Strong concession:* Make a proposal that is strictly better for each of the other agents.

(2) *Weak concession:* Make a proposal that is strictly better for at least one of the other agents.

(3) *Pareto concession:* Make a proposal that is at least as good for all of the other agents and strictly better for at least one of them.

(4) *Utilitarian concession:* Make a proposal such that the sum of utilities of the other agents increases (utilitarian social welfare).

(5) *Egalitarian concession:* Make a proposal such that the minimum utility amongst the other agents increases (egalitarian social welfare).

(6) *Nash concession:* Make a proposal such that the product of utilities of the other agents increases (Nash product).

(7) *Egocentric concession:* Make a proposal that is worse for yourself.[5]

We are first going to clarify the choice of name for some of these concession criteria and then turn to the analysis of their properties.

Relation to Social Welfare Concepts

Recall that, in welfare economics, a *Pareto improvement* is a move to a different agreement that harms nobody but benefits at least one member of society (and a Pareto optimal agreement is one that does not admit any further Pareto improvements). Analogously, a Pareto *concession* by agent i is a concession that results in a Pareto improvement for the group of agents $\mathcal{A} \setminus \{i\}$. The names for criteria (4)–(6) are also inspired by concepts from welfare economics. These are all concepts that are used to assess the well-being of a group (or *society*) of agents in terms of the individual utilities of its members [1, 8].

The *utilitarian social welfare* enjoyed by a group, for instance, is defined as the sum of the utilities of its members. This is a useful metric for assessing the well-being of a group if we adopt a classical utilitarian point of view (note that this is also a metric for *average* utility, *i.e.* an agent making a utilitarian concession would improve the average utility of its opponents). The *egalitarian social welfare*, on the other hand, is defined as the utility of the agent with the currently lowest utility level (*i.e.* in an egalitarian system we would measure the success of society in terms of the well-being of its poorest members). The *Nash product* is an interesting compromise; it measures social welfare in terms of the product of individual utilities. This means that both overall increases in utility and inequality-reducing utility transfers would be considered beneficial to society. Other notions of social welfare studied in the literature would give rise to further concession criteria.

[5]Here *egocentric* is not to be misread as *selfish*; it simply means that this notion of concession is based on the agent's own valuations rather than that of other agents. This makes sense in domains where a reduction in utility for one agent can generally be assumed to result in an increase in utility for (some of) the other agents.

Relation to the Two-Agent Case

If there are just two agents, then making a concession of either one of the first six types simply amounts to making a new proposal that is strictly better for your (single) opponent. Hence, criteria (1)–(6) are all faithful extensions of the two-agent case.

In fact, criterion (7) is also a faithful extension of the two-agent case, at least if we assume that an agent would never make a proposal that is dominated by another potential proposal. This is so, because moving to a new proposal that is worse for yourself but not better for your opponent than your current proposal amounts to moving to a proposal that is dominated by your current proposal.

5. PROTOCOL PROPERTIES

In this section, we are going to analyse various interesting properties for the different monotonic concession protocols entailed by our seven multilateral concession criteria.

Termination

An important property of a negotiation protocol is whether it can guarantee that any negotiation process following the protocol will eventually terminate. Each of the multilateral concession criteria we have proposed gives rise to a different negotiation protocol. The following proposition summarises some simple termination results for these protocols:

PROPOSITION 1. *Except for weak concessions, each of the seven proposed concession criteria guarantees termination of the negotiation protocol.*

PROOF. Each of the concession criteria, except that of weak concession, is defined in terms of a metric that induces a strict partial (in some cases even total) order $\prec_i$ over the space of proposals from the viewpoint of each individual agent i. For instance, in the case of a utilitarian concession by agent i, the sum of utilities for the remaining agents has to increase, *i.e.* you may define $x \prec_i y$ iff $\sum_{k\in\mathcal{A}\setminus\{i\}} u_k(x) < \sum_{k\in\mathcal{A}\setminus\{i\}} u_k(y)$. Recall that the overall number of possible proposals is assumed to be finite. Hence, each agent i can only make a finite number of concessions, as each concession will take its own current proposal higher up in the $\prec_i$-order. Hence, as the overall number of agents is assumed to be finite as well, there can only be a finite number of concessions overall, *i.e.* negotiation is bound to terminate and either conflict or an agreement will be reached eventually. □

Note that any such termination result can only ever apply to the *protocol* as such, not to negotiation processes in general. If one of the agents does not make a move during one of the rounds (because, for instance, its reasoning process for deciding the next move does not terminate), then the negotiation gets stuck. In practice, this problem can be tackled by introducing deadlines ("if you do not make a move within 1 minute, then this counts as a refusal to concede").

Clearly, in the case of weak concessions, we cannot guarantee termination (unless there are only two agents). Indeed, an agent could alternate between two proposals indefinitely and make a weak concession each time. This is possible when there are two candidate proposals, such that one of them is strictly preferred by the agent's first opponent and the other is strictly preferred by its second opponent.

Compositionality

Closely related to the question of termination is what one might want to term *compositionality*. This property holds iff the composition of two consecutive concessions each meeting a given concession criterion will always meet that same criterion as well. That is, whenever the move from x to x' is considered a valid concession, and the move from x' to x'' is as well, then the direct move from x to x'' will constitute a valid concession as well.

Clearly, all of our proposed concession criteria satisfy the compositionality property, with the sole exception of weak concessions. In the case of a Nash concession, for instance, if two consecutive concessions each increase the product of utilities for the other agents, then the product of utilities will have increased as well with respect to the entire negotiation process. For weak concessions, on the other hand, the same counterexample given for termination applies: the second concession may take us back to the initial proposal.

Deadlock-freedom

Another important property of negotiation protocols to consider is deadlock-freedom. A *deadlock* is a situation where no agent can make any further move that would be compliant with the negotiation protocol, but none of the terminal states (either agreement of conflict) of the protocol has been reached either. Of course, in the context of a monotonic concession protocol, each agent always has the move of not conceding available to them. That is, for any of our concession criteria, it will always be possible for agents to continue negotiation in a fashion deemed legal by the protocol. However, there may be situations where an agent would not be able to make a concession, even if they would be prepared to give up their current position. Naturally, we would prefer to avoid such situations and use a concession criterion satisfying the following property of deadlock-freedom:

> *We call a concession criterion deadlock-free iff it guarantees that at least one agent can make a concession satisfying the criterion at any stage during negotiation, until an agreement has been reached.*

It is not difficult to see that any of our criteria must be deadlock-free in case there are only two agents in the system:

PROPOSITION 2. *In the two-agent case, each of our seven concession criteria is deadlock-free.*

PROOF. Let x_1 and x_2 be the current proposals of agents 1 and 2, respectively. If no agreement has been reached yet, then we must have both $u_1(x_1) > u_1(x_2)$ and $u_2(x_2) > u_2(x_1)$. As argued earlier, in the two-agent case criteria (1)–(6) coincide; they are fulfilled if one of the agents makes a new proposal that is better for its opponent than its current offer. Hence, x_2 would be a legal concession for agent 1 for any of the criteria (1)–(6). Furthermore, it would also be a legal concession according to criterion (7). Hence, there can never be a deadlock in the two-agent case. □

In the general case, with potentially more than just two agents, however, the situation is different. Now just some of our criteria are deadlock-free, while others are not.

Furthermore, for one of them (the Nash concession), deadlock-freedom depends on a seemingly minor detail of the negotiation scenario. Recall that we require all utility functions to be non-negative. We say that utilities are *required to be positive* in case we do require all utilities, except for the conflict deal, to be greater than 0. We are now able to state our results regarding deadlock-freedom:

PROPOSITION 3. *The weak, the utilitarian, and the egocentric concession criteria are all deadlock-free. The Pareto, the strong, and the egalitarian concession criteria are not deadlock-free. The Nash concession criterion is deadlock-free iff utilities are required to be positive.*

PROOF. We begin with the negative results, more specifically with the case of *Pareto concessions*. Suppose there are three agents with the following current proposals (which are also the only possible outcomes) and associated utilities:

	x_1	x_2	x_3
u_1	4	2	2
u_2	3	2	2
u_3	1	2	2

It is easy to see that agreement has not been reached and that no agent is in a position to make a Pareto concession. Hence, this example constitutes a deadlock. Every *strong concession* is also a Pareto concession, *i.e.* strong concessions cannot be deadlock-free either.

To construct an example that proves that *egalitarian concessions* are not deadlock-free, let ϵ be the minimal utility assigned to any outcome by any agent. Then in any game where for each possible outcome x there are at least two agents assigning utility ϵ to x, no agent can ever make an egalitarian concession (because the minimum utility of the other agents is the same for all possible proposals).

Now let us move on to the positive results. The *weak concession* criterion is clearly deadlock-free. In fact, at any stage *each* agent i could make a weak concession (until an agreement is reached). If no agreement has been reached, then there must be at least one other agent j such that $u_j(x_j) > u_j(x_i)$. But then proposing x_j would constitute a weak concession for i. An analogous argument can be used for the case of *egocentric concessions*.

Next consider the case of *utilitarian concessions*. Let i be (one of) the agent(s) making a proposal x_i yielding a maximal sum of utilities (amongst the current proposals). If there is no agreement yet, then there must be another agent j who likes x_i less than their own proposal: $u_j(x_i) < u_j(x_j)$. But we also have $\sum_{k\in\mathcal{A}} u_k(x_i) \geq \sum_{k\in\mathcal{A}} u_k(x_j)$. Hence, $\sum_{k\in\mathcal{A}\setminus\{j\}} u_k(x_i) > \sum_{k\in\mathcal{A}\setminus\{j\}} u_k(x_j)$. That is, x_i constitutes a legal utilitarian concession for agent j and there is no deadlock.

An analogous argument can be used in the case of *Nash concessions*. However, in this case the validity of the last step in the argument relies on $u_j(x_i)$ being greater than 0. That is, this proof will only go through in case utilities can be assumed to be positive. If zero utilities are admissible, then we can use a similar argument as the one used in the case of egalitarian concessions to show that Nash concessions are *not* deadlock-free. Take a game where for each possible outcome x there are at least two agents assigning utility 0 to x. Then the product of utilities of the "other" agents will always be 0, *i.e.* no agent can ever make a Nash concession. □

Lack of deadlock-freedom is a serious deficiency of a negotiation protocol. Arguably, deadlock-freedom is even more im-

portant than termination, because a lack of termination can be addressed by refining the concession criterion in question, while deadlock-freedom could only be recovered by loosening the definition of a criterion.

Wooldridge *et al.* [14], for instance, who propose a multilateral negotiation mechanism that draws on ideas from the monotonic concession protocol for the two-agent case, require concessions to satisfy both the utilitarian and the Pareto concession criteria. They recognise that their approach is not deadlock-free (without using that expression), and suggest to overcome this problem by introducing the option of *backtracking*, *i.e.* of proposing a deal that is neither a concession nor the same deal proposed in the previous round. Arguably, such an extension of the protocol takes us outside of the realm of monotonic concession protocols.

Verifiability and Privacy

Next we turn our attention to two inter-related issues: *verifiability* and *privacy*. A negotiation protocol should be verifiable in the sense that it should be possible to check whether everybody is really following the rules laid down by the protocol. But who should check?

The first type of verifiability is verifiability by an *outside observer*. Clearly, an outside observer could verify some of the more operational issues, e.g. whether agents really make simultaneous proposals. However, an outside observer usually cannot check whether every agent who is changing their proposal is really making a true concession. This would require an accurate knowledge of the utility functions of the agents concerned and, for reasons of privacy, these agents may not be prepared to publish their utility functions (or if they do, they may not always be entirely truthful about them). Of course, if we assume the presence of an *omniscient observer*, then full verifiability is clearly given for any of the variants of the protocol considered here, but it is also not very interesting.

The issue of privacy does not just affect verifiability, but is a somewhat critical issue about the whole setup of the monotonic concession protocol. Nevertheless, the two-agent monotonic concession protocol has the very desirable property that each individual agent can verify whether their opponent is conforming to the rules of the protocol. They only need to know their *own* utility function. Whether or not they report their utility function truthfully is up to them, but they can always check whether a new proposal constitutes a concession with respect to their true utility function (and, of course, also with respect to their reported utility function). In the case of more than two agents, this is not the case anymore, simply because concession criteria are defined in terms of more than one utility function (except for the egocentric criterion).

In the multilateral case, it seems interesting to introduce a concept of *distributed verifiability*. Is it possible that all the other agents together verify whether or not the latest move by a particular agent constitutes a true concession? Of course, the other agents may also be lying to each other, but we can at least check whether a concession criterion admits distributed verifiability in the following sense:

> *A concession criterion admits distributed verification iff for any move that is not a true concession, at least one of the other agents can detect that violation.*

It turns out that only the strong concession criterion is verifiable in a distributed manner, although the weak and the Pareto concession criteria also admit a slightly weaker form of distributed verification:

(1) The *egocentric* concession criterion is not verifiable, because only the proposing agent could check.

(2) The *utilitarian*, *egalitarian*, and *Nash* concession criteria are not verifiable in the distributed sense, because no individual agent can check whether the sum/minimum/product has increased.

(3) The *strong* concession criterion is verifiable in a distributed manner: for any violation, at least one of the agents will be worse off.

(4) The *weak* and the *Pareto* concession criteria are verifiable in a distributed manner if agents can communicate (if an agent has received a strict improvement they should announce that fact). If no agent reports a strict improvement, then a violation has occurred (in addition, for a Pareto concession, each agent would have to check that they did not suffer a loss in utility).

This concludes our discussion of the properties of the seven variants of the monotonic concession protocol.

6. NEGOTIATION STRATEGIES

Our main interest in this paper has been concerned with monotonic concession *protocols* for multilateral negotiation (and thereby also the nature of multilateral concessions), but this investigation also clearly raises the question what *strategy* an individual agent participating in a negotiation regulated by such a protocol should follow. A proper game-theoretical analysis of this question would be of considerable interest, but also technically demanding. Such an analysis lies outside the scope of this paper.

Still, in this section, we want to briefly review a number of seemingly obvious choices.

Choicepoints

It seems reasonable to assume that agents always start with a proposal that is optimal for themselves. Of course, from a "psychological" point of view it may be considered advantageous to start with a more realistic proposal straight away, but we are not going to be concerned with such questions here. We are also going to ignore the question as to *which* of the optimal proposals to select in case there are several.

In every subsequent round, each agent has to answer two questions:

(1) Should I make a concession?

(2) If yes, how much should I concede?

Of course, just as it is unclear how to characterise the concept of a concession in a multilateral negotiation context, it may also seem unclear how to quantify the extent of such a concession. Nevertheless, there is in fact a rather simple answer to our second question: A concession should always be *minimal* with respect to the utility loss incurred by the agent making the concession. That is, amongst the pool of potential proposals that would satisfy the concession criterion enforced by the protocol, the agent should choose the

proposal that gives the highest utility to themselves (again, in this tentative discussion, we are going to ignore the question of what to do in case there are several potential concessions yielding maximal utility).

The concept of minimal concessions is useful when discussing these questions at an abstract level. In practice, it can and should be further refined. For the Zeuthen strategy as formulated by Rosenschein and Zlotkin [10], for instance, agents are supposed to make *sufficient* rather than *minimal* concessions (sufficient in the sense of forcing the opponent to concede in the next round). Of course, for most concession criteria, a sufficient concession can always be decomposed into a series of minimal concessions; so there is no important qualitative difference at the abstract level.[6]

To summarise, the question of strategy reduces to the question of *when* to make a concession. In the two-agent case, the Zeuthen strategy settles this question by letting the agents compute the *willingness to risk conflict* for both agents and asking the agent for whom this value is lower to make the next concession (with suitable modifications in case the two values are equal). In the sequel, we are going to consider three possible generalisations of the Zeuthen strategy to the multilateral case.

Willingness to Risk Conflict

In the two-agent case, the Zeuthen strategy is built around the concept of an agent's willingness to risk conflict. This value is computed as the quotient of the utility loss incurred by accepting the opponent's proposal and the utility loss incurred by settling with the conflict deal (both with respect to the utility of the agent's own current proposal). So for agent 1, we get the following value: $\frac{u_1(x_1)-u_1(x_2)}{u_1(x_1)}$.

A natural generalisation of this criterion to the multilateral case would be to evaluate the loss in utility in case of concession assuming the worst possible outcome for the agent. That is, for agent i, we obtain the following formula for its willingness to risk conflict:

$$Z_i \quad = \quad \begin{cases} 1 & \text{if } u_i(x_i) = 0 \\ \dfrac{u_i(x_i) - \min\{u_i(x_k) \mid k \in \mathcal{A}\}}{u_i(x_i)} & \text{otherwise} \end{cases}$$

Then the agent with the lowest willingness to risk conflict should make the next concession. This criterion has also been proposed by Wooldridge *et al.* [14].

While this strategy seems to be a natural generalisation of the two-agent Zeuthen strategy, it can unfortunately lead to a deadlock. Consider the following example. There are three agents and three possible outcomes. Suppose agent 1 is currently proposing x_1, agent 2 is proposing x_2, and agent 3 is proposing x_3:

	x_1	x_2	x_3
u_1	10	8	8
u_2	9	10	5
u_3	9	5	10

$\rightsquigarrow$ $Z_1 = 0.2$, $Z_2 = 0.5$, $Z_3 = 0.5$

Note that agreement has not yet been reached. According to our strategy, agent 1 should make a concession. However, agent 1 is not *able* to make a concession that would either affect the Z-value of any of its opponents or increase its own.

[6] An exception to this rule are the weak concessions, which —as we have seen earlier— are not decomposable. That is, here choosing a certain minimal concession may block the way to a suitable sufficient concession later on.

This observation suggests that simply checking for which agent the Z-value is minimal is not a sufficiently sophisticated criterion for deciding who should make the next concession. A potential way around this problem may be to select the agent with the minimal Z-value amongst those that are actually able to make an *effective* concession.

A Product-increasing Strategy

As discussed in Section 2, Harsanyi [4] showed that the Zeuthen strategy corresponds to a product-increasing strategy. That is, the agent whose proposal yields the lower product of utilities should make the next concession. This suggests another obvious generalisation of the strategy, namely that also in the multilateral case any agent whose proposal yields a minimal product of utilities should make a concession and propose a new deal with a higher product.

$$Z_i' \quad = \quad \prod_{k \in \mathcal{A}} u_k(x_i)$$

One may be inclined to believe that this strategy is bound to result in an agreement with maximal product of utilities, *i.e.* that the product-increasing strategy should be efficient. However, it is possible to construct scenarios where this is not so. The problem is that also a proposal with non-maximal product may be found to be acceptable to everyone. Take the following example (suppose agent 1 proposes x_1, agent 2 proposes x_2, and agent 3 proposes x_3):

	x_1	x_2	x_3
u_1	5	4	4
u_2	3	2	10
u_3	3	10	2

$\rightsquigarrow$ $u_1(x_1) \cdot u_2(x_1) \cdot u_3(x_1) = 45$, $u_1(x_2) \cdot u_2(x_2) \cdot u_3(x_2) = 80$, $u_1(x_3) \cdot u_2(x_3) \cdot u_3(x_3) = 80$

Here x_1 is the proposal with the lowest product of utilities, but it is also the only proposal that would be acceptable to all agents (as it gives them at least as much utility as their own current proposals). Whether or not such a situation could really occur in an actual negotiation remains to be investigated (note that the example is somewhat unrealistic, because agents 2 and 3 did not propose their favourite agreements first).

Sum of Products of Pairs

Yet another potential generalisation of the Zeuthen strategy, also building on its interpretation as a product-increasing strategy, would be to compute the sum of products of pairs of utilities for every proposal and to ask the agent for whose proposal that value is minimal to make a concession.

$$Z_i'' \quad = \quad \sum_{j \neq k \in \mathcal{A}} u_j(x_i) \cdot u_k(x_i)$$

This appears to be another promising approach, although further investigation is required before any kind of conclusive judgement would be possible.

Stability

We conclude our preliminary discussion of issues surrounding the definition of suitable strategies for multilateral negotiation with a general observation regarding the stability of such mechanisms. Recall that a set of strategies is said to be stable (or in Nash equilibrium) iff no individual agent would have an incentive to deviate unilaterally from their assigned strategy [9].

Any pure strategy where conflict occurs whenever a single agent deviates is stable. This follows from the fact that conflict is assumed to be the worst possible outcome for any of the participating agents. Hence, as in the two-agent case, the only critical situation is when several agents should concede in the same round (and in fact this only makes a difference when this situation occurs immediately before an agreement is found). Whatever the exact criterion may be, to guarantee stability it would have to be enhanced with a mixed equilibrium strategy for the n-person game of the final round.

7. CONCLUSION

As we have argued in the introduction, *multilateral negotiation* is often a necessity, *i.e.* it may not be possible to decompose a multilateral deal into a sequence of bilateral deals that would still be acceptable to all parties. In this paper, we have discussed the generalisation of the well-known *monotonic concession protocol* for two negotiating agents to a multilateral scenario where any number of agents should be able to forge agreements. As we have seen, the central question in this context concerns the appropriate definition of a multilateral concession. We have proposed seven alternative definitions, and also argued that there may well be further candidate definitions of interest. Further social welfare orderings, such as the *leximin* ordering for example [8], could provide useful hints for additional definitions.

We have then analysed some of the properties of the negotiation protocols induced by these different definitions: termination, compositionality, deadlock-freedom, and verifiability. All but one of the proposed concession criteria, namely weak concessions, guarantee termination; and weak concessions are also the only ones that are not composable. Our results on deadlock-freedom show that some of the proposed criteria (weak, utilitarian, and egocentric) are deadlock-free, while others are not (Pareto, strong, and egalitarian). Whether or not the Nash concession criterion is deadlock-free depends on the restrictions we put on utility functions, namely whether or not they are required to assign strictly positive utilities to all outcomes but the conflict deal. Our discussion of verifiability issues shows that only the strong concession criterion is verifiable by the participating agents in a distributed manner. The weak and the Pareto criterion can also be taken to be verifiable under certain assumptions on the ability and willingness of the agents to communicate with each other on this matter.

Finally, we have also discussed some of the issues at stake when trying to define a suitable negotiation strategy for agents following a multilateral monotonic concession protocol. In particular, we have suggested three possible generalisations of the well-known Zeuthen strategy, but also pointed out some of the problems inherent in these somewhat simplistic generalisations. A serious game-theoretical analysis of the problem promises to provide a number of new and very interesting insights.

Monotonic concession protocols are but one way of coming to an agreement within a group of agents. As discussed already at the beginning of Section 3, a simple one-step protocol that directly selects a Nash bargaining solution, *i.e.* an agreement maximising the product of individual agent utilities [9, 10], would be another option. In negotiation domains with transferable utilities (*i.e.* if agents can reimburse each other through monetary side payments, and there is global agreement on the marginal utilities associated with such payments), the well-known Shapley value [8, 9] provides yet another solution. The work of Hart and Mas-Colell [5] offers a unified view on this type of approach to multilateral negotiation.

We should stress again that we do not claim that monotonic concession protocols are the "best" way of regulating negotiation, or even that they would be appropriate in all cases. Winoto *et al.* [12], for example, argue against monotonic concessions in domains where utilities can change over time. For instance, a seller's valuation of a perishable good may be assumed to decrease over time, *i.e.* a potential buyer may be well-advised to lower (rather than improve) their offers in case negotiation continues over a significant amount of time. Our argument in favour of monotonic concession protocols is simply that they are such an immediate formalisation of our everyday-understanding of negotiation.

ABSTRACT

In situations where self-interested agents interact repeatedly, it is important that they are endowed with negotiation techniques that enable them to reach agreements that are profitable in the long run. To this end, we devise a novel negotiation algorithm that generates promises of rewards in future interactions, as a means of permitting agents to reach better agreements, in a shorter time, in the present encounter. Moreover, we thus develop a specific negotiation tactic based on this reward generation algorithm and show that it can achieve significantly bettter outcomes than existing benchmark tactics that do not use such inducements. Specifically, we show, via empirical evaluation, that our tactic can lead to a 26% improvement in the utility of deals that are made and that 21 times fewer messages need to be exchanged in order to achieve this under concrete settings.

1. INTRODUCTION

Negotiation is a fundamental concept in multi-agent systems (MAS) because it enables (self-interested) agents to find agreements and partition resources efficiently and effectively. Recently, a growing body of work has advocated the use of arguments as a means of finding good agreements [9]. Specifically, it is hypothesised that negotiation using persuasive arguments (such as threats, promises of future rewards, and appeals) allows agents to influence each others' preferences to reach better deals either individually or as a group. Most approaches to *persuasive negotiation* (PN), however, either focus mainly on the protocol [6, 8] used to argue and do not give any insight into the negotiation strategies to be used or fail to give clear semantics for the arguments that are exchanged in terms of their relationship with the negotiated issues [11, 5]. Moreover, most PN reasoning mechanisms adopt a defeasible logic approach [1, 9], rather than the utilitarian approach that we use here. The downside of this logic focus is that it cannot cope as well with the many forms of uncertainty that inevitably arise in such encounters and that it can hardly be benchmarked against standard negotiation algorithms [2, 3].

Against this background, in this work we present a novel reasoning mechanism and protocol for agents to engage in persuasive negotiation in the context of repeated games. We choose repeated games because it is a type of encounter where we believe that persuasive techniques are likely to be most effective (as arguments can be constructed to directly impact future encounters). Now, such encounters have been extensively analysed in game theory [7], but are seldom considered by agent-based negotiation mechanisms. This is a serious shortcoming because in many applications agents need to interact more than once. Specifically, our mechanism constructs possible rewards[1] in terms of constraints on issues to be negotiated in future encounters (hence their semantics are directly connected to the negotiated issues) and our protocol is an extension of Rubinstein's alternating offers protocol [12] that allows agents to negotiate by exchanging arguments (in the form of promises of future rewards or requests for such promises in future encounters).

In more detail, our mechanism gives agents a means of influencing current and future negotiations through promises of rewards, rather than just exchanging offers and counter offers that only impact on the outcome of the present encounter [5, 11]. Thus, we make the rewards endogenous to the negotiation process by assimilating a promise of a reward to promised constraints on resources that need to be negotiated in future. In so doing, we directly connect the value of the argument to the value of the negotiated issues and this allows us to evaluate arguments and offers on the same scale. For example, a car seller may reward a buyer (or the buyer might ask for the reward) who prefers red cars with a promise of a discount of at least 10% (i.e. a constraint on the price the seller can propose next time) on the price of her yearly car servicing if she agrees to buy a blue one instead at the demanded price (as the buyer's asking price for the red car is too low for the seller). Now, if the buyer accepts, it is a better outcome for both parties (the buyer benefits because she is able to make savings in the future that match her preference for the red car and the seller benefits in that he reduces his stock and obtains immediate profit).

Such promises are important in repeated interactions for a number of reasons. First, agents may be able to reach an agreement faster in the *present* game by providing some guarantees over the outcome of subsequent games. Thus, agents may find the current offer and the reward worth more than counter-offering (which only delays the agreement and future games). Second, by involving issues from future nego-

[1]We focus on rewards because of their clear impact on agreements in the context we consider and because we expect threats and appeals to follow similar principles to those we elucidate here.

tiations in the *present* game (as in the cost of servicing in the example above), we effectively expand the negotiation space considered in the present game and, therefore, provide more possibilities for finding (better) agreements [4]. For example, agents that value future outcomes more than their opponent (because of their lower discount factors) are able to obtain a higher utility in future games, while the opponent who values immediate rewards can take them more quickly. Thirdly, if guarantees are given on the *next game*, the corresponding negotiation space is constrained by the reward, which should reduce the number of offers exchanged to search the space and hence the time elapsed before an agreement is reached. Continuing the above example, the buyer starts off with an advantage next time she wants to negotiate the price to service her car and she may then not need to negotiate for long to get a reasonable agreement.

Given this, this work advances the state of the art in the following ways. First, we develop a Reward Generation Algorithm (RGA) that calculates constraints (which act as rewards) on resources that are to be negotiated in future games. The RGA thus provides the first heuristics to compute and select rewards to be given and asked for in our new extension of Rubinstein's protocol. Second, we develop a specific Reward Based Tactic (RBT) for persuasive negotiation that uses the RGA to generate combinations of offers and rewards. In so doing, we provide the first persuasive negotiation tactic that considers the current negotiation game as well as future ones, to generate offers and arguments and thus reach better agreements faster than standard tactics in the long run.

The rest of the paper is structured as follows. Section 2 provides the basic definitions of the negotiation games we consider, while section 3 describes how persuasive negotiation can be used in such games. Section 4 details RGA and section 5 shows how offers and promises are evaluated. Section 6 describes RBT and section 7 evaluates its effectiveness. Finally, section 8 concludes.

2. REPEATED NEGOTIATION GAMES

Let Ag be the set of agents and X be the set of negotiable issues. Agents negotiate about issues $x_1, \cdots, x_n \in X$ where each one has a value in its domain $D_1, \cdots, D_n$. Then, a contract $O \in \mathcal{O}$ is a set of issue-value pairs, noted as $O = \{(x_1 = v_1), \cdots, (x_m = v_m)\}$.[2] We will also note the set of issues involved in a contract O as $X(O) \subseteq X$. Agents can limit the range of values they can accept for each issue, termed its negotiation range and noted as $[v^{min}, v^{max}]$. Each agent has a (privately known) utility function over each issue $U_x : D_x \rightarrow [0, 1]$ and the utility over a contract $U : \mathcal{O} \rightarrow [0, 1]$ is defined as $U(O) = \sum_{(x_i=v_i)\in O} w_i \cdot U_x(v_i)$, where w_i is the weight given to issue x_i and $\sum w_i = 1$. We consider two agents $\alpha, \beta \in Ag$ having utility functions designed as per the Multi-Move Prisoners' Dilemma (MMPD) (this game is chosen because of its canonical and ubiquitous nature) [13]. According to this game, α's marginal utility δU is higher than β's for some issues, which we note as O^α, and less for others, noted as O^β, where $O^\alpha \cup O^\beta = O$.

While it is possible to apply rewards to infinitely or finitely repeated games, we focus on the base case of one repetition in this work because it is simpler to analyse and we aim to understand at a foundational level the impact that such promises may have on such encounters. These games are played in sequence and there may be a delay θ between the end of the first game and the beginning of the second one. In a game, one agent (α or β) starts by making an offer $O \in \mathcal{O}$ and the opponent may then counter-offer or accept. The agents may then go on counter-offering until an agreement is reached or one of the agents' deadlines (t^α_{dead} or t^β_{dead}) is reached. If no agrement is reached before the deadline, the agents obtain zero utility (in either the first or second game). We also constrain the games, and further differentiate them from the case where agents play one game each time independently of the previous one, by allowing the second game to happen *if and only if* the first game has a successful outcome (i.e. an agreement is reached within the agents' deadlines and the contract is executed). In so doing, there is no possibility for agents to settle both outcomes in one negotiation round. The agents may also come to an agreement in the first game but fail to reach one in the second one, in which case the agents only obtain utility from the outcome of the first game.

If an agreement is reached, the agents are committed to enacting the deal settled on. This deal comes from the set of possible contracts which, in the first game, is captured by $\mathcal{O}_1$ and, in the second one, by $\mathcal{O}_2$. During these games, as time passes, the value of the outcome decreases for each agent according to their discount factor (noted as ϵ_α for agent α). This factor denotes how much the resources being negotiated decrease in usefulness over time.'The time between each illocution trasmitted is noted as τ. Then, the discount due to time is calculated as $e^{-\epsilon(\theta+t)}$ between the two games and $e^{-\epsilon(\tau+t)}$ between offers [7] where t is the time since the negotiation started (note that we expect $\theta >> \tau$ generally). The value of ϵ scales the impact of these delays, where a higher value means a more significant discounting of an offer and a lower value means a lower discounting effect. Each agent is also assumed to have a *target utility* to achieve over the two games (noted as $L \in [0, 2]$). This target can be regarded as the agent's aspiration level for the combined outcomes of the two games [3]. This target must, therefore, be less than or equal to the sum of the maximum achievable utility over the two games (2 in the case an agent has a $\epsilon = 0$ and exploits both games completely); that is $L \leq 1 + e^{-\epsilon(\theta+t)}$, where 1 is the maximum achievable utility in an undiscounted game.

Agents use the illocutions $propose(\alpha, \beta, O)$ and $accept(\alpha, \beta, O)$ to make and accept offers respectively. Additionally, they may use persuasive illocutions such as $reward(\alpha, \beta, O_1, O_2)$ and $askreward(\alpha, \beta, O_1, O_2)$. The former means α makes an offer O_1 and promises to give reward O_2. The latter that α asks β for a promise to give reward O_2 (we detail the contents of O_2 in the next section). Hence, while the promise of a reward aims to entice an opponent to accept a low utility contract in the current encounter, asking for a reward allows an agent to claim more in future negotiations (in return for concessions in the current one).

3. APPLYING PERSUASIVE NEGOTIATION

In persuasive negotiation, agents either promise to give rewards to get their opponent to accept a particular offer or ask for such promises in order to accept an offer. In our case, rewards are specified in the second game in terms of a range of values for each issue. Thus, giving a reward equates to specifying a range such as $v_x > k$ (where $k \in D_x$ is a constant) for issue x in $O_2 \in \mathcal{O}_2$ to an agent whose utility increases for increasing values of x. Conversely, asking for a reward means specifying $v_x < k$ in O_2 for the asking agent (whose utility increases for decreasing values of x). Now,

[2] Other operators $\geq, \leq$ could also be used.

agents may find it advantageous to accept such rewards if it costs them more to counter-offer (due to their discount factor) or if they risk passing their deadline (or their opponent's). Here, we do not deal with the issues related to whether the agents keep to their promises or how to tackle the uncertainty underlying this (we simply assume they do), but rather we focus on the reasoning mechanism that the agents require in order to negotiate using rewards.

Specifically, we propose that agents use the level to which they concede in the first game in order to decide on what to offer or ask for as a reward in the second one. This is graphically illustrated in figure 1 where $O_1 \in \mathcal{O}_1$ and $O_2 \in \mathcal{O}_2$ are the proposed offer and reward respectively.

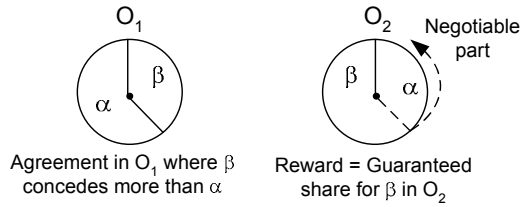

Figure 1: Representation of an offer O_1 made in the first game and a reward O_2 for β in the second game.

As can be seen, α exploits β (by taking a larger share of the pie) through the offer O_1 or alternatively β concedes more than α (depending on who makes the offer). The promised reward offered or asked for in the second game then tries to compensate for the exploitation/concession applied to the first game. Now, one strategy that produces this behaviour is the following: the higher the concession, the higher will be the reward demanded, while the lower the concession, the higher will be the reward given.[3] This strategy can be seen as a type of trade-off mechanism whereby agents take gains in the present (or the future) in return for losses in the future (or in the present) [10].

4. REWARD GENERATION

Building on the reasoning mechanism presented in section 3, we now develop our reward generation algorithm (RGA) that determines the level of concession made in the first game and hence determines the value of the corresponding reward, and finally decides whether to send it or not. First, we assume that an agent has some means of generating offers $\mathcal{O}_1$. In line with most work on negotiation in the presence of deadlines, we assume the agent's negotiation tactic concedes to some extent until an agreement is reached or the deadline is passed [2]. Then, at each step of the negotiation, based on the concessions made in an offer $O_1 \in \mathcal{O}_1$, RGA computes the reward $O_2 \in \mathcal{O}_2$ and decides if it is to be asked for or given. In more detail, algorithm 1 outlines the main steps of RGA which are then detailed in the following subsections.

4.1 Step 1: Compute Concession Degrees

In this context, the degree to which an agent concedes in any game is equivalent to the value it loses on some issues to its opponent relative to what the opponent loses to it on other issues. Assuming $(x = v_x) \in O$ is the value of an issue x, and $[v_x^{max}, v_x^{min}]$ is its negotiation range, then we define $\mu_x = U_x(v_x)$, $\overline{U}_x = \max\{U_x(v_x^{min}), U_x(v_x^{max})\}$, and $\underline{U}_x = \min\{U_x(v_x^{max}), U_x(v_x^{min})\}$. From these, we can compute the maximum an agent could get as $\overline{U} = \sum_{x \in X(O)} w_x \overline{U}_x$, the minimum as $\underline{U} = \sum_{x \in X(O)} w_x \underline{U}_x$ and the actual utility as $\Upsilon = \sum_{x \in X(O)} w_x \mu_x$ where w_x is α's relative weight of issue x and $\sum w_x = 1$. These weights can be ascribed the same values given to the weight the issue has in the utility function and can be normalised for the number of issues considered here. Then, an agent α computes the concession degree on the offer O as:

$$con^{\alpha}(O) = \frac{\overline{U} - \Upsilon}{\overline{U} - \underline{U}} \quad (1)$$

It is then possible to calculate concessions on issues with higher and lower δU for α using $con^{\alpha}(O^{\alpha})$ and $con^{\alpha}(O^{\beta})$ respectively. Then, the complement of these functions (i.e. $1 - con^{\alpha}(O^{\alpha})$ and $1 - con^{\alpha}(O^{\beta})$) represents how much β concedes to α from α's perspective (or how much α exploits β).

Algorithm 1 Main steps of the RGA

Require: $O_1 \in \mathcal{O}_1, L$

1: Compute concessions in O_1^{α} and O_1^{β}. {Here the agent determines how much both agents concede on the issues for which they have a higher and lower δU than their opponent.}
2: Select $O_2 \in \mathcal{O}_2$ that matches the level of concession in O_1
3: Check whether the combination of O and O_2 satisfies L, adjust $[v^{min}, v^{max}]$ for second game according to values in O_2 and send offer and reward.

4.2 Step 2: Determine Rewards

To determine which agent concedes more in the game (given that they play a MMPD), α needs to compare its degree of concession on the issues with higher δU than β (i.e. O_1^{α}) and those with lower δU than β (i.e. O_1^{β}) (in a zero sum game this is calculated for all issues). To this end, we define three conditions which refer to the case where α concedes as much as β ($COOP$), concedes more to β ($CONC$), and concedes less than β ($EXPL$) respectively as follows:

- $COOP = true$ when $con^{\alpha}(O_1^{\alpha}) + con^{\alpha}(O_1^{\beta}) = 1$ (i.e. α has no grounds to give or ask for a reward).
- $CONC = true$ when $con^{\alpha}(O_1^{\alpha}) + con^{\alpha}(O_1^{\beta}) > 1$ (i.e. α can ask for a reward).
- $EXPL = true$ when $con^{\alpha}(O_1^{\alpha}) + con^{\alpha}(O_1^{\beta}) < 1$ (i.e. α should give a reward).

The above conditions capture the fact that an agent can only ask for a reward if it is conceding in the first game and can only give one if it is exploiting in the first game. It is possible to envisage variations on the above rules as agents may not always want to give a reward to their opponent if they are exploiting in the first game or they may want to ask for one even if they are not conceding. However, these behaviours could be modelled in more complex strategies (which we will consider in future work). But, in so doing, an agent may also risk a failed negotiation. Here, therefore, we focus on the basic rules that ensure agents try to maximise their chances of reaching a profitable outcome.

Now, having determined whether an argument is to be sent or not and whether a reward is to be asked for or given, we can determine the value of the reward. Given that an agent aims to achieve its target L, the value chosen for a reward will depend on L and on $(con^{\alpha}(O_1^{\alpha}), con^{\alpha}(O_1^{\beta}))$ (i.e. the

[3]It should be noted that while the figure pictures a zero-sum game, the applicability of rewards is not limited to such situations. Instead, they can be applied to more complex games such as the MMPD, for which we detail the procedure in the next section (and which we use in our experiments in section 7).

degrees of concession of the agent). We will consider each of these points in turn.

Given O_1, the first game standing offer, the minimum utility α needs to get in the second game is $l_2 = L - U(O_1)$. We then need to consider the following two cases (remember $e^{-\epsilon(\theta+t)}$ is the maximum that can be obtained in the second game with discounts). Firstly, if $l_2 \leq e^{-\epsilon(\theta+\tau+t)}$ it is still possible for α to reach its target in the second game (provided the agents reach an agreement in the first one) and, therefore, give (or ask for) rewards as well. The larger l_2 is, the less likely that rewards will be given (since less can be conceded in the second game and still achieve L). Secondly, if $l_2 > e^{-\epsilon(\theta+\tau+t)}$, it is not possible to give a reward, but an agent may well ask for one in an attempt to achieve a value as close as possible to l_2.

For now, assuming we know $l_2 \leq e^{-\epsilon(\theta+\tau+t)}$, it is possible to determine how much it is necessary to adjust the negotiation ranges for all or some issues in O_2 in order to achieve l_2. Specifically, the agent calculates the undiscounted minimum utility $\frac{l_2}{e^{-\epsilon(\theta+\tau+t)}}$ it needs to get in the second game. Then, it needs to decide how it is going to adjust the utility it needs on each issue, hence the equivalent bound ν_{out} for each issue, in order to achieve *at least* $\frac{l_2}{e^{-\epsilon(\theta+\tau+t)}}$. Here, we choose to distribute the utility to be obtained evenly on all issues.[4] Thus, the required outcome ν_{out} of an issue in the second game can be computed as $\nu_{out} = U_x^{-1}\left(\frac{l_2}{e^{-\epsilon(\theta+t)}}\right)$.

Having computed the constraint ν_{out}, the agent also needs to determine how much it should reward or ask for. To this end, the agent computes the contract $\bar{O}$ which satisfies the following properties:

$$con^{\alpha}(\bar{O}_2^{\alpha}) = 1 - con^{\alpha}(O_1^{\beta}) \text{ and } con^{\alpha}(\bar{O}_2^{\beta}) = 1 - con^{\alpha}(O_1^{\alpha})$$

This is equivalent to our heuristic described in section 3 where the level of concession or exploitation in the offer in the first game (i.e. here $O_1 = O_1^{\alpha} \cup O_1^{\beta}$) is mapped to the reward asked for or given in the second one (i.e. here $\bar{O}_2 = \bar{O}_2^{\alpha} \cup \bar{O}_2^{\beta}$). Here also we adopt the same approach as for ν_{out} and distribute the concessions evenly on all issues. Then, assuming linear utility functions and finite domains of values for the issues, the above procedure is equivalent to reflecting the level of concession on issues with higher δU by α onto those with higher δU for β. This is the same as inverting equation 1 given a known $\overline{U}$ and $\underline{U}$ (as defined in step 1), and finding v_x by assigning $\mu_x = \Upsilon$ and inverting μ_x for each issue (a procedure linear in time with respect to the number of issues considered). Let us assume that for an issue x this results in a **bound** ν_r (a maximum or minimum according to the type of argument to be sent). Thus, from $\bar{O}_2$, α obtains bounds for all issues in the rewards it can ask from or give to β. Given this, we will now consider whether to send a reward based on how ν_r and ν_{out} compare for an issue x.

4.3 Step 3: Sending Offers and Rewards

Assume that α prefers high values for x and β prefers low ones and that it has been determined that a reward should be offered (the procedure for asking for the reward is broadly similar and we will highlight differences where necessary).

[4] Other approaches may involve assigning a higher ν_{out} (hence a higher utility) on some issues which have a higher weight in the utility function. In so doing, ν_{out} may constrain the agent's negotiation ranges so much for such issues that the two agents' ranges may not overlap and hence result in no agreement may be possible. Our approach tries to reduce this risk.

Now, α can determine whether a reward will actually be given and what its value should be according to the following constraints:

1. $\nu_r \geq \nu_{out}$: α can promise a reward implying an *upper bound* ν_r on the second game implying that α will not ask for more than ν_r. This is because the target ν_{out} is less than ν_r and α can, therefore, negotiate with a revised upper bound of $v^{max'} = \nu_r$ and a lower bound of $v^{min'} = \nu_{out}$. When asking for a reward, α will ask for a *lower bound* ν_r (i.e. $v^{min'} = \nu_r$) and negotiate with the same upper bound $v^{max'}$ in order to achieve a utility that is well above its target.
2. $\nu_{out} > \nu_r$: α cannot achieve its target if it offers a reward commensurate with the amount it asks β to concede in the first game. In this case, α revises its negotiation ranges to $v^{min'} = \nu_{out}$ (with v^{max} remaining the same). In this case, the agent does not send a reward but simply *modifies its negotiation ranges*. Now, if it were supposed to ask for a reward, α cannot achieve its target with the deserved reward. However, it can still ask β for the reward ν_r (as a lower bound) *and* privately bound its future negotiation to $v^{min'} = \nu_{out}$ while keeping its upper bound at v^{max}. In so doing, it tries to gain as much utility as possible.

Now, coming back to the case where $l_2 > e^{-\epsilon(\theta+\tau+t)}$ (implying $\nu_{out} > \nu_r$ as well), the agent that intends to ask for a reward will not be able to constrain its negotiation range to achieve its target (as in point 2 above). In such cases, the negotiation range is not modified and the reward may still be asked for (if $CONC = true$).

Given the above final conditions, we can summarise the rules that dictate when particular illocutions are used and negotiation ranges adjusted, assuming an offer O_1 has been calculated and O_2 represents the associated reward as shown below:

Algorithm 2 Step 3 of RGA.

if $COOP$ or ($EXPL$ and $\nu_{out} > \nu_r$) for at least one $x \in X(O_2)$ **then**
  $propose(\alpha, \beta, O_1)$.
end if
if $CONC$ and $l_2 \leq e^{-\epsilon(\theta+\tau+t)}$ **then**
  $askreward(\alpha, \beta, O_1, O_2)$ and modify $[v^{min}, v^{max}]$ for second game.
end if
if $CONC$ and $l_2 > e^{-\epsilon(\theta+\tau+t)}$ **then**
  $askreward(\alpha, \beta, O_1, O_2)$.
end if
if $EXPL$ and $\nu_{out} \leq \nu_r, \forall x \in X(O_2)$ **then**
  $reward(\alpha, \beta, O_1, O_2)$ and modify $[v^{min}, v^{max}]$ for second game.
end if

With all this in place, the next section describes how the recipient of the above illocutions reasons about their contents.

5. EVALUATING OFFERS AND REWARDS

We now describe how an agent evaluates the offers and rewards it receives. Generally, when agents negotiate through Rubinstein's protocol, they accept an offer only when the next offer O_{next} they intend to put forward has a lower (additionally discounted due to time) utility than the offer O_{given} presented to them by their opponent. However, agents using persuasive negotiation also have to evaluate the incoming offer together with the reward they are being asked for or

are being promised. To address this, we follow a similar line of reasoning as above and evaluate a received offer and reward against the offer and reward the agent would have sent in the next negotiation step. From the previous section, we can generally infer that a reward will imply a value ν_r for a given issue which defines either a lower or an upper bound for that issue in the next negotiation game. Therefore, given this bound, the agent may infer that the outcome ev of any given issue will lie in $[v^{min'}, v^{max'}]$ which might be equivalent to or different from the agent's normal negotiation ranges $[v^{min'}, v^{max}]$ and may take into account the agent's target ν_{out} (given its target l_2) or the value ν_r itself (as discussed in the previous section).

Specifically, assume β is the agent that is the recipient of a reward (given or asked for) and that β prefers small values for the issue x being considered. Then, let β's negotiable range be $[v^{min}, v^{max}]$ for the issue x and β's target be l_2^{β} in the second game (which implies that it needs at least ν_{out} for the issue in the second game). Now, if β receives $reward(\alpha, \beta, O, O_a)$ (or $askreward(\alpha, \beta, O, O'_a)$) for the second game, O_a implies that ν_r^{α} is the upper bound proposed for each issue x in O_a (ν_r^{α} would be a lower bound in O'_a). In the meantime, β has calculated another offer O_{new} with a reward O_b in which a bound ν_r^{β} is to be given to each issue x in O_b. Then, for each issue x, β calculates the negotiable ranges given ν_r^{α} as $[v^{min}, \min\{\nu_r^{\alpha}, \nu_{out}\}]$ (or $[\nu_r^{\alpha}, \min\{\nu_{out}, v^{max}\}]$ if O'_a is asked for[5]) while it calculates $[\nu_r^{\beta}, \min\{\nu_{out}, v^{max}\}]$ given ν_r^{β}. We assume β can then calculate (e.g. by picking a value over a normal distribution defined in the negotiation range[6]) the expected outcome of each range as ev_x^{α} for $[v^{min}, \nu_r^{\alpha}]$ (or $[\nu_r^{\alpha}, \min\{\nu_{out}, v^{max}\}]$ in the case of O'_a) and ev_x^{β} for $[\nu_r^{\beta}, \min\{\nu_{out}^{\beta}, v^{max}\}]$ in the case of O_b. Given each of these expected outcomes for each issue, the overall expected outcomes, $EO_a \in \mathcal{O}_2$ and $EO_b \in \mathcal{O}_2$, of the second game can be calculated given a reward. Thus, EO_a is the expected outcome of the reward given by α and EO_b is that for the promise of β. Given that these outcomes have been calculated, the agent then decides to accept or counter offer using the rule below. This evaluates the offer generated against the offer received to decide whether to accept the offer and promise received or send a *reward* illocution (note the addition of discount factors to reflect the time till the next game and between illocutions, that is, sending the counter offer, receiving an accept, and sending the first offer in the second game):

---

if $U(O_{new}) \cdot e^{-\epsilon_\beta(\tau+t)} + (U(EO_b) \cdot e^{-\epsilon_\beta(\theta+\tau+t)} \leq U(O) \cdot e^{-\epsilon_\beta(2\tau+t)}) + (U(EO_a) \cdot e^{-\epsilon_\beta(\theta+3\tau+t)}$ **then**
  $accept(\beta, \alpha, O)$
else
  $reward(\beta, \alpha, O_{new}, O_b)$
end if

As can be seen above, if the sum of the utility of the offer and the expected utility of the promise is higher than the offer and reward to be proposed by β (discounted over time), α's proposition is accepted. Otherwise, β counteroffers with its promise. If instead, a reward O'_b were to be asked for by β along with an offer O_{new}, then β will apply a similar decision rule as above (where EO'_b is the expected outcome β calculates for the reward it asks from α) in which we simply replace EO_b with EO'_b. Finally, in the case where β has received a persuasive offer and can only reply with another offer without any argument, β calculates the expected outcome of the second game using only its altered negotiation range $[v^{min}, \min\{\nu_{out}, v^{max}\}]$ to elicit EO''_b (which we use to replace EO_b with in the rule above). Note that the second game is left more uncertain in the latter case since the negotiation range has not been tightened by any reward and so the agents may take more time to reach an agreement in the second game (as per section 1).

Having described our mechanism for sending and evaluating rewards and offers, we will now propose a novel tactic that uses it to perform persuasive negotiation.

6. THE REWARD BASED TACTIC

As described in section 4, RGA requires an offer to be generated by some negotiation tactic in order to generate the accompanying reward. In this vein, the most common such tactics can be classified as: (i) behaviour-based (BB) – using some form of tit-for tat or (ii) time-based – using Boulware (BW) (concedes little in the beginning before conceding significantly towards the deadline) or Conceder (CO) (starts by a high concession and then concedes little towards the deadline) [2].[7] Now, many of these tactics start from a high utility offer for the proponent (here α) and gradually concede to lower utility ones. In our model, this procedure automatically causes RGA to start by promising rewards and then gradually move towards asking for rewards.

To ground our work, we present a novel reward-based tactic (RBT) (based on Faratin's trade-off tactic [3]) that either asks for or gives a reward at any point in the negotiation in order to reach an agreement. To do so, however, the agent needs to know how to evaluate incoming offers and rewards and generate counter-offers accordingly. Given this, we will consider the three main cases in calculating the response to having received an offer and a proposed reward (see algorithm 3).

Case 1: *An offer and a reward have been received and it is possible to counter offer with a reward.*
In this case, α needs to calculate combinations of rewards and offers and choose the combination that it deems most appropriate to send to β. To calculate these combinations, α first needs to determine the overall utility each combination should have. To achieve this, we use a hill climbing method similar to Faratin et al.'s tactic. In this method, the agent tries to find an offer that it believes is most favourable to its opponent, while not necessarily conceding too much. In our case (particular for the MMPD), this procedure equates to the agent trying to gain more utility on the issues on which it has a higher δU and less on those for which it has a lower δU than β.[8] In so doing, the strategy can maximise joint gains in the repeated negotiation encounter.

Thus, the utility to be conceded in the next offer (or utility step), Su, is calculated according to the difference that exists between the agent's previous offer and the last one sent by

[5]This range assumes $\nu_{out} \geq \nu_r^{\alpha}$, but in cases where this is not true the reward proposed by α is automatically rejected.

[6]This is the technique we adopt here. However, other techniques such as fuzzy reasoning or learning mechanisms could also be used to get this value.

[7]Other negotiation tactics might also be resource-based or dependent on other factors. The tactics we select here have been chosen because they have been demonstrated to be relatively successful and are among the most common ones studied in the literature [10, 2].

[8]Note this is different from the point discussed in footnote 4 since here we do not constrain the negotiation ranges, but rather search for offers that may be profitable to both parties.

its opponent.

$$Su(O_1, O_2, O'_1, O'_2) = \begin{array}{l} U(O_1)e^{-t} + U(EO_2)e^{-(\theta+t)} \\ -U(O'_1)e^{-(\tau+t)} + U(EO'_2)e^{-(\theta+2\tau+t)} \end{array}$$

where O_1 and EO_2 are the previous offer and expected outcome in the second game from α's reward O_2 respectively and O'_1 and EO'_2 are the current offer and the expected outcome of β's argument O'_2, respectively. If α does not specify a reward O_2, EO_2 is calculated as per section 5 given the normal negotiation ranges. Similarly, EO'_2 is also calculated in the same way if β does not specify a reward with the previous offer.

Given the utility step Su, it is then possible to calculate the utility Nu of the combination of the next offer and reward using the following equation:

$$\begin{array}{rl} Nu = & U(O_1)e^{-(2\tau+t)} + U(EO_2)e^{-(\theta+3\tau+t)} \\ & -Su(O_1, O_2, O'_1, O'_2, f) \end{array} \quad (2)$$

The next step involves generating combinations of offers and rewards whose combined utility is as close as possible to Nu. To this end, we use an optimisation function $OptComb$: $[0,2] \times \mathcal{O}_1 \times \mathcal{O}_2 \times \mathcal{O}_1 \times \mathcal{O}_2 \rightarrow \mathcal{O}_1 \times \mathcal{O}_2$, based on linear programming, that calculates the reward and offer whose values are most favourable to β (but still profitable for α). $OptComb$ therefore runs through RGA to find the best possible rewards and the associated offers whose combined utility is less than or equal to Nu and that concede more on issues for which β has a higher marginal utility. RGA also informs RBT whether the reward is to be asked for or given and whether negotiation ranges need to be modified (as described in section 4). However, $OptComb$ can also *fail* to find an optimal output (as a result of the constraints being too strong (e.g. the target L being too high) or the optimizer not being able to find the solution in the specified number of steps) and in these cases, we resort to another procedure described next (i.e. Cases 2 and 3).

CASE 2: *OptComb fails and the last offers made involved rewards.*
The agent cannot find a combination of a proposal and a reward whose utility matches Nu. Therefore, it calculates an offer using the time-based heuristics presented earlier.[9]

CASE 3: *OptComb fails and the last offers made did not involve rewards.*
It is possible to continue the same step-wise search for an agreement as in case 1. Here, our tactic calculates the offer whose utility is as close as possible to Nu (without $U(EO'_2)$ or $U(EO_2)$). Moreover, the offer calculated is such that it is the one that is most similar to the offer by β. This is achieved by running an optimization function $OptProp : [0,2] \times \mathcal{O}_1 \times \mathcal{O}_1 \rightarrow \mathcal{O}_1$ that calculates an offer O_1 such that O_1 maximises the level of concession on issues with higher marginal utility for the opponent (as in case 1) while still achieving Nu. In case the issues being negotiated are qualitative in nature, the similarity based algorithm by [3] may be used.

[9]In this case, BB tactics would not be appropriate to generate an offer given previous offers by the opponent. This is because some offers have been proposed in combination with a reward such that the concessions in the offers may not be monotonic (an asked for reward may compensate for a concession in the offer or a concession in the given reward may be compensated for by the higher utility of the offer). The latter property is a requirement for BB (or even all hill-climbing tactics [3]) to work . Therefore, either BW or CO is used to generate the offer since these are independent of the previous offers made by the opponent.

Algorithm 3 The RBT algorithm.

Require: O_1, O_2, O'_1, O'_2
1: Use a mechanism to calculate EO_2, EO'_2 {α calculates the expected outcomes of the arguments as discussed in section 5.}
2: step = $Su(O_1, O_2, O'_1, O'_2)$ {calculate the utility concession.}
3: nu = $U(O_1)e^{-(2\tau+t)} + U(EO_2)e^{-(\theta+3\tau+t)}$ − step {calculate the utility of the combination of offer and reward to be generated.}
4: $(O''_1, O''_2) = OptComb(\text{nu}, O_1, O_2, O'_1, O'_2)$ s. t. $U(O''_1)e^{-(2\tau+t)} + U(EO''_2)e^{-(\theta+3\tau+t)} \leq$ nu {here the values in the combination are optimised to be more favourable to β and as close as possible to nu.}
5: **if** $OptComb$ succeeds **then** {**Case 1**}
6: send O''_1 and O''_2 {RGA decides whether the reward is asked from or given to β.}
7: **else if** $OptComb$ fails & (both or one of O_2 or O'_2 is not null) **then** {**Case 2**}
8: use BW or CO to generate O''_1
9: send offer O''_1 and modify $[v^{min}, v^{max}]$ to achieve L as in RGA.
10: **else if** $OptComb$ fails & (both O_2 and O'_2 are null) **then** {**Case 3**}
11: step' = $Su(O_1, null, O'_1, null)$ {calculate the step in utility.}
12: nu' =$U(O_1)e^{-(2\tau+t)}$ − step' {calculate the utility of the offer to be generated.}
13: O''_1 = $OptProp(\text{nu}', O_1, O'_1)$ s.t. $U(O''_1) \leq$ nu' {find the offer that is most favourable to β but as close as possible to nu'.}
14: send offer O''_1 and modify $[v^{min}, v^{max}]$ to achieve L as in RGA.
15: **end if**

We capture all the above three cases in algorithm 3. As can be seen, RBT only generates offers and rewards in the first game. In the second one, we use a time-based or behaviour-based heuristic to calculate offers. While it is certainly possible to generate offers using the optimisation function of RBT in the second game, we do not do so in order to focus our analysis on the effect the bounds imposed by rewards have on the outcome of the second game when agents use basic tactics.

7. EXPERIMENTAL EVALUATION

In this section, we describe a series of experiments that aim at evaluating the effectiveness and efficiency of our PN model in repeated interactions. To this end, we evaluate it against basic tactics using standard benchmark metrics. In the following sections, we first detail the experimental settings and then provide the results of these experiments.

7.1 Experimental Settings

Agents α and β negotiate over 4 issues $x_1, ..., x_4$ and their preferences are as per a MMPD. Thus, $\delta U^{\alpha}_x > \delta U^{\beta}_x$, where $x \in x_1, x_2$ such that x_1 and x_2 are more valued by α than β, while x_3 and x_4, are more valued by β than α (i.e. $\delta U^{\alpha}_y < \delta U^{\beta}_y$, where $y \in x_3, x_4$). t_{max} is set to 2 seconds which is equivalent to around 300 illocutions being exchanged between the two agents (in one game).[10] The agents' deadlines, t^{α}_{dead} and t^{β}_{dead}, are defined according to a uniform distribution between 0 and 2 seconds. The discount factors, ϵ_{α} and ϵ_{β}, are set to a value between 0 and 1 and are drawn from a uniform distribution. The targets of the agents L^{α} and L^{β} are drawn from a uniform distribution between 0 and 2. We set $\theta = 0.5$ and $\tau = 0.0001$ to simulate instantaneous replies and set the degree of intersection of the negotiation ranges

[10]Preliminary experiments with the negotiation tactics suggest that if the agents do not come to an agreement within this time period, they never achieve any agreement (even if the maximum negotiation time is extended).

to 0.8 (which means that $[v_\alpha^{min}, v_\beta^{max}]$ overlap $[v_\alpha^{min}, v_\alpha^{max}]$ and $[v_\beta^{min}, v_\beta^{max}]$ by 80%).

	Utility function and weight of each issue			
	U_{x_1}, w_{x_1}	U_{x_2}, w_{x_2}	U_{x_3}, w_{x_3}	U_{x_4}, w_{x_4}
α	$0.4x_1$, 0.5	$0.9x_2$, 0.2	$1 - 0.2x_1$, 0.2	$1 - 0.6x_2$, 0.1
β	$1 - 0.2x_1$, 0.4	$1 - 0.6x_2$, 0.1	$0.9x_2$, 0.3	$0.4x_1$, 0.2

Table 1: Utility functions and weights of issues for each agent.

We will further assume that the first offer an agent makes in any negotiation is selected at random from those that have the highest utility. Also, the agent that starts the negotiation is chosen at random. This reduces any possible first-mover advantage that one strategy may have over another (i.e. which loses less utility due to discount factors). Moreover, in order to calculate the expected outcome of the second game (as discussed in section 5), agents draw the outcome for each issue from a normal distribution with its mean centred in the middle of the agent's negotiation range for the second game with a variance equal to 0.5. Finally, in all our experiments we use ANOVA (ANalysis Of VAriance) to test for the statistical significance of the results obtained.

Given these game settings, we define the populations of negotiating agents in terms of the tactics they use. As discussed in section 6, a number of tactics are available in the literature for experimentation and we will use BB tactics, as well as BW and CO, to generate offers for the RGA algorithm. Moreover, we will compare the performance of these with RBT. The settings of the strategies (i.e. the combination of tactics for the two games) played by the agents is given in table 2. Here, the populations of standard non-persuasive agents (i.e. disconnected from RGA) using only BB, BW, or CO in both games are noted as NT (negotiation tactics), while those that are connected to RGA are noted as PNT (persuasive negotiation tactics). The population of agents using RBT is noted as RBT.

Game	Strategies		
	Non-Persuasive	Persuasive	
Type	NT	PNT	RBT
1	BB, BW, CO	PBB, PBW, PCO	RBT
2	BB, BW, CO	BB, BW, CO	ANY

Table 2: Settings for agents' tactics.

As can be seen from the above table, agents can use rewards in the first game and revert to standard tactics for the second one. For example, a PNT agent, using BW with RGA in the first game, uses BW in the second game. For RBT agents, we randomly select among the three standard tactics.

Given that persuasive strategies like PNT and RBT can constrain their rewards and negotiation ranges according to their target L (as shown in section 4.2), we also need to allow other non-persuasive tactics to constrain their ranges accordingly to ensure a fair comparison. Thus, we allow all tactics to constrain the ranges of the issues in the second game according to their target whenever they reach agreements without the use of any arguments. The procedure to do so is similar to that described in section 4.2.[11] In the following experiments, we use homogeneous populations of 80 agents for each of NT, PNT, and RBT and also create a population of equal numbers of RBT and PNT agents (40 each) which we refer to as PNT&RBT to study how RBT and PNT agents perform against each other.

[11]The difference between the constraint applied by the reward and by the target is that the former applies the constraint to both agents, while the latter only applies separately to each agent according to their individual targets.

Given the populations of agents described above we next define the means used to decide whether PN indeed achieves *better* agreements *faster* than standard negotiation mechanisms. We therefore apply the following metrics:

1. Average number of offers — the average number of offers that agents need to exchange before coming to an agreement. The smaller this number the less time the agents take to reach an agreement.
2. Success rate — the ratio of agreements to the number of times agents meet to negotiate.
3. Average utility per agreement — the sum of utility of both negotiating agents over all agreements divided by the number of agreements reached.
4. Expected utility — the average utility weighted by the probability that an agreement is reached.

Given these requirements, in the following subsection we detail experiments with populations defined above and evaluate their performances.

7.2 Empirical Results

In this section, we postulate a number of hypotheses regarding the performance of RGA and RBT and describe the results which validate them.

H1 *Negotiation tactics that use RGA are more time efficient than those that do not.*

This hypothesis follows from the fact that we expect arguments to help agents find agreements faster. Here we record the average number of offers (the lower this number the more time efficient the agents are) an agent makes in order to reach an agreement. For all populations of tactics, each agent meets another agent 50 times and this is repeated 15 times and the results averaged. Thus it was found that NT takes an average of 547 offers to reach an agreement, while PNT strategies take 58 and PNT&RBT takes 56.5 offers per agreement (nearly 10 times less than NT). Thus, the performance of RBT is significantly better than the other populations since it reaches agreements within only 26 offers (which is less than NT by a factor of 21). Now, the reason for the superior performance of persuasive tactics in general is that the rewards make offers more attractive and, as we expected, the shrinkage of negotiation ranges in the second game (following from the application of the rewards) further reduces the negotiation space to be searched for an agreement. The additional improvement by RBT can be attributed to the fact that both negotiating agents calculate rewards and offers (through the hill-climbing algorithm) that give more utility to their opponent on issues for which they have a higher marginal utility (as explained in section 6). Hence, this is faster than for PNT&RBT in which only one party (the RBT) performs the hill-climbing.

These results suggest the outcomes of RBT and PNT populations should be less discounted and should also reach more agreements (since they take less time to reach an agreement and hence do not go over the agents' deadlines). However, it is not clear whether the utility of the agreements reached will be significantly higher than for NT agents.

H2 *Negotiation tactics that use the RGA achieve a higher success rate, expected utility, and average utility than those that do not.*

To test this hypothesis, we run the same experiments as above and record the average utility per agreement and the number of agreements reached. Thus, it is possible to calculate the expected utility, average utility per encounter, and the success rate per game as explained earlier.

It was found that the success rate of persuasive strategies is generally much higher than NT (0.87/encounter for NT, 0.99/encounter for PNT only, 1.0/encounter for PNT&RBT, and 1.0/encounter for RBT). This result[12] clearly shows that the use of RGA increases the probability of reaching an agreement. The similar performance of RBT and PNT&RBT and the difference between PNT&RBT and PNT shows that RBT agents, as well as being able to find agreements readily with their similar counterparts, are also able to persuade PNT agents with more attractive offers. This is confirmed by the fact that the average utility of persuasive strategies is generally higher[13] (i.e. 1.9/encounter for PNT, 1.95/encounter for PNT&RBT, and 2.03/encounter for RBT) than NT (i.e. 1.84/encounter). Note that the difference in utility between NT and other tactics would be much greater if discount factors ϵ_α and ϵ_β were bigger (given the high average number of offers NT uses (i.e. 547)).

Given the trends in success rate and average utility, the expected utility followed a similar trend with NT agents obtaining 1.6/encounter, PNT 1.88/encounter (i.e. a 17.5% improvement over NT), PNT&RBT 1.95/encounter, and 2.03/encounter for RBT agents only (representing a 26% better performance than NT). Generally speaking, from the above results, we can infer that RGA, used together with basic tactics, allows agents to reach better agreements much faster and more often.

These results also suggest that PNT agents reach broadly similar agreements (in terms of their utility) to NT agents (if we discount the fact that rewards significantly reduce the time to reach agreements and increase the probability of reaching an agreement). Now, as discussed in section 6, PNT agents usually generate offers first (starting from high utility ones as for the NT agents) and then calculate the rewards accordingly. Given this, the agents tend to start by giving rewards and end up asking for rewards. As the negotiation proceeds (if the offers are not accepted), the offers generally converge to a point where agents concede nearly equally on all issues (irrespective of the marginal utilities of the agents) and the rewards converge to a similar point. This, in turn, results in a lower overall utility over the two games than if each agent exploits the other one in each game in turn. Now, if rewards are selected in a more intelligent fashion, as in RBT, the agents reach much higher overall utility in general. This is because agents exploit each other more on the issues for which they have a higher marginal utility than their opponent. This is further demonstrated by the results of the RBT agents which suggest they reach agreements that have high utility for both participating agents. However, it is not apparent whether RBT agents are able to avoid being exploited by their PNT counterparts in such agreements which RBT tries to make more favourable to PNT agents (as described in section 6).

H3 *Agents using RBT are able to avoid exploitation by standard tactics connected to RGA (i.e. PNT).*

In order to determine which tactic is exploited, we recorded PNT's and RBT's average utility separately. Thus, it was found that on average, both RBT and PNT agents obtained about the same average utility per agreement (i.e. 0.96/agreement). This result[14] validates **H3** and suggests that the hill-climbing mechanism of RBT agents calculates offers that can convince the opponent without reducing the utility of both RBT and PNT agents significantly (i.e. in small steps) and also that it maximises joint gains through *OptComb*.

8. CONCLUSIONS

In this paper we introduced a novel persuasive negotiation protocol that allows agents in the present encounter to give and ask for rewards in future encounters. To complement this protocol, we also developed a reasoning mechanism that consists of a reward generation algorithm (RGA) and a reward based tactic (RBT). We then showed that RGA can improve the utility gain of standard negotiation tactics by up to 17%, and that RBT provides an additional utility gain of 26% while using 21 times fewer messages to reach a deal in our context.

Future work will look at extending RGA and RBT to more than two games and exploring other strategies to generate rewards, as well as other types of arguments such as threats and appeals. Furthermore, using trust models, we will develop techniques to deal with agents that may not fulfill their promises.

[12] Using ANOVA, it was found that for a sample size of 15 for each population of PNT, PNT and RBT, and PNT only, with $\alpha = 0.05$, $F = 8.8 > F_{crit} = 3.15$ and $p = 4.41 \times 10^{-4}$. These results prove that there is a significant difference between the means of PNT and the other strategies. The success rate of NT agents was found to be always lower than the other populations.

[13] These results were validated statistically using ANOVA, where it was found that $F = 3971 > F_{crit} = 2.73$, and $p = 7.36 \times 10^{-80}$, for a sample size of 15 per population and $\alpha = 0.05$. These results imply that there is a significant difference between the means of the populations.

[14] We validated this result using ANOVA with a sample of size 15 per strategy and $\alpha = 0.05$. Thus it was found that the null hypothesis (i.e. equal means for the two samples) was validated with $F0.13 < F_{crit} = 4.10$ and $p = 0.71 > 0.05$.

Negotiation Coalitions in Group-Choice Multi-Agent Systems

ABSTRACT
In Group-Choice Decision Making (GCDM) where a number of stakeholders are involved in choosing a single solution from a set of available solution options, it is common for the stakeholders to form coalitions during negotiations in order to increase their individual welfare. It is also common to use Multi-Agent Systems (MAS) to automate GCDM processes. In such MAS, agents have to form coalitions like their human counterparts. Within each coalition, the individual agents behave according to the strategies of their clients. In this paper we present a coalition formation model which can employ multiple coalition formation algorithms. The model is motivated by a real-world group-choice multi-agent system that we developed; in the system, agents can form coalitions dynamically based on the similarity between their preferences, and based on the ownership criteria. Finally, this paper presents simulation results that illustrate the operational effectiveness of our coalition formation model.

Keywords
Coalition-formation, Negotiation, Group-Choice, Game-Theory, Qualitative-Reasoning.

1. INTRODUCTION
Coalition formation has the potential of increasing the welfare of negotiating entities. Therefore, the notion of forming coalitions is normally applied in various domains, including commerce, engineering and social planning. Furthermore, coalition formation in MAS has attracted a lot of attention because agents can easily be used to represent the negotiating entities, and they are capable of finding more profitable coalitions than humans in complex environments.

Although a variety of automatic coalition formation models have been proposed in literature, they all fall under the following two distinctive categories:

1. Utility based models: These models (e.g. Game Theoretic Models) normally aim at identifying stable coalitions of negotiating agents, as well as determining appropriate models for sharing coalition benefits [1, 2, 3 and 8]. Most of these algorithms are naturally centralized; this is against the principle of decentralization which is fundamental to the concept of MAS. The computational requirements of utility based coalition formation algorithms usually make them impossible to implement [4]. Moreover, the algorithms normally assume that the agents surrender all their autonomy to their coalitions.
2. Knowledge based models: Knowledge based models for coalition formation [5, 6 and 7], depend on the skills of the individual agents to establish the most beneficial coalition structures. These models are normally computationally feasible, but they invariably have the following shortfalls:
   - They are usually feasible for small MAS.
   - They implicitly assume that there is no coalition structure that is more beneficial to all agents than the grand (coalition of all negotiating agents) coalition [4].
   - Like the utility based coalition formation algorithms, knowledge based algorithms normally assume total loyalty of agents to their coalitions.

This paper presents a coalition formation model that can employ multiple coalition formation algorithms. Besides increasing the utility of the negotiating agents and controlling the dynamics of the negotiation process, our coalition formation model has the following advantages:

- Our coalition formation model allows each agent to have different commitment levels for different coalitions to which it belongs.
- The model is not limited to any particular type of coalition structures.
- The model does not add any extra communication requirements to the MAS.

- The model is effective for both small and large scale MAS.

The rest of this paper is arranged as follows, In Section 2, we present our coalition formation model. Section 3 deals with simulation experiments that illustrate the capabilities of the coalition formation model. Finally, conclusions are given in Section 4.

2. COALITION FORMATION MODEL

Our coalition formation model works in the context of Group-Choice Multi-Criteria Decision Making (GC-MCDM). Each agent in MAS evaluates the available solution option individually based on the preference model of its client, using a Multi-Criteria Decision Making (MCDM) model. Thereafter, the agents select the solutions with the highest score as the offers to their negotiation opponents. At the end of every negotiation round, each agent adjusts its preference value function in a way so to increase the utility associated with the solution that the agent regards to be the "best-fit" for its coalition. Figure 1 shows that the main components of our coalition formation model are the following: the Algorithm Component, the Social Component, and the Commitment Component.

The Algorithm Component of our coalition formation model can have multiple coalition formation algorithms. In view of that, the GC-DSS we developed has two coalition formation algorithms. The first algorithm is based on agent ownership. This algorithm is very simple; all it requires is for the agents to have the ability to identify the owners of their negotiation opponents. The second algorithm is based on the similarity of preferences, which is determined using the *Qualitative Reasoning* model presented in Wanyama and Far [11].For the ownership algorithm, the input is the identification of the negotiation opponent and the offer that the opponent has made. On the other hand, the input for the similarity algorithm is the offer made by the negotiation opponent. The output of both algorithms is the preference model of the negotiation opponent (proposer).

The preference model of the proposer is sent to the Social Component, which uses a MCDM model to determine the estimated scores of all the solution options for the proposer. The estimated scores of the solution options for all coalition members which have already made their offers, together with the scores of the solution options for the concerned agents are fed into a *Game Theory* model to generate the *Social Fitness Factors* (SF_f) of the Solutions [9, 10]. These factors represent the tradeoffs associated with the solution options in respect of the coalition.

Besides generating the estimated preference value functions of the offer proposers, the Algorithm Component of our GC-DSS determines the *Tradeoff Factors* (T_f) of the solution options. These factors represent the amount of tradeoff associated with the solution options with respect to the concerned agent. The *Tradeoff Factors* and the *Social Fitness Factors* of each of the solution options are combined in the Commitment Component to generate the *Acceptance factors* (A_f) of the solution options [10]. The *Acceptance Factor* of a solution option is a measure of the ability of the solution to satisfy the combined preferences of the coalition members, from the perspective of a given coalition member. The generated Acceptance factors are used to update the offer acceptance/rejection criteria in the decision making component of the agent before responding to the current offer. Furthermore, the *Acceptance factors* associated with the last offer in each negotiation round are used in the modification of the *preference value function* of the concerned agent [11].

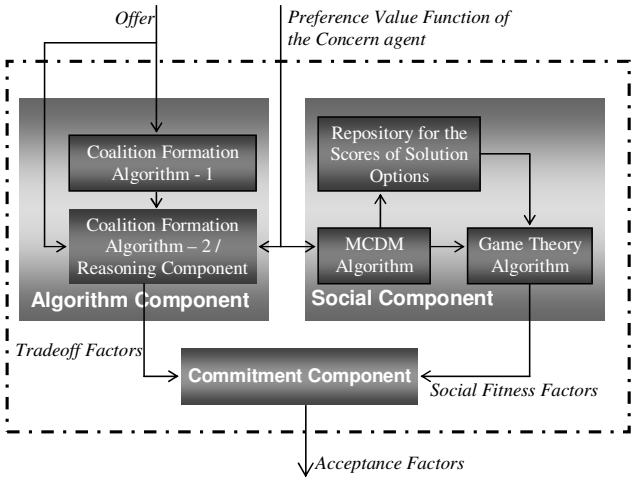

Figure 3. Coalition formation model

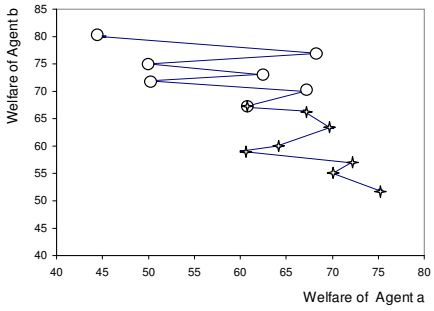
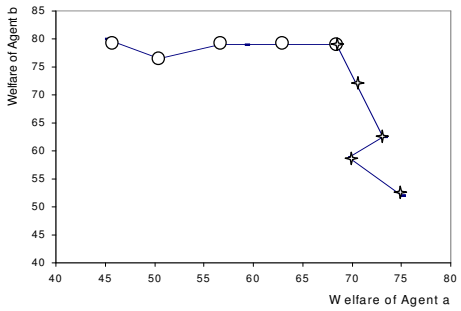
The proposed coalition formation model enables each agent to select individually its allies or coalition. Therefore, the model supports the formation of any coalition structure, and it does not require any extra communication or central coordination entity or agent. However, the model results in increased processing for each of the negotiating agents. The focus of this paper is the modeling of the coalition formation process, as well as the modeling of the commitment level of the agents to their coalitions. Therefore, in the following subsections, we briefly describe each of the three components on our coalition formation model.

3. EXAMPLE



We adopted a group-choice decision making problem from Wanyama and Far [10]. In the problem, three agents were required to evaluate four COTS products based on the preference models of their individual clients, and then

negotiate to select the best-fit product. The following simulation experiments were carried out:



- Negotiation without coalition formation.
- Negotiation with a grand coalition by assuming that all the agents have the same owner.
- Negotiation with each of the three agents being allowed to form an alliance with any other agent based on the similarity of their preferences.

3.1 Results

The results of the first and last simulation experiments are presented in Figures 2(a) and 2(b).

5(a) No coalition formation

5(f) All the three agents are free to form alliances based on the similarity of their preferences

3.2 Discussion of Results

Generally, coalition formation creases the utility (payoff) of the coalition members. That is, the utility of the agreement offer for no coalition formation negotiation (Figure 2(a)) is smaller then the utility of agreement offers for any of the negotiations with coalition formation (Figure 2(b)). Furthermore, Figure 2 illustrates that coalition formation controls the dynamics of the negotiation process, and that coalition formation expedites the negotiation process (forming coalitions resulted in few negotiation rounds).

4. CONCLUSIONS AND FUTURE WORK

This paper presents a coalition formation model that is capable of employing multiple coalition formation algorithms. Currently, the model has two coalition formation algorithms, one based of the ownership of the agents, and the other based on the similarities between the preferences of the agents. Finally, the paper presents an example that illustrates the capabilities of our coalition formation model.

For the future, we would like to model coalition membership such that agents that belong to multiple coalitions can exhibit different levels of commitment to the different coalitions.

Negotiation-based coalitions in the physical world

ABSTRACT

We present a negotiation based coalition formation scheme for autonomous agents residing in the physical world. While in the virtual world we can abstract the negotiation into a calculation of rewards and ignore the details of the physical substrate of the negotiation, in the physical world we need to concern ourselves with variables such as the geographical location of the agent, range of the communication devices, path planning, obstacles and hazards, the necessity of co-location and the temporal constraints assocatiated with it. We concentrate on agents with coordinated location and speed (convoys) which can improve their performance by being able to traverse previously inaccessible areas. We assume a model where agents can dynamically join and leave the coalition.

1. INTRODUCTION

Coalition formation between autonomous agents is a relatively well researched topic. We find however, that the techniques developed for purely software agents acting in the virtual world are not immediately applicable to embodied agents acting in the physical world (or a simulation of it).

In this paper we present a series of algorithms for coalition formation of agents acting in the physical world. We will concentrate on a particular type of coalition we will call a *convoy*[1]: a set of agents with the same location and movement characteristics. The benefits of participating in a convoy is that convoys can traverse geographic areas inaccessible to individual agents. Agents have individual goals which are tied to geographic locations. Agents are selfish, the decision on joining or leaving a convoy is based exclusively of how the action furthers the goals of the agent. The agents and convoys are using negotiation mechanisms to control the joining and leaving of agents from the convoy, as well as the shared goals of the convoy (as reflected in its path and destination).

One example of such a scenario is the search and rescue missions in disaster zones (such as New Orleans after Hurricane Katrina, or the tsunami-affected Asian coastline). A variety of agents are performing a set of operations at distinct geographical locations. The communication services are distrupted, and there are a variety of dangerous areas which can be traversed only by special "convoys" - such as by boat, under the protection of armed guards, with special escorts or in the presence of translators.

[1]Note that the definition of a convoy does not necessarily imply a convoy of vehicles; it can be agents aboard a vehicle such as a boat, or multiple agents physically joined together.

2. CONVOY FORMATION MECHANISM

The environment considered in this paper assumes a 2-dimensional geographic area, where we identify: *safe areas* which are traversable by any vehicle and convoy, *danger areas* which are traversable only by convoys and *inaccessible areas*.

In this environment, we consider the actions of a set of *embodied agents*, which have well-defined physical location and movement capabilities. In practice, these agents can be "RAP" (Robots, Agents and/or Persons). The goal of every agent is to execute a certain task at a destination location. For the purpose of this paper, we assume that these tasks are independent, and the collaboration between agents concerns only the movement towards the destination. We are currently working on negotiation models for the cases when the agents can collaborate in the execution of the tasks as well.

The agents try to reach their destination as soon as possible. The time to reach the destination can be improved by the formation of convoys. In certain cases, the agent can not reach the destination except through joining convoys. We assume the agents *self-interested* but *honest*; the agents keep their negotiated commitments. The agents can communicate wirelessly through message based communication, which can be either point to point or broadcasted to all other agents in the transmission range.

2.1 Convoy models

We define a *convoy* as a coalition of embodied agents which agreed on a common path. We allow a hierarchical structure of convoys to allow operations such as a convoy joining another convoy. For the sake of uniformity, we will consider that individual vehicles are being part of single-vehicle convoys.

A convoy C is described by a set of convoys $S = \{C_1, \ldots C_n\}$, a leader agent $A_L \in S$ and a set of commit-

ments $G = \{g_1, \ldots g_n\}$. The of commitments are usually expressed as constraints on the path of the convoy. The role of the leader is to negotiate on behalf of the convoy and to determine its path, taking into account the agreements G. The commitments of the convoys are related to passing through locations and can be classified as before (B) and after (A) commitments. A "before commitment" $B(L,t)$ commits the convoy to pass through location L *not later than* time t. An "after commitment" $A(L,t)$ commits the convoy to leave location L *not sooner than* time t (if the convoy reaches that location sooner, it can, of course wait in the location). We will call a commitment C_1 *stronger than* a commitment C_2 and denote it $C_2 \subset C_1$ if every set of actions which satisfies C_1 also satisfies C_2.

THEOREM 1.
$$\forall L, t_1 < t_2 \Rightarrow B(L,t_2) \subset B(L,t_1)$$
$$\forall L, t_1 < t_2 \Rightarrow A(L,t_1) \subset A(L,t_2)$$

We leave the proof of this theorem as an exercise to the reader.

2.2 Negotiation for an agent joining a convoy

Let us now consider the lifecycle of the embodied agents, and the objectives of the negotiation. Whenever an agent detects the presence of a convoy in its vicinity, it starts a negotiation process. If the negotiation is successful, the agent moves to join the convoy at a rendez-vous point. From then on, the agent moves with the convoy, until the pre-agreed leave point is reached. At the leave point the agent leaves the convoy, and moves independently to the destination. Even while the agent is in the convoy, it might start negotiations with other convoys, or simply consider to leave the convoy on its own. If the agent wants to leave the convoy before the leave point, the agent needs to negotiate for the leaving of the convoy with the convoy leader. If the negotiation is successful, the agent leaves the convoy, and it is free to follow its separate path to the destination, or join a different convoy.

We will denote with $\tau_C(L_1, L_2)$ the time it takes for convoy C to move from location L_1 to location L_2.

Let us consider the objective of the negotiation. In the simplest case, at time t an agent A with the destination D_A and corrent location L_A considers joining a convoy C, which has a current set of commitments G. The agent has its current expected arrival time $t_A = t + \tau_A(L_A, D_A)$. In the first approximation, the agent would join the convoy if it can add to its list of commitments an agreement $B(D_A, t'_A)$ with $t'_A < t_A$, that is, it can reach its final destination faster. However, even if this agreement is not feasible, it might be worth for the agent to join the convoy up to an intermediate location P, called the *leave point*. One sufficient condition for the agent to be worth joining the convoy until leave point L_{leave} is to have a commitment $B(L_{leave}, t_{leave})$ such that $t_{leave} + \tau_A(L_{leave}, L_A) < t_A$. This is however not a necessary condition; the agent might plan ahead for the joining a different convoy after leaving the current convoy at P.

A successful negotiation for an agent joining a convoy will add two commitments to the convoys' set of commitments: a commitment $A(L_{join}, t_{join})$ for the join location of the agent, and a commitment $B(L_{leave}, t_{leave})$ for the leave location of the agent.

Thus, the negotiation between the convoy and the agent is a multi-objective negotiation, with the $< L_{join}, L_{leave}, t_{join}, t_{leave} >$ quadruplet being the minimal negotiation set. In addition to these four objects, the negotiation might involve cost, penalties for contract breaking or other temporal constraints. In the following, we will briefly discuss the four negotiation objectives and their interrelationships.

L_{join} **the location to join the perspective convoy.** The interest of the agent is to negotiate a join location which is as close to its current location as possible, or to be in the general direction of the destination. The preferences of the convoy are (in order of preference) (a) to negotiate a join location L for which he already has an $A(L,t)$ commitment, (b) a location for which it has a $B(L,t)$ commitment, (c) a location which is on the current projected path of the convoy and (d) a location which is close to the current projected path of the convoy. Intuitively, (a) does not involve any new commitment for the convoy (if it manages to negotiate a join time earlier or the same as than the current commitment), (b) requires only a temporal commitment, without new restrictions on the path of the convoy. A location of type (c) restricts the ability of the convoy to change its path (although its current path remains ok), while a point of type (d) requires the convoy to change its path. These preferences will be inevitably reflected in the negotiation strategy of the convoy. One additional complexity is the number of negotiation choices. While the points of type (a) and (b) are coming from a limited set of discrete choices, the points (c) are coming from a one-dimensional while points (d) from a two dimensional continuum, limited only by the resolution of the raster maps on which the systems operate. This leads to an unrealistically large negotiation space. To reduce the negotiation space to a more realistic size, we chose to identify *segment locations* on the convoy path. These locations have special properties, such as they are situated on the intersection between safe and danger zones, or on the intersection between the convoys path and the agents path. In the first pass, we can eliminate the points which are not feasible because of one of the following reasons:

(i) The convoy has already passed that segment location. (ii) The vehicle can not reach the segment location before the convoy passes it. (iii) The segment location is unreachable by the vehicle (e.g. if it lies within a safe region surrounded by unreachable and danger zones).

t_{join} **- the joining time.** Once the agent and the convoy had identified its join location they need to negotiate the join time. In broad lines, the agent negotiates for the latest possible join time (to increase its safety margin in getting there), while the convoy for the earliest time (because that minimizes its commitment in waiting for the agent). The join time has to be at least the minimum time needed by the agent to reach the join point (the convoys minimal arrival time is not strictly relevant, as its commitment is to be arrive after the negotiated time). This is a simple linear negotiation, which (for all other negotiation objectives fixed) can be resolved with a monotonic concession protocol with Zeuthen strategy. However, we need to observe that once the hard requirement of $\tau(L_{current}, L_{join}) < t_{join} - t_{current}$ is met, the rest of the negotiation is only about safety margins. Thus an agent is more likely to concede in this parameter, which does not affect its predicted performance.

L_{leave} **- the leave location.** For this location, the interest of the agent is to negotiate a location as close as possible to its final destination (except the case when it is planning

to join another convoy on the leave location). The choices of the convoy are, in the order of preference (a) a location for which an existing B commitment exists, (b) a location for which an existing A commitment exists, (c) a point on the current planned path and (d) a point close to the current planned path. Note that the order of preferences for types (a) and (b) is reversed for this point compared to the join point. Similarly to the join location, for types (c) and (d) we consider segmentation approaches. Thus, the interest of the convoy might be to negotiate for leave points as far down as possible on its projected path. The ideal organization is a single leave point where all the participant agents depart for their individual destinations.

t_{leave} **- the leave time**. This parameter represents the guaranteed arrival time at the leave location. This parameter has a lower bound, limited by the physical time a convoy needs to reach the location on the optimal path, while still meeting its other commitments. The upper bound of this parameter is given by the limit at which it is not worth anymore for an agent to join the convoy $t_{leave}^{upper} = t_{current} + \tau_{agent}(L_{current}, L_{destination}) - \tau_{agent}(L_{leave}, L_{destination})$. Evidently, the interest of the agent is an earliest possible time - preferably the lower bound. The interest of the convoy is to minimize its commitment, by committing to as late time as possible. By accepting the lower bound, the convoy is essentially committing that it will not change its current path. This limits its ability to accommodate agents joining in the future.

2.3 Related Work

Coalition formation between objects residing in the physical world has been addressed by several researchers. Recently, [2] presents a coalition formation scheme in a Robocup team. [1] presents a scheme of operating large number of mobile robots using plan merging paradigm. Their scheme is based on local knowledge and incremental planning in a distributed manner. They attempt to resolve spatial movement conflicts between mobile robots using this approach. Although we have a similar problem domain, our effort differs in that 1) we use negotiations for coordinating the movement 2) our general goal has been to make mobile agents to agree on a meeting and leaving location rather than resolving the spatial movement conflicts.

Several research efforts like [9, 4] have used negotiation for forming teams of agents. Most of this work concerned agents residing in the virtual world. From the efforts which concern the physical world, we mention the DARPA Autonomous Negotiating Teams (ANTS) program. [8], used negotiation for resource allocation in multi sensor target tracking problem. A negotiation protocol for resource allocation problem in a multi-sensor based target tracking application is presented in [6]. [7] uses an auction based approach for task allocation for multiple robots exploring a map.

The negotiation process in our domain has to be time constrained. [5] is one of the classical papers on this topic. In our negotiation model, both parties lose if an agreement can not be reached in given time. So both parties are willing to accept any offer (even non-optimal) that can satisfy the join and leave constraints.

Part of our problem domain also resembles with multi agent meeting scheduling problem. [3] provides a good introduction to existing work in this domain. The focus in this domain has been mainly to make multiple agents agree on a given time slot for meeting, under static or dynamic user preferences. Our work differs in that our mobile agents schedule for spatial locations under dynamic temporal constraints.

3. CONCLUSIONS

In this paper we presented an approach for negotiation based coalition formation in the physical world. We find that many of the formal negotiation models are applicable, but the constraints of the physical world, such as temporal and spatial distances, communication constraints, as well as real-time operation requirements add new requirements. The model presented was simulated for convoy formation on real world maps. Future work include extending the coalition model to task oriented domains, development of better algorithms for real-time operation as well as implementation on physical embodied agents.

ABSTRACT

Modeling different types of dialogue between autonomous agents is becoming an important research issue. Several proposals exist with a clear definition of the dialogue protocol, which is the set of rules governing the high level behaviour of the dialogue. However, things seem different with the notion of strategy. There is no consensus on the definition of a strategy and on the parameters necessary for its definition. Consequently, there are no methodology and no formal models for strategies.

This paper argues that a strategy is a two steps *decision* process: i) to select the type of act to utter at a given step of a dialogue, and ii) to select the content which will accompany the act. The first step consists of selecting among all the acts allowed by the protocol, the best option which according to some *strategic beliefs* of the agent will at least satisfy the most important *strategic goals* of the agent. The second step consists of selecting among different alternatives (eg. different offers), the best one which, according to some *basic beliefs* of the agent, will satisfy the *functional goals* of the agent. The paper proposes then a formal model based on argumentation for computing on the basis of the above kinds of mental states, the best move (act + content) to play at a given step of the dialogue.

1. INTRODUCTION

In a multi-agent system, agents need the ability to engage in *dialogues* such as the ones identified in [4], namely persuasion and negotiation. Work in the literature has focused on defining formal models for dialogues. Generally, a dialogue system contains the following three components: the agents involved in the dialogue (i.e their *mental states* and reasoning capabilities), a *protocol*, and a set of *strategies*. The dialogue protocol is the set of *rules of encounter* governing the high-level behavior of interacting agents. A protocol defines: i) the set of permissible acts (eg. asking questions, making offers, etc.); ii) the legal replies for each act. Indeed, a protocol identifies the different possible replies after a given act. However, the exact act as well as a possible content to utter at a given step of the dialogue is a *strategy* matter. While the protocol is a public notion, strategy is crucially an individualistic matter.

In most works on modeling dialogues, the definition of a protocol poses no problems. However, the situation is different for dialogue strategies. There are very few works on strategies [3, 2]. There is no methodology and no formal models for defining them. There is even no consensus on the different ingredients involved when defining a strategy.

This paper argues that the strategy is a decision problem in which an agent tries to choose among different *alternatives* the best option, which according to its beliefs, will satisfy at least its most important goals. Two kinds of goals (resp. of beliefs) are distinguished: the *strategic* and the *functional* goals (resp. the *strategic* and *basic* beliefs). The strategic goals are the meta-level goals of the agent. Such goals will help an agent, on the basis of the strategic beliefs, to select the type of act to utter. Regarding functional goals, they will help an agent to select, on the basis of the basic beliefs to select the content of a move. We propose a formal model for defining strategies. The model takes as input two sets of goals: the strategic and the functional goals together with the strategic and basic beliefs and returns among the possible replies allowed by the protocol after a given act, the next move (act + its content) to play. The model is an extension of the argument-based decision framework proposed in [1]. The basic idea behind this model is to construct for each alternative the different arguments (reasons) supporting it, then to compare pairs of alternatives on the basis of the quality of their supporting arguments.

2. AGENT'S MENTAL STATES

Two kinds of goals are involved when selecting the next act to play and its content:

Strategic goals: For choosing the type of act to utter, an agent refers to what we call *strategic goals*. By strategic goals we mean the meta-level goals of the agent such as "minimizing the dialogue time", "selling at the end of the dialogue", etc. Suppose that at a given step of a negotiation dialogue, an agent has to choose between making an offer and asking a question. If the agent wants to minimize the dialogue time then it would choose to make an offer

instead of spending more time in questions. However, if the agent wants to get a maximum of information about the wishes of the other agent, then the agent would decide to ask a question. These goals are generally independent of the *subject* of the dialogue.

Functional goals: The goals of the agent which are directly related to the subject of the dialogue are called *functional goals*. They represent what an agent wants to achieve or to get regarding the subject of the dialogue. Let us take the example of an agent negotiation the place of a meeting. The agent may prefer a place which is not warm and not expensive. These functional goals are involved when selecting the content of a move. In a negotiation, an agent proposes offers that satisfy its goals.

As for goals, the beliefs involved in the two decision problems (selecting an act and a content) are also of different nature:

Strategic beliefs: which are the meta-level beliefs of the agent. They may represent the beliefs of the agent about the dialogue, about the other agents involved in the dialogue, and about ways for reaching the strategic goals. In negotiation dialogues where agents are trying to find a common agreement, agents may intend to simulate the reasoning of the other agents. Thus it is important for each agent to consider the beliefs that it has on the other agents'goals and beliefs.

Basic beliefs: represent the beliefs of the agent about the environment, the subject of the dialogue, and about ways for reaching the functional goals. Let us consider again the example of the agent negotiating the place of a meeting. Basic beliefs of the agent may include for instance the fact that "London is not warm", "Tunisia is hot", "London is very expensive", etc. This base may also contain some integrity constraints related to the dialogue subject such as the meeting cannot be at the same time in London and in Tunisia.

3. THE LOGICAL LANGUAGE

Let $\mathcal{L}$ be a propositional language and $Wff(\mathcal{L})$ the set of well-formed formulas built from $\mathcal{L}$. Each agent has the following bases:

$\mathcal{B}_b$ = $\{(k_p, \rho_p), p = 1, s_k\}$ where $k_p \in Wff(\mathcal{L})$, is the basic beliefs. The beliefs can be less or more certain. They are associated with certainty levels ρ_p. A pair (k_p, ρ_p) means that k_p is at least certain at a degree ρ_p.

$\mathcal{B}_s$ = $\{(l_j, \delta_j), j = 1, m\}$ where $l_j \in Wff(\mathcal{L})$ is the strategic beliefs base. Each of these beliefs has a certainty level δ_j.

$\mathcal{G}_s$ = $\{(g_q, \lambda_q), q = 1, t\}$ where $g_q \in Wff(\mathcal{L})$, is a base of strategic goals. The strategic goals can have different priority degrees, represented by λ_q. A pair (g_q, λ_q) means that that the goal g_q is important for the agent at least to a degree λ_q.

$\mathcal{G}_f$ = $\{(go_r, \gamma_r), r = 1, v\}$, where $go_r \in Wff(\mathcal{L})$, is the base of the functional goals of the agent. Each functional goal has a degree of importance denoted by γ_r.

The different certainty levels and priority degrees are assumed to belong to a unique linearly ordered scale T with maximal element denoted by 1 (corresponding to total certainty and full priority) and a minimal element denoted by 0 corresponding to the complete absence of certainty or priority.
We shall denote by $\mathcal{B}_b^*$, $\mathcal{B}_s^*$, $\mathcal{G}_s^*$ and $\mathcal{G}_f^*$ the corresponding sets of classical propositions when weights are ignored.

Let $\mathcal{S}$ be the set of speech acts allowed by the protocol. $\mathcal{S}$ may contain acts such as "'Offer' for making offers in negotiation dialogues, "Question" for asking questions, "Assert" for asserting information such as "the weather is beautiful", "Argue" for presenting arguments in persuasion dialogues, etc. The protocol precises for each act the possible replies to it. Let us suppose that the function `Replies` returns for each act, all the legal replies to it.

$$\texttt{Replies}: \mathcal{S} \longmapsto 2^{\mathcal{S}}$$

During a dialoge, agents exchange *moves* which are pairs: a *speech act* and its *content*. Formally:

DEFINITION 1 (MOVES). *A* move M *is a pair* (a, x), *where* $a \in \mathcal{S}$ *and* $x \in Wff(\mathcal{L})$.
$\texttt{Act}(M) = a$ *is a function which returns the speech act* a, *and* $\texttt{Content}(M) = x$ *is a function which returns the content* x.

The strategy problem is formalized as follows:

DEFINITION 2 (THE STRATEGY PROBLEM). *Let* (a, x) *be the current move in a dialogue. What is the next move* (a', x') *to utter such that* $a' \in \texttt{Replies}(a)$ *and* $x' \in Wff(\mathcal{L})$ *?*

To answer this question, one should find both a' and x'. Indeed, a' is the "best" element in $\texttt{Replies}(a)$ that satisfies $\mathcal{G}_s^*$ according to $\mathcal{B}_s^*$. This will be denoted by: $\mathcal{B}_s^*, a' \rightarrow \mathcal{G}_s^*$. Here by "best" we mean the act that satisfies as much important goals as possible.

Concerning x', this is also the "best" element among $X \subseteq Wff(\mathcal{L})$ that satisfies $\mathcal{G}_f^*$ according to $\mathcal{B}_b^*$. This will be denoted by: $\mathcal{B}_b^*, x' \rightarrow \mathcal{G}_f^*$. Here the set X is exactly the set of different alternatives concerning the content of a move. This set may contain different offers (eg. different town) if we have to choose the content of the act "offer", it may contain a set of formulas if we have to choose the content of the act "Assert", it may also contain a set of arguments if one has to select the content of the move "Argue", etc.

The solution to the strategy problem is the pair (a', x') such that $(\mathcal{B}_s^*, a' \rightarrow \mathcal{G}_s^*) \wedge (\mathcal{B}_b^*, x' \rightarrow \mathcal{G}_f^*)$.

4. THE ARGUMENTATION-BASED DECISION MODEL

Solving a decision problem amounts to defining a pre-ordering, usually a complete one, on a set $\mathcal{X}$ of possible choices (or alternatives), on the basis of the different consequences of each choice. In our case, the set $\mathcal{X}$ may be either the set $\texttt{Replies}(a)$ of the possible replies to a move, or the set $\texttt{Content}(a')$ with a' is the chosen act. Argumentation can provide such a pre-oredering. Recently, Amgoud [1] has proposed a formal framework for making decisions under uncertainty on the basis of arguments that can be built in favor of and against a possible choice. Such an approach has two obvious merits. First, decisions can be more easily explained. Moreover, argumentation-based decision is maybe closer to the way humans make decisions than approaches requiring explicit utility functions and uncertainty distributions. The basic idea behind an argumentation-based approach is to construct *arguments* in favor of each alternative from the different bases, to evaluate such arguments, and finally to apply some criterion or principle for comparing the alternatives on the basis of the arguments and their quality or strengths.
Let $\mathcal{B} = \{(b_i, \alpha_i), i = 1, \ldots, n\}$ be any *consistent* and *weighted* beliefs base, and $\mathcal{G} = \{(g_j, \beta_j), j = 1, \ldots, m\}$ be a *consistent* prioritized base of goals. $\mathcal{B}^*$ and $\mathcal{G}^*$ will denote the corresponding sets when weights are ignored. From these bases, different arguments in favor of elements of $\mathcal{X}$ can be built. The idea is that a choice is justified and supported if it leads to the satisfaction of at least one goal of the agent, taking into account its beliefs. Formally:

DEFINITION 3 (ARGUMENT). *An* argument in favor of *a choice* x *is a triple* $A = <S, g, x>$ *such that:*

- $S \subseteq \mathcal{B}^*$, $g \in \mathcal{G}^*$, *and* $x \in \mathcal{X}$
- $S \cup \{x\}$ *is consistent*
- $S \cup \{x\} \vdash g$
- S *is minimal (for set inclusion) among the sets satisfying the above conditions.*

S *is the* support *of the argument,* g *is the* goal *which is reached by the decision* x *and* x *is the* conclusion *of the argument. The set* $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$ *gathers all the arguments which can be constructed from* $\mathcal{B}$, $\mathcal{G}$ *and* $\mathcal{X}$. $\texttt{Arg}(x)$ *is the set of arguments whose conclusion is* x.

Since the bases $\mathcal{B}$ and $\mathcal{G}$ are weighted, arguments in favor of an alternative are more or less strong. Since an argument involves two kinds of information (beliefs and goals), its strength depends on the quality of both information. Thus, to each argument we associate a certainty level representing the degree of the less entrenched belief used in it, and a weight representing the importance of the goal reached by the conclusion of that argument.

DEFINITION 4 (STRENGTH OF AN ARGUMENT). *Let* $A = <S, g, x>$ *be an argument in* $\mathcal{A}(\mathcal{B}, \mathcal{G})$. *The* strength *of* A *is a pair* $<Level(A), Weight(A)>$ *such that:*

- $Level(A)$ = *min*$\{\rho_i \mid k_i \in S$ *and* $(k_i, \rho_i) \in \mathcal{B}\}$. *If* $S = \emptyset$ *then* $Level(A) = 1$. *It represents the* certainty level *of the argument.*
- $Weight(A) = \lambda$ *with* $(\lambda, g) \in \mathcal{G}$. *It represents the* degree of satisfaction *of the argument.*

The strengths of arguments make it possible to compare pairs of arguments in several ways, depending on whether the agent gives the same importance to the certainty level and the weight or not. The aim of this paper is not to give an exhaustive list of comparison criteria, but to show what are the main components that define a dialogue strategy. For the purpose of illustration, let us consider the following particular criterion in which goals take precedence over beliefs:

DEFINITION 5. *Let* A *and* B *be two arguments in* $\mathcal{A}(\mathcal{B}, \mathcal{G})$. A *is* preferred *to* B, *denoted* $A \succeq B$, *iff:*

- $Weight(A) > Weight(B)$, *or*
- $Weight(A) = Weight(B)$ *and* $Level(A) \geq Level(B)$

PROPERTY 1. *The relation* $\succeq$ *is a total preorder, i.e.* $\succeq$ *is reflexive and transitive.*

At the core of our framework is the use of a *principle* that allows for an argument-based comparison of alternatives. Each combination of a principle with a criterion for comparing arguments captures a particular agent *profile*, thus a particular strategy for selecting moves in a dialogue.

Below we present an example of a principle that takes as input the supporting arguments and prefers an alternative which has at least one supporting argument which is preferred to any supporting argument of the other alternative. Formally:

DEFINITION 6. *Let* $x, x' \in \mathcal{X}$. x *is preferred to* x', *denoted* $x \triangleright x'$, *iff* $\exists\ P \in \texttt{Arg}(x)$ *s.t* $\forall\ P' \in \texttt{Arg}(x')$, $P \succeq P'$.

PROPERTY 2. *The relation* $\triangleright$ *is a total preorder.*

DEFINITION 7 (BEST DECISIONS). *Let* $\mathcal{X}$ *be a set of possible decisions. The set of best decisions is* $\texttt{Best}(\mathcal{X}) = \{x \in X, s.t. \forall\ x' \in \mathcal{X}, x \triangleright x'\}$.

DEFINITION 8 (ARGUMENTATION-BASED DECISION FRAMEWORK). *An* argumentation-based decision framework *is a tuple* $<\mathcal{X}, \mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X}), \succeq, \triangleright\!\!>$ *where:*

- $\mathcal{X}$ *is a set of all possible decisions.*
- $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$ *is a set of arguments built from* $\mathcal{B}$, $\mathcal{G}$ *and* $\mathcal{X}$.
- $\succeq$ *is a (partial or complete) pre-ordering on* $\mathcal{A}(\mathcal{B}, \mathcal{G}, \mathcal{X})$.
- $\triangleright$ *defines a (partial or complete) pre-order on* $\mathcal{X}$.

5. COMPUTING THE NEXT MOVE IN A DIALOGUE

In the previous section, we have presented a formal framework for explaining, ordering and making decisions. In what follows, we will show how that framework can be used for move selection. Let (a, x) be the current move of the dialogue, and an agent has to choose the next one, say (a', x').
The act a' is returned as a best option by the framework $<\texttt{Replies}(a)$, $\mathcal{A}(\mathcal{B}_s, \mathcal{G}_s, \texttt{Replies}(a))$, $\succeq$, $\triangleright\!\!>$ (i.e $a' \in \texttt{Best}(\texttt{Replies}(a))$), whereas a content x' is among the best options returned by the framework $<\texttt{Content}(a')$, $\mathcal{A}(\mathcal{B}_f, \mathcal{G}_f, \texttt{Content}(a'))$, $\succeq$, $\triangleright\!\!>$, i.e. $x' \in \texttt{Best}(\texttt{Content}(a'))$.

6. CONCLUSION

This paper has proposed a formal framework for defining strategies. This framework can be regarded as two separate systems: one of them take as input the possible replies allowed by a protocol, a set of strategic beliefs and a set of strategic goals and returns the best speech act, and the second system takes as input a set of alternatives, a set of basic beliefs and a set of functional goals and returns the best content of a speech act. The two systems are grounded on argumentation theory. The basic idea behind each system is to construct the arguments in favour of and against each choice, to compute the strength of each argument and finally to compare pairs of choices on the basis of the quality of their supporting arguments. We have shown also the agents profiles play a key role in defining principles for comparing decisions. In this paper we have presented two examples: pessimistic agents which represent very cautious agents and optimistic agents which are adventurous ones.

ABSTRACT

We consider the problem of a shop agent negotiating *bilaterally* with *many* customers about a bundle of goods or services together with a price. To facilitate the shop agent's search for mutually beneficial alternative bundles, we develop a method for online learning customers' preferences, while respecting their privacy. By introducing extra parameters, we represent customers' highly nonlinear preferences as a linear model. We develop a method for learning the underlying stochastic process of these parameters online.

1. INTRODUCTION

We consider the problem of a shop agent negotiating *bilaterally* with *many* customers about a bundle (configuration)—an array of bits, representing the presence or absence of each of the shop's goods in the bundle—together with a price for the bundle. Like the work of [3, 2, 4, 1], the techniques developed in this paper try to benefit from the so-called win-win opportunities that arise with multi-issue negotiations.

The methods proposed in Faratin et al. [2], and Coehoorn and Jennings [1] are geared towards finding win-win opportunities through modeling the preferences of the negotiation partner, for issues with independent valuations. This paper follows a similar approach; like Klein et al. [3] and our earlier work [4], we consider *interdependencies* between issues, however, which make the problem considerably harder. The novelty of our current approach lies in the introduction of a new scalable and very fast method for *online* learning these complex customer preferences, while respecting their privacy. To respect customers' privacy, the method as developed only uses *anonymous* data on past negotiations: i.e., the shop cannot determine if he has dealt with a customer in the past. As the conducted computer experiments show, the necessary aggregate information, to significantly facilitate the search for mutually beneficial alternative bundles in future bilateral negotiations, is learned quickly for relatively large problems.

2. NEGOTIATION PROCESS

The shop sells a total of n goods, each of which may be either absent or present in a bundle, so that there are $2^n - 1$ distinct bundle-configurations containing at least 1 good, with $n = 20$. A negotiation concerns a bundle, together with a price for that bundle, and it is conducted in an alternating exchange of offers and counter offers. An example of such a practice may involve the sales of bundles of news items in categories like politics, finance, economy, sports, arts, etc.

During the negotiation, the shop will suggest a *limited number* of alternative bundles. Hopefully, these suggestions will lead to the bargainers finding mutually beneficial alternative bundles. Such bundles represents *Pareto improvements* because switching makes at least one bargainer better off without making the other worse off. Ideally, the shop will eventually find a *Pareto efficient* bundle: a bundle for which no Pareto improvements exits.

Typically, a customer initiates the negotiation process by submitting an initial bundle and opening price. The shop agent constructs an ordered set from all the bundles that lie in the initial bundle's neighborhood (i.e., all bundles which in binary representation have a hamming distance of 1 to the initial bundle); it orders the bundles based on the likelihood that they will result in Pareto improvements, starting with the most likely bundle. By advising the first bundle in this set first, the second bundle second, and so on, the shop agent searches (locally) for Pareto improvements (cf. [4] for further details). To assess the likelihood of a Pareto improvement requires statistical knowledge of customers' preferences. The focus of this paper lies on how we can obtain this knowledge based on anonymous negotiation data.

3. PROBLEM STATEMENT

First we show how we can rewrite customers' highly non-linear preferences as a linear model. In the absence of strategic behavior and stochasticity in customers' preferences, this will give use a direct solution to the learning problem. In the next section, we use the obtained insights to develop a fast method for online learning more about customer preferences given strategic behavior and stochasticity.

There are n individual goods from which customers can compile the bundle they wish to purchase. The column vector $\mathbf{b} = [b(1), \ldots, b(n)]^T$ denotes the binary representation of a bundle (i.e., $b(i) = 1$ if and only if good i is part of the bundle). Let a_i denote a customer's valuation for obtaining good i individually and $a_{i,j}$, $a_{i,j,l}$, etc. denote the synergy effects exclusively caused by obtaining a subset of goods $\{i,j\}$, $\{i,j,l\}$, etc.: e.g., a_{ij} is equal to the customer's valuation for bundle $\{i,j\}$ minus the valuation for obtaining the goods individually. There are $\binom{n}{1}$ parameters of the type a_i, $\binom{n}{2}$ parameters of the type a_{ij}, and so on; thus there are at most $k = \sum_{i=1}^{n} \binom{n}{i} = 2^n - 1$ parameters. In the experiments, we consider problems where $n = 20$. To make the number of parameters manageable we assume that beyond subsets of size 3 the synergy effect are always zero: i.e., there are only $k = \binom{n}{1} + \binom{n}{2} + \binom{n}{3}$ number of parameters.

Given some (arbitrary but) fixed encoding, denoted by $<\cdot>$, we can map all k parameters into the (k-dimensional) vector $\mathbf{a}$. We can now define a customer's monetary valuation for bundle $\mathbf{b}$, $v^c_{\mathbf{a}}(\mathbf{b})$, as follows:

$$v^c_{\mathbf{a}}(\mathbf{b}) = \sum_{i=1}^{n} \mathbf{a}_{<i>} b(i) + \sum_{i=1}^{n} \sum_{j=i+1}^{n} \mathbf{a}_{<i,j>} b(i) b(j) + \ldots + \mathbf{a}_{<1,\ldots,n>} b(1) b(2) \ldots b(n). \quad (1)$$

From Eq. (1) (and encoding $<\cdot>$), we can conclude that the seller can construct a mapping $\mathbf{f} : \{0,1\}^n \mapsto \{0,1\}^k$. For all customers, their monetary valuation for any bundle $\mathbf{b}$ can be expressed as a linear function of their k-parameters and $\mathbf{f}(\mathbf{b})$. *For example*, if there are only 3 goods—good 1,2, and 3—then $\mathbf{b} = (1,1,0)$ could (depending on the encoding) give $\mathbf{f}(\mathbf{b}) = (1,1,0,1,0,0,0)$. Irrespective of the encoding, $\mathbf{f}(1,1,0)$ should contain three 1's and four 0's: i.e., the parameters $a_{<1>}$, $a_{<2>}$, and $a_{<1,2>}$ contribute to the valuation of bundle $(1,1,0)$.

In the absence of strategic behavior and stochasticity, $\mathbf{a}$ is the same for all customers. The seller can then just obtain $\mathbf{a}$ by solving a system of linear equations. For example, suppose there are t observations and for each $i = 1, \ldots, t$ the seller has the observations v_i and $\mathbf{b}_i$, where v_i denotes customers' valuations for bundle $\mathbf{b}_i$. Then

$$\mathbf{v} = \mathbf{B}\mathbf{a} \quad (2)$$

with $\mathbf{v} = [v_1, \ldots, v_t]^T$ and $\mathbf{B} = [\mathbf{f}(\mathbf{b}_1), \ldots, \mathbf{f}(\mathbf{b}_t)]^T$ (thus $\mathbf{B}$ is a $t \times k$ matrix). Since the seller also knows $\mathbf{f}$, he knows both $\mathbf{v}$ and $\mathbf{B}$. Now if the rank of matrix $\mathbf{B}$ is equal to k, then the (Moore-Penrose) generalized matrix inverse of $\mathbf{B}$, denoted by $\mathbf{B}^+$, can be used to compute $\mathbf{a}$: i.e., $\mathbf{a} = \mathbf{B}^+\mathbf{v}$.

Typically, customer preferences differ from one customer to the next: i.e., $\mathbf{a}$, which completely describes customers' preferences, is a random vector. We assume $\mathbf{a}$ is normally distributed with a vector of means $\mu_{\mathbf{a}}$ and covariance matrix $\mathbf{\Sigma}_{\mathbf{a}}$. Moreover, since customers will behave strategically the seller will not directly observe their valuations.

4. LEARNING METHOD

The method we develop for estimating the vector of means $\mu_{\mathbf{a}}$ and covariance matrix $\mathbf{\Sigma}_{\mathbf{a}}$, contains (a) a sub method for learning $\mu_{\mathbf{a}}$ and $\mathbf{\Sigma}_{\mathbf{a}}$ in the absence of strategic behavior and (b) a sub method for preprocessing the negotiation data. First method (b) is applied to the data such that a sufficient amount of the noise caused by strategic behavior is removed.

(*Sub Method A*) As was discussed in Section 3, per customer we have an instance of the random vector $\mathbf{a}$, which completely specifies her preferences. For a customer c, let $\mathbf{a}_c$ denote such an instance. Suppose the seller would negotiate for a very long time with this customer c, while constantly suggesting different bundles. In the absence of strategic behavior, eventually the seller would have collected the negotiation data $\mathbf{v}_c = [v_{c1}, \ldots, v_{ct}]^T$, and $\mathbf{B}_c = [\mathbf{f}(\mathbf{b}_{c1}), \ldots, \mathbf{f}(\mathbf{b}_{ct})]^T$ such that $\mathbf{B}_c$ has rank k. Analogous to Eq. (2), the seller can then just obtain $\mathbf{a}_c$ by solving $\mathbf{v}_c = \mathbf{B}_c\mathbf{a}_c$: i.e., $\mathbf{a_c} = \mathbf{B}_c^+\mathbf{v}_c$, where $\mathbf{B}_c^+$ is again the generalized matrix inverse of $\mathbf{B}_c$.

For large k, bargainers will break off the negotiations or reach a deal, before the matrix $\mathbf{B}_c$ grows into a rank k matrix. Therefore, the seller suggests instead a sequence of bundles such that the union of the goods contained in these bundles has strictly less goods than is possible. (In the experiments, 4, 5, or at most 6 individual goods are being considered.) In that case, relative to k the matrix $\mathbf{B}_c$ contains only a few nonzero columns. Whenever k', the rank of the matrix $\mathbf{B}_c$, equals the number of nonzero columns, we can obtain $\mathbf{a}'_c$—the k'-dimensional vector containing all the identifiable parameters of $\mathbf{a}_c$—by solving $\mathbf{v}_c = \mathbf{B}'_c\mathbf{a}'_c$ (i.e., $\mathbf{a}'_c = \mathbf{B}'^{+}_c\mathbf{v}_c$); we get the matrix $\mathbf{B}'_c$ by removing all zero columns from $\mathbf{B}_c$. Based on these newly computed parameter values, it is now relatively straightforward to obtain estimations of the mean, and covariance matrix.

(*Sub Method b*) With strategic behavior the seller does not observe $\mathbf{v}_c = [v_{c1}, \ldots, v_{ct}]^T$. Instead he observes $\mathbf{p}_c = [p_{c1}, \ldots, p_{ct}]$, the sequence of bids submitted by the customers, where there is generally a difference between p_{ci} and v_{ci}. To deal with strategic behavior requires some implicit or explicit model of customers' bidding strategies. For example, in [4, 1] they learn more about customer preferences based on the difference between two consecutive bids. This implies some implicit model of a customer's bidding behavior, however. We want to make this model explicit so that we can check whether the model is consistent with a customer's bidding behavior.

Strategic behavior of customers can roughly be split into a fixed and variable component. The fixed component specifies how much a customer c is at most willing to bid for a bundle $\mathbf{b}$ worth $\mathbf{f}(\mathbf{b})^T\mathbf{a}_c$, irrespective of the current state of the negotiation; the variable component specifies how a customer concedes through time.

Filtering out the fixed component of a customer's bargaining strategy is impossible. Especially in the case of bundling, the seller can eradicate most of the second type of noise, however. The idea is that at the end of a negotiation process the seller will use some of the gathered negotiation data to model how the opponent concedes trough time; the rest of the data can then be used to check whether the developed model correctly predicts how a customer concedes through time. It is very unlikely that such a test is passed incorrectly (error of the first kind) because both the correctness of the estimated values for the identifiable parameters ($\mathbf{a}'_c$) and the concession model are tested jointly. The other pos-

sibility, of not being able to model a negotiation process is even less problematic; the seller can just simple ignore this negotiation. In real world applications the seller could have a collection of typical models and check which of the models fits the data of a particular negotiation best. Consequently, enough negotiation data can be preprocessed and fed to sub method (a) to ensure good estimations of $\mu_{\mathbf{a}}$ and $\mathbf{\Sigma_a}$.

5. NUMERICAL EXPERIMENTS

Customers are at most willing to pay x% of their true valuation; for each customer x is randomly drawn between 85 and 95. Moreover, customers and shop use time dependent bidding strategies: the offer submitted by a customer (shop) is monotonically increasing (decreasing) in both the number of bidding rounds and the valuation.

We compare our new approach of having *no a priori information* and learning customer preferences online (as discussed in Section 4), to the one where—for example because of expert knowledge—the shop already knows the underlying joint probability distribution of all bundle valuations. Besides comparing our new online procedure (referred to as ML) with the previous method (called S), we also perform the same series of experiments with a benchmark procedure (called B), which simply recommends a random bundle from the current bundle's neighborhood. That is, the benchmark does not base the order in which it recommends the next bundle on the estimated likelihood of Pareto improvements, as the ML and S-systems do.

Customers initiate the negotiation by submitting an offer containing an initial bundle b_{init}. To give the shop some room for improvement, we initialize the customer's initial bundle by randomly selecting a bundle b which, in binary representation, has a Hamming distance of 5 to the bundle b^* that is associated with the highest gains from trade.

Both ML and S-system greatly outperform the B-system. To illustrate how well the ML-system performs compared to the S-system, figure 1 shows the relative performance and the number of rounds within which a deal is reached (if a deal is reached in the first place) per customer. Relative performance specifies the percentage of the maximal obtainable Pareto improvements (given the starting point) that is actually realized at the end of a negotiation. To simplify the comparison we hard wired the ML-system to stop exploring after 500 customers. (Remember, learning is completely online, however.) In the exploitation phase of the ML-system, the two systems generate virtually the same performance. Figure 1 illustrates the great advantage of using negotiation data. In the exploration phase 500 customers suffices for the ML-system, because per customer the system obtains roughly 55 high quality data points.

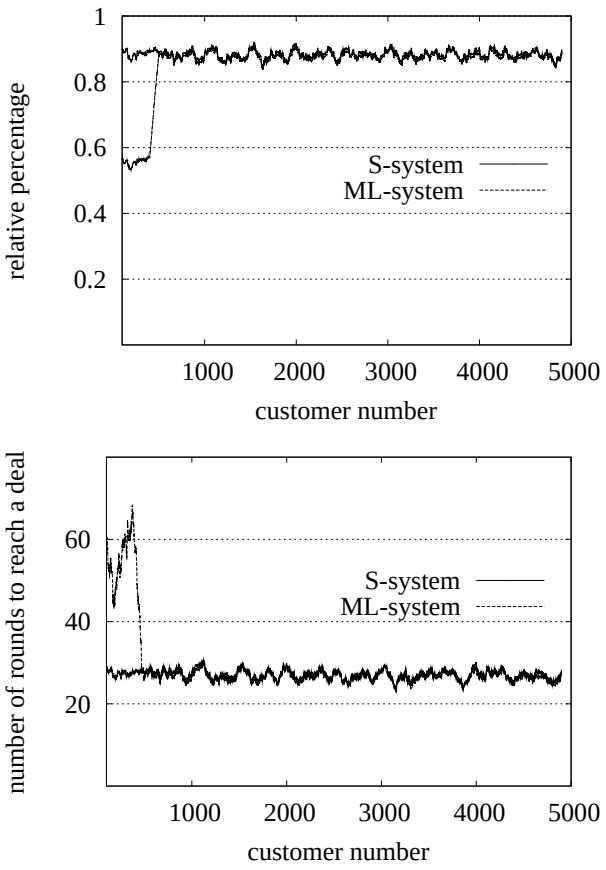

Figure 1: 100-step moving average of the relative % and the number of rounds to reach a deal.

6. CONCLUSIONS

We conduct computer experiments with simulated customers that have highly *nonlinear* preferences and are interested in bundles containing up to 20 individual goods. We compare our new method of having *no a priori information* and learning about customer preferences online, to the one where—for example because of expert knowledge—the shop already knows the underlying joint probability distribution of all bundle valuations. Our experiments show how, after 500 customers, the two approaches have virtually the same performance. Both methods significantly increase the speed with which deals are reached, as well as the number and the Pareto efficiency of the deals reached, compared to a benchmark. Moreover, the experiments show that the new procedure is able to learn the necessary information online, even if due to strategic behavior customers' best offers are significantly less than their reservation values.

ABSTRACT

Detecting and preventing the adversarial action of an agent with respect to the community of agents can be a serious issue in the design of open multi-agent systems. This task is severely domain dependent and it is hard to find a general solution. This contribution presents a utility based model of adversarial action and analyses few properties of adversarial behavior in multi-agent systems. Potential use and important drawbacks of this model are discussed in the paper.

1. INTRODUCTION

In this contribution, we use the conflict theory [5] and some fundamental principles from the economy and law [2] to consistently define the adversarial behavior in the multi-agent system. The agents in such system can have their own, sometimes completely antagonistic goals and they often compete for the shared resources or opportunities. Tackling a similar problem in conflict theory, James Fearon [5] analyzes the war between perfectly rational states, where the most important property of the war is the war's **ex-post inefficiency** – he argues that the states can reach the same result by negotiation, eliminating the cost of the adversarial actions. In [9], the aggression is defined as an action that is *socially undesirable and imposing net social cost*, consistently with [2], where the criminal activity is defined by imposing that *the gains of criminal are smaller than the social cost of act*.

2. ADVERSARIAL ACTION DEFINITION

Consistently with previous work [3], we will define a simple abstract game model featuring agent set $Ag = \{A, B, C, ...\}$ with the agents playing a non-extensive (single round) game that is not strictly competitive – sum of all agents' utilities is not constant. Each agent X has a set of available actions denoted a^*_X, with actions $a^i_X \in a^*_X$ (whenever possible, we only write a_X). From this set, agent selects its action using its strategy. We suppose that all agents do the selection at one moment and therefore the selected actions are independent. The final state, *outcome* of the game $o(a_A, a_B, ...)$ is determined by strategies of the agents and determines both the individual agents' utilities $u_A(o), u_B(o), u_C(o), ...$ and the social choice function $u(o) = u_A(o)+u_B(o)+u_C(o)+...$, considered to represent the *social welfare* [4].

Utility is defined as *"a value which is associated with a state of the world, and which represents the value that the agent places on that state of the world"* by [8].

In the cooperative environment, all agents do share a single utility function.

DEFINITION 1. *We say that agent's A action a^{coop}_A is a* **cooperative action** *if it maximises social welfare:*

$$\texttt{coop}(a^{coop}_A) \Leftrightarrow u(a^{coop}_A, a_B, ...) = \max_{a^i_A \in a^*_A} u(a^i_A, a_B, ...)$$

The complete opposite is the self-interested environment, where the agents are trying to maximise their profit.

DEFINITION 2. *We say that agent's A action a^{si}_A is a* **self-interested action** *if it maximises agents' individual utility:*

$$\texttt{si}(a^{si}_A) \Leftrightarrow u_A(a^{si}_A, a_B, ...) = \max_{a^i_A \in a^*_A} u_A(a^i_A, a_B, ...)$$

In many contexts, the terms self-interestedness and competitiveness are considered to be synonymous. However, we consider the competitiveness to be more strict. In [3], self interestedness is defined as not taking the utility of the others into the consideration while maximizing own utility, while [6] requires the trust between competitors, allowing them to avoid globally undesirable outcomes. In the systems with carefully programmed mechanisms, the results are equivalent in both cases. However, in many real-world cases the total utility may decrease, even if each agent optimizes locally (a prison dilemma is an example of this situation).

In the competitive environment, agents select actions to maximize their own private utility, but they restrict their choice to the actions that at least conserve the social welfare.

DEFINITION 3. *We say that agent's A action a_A^{comp} is a* **competitive action** *provided that it maximizes individual profit while does not allow drop of the social welfare:*

$$\texttt{comp}(a_A^{comp}) \Leftrightarrow u_A(a_A^{comp}, a_B, ...) = \max_{a_A^i \in a_A^{**}} u_A(a_A^i, a_B, ...),$$

where $\forall a_A^i \in a_X^{**} : u(a_A^i, a_B, ...) \geq u(a_B, ...)$.

The expression $u(a_B, ...)$ represents hypothetical outcome of the community in the case when the agent A performs no action or is not in the community at all. This situation is illustrated later on Figure 1 by $\sim$ symbol.

Finally, let us try to define the concept of the adversarial action. The most intuitive definition would be that the adversarial action is such an action that is deliberatively preferred to another action that is equally achievable but has got higher social welfare utilities.

DEFINITION 4. *We say that agent's A action a_A^{adv} is an* **adversarial action** *if:* $\texttt{adv}(a_A^{adv}) \Leftrightarrow \exists a_A^i \in a_A^* :$

1. $u(a_A^{adv}, a_B, ...) \ll u(a_A^i, a_B, ...)$ *and*
2. $u(a_A^i, a_B, ...) - u(a_A^{adv}, a_B, ...) \gg u_A(a_A^{adv}, a_B, ...) - u_A(a_A^i, a_B, ...)$.

The definition 4 above states that the adversarial action a_A^{adv} selected by A from the set a_A^* hurts the social welfare without strong incentive. To make the formalism simpler, we have assumed that there is only single action a_A^{adv} of agent A that hurts the social welfare. There are several interesting points to consider in the general definition.

The first point is the non-emptiness of the set $a_A^* \setminus \{a_A^{adv}\}$ - we don't consider the behaviour with no alternative as adversarial.

Motivation and justification of the adversarial action is closely related to two relational operators used in the definition: $\ll$ and $\lesssim$. The first inequality $\ll$ signifies that the agent shall not cause significant harm to the common welfare, while the inequality $\lesssim$ means that the agent remains self-interested and it will not lose a significant part of its welfare to save the utility of other agents. The concept is illustrated by Fig. 1. In this context, it is important not to take our simplification of the game formalism literally and to consider only immediate payoff as the utility – in most systems, agents expect to encounter their partners again in the future and we suppose that the attitudes of their partners towards them and expected future profits are included in the utility u_X. Formally, we may pose:

DEFINITION 5. *We say that* ***action*** *a_A^j of agent A is* ***rationally adversarial*** *if it is both self-interested and adversarial. In the action is not self-interested and is adversarial, it is* ***irrationally adversarial****.*

2.1 Properties of Adversarial Action

2.1.1 Pareto-Optimality

In this context, we may mention the relationship between adversariality and Pareto-Optimality[1].

An outcome of an adversarial action is not Pareto optimal. Rationally adversarial action is not Pareto optimal in the situations

[1]Following [7], we denote as o^* a set of all achievable outcomes and we define: Outcome o is considered to be **Pareto optimal** if : (i) it is achievable (i.e. $o \in o^*$) and (ii) not majored by any other outcome $o' \in o^* \setminus \{o\}$, where we define majoring as: $\forall_{X \in Ag} u_X(o') \geq u_X(o)$ and $\exists_{X \in Ag} u_X(o') > u_X(o)$.

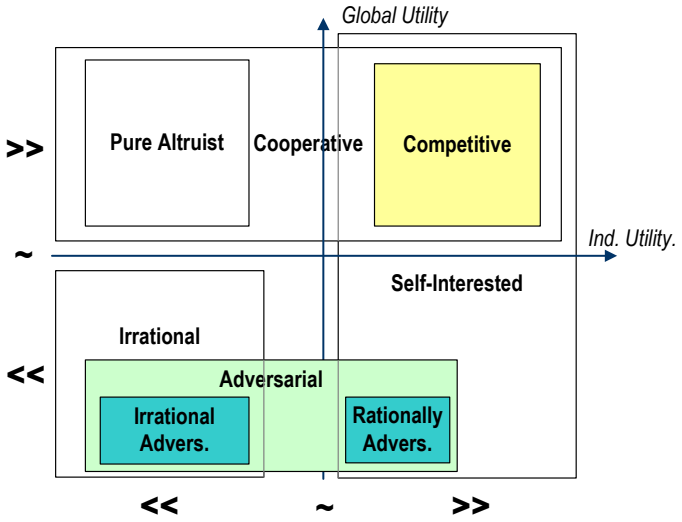

Figure 1: Classification of action with respect to global utility (social welfare) and individual utility of acting agent. The $\sim$ symbol corresponds to the situation where the agent A performs some neutral action or is not in the community at all, i.e. $u(a_B, ...)$.

where the agents may negotiate and transfer the utility - in such situations, the agents may always transfer enough utility to motivate the adversarial agent to behave cooperatively, therefore achieving socially acceptable outcome. When the utility is not transferable (e.g. indivisibility as defined in [5]), the set o^* is severely restricted and even an action that causes the overall social loss may be considered non-adversarial due to the lack of alternative. In the irrationally adversarial case, Pareto optimality does not hold neither, as the utility is lost both by adversarial agent and the society as a whole.

As stated above, an outcome of an adversarial action is not Pareto optimal in the situations:

- where the agents may negotiate and transfer the utility, and
- the action is irrationally adversarial – $u_A(a_A^{adv}) < 0$.

This property can be used mainly in the situation where the community consists of a coalition of mutually trusted actors and one agent whose adversariality is subject of investigation.

On the other hand, Pareto optimality as such doesn't preserve social welfare (due to the indivisibility), it only ensures that all agents behave rationally given the knowledge about the action of the others.

2.1.2 Implication of Adversarial Behaviour

We are interested in the impact of the adversarial action on the global social welfare of the community Ag. We can say that:

- decrease of social welfare *does not imply* existence of an adversarial behavior in the community,
- unnecessary decrease of social welfare *implies* existence of an adversarial behavior (intentional or unintentional) in the community, while
- existence of an adversarial behavior in the community *does not imply* decrease of social welfare.

3. EXAMPLE: UAV DECONFLICTION

In this example, we will illustrate rather abstract definitions of adversarial action provided above with the real example from domain of UAV (Unmanned Aerial Vehicle) flight-plan deconfliction. Let us operate two UAVs A and B. We have situation where the two UAVs are facing a collision and they individually deliberate about the actions $d(A)$ – the UAV A making the deconfliction manoeuver, the action $d(B)$ – the UAV B making the deconfliction manoeuver and $d(A, B)$ – the both UAVs making the deconfliction manoeuver. As the UAVs are different, they loss of their individual utility associated with the manoeuver is different. Let us assume:

- $mu_{\mathtt{d}(A)}(A) > mu_{\mathtt{d}(B)}(B) > mu_{\mathtt{d}(A,B)}(B) + mu_{\mathtt{d}(A,B)}(A)$
- $mu_{\mathtt{d}(A,B)}(A) > mu_{\mathtt{d}(A)}(A)$,
- $mu_{\mathtt{d}(A,B)}(B) > mu_{\mathtt{d}(B)}(B)$

The A UAV is smaller than the B UAV, which implies that it is cheaper for A to make the manoeuver than it is for B. However B making the manoeuver is even cheaper than sum of costs for both UAVs making the manoeuver. However, for each UAV it is cheaper to participate in a collective manoeuver than doing the manoeuver individually.

In the *cooperative environment* the UAVs with conflicting plans do minimize overall disruption and fuel consumption while solving deconfliction problems[2]:

- $A, B : \mathtt{d}(A) \succ \mathtt{d}(B) \succ \mathtt{d}(A, B) \succ \neg\mathtt{d}(A, B)$

Both the cooperative UAVs have the same strategy, that is the smaller UAV deconfliction is preferred to the bigger UAV deconfliction that is preferred to both plans deconfliction and which is preferred to a confliction.

In the *competitive environment* each UAV minimizes its own plan disruption and fuel consumption, but conserves overall welfare:

- $A : \mathtt{d}(B) \succ \mathtt{d}(A) \succ \mathtt{d}(A, B) \succ \neg\mathtt{d}(A, B)$
- $B : \mathtt{d}(A) \succ \mathtt{d}(B) \succ \mathtt{d}(A, B) \succ \neg\mathtt{d}(A, B)$

More specifically, if two UAVs would collide and only one evasive maneuver is necessary, it will try to make the other UAV divert from its course, but without compromising the security.

In the *self-interested environment* each UAV minimizes its own plan disruption and fuel consumption, regardless of the others.

- $A : \mathtt{d}(B) \succ \mathtt{d}(A, B) \succ \mathtt{d}(A) \succ \neg\mathtt{d}(A, B)$
- $B : \mathtt{d}(A) \succ \mathtt{d}(A, B) \succ \mathtt{d}(B) \succ \neg\mathtt{d}(A, B)$

In case of conflict, it only diverts from its course to protect its own safety.

In the adversarial environment the adversarial UAV causes a significant disruption of the other's plans, or even endangers them. Let us assume $mu_{\mathtt{d}(A)}(A) \ll mu_{\mathtt{d}(B)}(B)$ (e.g. A is pushing B away).

- $A : \mathtt{d}(B) \succ \neg\mathtt{d}(A, B) \succ \{\mathtt{d}(A, B), \mathtt{d}(A)\}$
- $B : \mathtt{d}(A) \succ \mathtt{d}(A, B) \succ \mathtt{d}(B) \succ \neg\mathtt{d}(A, B)$

If the B flying over an enemy area does not want to be pushed, the situation is as follows:

- $A : \mathtt{d}(B) \succ \neg\mathtt{d}(A, B) \succ \{\mathtt{d}(A, B), \mathtt{d}(A)\}$
- $B : \mathtt{d}(A) \succ \mathtt{d}(A, B) \succ \neg\mathtt{d}(A, B) \succ \mathtt{d}(B)$

[2]The symbol $\succ$ stands for collective choice preference

4. CONCLUSION

The problem of adversariality in the multi-agent systems is real. While the irrationally adversarial agents may be easy to identify, it may be much more difficult to identify the rationally adversarial behavior, especially if all the agents in the system are self-interested. In this context, the question of *bounded rationality* of agent's reasoning is crucial. To better illustrate the concept, we will cite several accepted causes for the emergence of the conflict between the rational actors. It is easy to realize that most of these causes can plausibly exist in the multi-agent system and shall be considered while designing autonomous agents: **Private information** of each agent is not available to the others, providing one of the causes of **miscalculation** about **capabilities or attitudes** of the other party. Such miscalculation may cause an adversarial behavior, as the agents will not be able to correctly estimate the utility function of the partners. Agents are often willing to **misrepresent** the reality about themselves, in order to obtain better payoff or negotiation position in the future.

ABSTRACT

It is difficult to reach optimal outcomes in bilateral negotiations with multiple issues when the agents' preferences and priorities of the issues are not common knowledge. Self-interested agents often end up negotiating inefficient agreements in such situations. Some existing multiagent negotiation frameworks involve agents revealing their preferences to a trusted mediator. But in real-life situations, such a third party, trusted by both the agents may not be found. We design a protocol for bilateral multi-issue negotiation. This protocol guarantees envy-free and Pareto optimal agreement with minimum revelation of their preferences when both negotiators are rational and have the same ordinal preferences. This protocol also leads rational agents to envy-free and near-optimal solution in all cases.

1. INTRODUCTION

Negotiation is the most well-known approach for resolving conflicts in human and agent societies. With the rapid growth of E-commerce, research in automated negotiation has become increasingly important [4]. In automated negotiation, agents negotiate contracts on behalf of real-life negotiating parties they represent. An agent can negotiate resources and services with other agents or humans. Agents may bargain over a single issue of contention, but negotiations often involve bargaining over multiple issues [5], which may or may not be correlated. The issues are considered to be correlated if the utility of one issue depends on the consumption of any other issue(s). In this paper, we consider one-time negotiations with two agents negotiating over multiple, unrelated issues. We assume that the participating agents have no *a priori* knowledge about the preferences of the other agent. This situation is common in E-commerce negotiations, where the number and diversity of agents is so large that an agent may not have any estimate about the preferences of any particular agent it is negotiating with.

A negotiation process can be *distributive* or *integrative* in nature. In a *distributive* negotiation scenario, a gain for one participant implies a loss for the other. In *integrative* negotiation, agents can reach outcomes that are mutually beneficial. A single issue negotiation is usually a *distributive* negotiation. Multi-issue negotiations, on the other hand, where the ordinal and cardinal preferences are different, are integrative negotiations. In multi-issue negotiation, agents with known, divergent preferences can cooperate to reach agreements beneficial for both agents. But when the preferences are not known, using existing protocols, self-interested agents often fail to explore win-win possibilities and end up with inefficient agreements. By efficient or optimal solution, we refer to a solution which is *envy-free* and *Pareto optimal* [1].

Existing research shows that, if the agents are willing to reveal their complete preferences, it is possible to reach an efficient solution [3, 5]. If the agents, however, are unwilling to reveal their preferences at all, rational agents will end up with an equal split solution[1], which is not Pareto optimal unless both agents have identical preferences. So, there exists an efficiency-revelation trade-off. Our goal in this paper is to find out effective protocols for bilateral, multi-issue negotiation that can lead the participating agents to optimal or near-optimal outcomes while revealing only minimal information. Our work has some similarity with the work on contract negotiation by Sandholm [6] and Endriss *et al* [2] in the context of task allocation, where agents negotiate to reallocate tasks. But they want to identify, under complete information, necessary deals or exchanges required among agents to reach efficient allocation from an arbitrary initial allocation. We, on the contrary, want to find mechanisms that lead agents, without any prior information about opponent's preferences, to efficient outcomes without any third party intervention.

[1]Each agent gets exactly half of each issue.

2. NEGOTIATION FRAMEWORK

We formally describe a representative negotiation scenario for allocation of available resources as a 3-tuple $\langle \mathcal{A}, R, \mathcal{U} \rangle$, where $\mathcal{A} = \{A_1, A_2\}$ is the set of agents, R is the resource whose allocation is being negotiated, and $\mathcal{U} = \{U_1, U_2\}$ is the set of utility functions, where U_i is the utility function of agent i. The resource $R = \{r_1, r_2, \ldots, r_H\}$ has $H \geq 2$ components and we assume that one continuously divisible unit of each component is available for allocation. Each component can be considered as a negotiation issue. Henceforth we will use the terms "component" and "issue" interchangeably. The negotiating agents must agree on the allocation of each component of the resource. An agent wants to obtain the entire unit of each components and some components are more important to it than others. Each agent has a complete preference order over the different components, which is not known to the other agent. Each agent can only assume that other agent is rational and maximizes its utility.

We now define some terms formally:

Outcome: An outcome O is an allocation of the resource components to different agents. Formally, $O : R \mapsto \mathbb{R}^{2\times H}_{[0,1]}$, where $\mathbb{R}^{2\times H}_{[0,1]}$ is a $2 \times H$ matrix, whose (i, j) cell, $x^O_{ij} \in [0, 1]$, presents agent i's allocation of the jth resource or component such that $x^O_{1j} + x^O_{2j} \leq 1$. If the agents cannot reach an agreement, they receive no share of the component, *i.e.*, $x^O_{ij} = 0$ for all i and j. Otherwise, $\sum_{i=1}^{2} x^O_{ij} = 1$, for $j \in \{1, \ldots, H\}$, *i.e.,* each component is exhaustively partitioned between the agents.

Total preference information: This is the relative importance of all the issues to a particular agent. For any agent i, total preference information is given by $\{w_{i1}, \ldots, w_{iH}\}$, where $w_{ij} \geq 0$ and $\sum_{j=1}^{H} w_{ij} = 1$. This is an agent's private information.

Utility: For agent i, utility of an outcome O, is defined as:

$$U^O_i = \sum_{j=1}^{H} w_{ij} * x^O_{ij}. \quad (1)$$

Pareto optimality: An outcome O is Pareto optimal, if there exists no other outcome O' such that all agent's utility in O' is at least as good as their utility in O and at least one agent's utility is more in O'. If outcome O is Pareto optimal, then there cannot exist any outcome O' such that, $U^{O'}_i \geq U^O_i$ for both $i = 1, 2$ and $U^{O'}_i > U^O_i$ for at least one i.

Envy-free: An outcome is envy-free, if and only if each agent's total utility for its own share is at least as much as its utility for the share assigned to the other agent [1].

3. PROPOSED NEGOTIATION PROTOCOL

In this section, we present the protocol that guarantees envy-free and Pareto optimal outcomes to two rational agents negotiating over multiple issues if their ordinal preferences are same. We refer to this protocol as the protocol leading to Pareto Optimal Solution through Equivalence (POSE).

3.1 POSE Protocol

In this protocol, two agents interact with a commonly observable random device. Two agents are negotiating over $H \geq 2$ components where each component has one continuously divisible unit. The protocol is as follows:

Step 1: Number the components from 1 to H and for each component the unit is initially split in equal halves between the two agents. Hence, each agent possesses 0.5 unit of all the components. Let, D^i_t is Agent A_i's current possession of component t. So, initially, $D^i_t = 0.5$, for all $t = 1 \ldots H$, and $i = 1, 2$.

Step 2: The random device chooses one of the two agents, S, to start. Let the set of components yet to be negotiated be G. Initially, $G = R$.

Step 3: Now, S will choose one of the remaining components from G, say C, and propose an exchange offer $E(C, Q_C)$. The offer means that S is ready to trade Q_C units of each of the $G - \{C\}$ components for one unit of C.

Step 4: The other agent, say S', can choose whichever of the options it prefers: either one unit of component C or Q_C units of each of the components in the set $G - \{C\}$.

For S', one unit of C produces $w_{S'C}$ utility and Q_C unit of each of the remaining $G - \{C\}$ components together produces $\sum_{j \in G-\{C\}} Q_C * w_{S'j}$ utility. S' will choose whichever one is more profitable to it. $D^{S'}_C$ and $D^S_C = 1 - D^{S'}_C$ are the amount or unit of component C currently possessed by agent S and S' respectively.

If S' prefers C, then it can earn up to $(1 - D^{S'}_C)$ unit of C in exchange of its own $\{(1 - D^{S'}_C) * Q_C\}$ unit of each component in $G - \{C\}$. But if $\{(1 - D^{S'}_C) * Q_C\} > D^{S'}_{a \in G-\{C\}}$, then the entire exchange is not possible[2]. In this situation S' can give $D^{S'}_{a \in G-\{C\}}$ unit of each component in $G - \{C\}$ and earn $\frac{D^{S'}_{a \in G-\{C\}}}{Q_C}$ unit of C in return. On the other hand if it chooses the other option, it will receive $\{(1 - D^S_C) * Q_C\}$ unit of each component in $G - \{C\}$ from S and S will receive $(1 - D^S_C)$ unit of C from S' and thereby own the entire unit of C. Similar to the earlier case, if $\{(1 - D^S_C) * Q_C\} > D^S_{a \in G-\{C\}}$, S' will receive $D^S_{a \in G-\{C\}}$ unit of each component in $G - \{C\}$ and give $\frac{D^S_{a \in G-\{C\}}}{Q_C}$ unit of C to S. D^i_a values are updated accordingly to present agent i's current possession of component a.

Step 5: The roles of agents S and S' are swapped and G is changed to $G - \{C\}$. If $|G| > 1$ return to Step 3, Otherwise stop. The final allocation is given by $x_{ij} = D^i_j$, where x_{ij} is the agent i's possession of component j.

In this protocol, agents only alternatively reveal their partial preference information.

[2]Since all the remaining issues are taken together for every exchange, for each agent, its possession of each of the issues yet to be negotiated will be same, i.e., for any agent S, D^S_a is same for all $a \in G - \{C\}$.

Proposition 1: *In POSE protocol rational agents produce an envy-free, Pareto-optimal solution if they have identical ordinal preferences*[3].

3.1.1 Rational strategy of agents in POSE

Now we analyze an agent's rational behavior when using the POSE protocol for negotiation. The negotiation strategy consists of two decisions. First, when an agent is proposing an exchange offer, denoted by E, which component, C, will it choose and what should be corresponding exchange ratio, Q_C. The other decision by an agent involves selecting between two options proposed by the other agent.

Statement 1: *When an agent has to select between two options, it will choose the one with higher utility.*

Proposition 2: *While proposing, an agent i, should choose the component C such that, $C = \arg\min_{j \in G}(w_{ij})$ and should propose a ratio Q_C, such that*

$$w_{iC} = \sum_{j \in G - \{C\}} w_{ij} * Q_C.$$

An agent proposes, according to its true preference, its least preferred option from the remaining issues.

3.1.2 An example

Let us illustrate the protocol with an example: two rational agents A_1 and A_2 are negotiating for a resource with three components. One unit of each of the three components are available for negotiation. Suppose ordinal preferences of both the agents are same and their total preference is given by $\{0.1, 0.4, 0.5\}$ and $\{0.2, 0.3, 0.5\}$ respectively. So, $w_{i1} \leq w_{i2} \leq w_{i3}$ for both the agents $i = 1, 2$. Initially each of the components is divided equally between the two agents, *i.e.,* each agent receives 0.5 unit of each component. Now, suppose, the random device chooses A_2 as the first agent (denoted by S in the POSE protocol). Then A_2 will choose the first issue to propose as this issue has the least relative weight to A_2 and it proposes an offer $E(1, \frac{0.2}{0.3+0.5} = 0.25)$ to A_1. So, A_2 is willing to trade 0.25 units of each of components 2 and 3 for one unit of component 1. For A_1, 0.25 unit of components 2 and 3 together is of higher utility than one unit of component 1. So, it will exchange its possession of 0.5 unit of component 1 for $0.25 * 0.5 = 0.125$ units of components 2 and 3 from A_2. So, after this exchange, the possession of components is $\{0, 0.625, 0.625\}$ for A_1 and $\{1, 0.375, 0.375\}$ for A_2 and the set of issues which are yet to be negotiated is $\{2, 3\}$. Now it is A_1's turn to propose and it chooses component 2, its least preferred issue among the remaining issues and offers $E(2, \frac{0.4}{0.5} = 0.8)$. A_2 prefers 0.8 units of component 3 than one unit of component 2. A_2 has 0.375 unit of component 2. So, it will relinquish 0.375 unit of component 2 and receive $0.375 * 0.8 = 0.3$ unit of component 3 from A_1. So, after this exchange the possessions of A_1 and A_2 are $\{0, 1, 0.325\}$ and $\{1, 0, 0.675\}$, respectively. The utility of A_1 and A_2 are 0.5625 and 0.5375, respectively. Now, the number of issues left to be negotiated is one. So, we stop this process and we claim that this allocation of the units is Pareto optimal as one agent's utility cannot be improved without decreasing the other agent's utility. In Figure 1, the corresponding utility pair is shown by point $P_1 = (0.5625, 0.5375)$.

[3]We exclude the proof of the propositions due to space limitation.

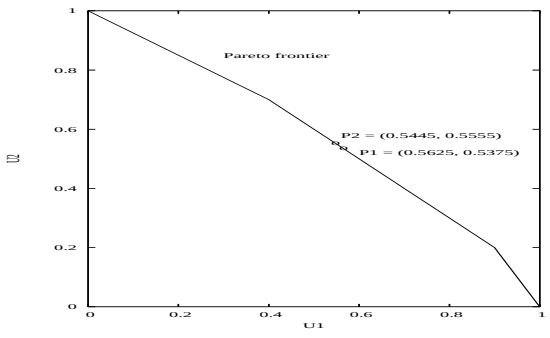

Figure 1: Bargaining solutions when weight of agent 1 is $\{0.1, 0.4, 0.5\}$ and weight of agent 2 is $\{0.2, 0.3, 0.5\}$.

If the random device chooses A_1 as the first agent instead of A_2 as in the above example, a similar process would lead the agents to the outcome where the possessions of A_1 and A_2 are $\{0, 1, 0.289\}$ and $\{1, 0, 0.711\}$, respectively, and the resultant utility pair is $P_2 = (0.5445, 0.5555)$, shown in Figure 1. Both the outcomes, P_1 and P_2, lie on the Pareto-frontier.

4. CONCLUSIONS AND FUTURE WORK

In multi-issue negotiation between two rational agents, there is a trade off between the quality of the agreement reached and the amount of information revealed. We proposed one protocol, where rational agents, without prior knowledge of the opponent preference, are guaranteed to reach a stable, envy-free, Pareto optimal solution if their ordinal preference rankings are identical. For arbitrary agent preferences, this protocol will lead rational agents to Pareto optimal solutions in most cases or otherwise very close to the Pareto optimal solutions while revealing minimal information.

ABSTRACT

Social in uences play an important part in the actions that an individual agent may perform within a multi-agent society. However, the incomplete knowledge and the diverse and con icting in uences present within such societies, may stop an agent from abiding by all its social in uences. This may, in turn, lead to con icts that the agents need to identify, manage, and resolve in order for the society to behave in a coherent manner. To this end, we present an empirical study of an argumentation-based negotiation (ABN) approach that allows the agents to detect such con icts, and then manage and resolve them through the use of argumentative dialogues. To test our theory, we map our ABN model to a multi-agent task allocation scenario. Our results show that using an argumentation approach allows agents to both ef ciently and effectively manage their social in uences even under high degrees of incompleteness. Finally, we show that allowing agents to argue and resolve such con icts early in the negotiation encounter increases their ef ciency in managing social in uences.

Argumentation-based Negotiation, Con ict Resolution.

1. SOCIAL ARGUMENTATION MODEL

In abstract, our framework consists of four main elements: (i) a *schema* for reasoning about social in uence, (ii) a set of *social arguments* that make use of this schema, (iii) a *language and protocol* for facilitating dialogue about social in uence, and (iv) a set of *decision functions* that agents may use to generate dialogues within the protocol (for a comprehensive formal representation of the framework refer to [3, 4]).

1.1 Social Influence Schema

The notion of *social commitment* [1] acts as our basic building block for capturing social in uence. In essence, a social commitment ($\mathrm{SC}_{\theta}^{x \rightarrow y}$) is a commitment by one agent x (termed the *debtor*) to another y (termed the *creditor*) to perform a stipulated action . As a result of such a social commitment, the debtor is said to attain an *obligation* toward the creditor, to perform the stipulated action. The creditor, in turn, attains certain rights (i.e., the right to demand or require the stipulated action, the right to question its non-performance, and the right to demand compensation to make good any losses suffered due to its non-performance). We refer to these as *rights to exert influence*. We extend this notion to capture social in uences resulting due to factors such as roles and relationships within a wider multi-agent society (i.e., those that rely on the structure of the society, rather than the speci c individuals who happen to be committed to one another). Speci cally, since most relationships involve the related parties carrying out certain actions for each other, we can view a relationship as an encapsulation of social commitments between the associated roles. Figure 1 formulates these notions as a schema of social in uence.

1.2 Social Arguments

The social in uence schema can be used to systematically identify social arguments that can be used to negotiate in the presence of social in uences. Speci cally, we identify two major ways:

Socially Influencing Decisions: In a social context, an agent can affect another agent's decisions by arguing about the validity of the other's social reasoning. Speci cally, agents can argue about the premises within the social in uence schema to undercut and rebut the justi cations to perform certain actions within a society.

Negotiating Social Influence: Agents can also use social in uences (i.e., obligations and rights) as additional parameters within their negotiations. Speci cally, here the agents use negotiation as a tool for trading social in uences .

1.3 Language and Protocol

To enable agents to express their arguments, we de ne two complimentary languages: the *domain language* and the *communication language*. The former allows the agents to express premises about their social context and the latter to construct arguments to engage in their discourse to resolve con icts. The protocol indicates the legal ordering of communication utterances and has six main stages: (i) *opening*, (ii) *conflict recognition*, (iii) *conflict diagnosis*, (iv) *conflict management*, (v) *agreement*, and (vi) *closing*. In operation, it is de ned as a dialogue game protocol which gives locutions rules, commitment rules, and structural rules for each of the locutions in the communication language.

1.4 Decision Making Functionality

The protocol described above gives agents a number of different options, at various stages, as to what utterances to make. For instance, after a proposal the receiving agent could either accept or reject it. After a rejection, the agent may choose to challenge this rejection, end the dialogue, or forward an alternative proposal. An

agent, therefore, still requires a decision mechanism for selecting a particular utterance among the available legal options. To this end, for each of the possible dialogue moves, we specify general decision making algorithms to give the agents that capability (see [3]).

2. ARGUMENTATION CONTEXT

To evaluate how our argumentation model can be used to manage social in uences, we require a computational context, in which a number of agents interact in the presence of social in uences and con icts arise as a natural consequence of these interactions. In abstract, the context is based on a multi-agent task allocation scenario where a collection of self-interested agents interact to obtain services to achieve a given set of actions (similar to that of [2]).

2.1 Modelling Social Influences

To map social in uences to this context we *first* embody a role-relationship structure into the multi-agent society by randomly linking a de ned number of roles to create relationships (see Figure 2(a) where 1 indicates that a relationship exists between the two related roles). *Second*, to this structure, we randomly specify a set of social commitments. We do so by de ning a decommitment penalty cost for each capability in each of the active edges (see Figure 2(b)). For instance, in Figure 2(b) the entry [400:100] in row 1, column 2 indicates that the role r_0 is committed to provide capabilities c_0 and c_1 to a holder of the role r_1. If the agent holding the role r_0 chooses to violate this commitment it will have to pay 400 and 100 (respectively for c_0 and c_1) if asked. *Finally*, we assign these roles to the actual agents using the mapping shown in Figure 2(c).

Since one of the aims in our experiments is to test how agents use argumentation to manage and resolve con icts created due to incomplete knowledge about their social in uences, we generate a number of settings by varying the level of knowledge seeded to the agents. Speci cally, we give only a subset of the agent-role mapping. Thus, a certain agent may not know all the roles that it or another agent may act. This lack of knowledge may, in turn, lead to con icts within the society, since certain agents may know certain facts about the society that others are unaware of. By controlling the level of missing knowledge, we generate an array of settings ranging from perfect knowledge (0% missing knowledge) to the case where agents are completly unaware of their social in uences (100% missing knowledge) within the society.

2.2 Agent Interaction

Agents within the system argue and negotiate with each other to nd willing and capable partners to accomplish their actions. In essence, an agent that requires a certain capability will generate and forward *proposals* to another selected agent within the community requesting it to sell its services in exchange for a certain reward. If

2: H_p ← generateJustification() {Generate personal justification}
3: if (isValid(H_o) = false) then
4:     {Assert invalid premises of H_o}
5: else
6:     {Adopt premises of H_o into personal knowledge}
7: if (isValid(H_p) = false) then
8:     {Correct invalid premises of H_p within personal knowledge}
9: else
10:    {Assert H_p}
```

the receiving agent perceives this proposal to be viable and believes it is capable of performing it, then will *accept* it. Otherwise it will *reject* the proposal. In case of a reject, the original proposing agent will attempt to forward a modi ed proposal (Algorithm 1).

Agents detect con icts (such as the one highlighted in Section 2.1) by analysing the decommitment penalties paid by their counterparts for violating their social commitments. Once detected, agents attempt to resolve them by exchanging their respective justi cations. These would take the form of the social in uence schema and are then analysed to diagnose the cause of the con ict. If there are inconsistencies between them, social arguments are used to highlight these. If they are both valid, then each agent would point-out alternative justi cations via asserting missing knowledge (Algorithm2).

3. MANAGING SOCIAL INFLUENCES

To empirically evaluate how our ABN model allows agents to manage their social in uences, we de ne a number of different interaction strategies to allow the agents to manage con icts related to their social in uences and experiment their relative performance bene ts. The underlying motivation for these strategies is our social in uence schema, which gives the agents different rights; namely the right to demand compensation and the right to challenge non-performance of social commitments.

3.1 Demanding Compensation

If an agent violates a social commitment, one of the ways its counterpart can react is by exercising its right to demand compensation (see Section 1.1). This formulates our baseline strategy which extends our negotiation algorithm by allowing the agents to demand compensation in cases where negotiation fails (Algorithm 3). Once requested, the agent that violated its social commitment will pay the related the penalty. However, in imperfect information settings, a particular agent may violate a social commitment simply because it was not aware of it (i.e., due to the lack of knowledge of its roles or those of its counterparts). In such situations, an agent may pay a decommitment penalty different to what the other believes it should get, which may, in turn, lead to con icts. In such situations, our second strategy allows agents to use social arguments to argue about their social in uences and, thereby, manage their con icts (Algorithm 4). Our hypothesis here is that by allowing agents to argue about their social in uences we are providing them with a coherent mechanism to manage and resolve their con icts and, thereby, allowing them to gain a better outcome as a society. To this end, the former strategy acts as our control experiment and the latter as the test experiment (see Figure 3).

Algorithm 3 Claim-Penalty-Non-Argue strategy.

1: $isAccepted \leftarrow$ *negotiate*()
2: **if** $(isAccepted =$ **false**$)$ **then**
3: compensation $\leftarrow$ *demandCompensation*()

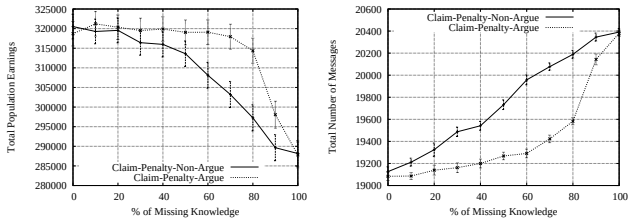
Algorithm 4 Claim-Penalty-Argue strategy.

1: $isAccepted \leftarrow$ *negotiate*()
2: **if** $(isAccepted =$ **false**$)$ **then**
3: compensation $\leftarrow$ *demandCompensation*()
4: **if** (compensation $<$ rightToPenalty) **then**
5: *argue*()

Observation 1: *The argumentation strategy allows agents to manage their social influences even at high uncertainty levels.*

The effectiveness of the the non-argue strategy falls more rapidly than the argue one. This is because the argue method allows agents to manage and resolve con icts of opinion that they may have about their social in uences. For instance, if a certain agent is unaware of a role that another acts, it may correct this through arguing with that agent. Thus, arguing allows agents to correct such gaps in their knowledge and, thereby, resolve any con icts that may arise as a result. In this manner, ABN allows the agents to manage their social in uences even at high uncertainty levels. Thereby, as a society, the agents can accomplish more of their actions and gain a higher total earnings value. The non-arguing approach, which does not allow them to argue about their social in uences, leaves such con- icts unresolved and reduces the population earnings as knowledge imperfections increase within the society.

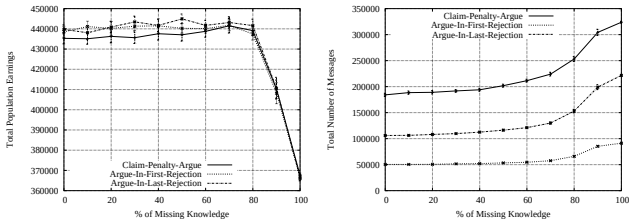
Observation 2: *In cases of perfect information and complete uncertainty both strategies perform equally.*



The reason for both strategies performing equally when there is perfect information (0 level) is because there are no knowledge imperfections. Thus, agents do not need to argue to correct con- icts simply because such con icts do not exist. The reason for both strategies performing equally when there is a complete lack of knowledge is because none of the agents in the society are aware of any social in uences (even though they exist). Thus, they are not able to detect any con icts or violations and, as a consequence, agents do not resort to arguing to manage such con icts. Therefore, when there is a complete lack of knowledge, the strategy that uses the argue performs the same as the non-argue one.

Observation 3: *At all knowledge levels, the argumentation strategy exchanges fewer messages than the non-arguing one.*

The reason for this is that, even though agents use some messages to argue and correct their incomplete knowledge, thereafter the agents use their corrected knowledge in subsequent interactions. However, if the agents do not argue to correct such knowledge imperfections, they negotiate more frequently since they cannot use their social in uence. Thus, this one-off increase of argue messages becomes insigni cant when compared to the increase in the propose, accept, and reject messages due to the increased number of negotiations.



3.2 Questioning Non-Performance

When a particular social commitment is violated our social in uence schema also gives the agents the right to challenge and demand a justi cation for this non-performance. It is generally argued in ABN theory that allowing agents to exchange meta-information gives them the capability to understand each others' reasons and, thus, provides a more ef cient method of resolving con icts under uncertainty. In a similar manner, we believe that providing the agents with the capability to challenge and demand justi cations for violating social commitments allows the agents to gain a wider understanding of the internal and social in uences affecting their counterparts, thereby, providing a more ef cient method for managing social in uences in the presence of incomplete knowledge. Using this intuition as the underlying hypothesis, we use our

(a) Effectiveness (b) Efficiency

Figure 4: Efficiency and Effectiveness of the various argumentation strategies.

previous best strategy *Claim-Penalty-Argue* as the control experiment and design two other strategies (*Argue-In-First-Rejection* and *Argue-In-Last-Rejection*) to experiment with the effect of allowing the agents to challenge non-performance at different stages within the negotiation encounter. The former allows the agent to challenge after the receipt of the rst rejection and the latter after the last rejection. Figure 4 shows our results.

Observation 4: *The effectiveness of the various argumentation strategies are broadly similar.*

This is because all three strategies argue and resolve con icts even though they decide to argue at different points within the encounter. Thus, we do not expect to have a signi cant differences in the number of con icts resolved. Thus, the effectiveness stays the same.

Observation 5: *Challenging earlier in the dialogue, significantly increases the efficiency of managing social influences.*

The reason for this behaviour is based on how the agents use these reasons exchanged during the argue phase. In the *Claim-Penalty-Argue* strategy the main objective of arguing is to resolve the con- ict regarding the penalty value that should be paid. It does not however, attempt to nd out the reason for why its counterpart rejected its proposal. By challenging the reason for the rejection, the latter two strategies gain certain meta-information, which the agents constructively use in their subsequent interactions. For instance, if the counterpart rejected the proposal due to lack of capability, it can be excluded in future if the agent requires a capability which is equal or greater. Arguing in the rst rejection provides this information earlier in the negotiation, which, in turn, gives the agent more capacity to exploit such information (even in the present negotiation) than getting it in the last encounter.

ABSTRACT

This paper presents a fuzzy constraint based model for bilateral multi-attribute agent purchase negotiations in competitive trading environments. Argumentation is used as a key mechanism to improve agreements, in contrast to other fuzzy constraint based models which are limited to quantitative offers and counter-offers. A set of locutions and decision mechanisms which fire them are specified, so that each agent may decide its degree of cooperation and expressiveness.

1. INTRODUCTION

The use of fuzzy constraints is an efficient way of capturing requirements, and a useful mechanism for representing trade-offs between the possible values of attributes [1, 3]. Moreover, the solution space can be explored in a given exchange and so means that the search for an agreement is more efficient. The problem with previous approaches is that the ability of the seller agent to express its needs is limited [3]. As a consequence the joint decision process is not balanced. We develop a more expressive approach which lets the buyer agent value the degree of importance that each submitted constraint has, and lets the seller agent inform how constraints should be relaxed. We propose a general framework to implement these mechanisms, so that each agent may decide its degree of cooperation and expressiveness, which in turn may have effects on the speed of convergence and the quality of the agreement.

2. DOMAIN KNOWLEDGE

Let $\mathcal{B}_{req} = (X, D, C^f, N_b)$ be the requirement model of the buyer agent, where $X = \{x_i | i = 1, ..., n\}$ is the set of attributes, $D = \{d_i | i = 1, ..., n\}$ is the set of domains of the attributes, and $C^f = \{R_i^f | i = 1, ..., m\}$ is the set of fuzzy constraints which expresses the requirements on the attributes. $N_b = \{\xi, \eta\}$ is the negotiation profile, where $\xi \in \{0, 1\}$ controls the use of purchase requirement valuations, and $\eta \in [0, 1]$ modulates the buyer's attitude regarding a relax requirement. The function that indicates how well a given constraint R_i^f is satisfied is the *satisfaction degree function*: $\mu_{R_i^f}(X) \rightarrow [0, 1], i = 1, ..., m$. The *overall (or global) satisfaction degree* of a potential solution p_X is defined as: $\alpha(p_X) = \oplus \left\{\mu_{R^f}(p_X) | R^f \in C^f\right\}$, where $\oplus$ is an aggregation from $[0, 1]^m$ to $[0, 1]$.

DEFINITION 1. *A purchase requirement is defined as* $\lambda_{\mathcal{B}_{req}} = \bigcap \left\{ R_i^{c(\sigma_j^i)} \right\}$, *where* $R_i^{c(\sigma_j^i)}$ *is the induced crisp constraint at cut level* $\sigma_j^i \in [0, 1]$. *A purchase requirement may be formed by a subset of fuzzy constraints, where* $\text{cons}(\lambda_{\mathcal{B}_{req}})$ *denotes the set of constraints associated with each* $\lambda_{\mathcal{B}_{req}}$.

DEFINITION 2. *Given a* $\lambda_{\mathcal{B}_{req}}$, *the potential overall satisfaction degree (posd) the buyer gets if this requirement is met is* $\alpha^{\lambda_{\mathcal{B}_{req}}} = \oplus \left\{\sigma_j^i\right\}$, *where the cut level applied to constraints which are not included in the* $\lambda_{\mathcal{B}_{req}}$ *takes value* 1.

DEFINITION 3. *Given a* $\lambda_{\mathcal{B}_{req}}^k$ *defined at instant* k, *a concession strategy may be defined as a mechanism which generates a new* $\lambda_{\mathcal{B}_{req}}^{k+1}$ *such that* $\alpha^{\lambda_{\mathcal{B}_{req}}^{k+1}} < \alpha^{\lambda_{\mathcal{B}_{req}}^{k}}$, *where* $\alpha^{\lambda_{\mathcal{B}_{req}}^{k}} - \alpha^{\lambda_{\mathcal{B}_{req}}^{k+1}}$ *is minimized.*

DEFINITION 4. *Given a* $\lambda_{\mathcal{B}_{req}}^k$, *a trade-off strategy may be defined as a mechanism which generates a new* $\lambda_{\mathcal{B}_{req}}^{k+1}$ *such that* $\alpha^{\lambda_{\mathcal{B}_{req}}^{k+1}} \geq \alpha^{\lambda_{\mathcal{B}_{req}}^{k}}$ *and* $\lambda_{\mathcal{B}_{req}}^{k+1} \neq \lambda_{\mathcal{B}_{req}}^{j} | \forall j < k + 1$.

DEFINITION 5. *Given a* $\lambda_{\mathcal{B}_{req}}^k$, *a purchase requirement valuation is defined as a set* $v_{\mathcal{B}_{req}} = \{v_i | v_i \in [0, 1], i \in \text{cons}(\lambda_{\mathcal{B}_{req}})\}$, *where* v_i *represents the degree of importance that the constraint* i *has for the buyer agent.*

Let $\mathcal{S}_{req} = (S, N_s)$ be the requirement model of the seller agent, which is defined by the set of products the seller holds and the profit that the seller agent gets if the product is sold, $S = \{s_j | s_j = (p_j, u_j), p_j = (a_{j1}, ..., a_{jn}), 0 \leq j \leq k\}$, where k is the total number of products; and a negotiation

profile $N_s = \{\psi, \beta\}$, where $\psi \in \{0, 1\}$ controls if the seller agent expresses its preferences for a specific relaxation of the buyer's demands, and $\beta \in [0, 1]$ modulates the seller's attitude regarding a purchase requirement valuation.

DEFINITION 6. *A sale offer is defined as* a product p_j.

DEFINITION 7. *A relax requirement is defined as a set* $\rho_{\mathcal{B}_{req}} = \{r_i | r_i \in [0, 1], i \in \text{cons}(\lambda_{\mathcal{B}_{req}})\}$, *where* r_i *represents the preference for constraint* i *to be relaxed.*

3. THE NEGOTIATION DIALOGUE

Our purchase negotiation dialogue is a four stage sequence [2]: *open dialogue* (L1-2), *negotiate* (L3-8), *confirm* (L9-10) and *close dialogue* (L11). A negotiation will involve a seller participant P_s who joins any dialogue initiated by a potential buyer P_b. These are the main locutions:

L3: willing_to_sell(P_s, P_b, p_j) indicates to the buyer P_b a willingness to sell a product p_j.
L4: desire_to_buy$(P_b, P_s, \lambda^k_{\mathcal{B}_{req}})$ requests to purchase a product which satisfies $\lambda^k_{\mathcal{B}_{req}}$.
L5: prefer_to_sell$(P_s, P_b, \lambda^k_{\mathcal{B}_{req}}, \rho_{\mathcal{B}_{req}})$ requests to relax $\lambda^k_{\mathcal{B}_{req}}$, and expresses which constraints are preferred to be relaxed by means of $\rho_{\mathcal{B}_{req}}$.
L6: prefer_to_buy$(P_b, P_s, \lambda^k_{\mathcal{B}_{req}}, \upsilon_{\mathcal{B}_{req}})$ requests to purchase a product which satisfies $\lambda^k_{\mathcal{B}_{req}}$. A purchase requirement valuation $\upsilon_{\mathcal{B}_{req}}$ is used.
L7: refuse_to_buy(P_b, P_s, p_j) expresses a refusal to purchase a product p_j.
L8: refuse_to_sell$(P_s, P_b, p_j | \lambda_{\mathcal{B}_{req}})$ expresses a refusal to sell a product p_j or products which satisfy the purchase requirement $\lambda_{\mathcal{B}_{\text{req}}}$.
L9: agree_to_buy(P_b, P_s, p_j) and
L10: agree_to_sell(P_s, P_b, p_j) express a commitment to buy or sell a product p_j.

4. THE DECISION MECHANISMS

According to the participants (Buyers **B** or Sellers **S**):
B1: Recognize Need initiates a purchase dialogue by means of a user interface. **Outputs:** have_need(θ), where θ is a category of products.
B2: Generate Purchase Requirement generates a new purchase requirement. **Outputs:** $\emptyset$, $\lambda^k_{\mathcal{B}_{req}}$.

There are two basic strategies: **(a)** add a new constraint when the first $\lambda_{\mathcal{B}_{req}}$ is generated or when a sale offer cannot be accepted, or **(b)** relax $\lambda^k_{\mathcal{B}_{req}}$. An empty set $\emptyset$ is generated as output if none of these strategies can be used. In case (b), if the received locution is a refuse_to_sell(), we define a meta strategy which consists in applying when possible the trade-off strategy, and otherwise the concession one, so the loss of posd is minimized. If the received locution is a prefer_to_sell(), a cooperative strategy may be applied:

DEFINITION 8. *Given* $\rho^k_{\mathcal{B}_{req}}$ *as a response to a* $\lambda^k_{\mathcal{B}_{req}}$, *a cooperative strategy is a mechanism which generates a new* $\lambda^{k+1}_{\mathcal{B}_{req}cooperative}$ *as a function of* $\rho^k_{\mathcal{B}_{req}}$ and $\lambda^k_{\mathcal{B}_{req}}$, *which must integrate the demands of the seller agent.*

This strategy is useful when a buyer agent has several alternatives to generate a new purchase requirement. Taking into account the demands of the seller agent, the speed of convergence and the joint utility may be increased. Obviously, both parameters must be requirements for the buyer agent. We propose the following algorithm to relax a purchase requirement.

Algorithm 1 (1) Obtain the set $\{\alpha^{\lambda^{k+1}_{\mathcal{B}_{req}}}_{R^f_i} | \forall i \in \text{cons}(\lambda^{k+1}_{\mathcal{B}_{req}})\}$, where $\alpha^{\lambda^{k+1}_{\mathcal{B}_{req}}}_{R^f_i}$ is the *posd* when R^f_i is relaxed; (2) Compute $\alpha^{\lambda^{k+1}_{\mathcal{B}_{req}cooperative}} = \odot(\{\alpha^{\lambda^{k+1}_{\mathcal{B}_{req}}}_{R^f_i} | \forall i \in \text{cons}(\lambda^{k+1}_{\mathcal{B}_{req}})\})$, where $\odot$ is an aggregation operator; (3) Obtain $_{feasible}\{\lambda^{k+1}_{\mathcal{B}_{req}}\}$ as the set of elements which satisfy $\alpha^{\lambda^{k+1}_{\mathcal{B}_{req}}}_{R^f_i} \geq \alpha^{\lambda^{k+1}_{\mathcal{B}_{req}cooperative}}$; (4) Relax the constraint obtained by means of the csf function:

$$\arg\Big(\max_{feasible\{\lambda^{k+1}_{\mathcal{B}_{req}}\}} \alpha^{\lambda^{k+1}_{\mathcal{B}_{\text{req}}}}_{R^f_i} + r_i * \eta\Big)$$

B3: Generate Purchase Requirement Valuation obtains the valuation of a $\lambda_{\mathcal{B}_{req}}$. **Outputs:** $\emptyset$, $\upsilon_{\mathcal{B}_{req}}$.

If $\xi = 0$ this mechanism returns an empty set $\emptyset$. Otherwise, a valuation of the purchase requirement must be obtained. A high valuation implies that the buyer agent prefers not to relax the constraint.

Algorithm 2 (1) Given a $\lambda^{k+1}_{\mathcal{B}_{req}}$ then obtain a vector with the *posd* for all the possible future purchase requirements: $\{\alpha^{\lambda^{k+2}_{\mathcal{B}_{req}}}_{R^f_i} | \forall i \in \text{cons}(\lambda^{k+2}_{\mathcal{B}_{req}})\}$; (2) Then apply the purchase requirement valuation function $prvf : \{\alpha^{\lambda^{k+2}_{\mathcal{B}_{req}}}_{R^f_i} | \forall i \in \text{cons}(\lambda^{k+2}_{\mathcal{B}_{req}})\} \rightarrow \upsilon_{\mathcal{B}_{req}}$. It represents a general framework to obtain the valuation of $\lambda_{\mathcal{B}_{req}}$.
B4: Consider Offers decides at a particular whether to: **(a)** accept an offer, when $\alpha(p_j) \geq \alpha^{\lambda^k_{\mathcal{B}_{req}}}$; **(b)** reject an offer, when for some reason it does not fall within a previously submitted $\lambda_{\mathcal{B}_{req}}$; or **(c)** generate a new $\lambda_{\mathcal{B}_{req}}$ when it does not exceed the actual *posd*. **Outputs:** accept_offer(p_j), reject_offer(p_j), generate_purchase_requirement(p_j).
B5: Consider Withdrawal generates the withdraw(θ) output. **Outputs:** withdraw(θ).
S1: Recognize Category assesses whether the seller has products to sell. **Outputs:** enter(θ), not_to_enter(θ).
S2: Assess Purchase Requirement assesses whether a proposed $\lambda_{\mathcal{B}_{req}}$ can be satisfied. **Outputs:** $\emptyset$, $\lambda^k_{\mathcal{B}_{req}}$, p_j.

Algorithm 3 (1) The seller agent searches for products which satisfy the purchase requirement; (2) If it cannot be satisfied and parameter $\psi = 0$, an empty set $\emptyset$ is returned; (3) If it cannot be satisfied and parameter $\psi = 1$ then $\lambda^k_{\mathcal{B}_{req}}$ is returned; (4) From the products which satisfy the buyer's requirement, choose those with the highest utility and which has been a sale offer a minimum number of times.
S3: Generate Potential Sale Offers selects products which the seller agent considers as good candidates for a future sale offer. **Outputs:** set S_p of products.

If a seller agent cannot satisfy a $\lambda_{\mathcal{B}_{req}}$, it may encourage the buyer agent to change its proposals. A good alternative to promote a convergence in the negotiation is to express how $\lambda_{\mathcal{B}_{req}}$ should be relaxed. This mechanism treats the first task in this process: the selection of products which the seller agent would prefer to sell. We have identified two main aspects when making this selection: *local utility*, which depends on the u_j parameter; and *viability*, which depends on the similarity between the product p_j and $\lambda^k_{\mathcal{B}_{req}}$, as well as on an estimate of the sale offer p_j buyer's valuation. The β parameter modulates both aspects. So we define the *prefer*

function which measures the goodness of a sale offer in terms of utility and viability as:

$$prefer(p_j) = \beta * u_j + (1 - \beta) * \hat{viability}(p_j, \lambda^k_{\mathcal{B}_{req}}, \upsilon_{\mathcal{B}_{req}})$$

Algorithm 4 (1) Take all the products in the catalogue and compute the function *prefer*; (2) Fix a threshold and select those products with a *prefer* value exceeding this threshold. This is the set S_p.

S4: Generate Relax Requirement obtains the relax-requirement $\rho_{\mathcal{B}_{req}}$. **Outputs:** $\rho_{\mathcal{B}_{req}}$.

Given a set of potential sale-offers S_p, it generates a $\rho_{\mathcal{B}_{req}}$ in order to encourage the buyer agent to buy one of the products contained in S_p.

Algorithm 5 (1) For each potential sale-offer see which constraints from $\lambda_{\mathcal{B}_{req}}$ are not satisfied; (2) Generate $\rho_{\mathcal{B}_{req}}$, where $r_i = 1$ when constraint R^f_i has not been satisfied for any product, and otherwise $r_i = 0$.

S5: Accept or Reject Offer returns accept(p_j) if the sale-offer accepted by the buyer agent still exists and otherwise reject(p_j). **Outputs:** accept(p_j), reject(p_j).

S6: Consider Withdrawal generates the withdraw(θ) output when invoked. **Outputs:** withdraw(θ).

5. OPERATIONAL SEMANTICS

Operational semantics provides a formal linkage between the dialogue locutions and the semantic mechanisms previously defined. We use the notation in [2] which defines $\langle P_x, \mathbf{K}, s\rangle$ to denote the mechanism with number K and with output s of agent P_x. The transition rules are:

TR1: $\langle P_b, \mathbf{B1}, have\_need(\theta)\rangle \xrightarrow{\mathbf{L1}} \langle P_s, \mathbf{S1}, .\rangle$
TR2: $\langle P_s, \mathbf{S1}, not\_to\_enter(\theta)\rangle \rightarrow \langle P_s, \mathbf{S1}, .\rangle$
TR3: $\langle P_s, \mathbf{S1}, enter(\theta)\rangle \xrightarrow{\mathbf{L2}} \langle P_b, \mathbf{B2}, .\rangle$
TR4: $\langle P_b, \mathbf{B2}, \emptyset\rangle \rightarrow \langle P_b, \mathbf{B5}, .\rangle$
TR5: $\langle P_b, \mathbf{B5}, withdraw(\theta)\rangle \xrightarrow{\mathbf{L11}} \langle P_s, \mathbf{S6}, .\rangle$
TR6: $\langle P_s, \mathbf{S6}, withdraw(\theta)\rangle \xrightarrow{\mathbf{L11}} \langle P_b, \mathbf{B5}, .\rangle$
TR7: $\left\langle P_b, \mathbf{B2}, \lambda^k_{\mathcal{B}_{req}}\right\rangle \rightarrow \langle P_b, \mathbf{B3}, .\rangle$
TR8: $\langle P_b, \mathbf{B3}, \emptyset\rangle \xrightarrow{\mathbf{L4}} \langle P_s, \mathbf{S2}, .\rangle$
TR9: $\left\langle P_b, \mathbf{B3}, \upsilon_{\mathcal{B}_{req}}\right\rangle \xrightarrow{\mathbf{L6}} \langle P_s, \mathbf{S2}, .\rangle$
TR10: $\langle P_s, \mathbf{S2}, \emptyset\rangle \xrightarrow{\mathbf{L8}} \langle P_b, \mathbf{B2}, .\rangle$
TR11: $\langle P_s, \mathbf{S2}, saleoffer(p_j)\rangle \xrightarrow{\mathbf{L3}} \langle P_b, \mathbf{B4}, .\rangle$
TR12: $\left\langle P_s, \mathbf{S2}, purchasereq(\lambda^k_{\mathcal{B}_{req}})\right\rangle \rightarrow \langle P_s, \mathbf{S3}, .\rangle$
TR13: $\langle P_s, \mathbf{S3}, S_p\rangle \rightarrow \langle P_s, \mathbf{S4}, .\rangle$
TR14: $\left\langle P_s, \mathbf{S4}, \rho_{\mathcal{B}_{req}}\right\rangle \xrightarrow{\mathbf{L5}} \langle P_b, \mathbf{B2}, .\rangle$
TR15: $\langle P_b, \mathbf{B4}, generatepurchasereq(p_j)\rangle \rightarrow \langle P_b, \mathbf{B2}, .\rangle$
TR16: $\langle P_b, \mathbf{B4}, acceptoffer(p_j)\rangle \xrightarrow{\mathbf{L9}} \langle P_s, \mathbf{S5}, .\rangle$
TR17: $\langle P_b, \mathbf{B4}, rejectoffer(p_j)\rangle \xrightarrow{\mathbf{L7}} \langle P_s, \mathbf{S2}, .\rangle$
TR18: $\langle P_s, \mathbf{S5}, accept(p_j)\rangle \xrightarrow{\mathbf{L10}} \langle P_b, \mathbf{B5}, .\rangle$
TR19: $\langle P_s, \mathbf{S5}, reject(p_j)\rangle \xrightarrow{\mathbf{L8}} \langle P_b, \mathbf{B2}, .\rangle$

6. A PURCHASE SCENARIO

A buyer desires to buy a product θ such that: $X_\theta = \{price, brand\}$, $D_\theta = \{[0, 30000], \{A, ..., J\}\}$, and $\oplus = min$. Figure 1 shows the buyer's preferences in a colored plane. The seller's catalogue is shown as a set of stars, circles and triangles representing products which give the seller agent a profit of 1.0, 0.5 and 0.1, respectively. The line describes the progress of the negotiation for both the inexpressive (dotted line) and expressive strategies. The progress of the negotiation in the first steps is the same in both strategies because all the potential sale offers are far from the buyer requirements, so the seller indicates the same preferences in the relax requirement. However, when $\lambda_{\mathcal{B}_{req}}$ is near to $(17000, E)$ and $(15000, D)$, the seller agent indicates that the brand constraint should be relaxed. For the buyer agent it is the same to relax the price or the brand constraint, so it relaxes the brand. The aggregated utility of the outcome is 1.4, while in the inexpressive strategy is 0.5.

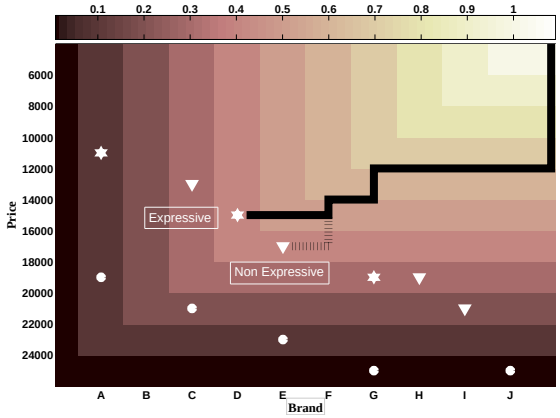

Figure 1: Expressive vs Inexpressive Strategies

7. CONCLUSIONS

This paper presents a model to support automated bilateral purchase negotiations using fuzzy constraints. All the internal decision mechanisms and the rules which govern interactions have been defined. In contrast to other fuzzy constraint models, in ours: (1) A buyer agent attends the seller's requirements in order to select the alternative from the set of trade-off proposals that is likely to benefit both agents. Typically this has been done employing an estimation of the similarity between an offer and the set of feasible counter-offers. The problem is that it is assumed that the potential offers are related among them, and this is not always the case. (2) Constraints can be valued in order to help the seller agent to make a more effective search. The purpose of this search is to select the more convenient potential sale offers in order to generate a balanced relax requirement. (3) Different attitudes for the seller and buyer agents can be easily modelled by means of the negotiation profiles.

ABSTRACT

In this paper we propose a formalism for symbolic negotiation. We regard symbolic negotiation as cooperative problem solving (CPS), which is based on symbolic reasoning and is extended with negotiation-specific rules. The underlying CPS formalism was previously presented in [3]. Here we extend the results and position symbolic negotiation according to other distributed problem solving mechanisms.

1. INTRODUCTION

Symbolic negotiation is regarded in the field of computer science as a process, where parties try to reach an agreement on the high-level means for achieving their goals by applying symbolic reasoning techniques. Formalisation of symbolic negotiation could contribute both to the studies of human behaviour and multi-agent systems. In the former field the rational part of human reasoning could be modelled, while in the latter field self-organising systems with adaptive behaviour could be implemented.

Previously, Küngas and Matskin proposed [2] that symbolic negotiation could be formalised as partial deduction (PD) for linear logic (LL). In [3] a formalisation of PD for LL was presented and its soundness and completeness was proved. The paper regarded symbolic negotiation as interleaved cooperative problem solving (CPS) and plan modification. However, the paper formalised only the CPS part of the process. In this paper we extend the proposed CPS formalism with plan modification operators and then analyse symbolic negotiaton as a whole. We also formalise the coalition formation process and analyse its effect to CPS and symbolic negotiation. Anyway, due to the limited space we do not present proofs for propositions and theorems in this paper.

We would like to underline that from a computational point of view, we can regard CPS as AI planning and symbolic negotiation as plan reuse/repair. It has been shown [5] that from problem solving point of view in general neither planning from scratch nor plan repair has an advantage over each-other. Therefore we expect both CPS and symbolic negotiation to be computationally equivalent. Moreover, both CPS and symbolic negotiation lead to the same results as we prove in this paper.

However, compared to CPS, symbolic negotiation provides a more human-like way of problem solving, which can be more naturally followed by human participants. In addition, symbolic negotiation may encode a sort of search heuristics, which would make CPS computationally less demanding. These heuristics, however, are not discussed in this paper.

2. LINEAR LOGIC AND PARTIAL DEDUCTION

2.1 Linear logic

LL is a refinement of classical logic introduced by J.-Y. Girard to provide means for keeping track of "resources". In LL two assumptions of a propositional constant A are distinguished from a single assumption of A. This does not apply in classical logic, since there the truth value of a fact does not depend on the number of copies of the fact. Indeed, LL is not about truth, it is about computation.

We consider the !-Horn fragment of LL (HLL) [1] consisting of multiplicative conjunction ($\otimes$), linear implication ($\multimap$) and "of course" operator (!). In terms of resource acquisition the logical expression $A \otimes B \vdash C \otimes D$ means that resources C and D are obtainable only if both A and B are obtainable. After the sequent has been applied, A and B are consumed and C and D are produced.

While implication $A \multimap B$ as a computability statement clause in HLL could be applied only once, $!(A \multimap B)$ may be used an unbounded number of times. When $A \multimap B$ is

applied, then literal A becomes deleted from and B inserted to the current set of literals. If there is no literal A available, then the clause cannot be applied. In HLL ! cannot be applied to formulae other than linear implications.

In order to explain HLL and demonstrate some other features of LL, not presented in HLL, let us consider the following LL sequent from [4]—$(D \otimes D \otimes D \otimes D \otimes D) \vdash (H \otimes C \otimes (O \& S) \otimes !F \otimes (P \oplus I))$, which encodes a fixed price menu in a fast-food restaurant: for 5 dollars (D) you can get an hamburger (H), a coke (C), either onion soup O or salad S depending, which one *you* select, all the french fries (F) you can eat plus a pie (P) or an ice cream (I) depending on availability (restaurant owner selects for you). The formula $!F$ here means that we can use or generate a resource F as much as we want—the amount of the resource is unbounded.

2.2 Partial deduction

Here we describe basic definitions required to understand PD. Most of the definitions in this section are from [3], where they were used to define a CPS formalism. The presented rules have to read in bottom-up manner.

DEFINITION 1. *Resultant is a linear implication*

$$\vdash I \multimap_{\lambda a_1,\ldots,a_n.f} O, n \geq 0,$$

where f is a term representing a function, which generates O from I by applying potentially composite functions over $a_1, \ldots, a_n$.

DEFINITION 2. *Forward chaining PD step $\mathcal{R}_f(L_i)$ is defined as a rule*

$$\frac{B \otimes C \vdash G}{A \otimes C \vdash G}\ \mathcal{R}_f(L_i)$$

where L_i is a labeling of linear implication $\vdash A \multimap_{L_i} B$. A, B, C and G are multiplicative conjunctions.

DEFINITION 3. *Backward chaining PD step $\mathcal{R}_b(L_i)$ is defined as a rule*

$$\frac{S \vdash A \otimes C}{S \vdash B \otimes C}\ \mathcal{R}_b(L_i)$$

where L_i is a labeling of linear implication $\vdash A \multimap_{L_i} B$. A, B, C and S are multiplicative conjunctions.

PD steps $\mathcal{R}_f(L_i)$ and $\mathcal{R}_b(L_i)$, respectively, apply L_i in forward and backward chaining manner.

3. AGENTS AND COALITION FORMATION

3.1 Agent representation

An agent is presented with the following HLL sequent:

$$\Gamma; S \vdash G,$$

where Γ is a set of agent capabilities, S is the initial state and G is the goal state of the agent. Both S and G are multiplicative conjunctions of HLL formulae.

Every element of Γ is a linear implication $\vdash I \multimap O$, where I and O are formulae which are, respectively, consumed and generated when a particular capability is applied. It has to be mentioned that a capability can be applied only, if conjuncts in I form a subset of conjuncts in S. It should be also underlined that in order to achieve their goals, agents have to construct (and then execute) the following plan from the elements of Γ:

$$\vdash S \multimap G.$$

Each agent is assumed to have a single task only. Whenever in an application an agent is supposed to have several task, it would be modelled in our framework as several agents, each having a single task.

DEFINITION 4. *Agent's task is a resultant in PD.*

Modifications of an agent's task are derived through PD. We consider all possible derivations of a task as instances of the same task. Moreover, we constrain an agent to consider only one derivation at time during distributed CPS. This would ensure that instances of the same task would not be solved concurrently.

DEFINITION 5. *Resource is a formula of HLL.*

3.2 Agent coalitions

The purpose of agent coalition formation in our formalism is to merge several tasks into a larger one. Then agents become able to perform tasks, which they would not have been able to perform individually. Thereby coalition formation could be seen as a way to optimize problem solving globally.

DEFINITION 6. *Agent coalition $\mathcal{C}$ is a structure $\langle \mathcal{A}, \mathcal{T}, \mathcal{R}, \triangleright, [] \rangle$, where $\mathcal{A}$ is a set of participanting agents, $\mathcal{T}$ is a coalition task and $\mathcal{R}$ is a set of resources shared between agents. $\triangleright$ is a mapping from agents to resources ($\triangleright : \mathcal{A} \times \mathcal{A} \rightarrow \mathcal{R}^*$), which one agent would deliver to another if a solution for a coalition task is found. Finally, $[]$ is a mapping from a coalition task to agents in the coalition ($[] : \mathcal{T} \rightarrow \mathcal{A}^+$), which agreed to solve the task together by sharing their resources.*

We interpret a coalition as an agreement between agents to solve their tasks together. In a coalition agents can also exchange resources directly between themselves. Additionally it should be emphasised that we model tasks as (composite) actions consuming and producing resources. Coalitions are formed by applying rule *merge*.

DEFINITION 7 (COALITION FORMATION RULE). *Coalition formation rule merge is defined as follows:*

$$\frac{\vdash A \otimes B \multimap C \otimes D}{\vdash A \multimap C \quad \vdash B \multimap D}\ \textit{merge}$$

Rule *merge* combines 2 tasks X and Y to create a task with the intended meaning: "task X could be performed by one agent, if another agent performs task Y" and vice versa. From a distributed theorem proving point of view it means that tasks X and Y are combined together and their search spaces are merged. If a coalition includes all agents of a system, then problem solving is seen as solving a single task in a distributed manner. This contrasts with our general case, where multiple tasks are solved concurrently in a distributed way.

PROPOSITION 1. *Solution of a coalition task $\mathcal{T}$, which was achieved through PD, solves the tasks of all coalition members $[\mathcal{T}]$.*

DEFINITION 8 (SOUNDNESS OF COAL. FORMATION). *If a solution of coalition task $\mathcal{T}$ solves the tasks of all participating agents $[\mathcal{T}]$, then coalition formation is sound.*

PROPOSITION 2. *Coalition formation is sound with respect to PD.*

Coalition formation could be seen from problem solving point of view as merging several tasks into one. Thus instead of solving multiple tasks concurrently, with coalitions we would solve a composed task.

PROPOSITION 3. *If a set of tasks included in a coalition task is solvable through PD independently, then so is the composed coalition task.*

DEFINITION 9 (COMPLETENESS OF COAL. FORMATION). *If agents' tasks were solvable individually and their coalition task is solvable as well, then coalition formation is complete.*

PROPOSITION 4. *Coalition formation is complete with respect to PD.*

DEFINITION 10. *A coalition task is implicitly solved, if no PD steps are required to solve the coalition task.*

4. SYMBOLIC NEGOTIATION

In this section we define the symbolic negotiation process with respect to PD. We define also symbolic negotiation rules for operating over forward (Θ_f) and backward chaining (Θ_b). Additionally some other negotiation-specific definitions are given. Finally, we prove that symbolic negotiation is sound and complete.

DEFINITION 11. *Negotiation rule $\Theta_f(a_k/a_i)$ is defined as the the following operational rule:*

$$\frac{\begin{array}{c}\vdash ((((I \setminus O(a_i)) \cup I(a_i)) \setminus I(a_k)) \cup O(a_k)) \\ \multimap_{a_1,\ldots,a_{i-1},a_k,a_{i+1},\ldots,a_n} O\end{array}}{\begin{array}{c}\vdash I \multimap_{a_1,\ldots,a_{i-1},a_i,a_{i+1},\ldots,a_n} O \\ I(a_k) \subseteq I(a_i) \quad O(a_i) \subseteq O(a_k)\end{array}} \Theta_f(a_k/a_i)$$

DEFINITION 12. *Negotiation rule $\Theta_b(a_k/a_i)$ is defined as the following operational rule:*

$$\frac{\begin{array}{c}\vdash I \multimap_{a_1,\ldots,a_{i-1},a_k,a_{i+1},\ldots,a_n} \\ ((((O \setminus I(a_i)) \cup O(a_i)) \setminus O(a_k)) \cup I(a_k))\end{array}}{\begin{array}{c}\vdash I \multimap_{a_1,\ldots,a_{i-1},a_i,a_{i+1},\ldots,a_n} O \\ I(a_k) \subseteq I(a_i) \quad O(a_i) \subseteq O(a_k)\end{array}} \Theta_b(a_k/a_i)$$

$I(a)$ and $O(a)$ in the preceding rules represent respectively resources required to apply and achieved by applying capability a. I represents resources available for solving a task while O represents resources, which must be achieved by the task. The preceding negotiation rules replace one PD step application in a task derivation with another. Rule $\Theta_f(a_k/a_i)$ replaces forward chaining steps while $\Theta_b(a_k/a_i)$ replaces backward chaining steps. The symbolic negotiation rules replace a capability in the derivation with another capability which consumed the same amount or less and generated the same amount or more resources than the previous capability. Therefore negotiation rules allow to optimise a task of agent X by agent Y. This means that some PD steps of agent X in its task are substituted by Y, if associated capabilities are more efficient in terms of resource consumption and generation.

DEFINITION 13 (SYMBOLIC NEGOTIATION). *Symbolic negotiation is PD with coalition formation and symbolic negotiation rules.*

DEFINITION 14 (CPS). *Cooperative problem solving is PD with coalition formation.*

DEFINITION 15 (COMPUTATIONAL EQUIVALENCE). *Two processes are computationally equivalent with respect to PD, if they would construct the same set of resultants.*

THEOREM 1. *CPS and symbolic negotiation are computationally equivalent.*

According to Theorem 1 symbolic negotiation could be view as a special case of CPS, where PD is guided at operational level.

DEFINITION 16. *Symbolic negotiation is sound, if it is sound with respect to PD, and all resultants achieved through symbolic negotiation are achievable through CPS.*

DEFINITION 17. *Symbolic negotiation is complete, if it is complete with respect to PD, and all resultants achieved through CPS are achievable through symbolic negotiation.*

THEOREM 2 (SOUNDNESS OF SYMBOLIC NEGOTIATION). *Symbolic negotiation is sound.*

THEOREM 3 (COMPLETENESS OF SYMB. NEGOTIATION). *Symbolic negotiation is complete.*

Soundness and completeness of our CPS formalism are directly derived from Proposition 2, Proposition 4 and completeness/soundness results of PD presented in [3].

ABSTRACT

Multi-issue negotiation mechanisms have been studied very widely and represent a promising eld because most negotiations in the real world are multi-issue negotiations. We model multi-issue negotiation with competitive agents. This re ects the real world in which people have to make agreements on constraints. A combinatorial winner determination mechanism is employed for solving a constraint satisfaction problem with competitive agents. The features of our protocol include Pareto e ciency on constraints. Our experimental results show that our proposed protocol is scalable with the number of agents, and that a heuristic method can achieve good utility. The above protocol is designed for linear utility domains. We also extend our protocol so that we can handle nonlinear utilities.

Multi-issue negotiation, Constraint Satisfaction, Nonlinear Utility

1. INTRODUCTION

Multi-Issue Negotiation mechanisms have been studied very widely[1][7][3][2][6] and represent a promising eld because most negotiations in the real world are multi-issue negotiations. In particular, in real world, issues are constrained with respect to each other. Also, even in collaborative situation, to get an agreement, agents need to act competitively because of their self-interested nature.

In multi-issue negotiations, agents need to nd a solution that consists of concrete issue values and concrete constraints. While this is frequent in real world negotiation, existing constraint satisfaction research does not address the notion of candidates for constraints. In this paper, we assume agents are competitive in the sense that they try to get an agreement that can give them a higher utility. The multistage bargaining protocol we proposed here instantiates constraints by using a combinatorial auction-like protocol, and then determining the issue values.

Most existing work also assumes that agents are totally collaborative. Our work focuses on mainly competitive agents. The competitive assumption can hold in many situation in the real world. Even in the collaborative negotiation, we believe that there are competitive situations. If designers are in one of the engine companies, for example, they have to competitively negotiate to make a decision in terms of the engine.

In addition, we extend our protocol so that it can handle nonlinear utility domains[4][5]. For the linear utility domain, we allow agents to aggregate the utilities of the issue-values by simple linear summation. However, in the real world, such aggregations are unrealistic. For example, we cannot just add up the value of a car's tyre and the value of a car's engine. First, we do not have any guarantees that such utilities can be added up. Second, there can be another constraint among the issues. For example, there can be a constraint between a car's color and engine. If a sports car does not have a gray body variant and there are only engines for sports cars, then we cannot select a gray body and a sports-type engine. In the real world, such constrains can exist in any situation. Therefore, in this paper, we extend our protocol to handle nonlinear utilities.

The rest of the paper is organized as follows. First we propose a bargaining protocol that achieves a desirable solution in multiple issue negotiations. Second we demonstrate the experimental results for a simple example. Then, we extend our protocol so that the protocol can handle nonlinear utilities. Finally concluding remarks are given in the nal section.

2. A COMPETITIVE COMBINATORIAL OPTIMZIATION NEGOTIATION

2.1 Multiple Issues Negotiations

A set of agents $a_1, a_2, \ldots, a_l$. Multiple issues, and constraints among issues.Each agent a_i has an evaluation value function $v_{a_i}(x_k)$ on each issue value x_k and an evaluation value function $v_{a_i}(c_k)$ on constraints. Agent a_i's utility is de ned as $u_{a_i} = \sum v_{a_i}(x_k) + \sum v_{a_i}(c_k) \quad c$, where $\sum v_{a_i}$ means the total of the evaluation values for issue values and constraints, and c is the payment for the auction. Agents try to maximize their utility. In this paper, we assume agents are competitive. This means that we cannot compute the entire optimal social welfare by making all agents reveal their utility functions.

2.2 Negotiation Mechanism

We adopt auction-like negotiations to determine constraints and issue values since agents are competitive.

(Stage 1 : Determining the constraints.) Each agent a_i makes bids on bundles of constraint instances. A bundle consists of one or more constraint instances that do not con- ict with each other. The mechanism selects a combination of bundles of constraint instances that maximizes social welfare i.e. maximizes the utilities of the accepted constraints. The mechanism announces the accepted constraints.

(Stage 2 : Determining the issue values.) Players make bids on the values of the issues. Auctions are held for each issues separately. We employ a 2nd price auction. The mechanism selects the combination of issue values that maximize social welfare for the issue values and satis es all constraints.

In this protocol, agents rst determine the constraints, and then determine issue values. In stage 1, a combinatorial auction maximizes social welfare with respect to constraints. In stage 2, a 2nd price auction maximizes social welfare with respect to issue values.

The proposed protocol is Pareto E cient. This is because the constraints are selected using a combinatorial optimization that maximizes social welfare in terms of the constraints. Then, the maximum utility issue values are selected so that these values can satisfy the selected constraints.

We propose a winner-based value assignment method for our negotiation protocol. Utilities on constraints can be related to utilities on issue values since satisfying a constraint totally depends on the issue values. We can expect that a user has high utilities for issue values that satisfy the related constraints. This means that a winner of constraints in stage 1 may have high utilities for the issue values that satisfy the constraints. Using this observation, we heuristically modi ed the stage 2 in the protocol as follows:

(Stage 2' : Determining the issue values by stage 1 winners.) Winners make bids on the values of the issues. Auctions are held for each issue separately. We employ a 2nd price auction. The mechanism selects a combination of issue values that maximizes the winners' social welfare with respect to issue values and satis es all constraints. Since the original stage 2 is a combinatorial optimization problem, it requires substantial computation power. The winner-based value assignment method can e ectively reduce this computation cost.

2.3 An Example

Here, we present an example of our negotiation protocol. Figure 1 outlines the problem. There are two constraints and three issues. Each constraint has two instances, $\{>, <\}$. Each issue has issue values, $\{1, 2, \ldots, 20\}$.

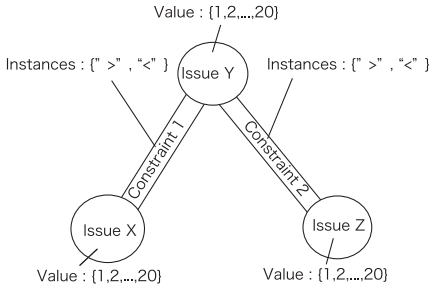

Figure 1: An example of the proposed protocol

We assume there are three agents. Also, we assume one coordinator agent who holds auctions and determines payments. In stage 1, each agent submits combinatorial bids on bundles of constraint instances. Each agent must solve a combinatorial problem to compute consistent bundles that do not con ict with each other. In this example, possible bundles include $\{<,\}, \{>,\}, \{,<\}, \{,>\}, \{>,>\}, \{<,>\}, \{>,<\}, \{<,<\}$. Each agent submits one or more bundles with their evaluation values.

Based on these submitted bundles, the coordinator agent searches for the combination of bundles that maximize social welfare and do not con ict with each other. The social welfare of a bundle is the sum of the evaluation values for the constraints in the bundle. We say there is a con ict in a bundle when there is no solution for the constraints in a bundle. The winners are determined.

The coordinator agent determines the payments for each winner, and announces the accepted constraint instances. For this example, we assume that the bundle $\{<,<\}$ is accepted.

For each issue, agents submit maximum evaluation values for issue values that satisfy the accepted constraints $\{<,<\}$. We do not need to assume agent's evaluation values are linear over issue values. For example, one agent can have the following evaluation values : \$20 for issue value 1, \$30 for issue value 2, and \$20 for issue value 3. Each agent searches for the maximum utility combination of evaluation values, and submits it.

The coordinator agent holds a second price auction for each issue, and determines the winner and the payment. This auction is strategy proof since the winner cannot manipulate his payment. Finally, the decided issue values and constraint instances are announced to all agents.

3. EXPERIMENTAL RESULTS

3.1 Definition of Agent's evaluation values

We conducted experiments using the example in the previous section. The negotiation problem is shown in Figure 1. We observed how the proposed negotiation protocols can obtain social surpluses when varying the number of agents.

For each experiment, we de ned the agent's evaluation values. There are 20 issue values and the maximum evaluation value is 10. We assume that each agent's evaluation value function has a single peak. The height of the peak

shows the maximum evaluation value for that issue. Each agent has evaluation value functions for each issue.

Evaluation values for constraints are de ned using the following equation: $v_{a_i}(c_k) = \max_S \sum_{x_{kj} \in S} u_{a_i}(x_{kj})$, where S is a set of values that satisfy constraint c_k. This shows that our domain is a linear utility domain. We describe how to extend it to nonlinear utility domains in the next section.

Figure 2 shows experimental results for a comparison in a competitive case. The vertical axis shows the obtained social surplus. The horizontal axis shows the number of agents. Even though the number of agents is large, we could determine winners since we assume just 2 items. The "CA-based protocol" is the combinatorial optimization based negotiation protocol proposed in section 2. The "CA & Winner-based Protocol" is the combinatorial optimization based negotiation protocol with the winner-based assignment method proposed From this graph, we can see that the CA & Winner-based protocol can work well even when the number of agents is 100; it obtains about %80 of the social surplus of the CA-based protocol.

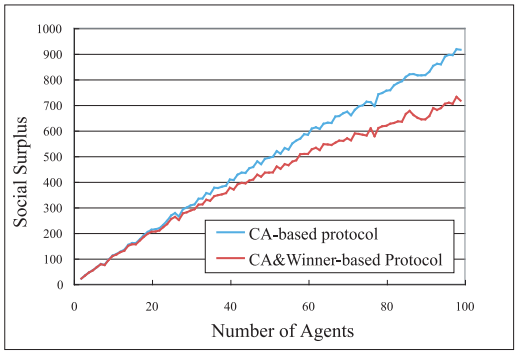

Figure 2: Experimental Results

4. A STEP TOWARD A NON-LINEAR UTILITY NEGOTIATION PROTOCOL

In the previous sections, we proposed a negotiation protocol for linear utility domains. In linear utility domains, we can sum up utilities among issues and constraints. However, in the real world, such aggregations are problematic. We cannot de ne the sum of the utilities for a car's color and a car's engine. Also, in the real world, we cannot assume that issues are independent. Multiple issues are almost always interdependent. In the previous sections, we assume that each agent calculates his utility for a constraint as the sum of the issue values that satisfy the constraint. This makes our domain a linear utility domain. In this section we relax this assumption so that our protocol can be applied to nonlinear utility domains.

First we slightly change the domain setting. A utility function is given that maps a contract (i.e. a set of issue values) to a utility value for each agent. Every agent has a set of constraints it wants to be satis ed. They can be binary constraints (e.g. $X > Y$) as well as unary constraints (e.g. $x = 3$). The binary constraints are what create the nonlinearity. Every constraint has a weight W. The utility of a constraint is W if the constraint is satis ed, and 0 if the constraint is not satis ed. The utility of a contract is the sum of the weights for every constraint that is satis ed by that contract The point is that the weights of the constrains are now the aggregation of the utilities of the issues.

Based on the above setting, the negotiation protocol can be modi ed as follows: A bid is a set of constraints. Agents calculate the utility of a bid by rst nding all contracts that satisfy all the constraints in the bid, and then returning the value of the best contract in that set. Agents conduct the VCG auction. Since each agent has to solve a constraint satisfaction problem, the computational cost is not low. However, we can handle nonlinear utility using this protocol.

The above protocol can generate multiple-optima utility functions that have valleys (for contracts that satisfy few or none of the constraints) as well as hills and mountains (for contracts that satisfy some or all of the constraints). Note that it is possible, even with this approach, to get a single optimum utility function, just depending on the particular constraints that apply for a given situation. But if we have a large enough space of possible contracts, as well as enough higher-order (binary or higher) constraints, it is likely that there will be multiple optima. In this case, in order to get the optimal contract, we have to have a method suitable for nonlinear optimization, e.g., stochastic search. In future work, we are going to construct such a negotiation protocol with competitive agents.

5. CONCLUSIONS

In this paper, we proposed an combinatorial optimization-based negotiation protocol among competitive agents. First we modeled a multi-issue negotiation with competitive agents. We proposed a variant of the auction-like negotiation protocol, in which we focus only on winners to reduce the size of the search space. The experimental results show the winner-based negotiation protocol can achieve good social surplus. In addition, we investigated the nonlinear utility model. The nonlinear utility model can represent more realistic negotiations. As a future work we are now investigating the nature of nonlinear utility negotiations.

ABSTRACT

We apply an adapted version of Particle Swarm Optimization to distributed unsupervised robotic learning in groups of robots with only local information. The performance of the learning technique for a simple task is compared across robot groups of various sizes, with the maximum group size allowing each robot to individually contain and manage a single PSO particle. Different PSO neighborhoods based on limitations of real robotic communication are tested in this scenario, and the effect of varying communication power is explored. The algorithms are then applied to a group learning scenario to explore their susceptibility to the credit assignment problem. Results are discussed and future work is proposed.

1. INTRODUCTION

Designing even simple behaviors for robots that are efficient and robust can be very difficult for humans; it is often not hard to implement a rudimentary controller that accomplishes the task, but achieving optimal performance can be very challenging. Unsupervised robotic learning allows for automated design of efficient, robust controllers, which saves much design time and effort. Unsupervised learning is also useful for allowing robots to adapt to situations where the task/environment is unknown beforehand or is constantly changing.

Genetic Algorithms (GAs) are a very common method of accomplishing machine learning and optimization. Candidate solutions to a problem are modeled as members of a population, and breeding (selection and crossover) and mutation are applied to "parents" (high performing solutions) in the population to generate "children" (new candidate solutions). GA can be used to shape an Artificial Neural Network (ANN) controller by using the parameter set as the weights, and the evaluative function as a measure of the performance of a desired robot behavior.

Particle Swarm Optimization (PSO) is a promising new optimization technique which models a set of potential problem solutions as a swarm of particles moving about in a virtual search space. The method was inspired by the movement of flocking birds and their interactions with their neighbors in the group. PSO can also be used to evolve ANN robotic controllers.

Both GA and PSO use groups of interacting virtual agents in order to achieve their optimization. In collective robotics, groups of robots interact to accomplish their goals. It may therefore be possible to implement these algorithms in a parallel distributed fashion for learning in multi-robot systems. Each robot would be responsible for several virtual agents, which it would need to evaluate at each iteration. After each set of evaluations, the robots would communicate to share the fitness information needed to progress to the next iteration of the algorithm. By running the algorithms in this fashion, we would need no external supervisor to oversee the learning process, and the speed of learning could be significantly improved, as many robots evaluating in parallel would decrease the number of required controller evaluations and therefore decrease the total learning time.

In the local neighborhood version of PSO, each particle only needs to be aware of the state of a small subset of particles in the population in order to update itself at each iteration. It may therefore be possible to implement PSO in a distributed manner where communication from any given node would only be necessary with several other nodes, making it a very scalable parallel approach. In contrast, the GA population manager must have knowledge of the entire population in order to implement standard breeding techniques, which prevents the same scalable technique from being applied.

In this paper, we explore the effectiveness of using a modified version of PSO on groups of realistically simulated robots performing distributed unsupervised learning. At the

maximum group size, the number of robots is set equal to the number of particles in the PSO population, allowing each robot in the group to manage a single unique particle. We test how the performance is affected if we adapt the standard PSO neighborhood structure to more closely model what is possible in a real robot group with limited communication abilities. Section 2 provides some background on GA, PSO, unsupervised robotic learning, and multi-robot learning. Section 3 examines how the effectiveness of distributed unsupervised learning is affected by the number of robots in the group. Section 4 analyzes how the learning performance is affected by different neighborhood structures based on the limitations of robotic communication when each robot contains a single particle. Section 5 focuses on one such neighborhood structure and tests the effect of varying the communication range of the robots. Section 6 applies the algorithms to a group learning task, to see how affected they are by the credit assignment problem and to see how the communication-based neighborhoods fare in different scenarios. Section 7 discusses the implications of the results and suggests future work, and Section 8 concludes.

2. BACKGROUND

Genetic algorithms were originally developed in the 1960s by John Holland. The algorithms are inspired by evolution, where the fittest members of a population tend to reproduce more often than the less fit members. Candidate solutions are modeled as a population of "chromosomes". At each iteration of the algorithm, a new population is generated from the previous one. Selection of the parents of the new generation is implemented using one or more of several schemes, such as elitism (using only the top performing members of the population), Roulette Wheel sampling (stochastically choosing parents with weight proportional to performance), and rank selection (ranking chromosomes from best to worst and stochastically choosing parents with weight proportional to the rank). After parents have been chosen, crossover between the parents can occur with some probability (each chromosome is split into two, and children use one part from one parent and the other part from the other). This allows positive aspects from different chromosomes to be merged into a single chromosome. Last, mutation is applied, where each element of the chromosome may have its value randomly changed with some probability. This provides a random local search, which allows solutions to continue to improve beyond the genetic diversity that was available in the original population ([6], [15]).

The original PSO method was developed by James Kennedy and Russel Eberhart ([9], [3]). Every particle in the population begins with a randomized position ($x_{i,j}$) and randomized velocity ($v_{i,j}$) in the n-dimensional search space, where i represents the particle index and j represents the dimension in the search space. Candidate solutions are optimized by flying the particles through the virtual space, with attraction to positions in the space that yielded the best results. Each particle remembers the position at which it achieved its highest performance ($x^*_{i,j}$). Each particle is also a member of some neighborhood of particles, and remembers which particle achieved the best overall position in that neighborhood (given by the index i'). This neighborhood can either be a subset of the particles (local neighborhood), or all the particles (global neighborhood). For local neighborhoods, the standard method is to set neighbors in a pre-defined way (such as using particles with the closest array indices as neighbors modulo the size of the population, henceforth known as a "ring topology") regardless of the particles' positions in the search space. The equations executed by PSO at each step of the algorithm are

$$\begin{aligned} v_{i,j} &= w \cdot (v_{i,j} + pw \cdot rand() \cdot (x^*_{i,j} - x_{i,j}) \\ &\quad + nw \cdot rand() \cdot (x^*_{i',j} - x_{i,j})) \\ x_{i,j} &= x_{i,j} + v_{i,j} \end{aligned}$$

where w is the inertia coefficient which slows velocity over time, pw is the weight given to the attraction to the previous best location of the current particle and nw is the weight given to the attraction to the previous best location of the particle neighborhood. $rand()$ is a uniformly-distributed random number in $[0, 1]$.

PSO has been shown to perform as well as or better than GA in several instances. Eberhart and Kennedy found PSO performs on par with GA on the Schaffer f6 function [3, 9]. In work by Kennedy and Spears [10], a version of PSO outperforms GA in a factorial time-series experiment. Fourie showed that PSO appears to outperform GA in optimizing several standard size and shape design problems [5].

Unsupervised learning describes learning scenarios where there is no external entity which decides upon the training set inputs for the learning agent(s). Rather, inputs are generated dynamically as the agents interact with their environment. This is as opposed to supervised learning, where the inputs are generated/collected first and then used repeatedly. In supervised learning, the accuracy of the system at each iteration is usually decided by an external "teacher" evaluating the system output. The pre-defined inputs are split into two separate sets, one for training the system and the other for testing the performance. Supervised learning tends to be easier than unsupervised, as the data does not change between iterations of the algorithm and can be preselected to avoid using unusual or particularly noisy data points. However, supervised learning is not possible in situations where the input data to the system depends on the current state of the learning agent; this is the case for online robotic learning, since the robot's movements affect what its sensors will perceive.

Evolutionary algorithms have been used extensively for unsupervised learning of robotic behavior. A good survey of the work is given in [12]. More specifically, standard GA has been shown to be effective in evolving simple robotic controllers [4], and modified noise-resistant versions of both GA and PSO were shown to achieve very good performance on simulated unsupervised robotic learning, outperforming the standard versions of the algorithms [18].

In collective robotics, many desired behaviors result in strong interactions between robots in the group, and the actions of one robot can significantly impact the performance of another. If a behavior is being learned and each robot is evaluating a different controller, this can give rise to the "credit assignment" problem, where robots do not know whether a good/bad fitness score was due to its own performance or to that of other robots. This effect can be particularly pronounced in cases where robots do not explicitly share their intentions through communication channels and can severely hamper the learning process. The credit assignment problem can arise in two different scenarios. The

first is when robots are learning individual behaviors, but the performance of their behavior can be impacted by the actions of other robots in the group, causing an inaccurate fitness evaluation. The second is when robots are learning a group behavior with a single collective fitness. Often, it is not easy to decompose the fitness value to know which robots positively affected the performance and which didn't. An elegant way to bypass the credit assignment problem in these cases is to use "homogenous" learning (as opposed to "heterogeneous" learning), where all the robots simultaneously evaluate the same controller and therefore contribute equally to the collective score on average. While this drastically slows the learning process, it is the only way of achieving good results in some highly stochastic scenarios, such as those investigated in Hayes et al. [7].

Multi-robot learning has been used and explored in various ways. Matarić studied mechanisms to encourage individual agents in a group to act in ways to help the group performance [11]. Multi-robot learning using several methods in a wide variety of scenarios has been explored ([2], [20]). Techniques for increasing individual learning speed via multi-robot learning were studied in [8] and [13]. A modified version of a genetic algorithm has been embedded onto a 2-robot system to allow for distributed parallel learning [17]. Particle swarm optimization has thus far not been used for learning in scalable multi-robot systems.

3. VARYING THE ROBOTIC GROUP SIZE

In Pugh et al. [18], unsupervised learning was used to teach robots obstacle avoidance behavior for both a single robot and two robots co-learning. We wish to expand this to test unsupervised learning on much larger robotic groups, where the evolving candidate solutions are distributed throughout the group to achieve faster learning.

3.1 Experimental Setup

We use the noise-resistant GA and PSO algorithms from [18]. GA uses elitism to select the best half of the population as the parent set, and then applies Roulette Wheel sampling to replenish the missing chromosomes. PSO uses a local neighborhood in a ring topology with one neighbor on each side. At every iteration, these algorithms reevaluate their previous best locations and parent sets for PSO and GA, respectively, combining the new fitness value with previous ones to get a more accurate measure of the actual fitness. Although this requires twice as many fitness evaluations at each iteration as their standard counterparts, this technique prevents noisy fitness evaluations from severely disrupting the learning process and gives much better results given the same amount of computational time.

We modify the noise-resistant PSO algorithm from its original form slightly: when updating the neighborhood best particle for particle i ($x^*_{i'}$), the neighborhood best is only changed if the new neighborhood best particle ($x^*_{i''}$) has higher fitness than the previous best location of the current particle. In other words

$$x^*_{i'} = x^*_{i''} \text{ only if } fitness(x^*_{i''}) > fitness(x^*_i)$$

It should be noted that this excludes the previous best location of a particle from ever being its neighborhood best. We found that this modification dramatically improved the performance of the learning over the standard update method. Although we are not certain why this is the case, it may be that the new technique encourages diversity by ensuring that every particle will have two distinct locations to which it is attracted.

The parameters for the algorithms are given in Table 1.

Table 1: GA and PSO Parameters for Unsupervised Learning

GA		PSO	
Population Size	20	Population Size	20
Crossover Probability	0.6	pw	2.0
Mutation Probability	0.15	nw	2.0
Mutation Range	[-5.0, 5.0]	w	0.6

We use Webots, a realistic simulator, for our robotic simulations [14], using the Khepera robot model [16]. The robot(s) operate in a 2.0 m x 2.0 m square arena (see Fig. 1). The robotic controller is a single-layer discrete-time artificial neural network of two neurons, one for each wheel speed, with sigmoidal output functions. The inputs are the eight infrared proximity sensors (six in front, two in back), as well as a recursive connection from the previous output of the neuron, lateral inhibitions and bias values (see Fig. 2), giving us 22 weights total. Sensors have a maximum range of 5.0 cm, and sensor output varies linearly from 0.0 at maximum range to 5.12 at minimum range (0.0 cm) with 10% noise. Slip noise of 10% is applied to the wheel speed. The time step for neural updates is 128 ms. We use the fitness function used in [18]. The fitness function is given by:

$$F = V \cdot (1 - \sqrt{\Delta v}) \cdot (1 - i)$$
$$0 \leq V \leq 1$$
$$0 \leq \Delta v \leq 1$$
$$0 \leq i \leq 1$$

where V is the average absolute wheel speed of both wheels, Δv is the average of the difference between the wheel speeds, and i is the average activation value of the most active proximity sensor over the evaluation period. These factors reward robots that move quickly, turn as little as possible, and spend little time near obstacles, respectively. The terms are normalized to give a maximum fitness of 1. The evaluation period of the fitness tests for these experiments is 480 steps, or approximately 60 seconds. Between each fitness test, the position and bearing of the robots are randomly set by the simulator to ensure the randomness of the next evaluation.

We test for robot group sizes of 1, 2, 5, 10, and 20 for 100 iterations of each algorithm. Since learning is being done in parallel, this has a significant effect on the simulated time needed ($\sim$67 hours for 1 robot compared to $\sim$3 hours for 20). In the case of 20 robots, each robot effectively contains a single candidate solution in the algorithm population.

3.2 Results

A comparison of the average fitnesses can be seen in Fig. 3. The progress of the average population fitness throughout the learning process for a 20-robot group can be seen in Fig. 4. There is no significant change in the performances of the algorithms for different robot group sizes, indicat-

ing that this technique is quite scalable. Although GA has initially faster convergence, the performance is noticeably lower than that of PSO for all group sizes. This was due to GA converging to poor solutions a large fraction of the time. A likely cause of this is the small population size (20 agents here as opposed to 60 in [18]), which does not provide enough genetic diversity for GA in this scenario, while PSO, though slower, is able to converge well with much smaller population sizes.

4. COMMUNICATION-BASED NEIGHBORHOODS

In multi-robot scenarios, communication range is often limited. Untethered robots have a very limited amount of available energy at their disposal, and it is important to conserve this by restricting transmission power. Also, if communication range is too large, interference between signals can decrease the rate at which data can be sent. If we distribute particles in a PSO population between robots and use the standard PSO local neighborhood model, robots may be required to share information with other robots that are far from their position. Therefore, to realistically model a scalable multi-robot system, particle neighborhoods should be set in such a way that robots are not required to communicate with other robots outside of some close proximity.

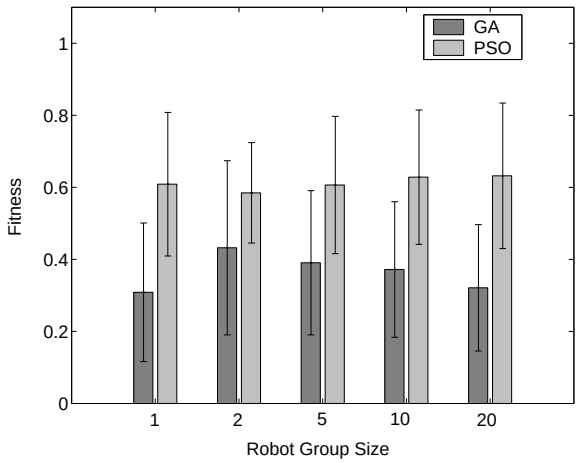

Figure 3: Average of final best performances over 20 evolutions for GA and PSO with different robotic group sizes. Error bars represent standard deviation across evolutionary runs.

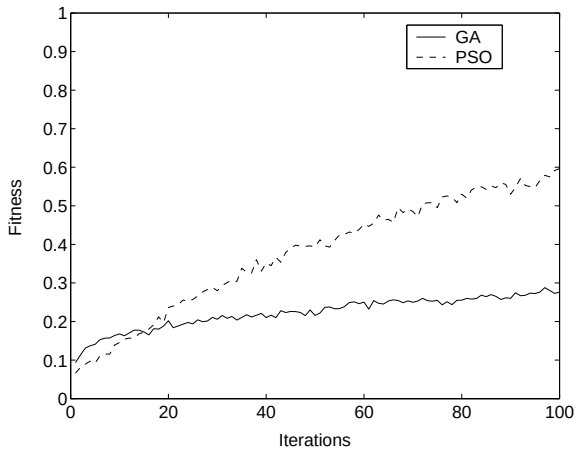

Figure 4: Average performance of population over 20 evolutions for GA and PSO with 20-robot groups.

4.1 Experimental Setup

We propose two such models for PSO neighborhoods to emulate realistic robot communication.

Model 1: Each robot contains one particle. At the end of each fitness evaluation, the robot selects the two robots closest to it, and uses their particles as its neighborhood for the next iteration of the algorithm. This maintains the same number of particles in the neighborhood, but allows for the neighbors to change over the course of the learning. As the physical location of the robots is independent of the particle indices, this should be roughly equivalent to randomly choosing two neighbors at each iteration of the algorithm, especially since obstacle avoidance behavior should result in a uniformly random distribution of robots within the environment.

Model 2: Each robot contains one particle. At the end of each fitness evaluation, the robot selects all robots within a fixed radius r, and uses their particles as its neighborhood for the next iteration of the algorithm. This results in a

variable number of neighbors, as the robot may be close to very few or very many robots randomly. However, it is perhaps more realistic than Model 1, since for very sparse robot distributions, there may be fewer than two other robots in close proximity at times.

We compare the performance of the original neighborhood topology to the two new models, using $r = 40$ cm, for a group of 20 robots. We use the setup previously described.

4.2 Results

A comparison of the average fitnesses is shown in Fig. 5. Both new neighborhood models achieve slightly better fitness than the original. This suggests that random neighborhood selection at each iteration is marginally superior to the fixed ring topology. The good performance of Model 2 indicates that the effectiveness of learning is not tied to keeping strictly two neighbors at each iteration. The success of these models shows that we can accomplish distributed unsupervised learning in a realistic multi-robot system.

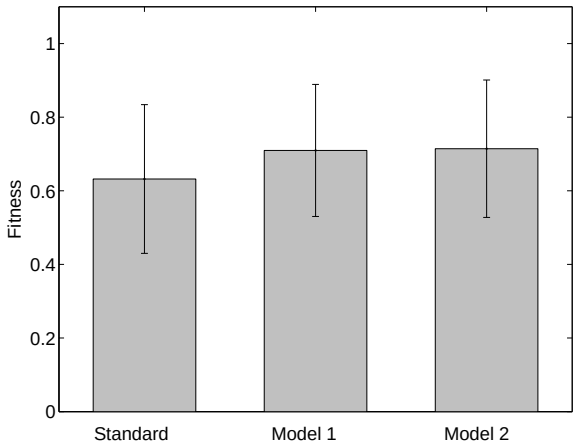

Figure 5: Average of final best performances over 20 evolutions for different neighborhood models. Error bars represent standard deviation across evolutionary runs.

5. VARYING COMMUNICATION RANGE

We now explore the effects of varying the communication range used in Model 2. This could be accomplished in a real robotic system by varying the output power of the transmission. It is useful to know the trade-off between output power and learning performance.

5.1 Experimental Setup

We use communication ranges of 10 cm, 20 cm, 40 cm, 80 cm, and 160 cm. The expected number of robots within communication range are given in Table 2, assuming a uniformly random distribution of robots within the arena. We therefore go from almost no interparticle communication to almost full interparticle communication.

5.2 Results

The average fitnesses for different communication ranges can be seen in Fig. 6. The progress of the average population fitness throughout the learning process for 10 cm, 40 cm, and 160 cm can be seen in Fig. 7. Both very high and very low communication ranges achieve fairly poor performance, while the intermediate ranges all achieve fairly good results.

Table 2: Expected Number of Neighboring Particles

r (cm)	Expected Number of Neighbors
10	0.14
20	0.54
40	2.0
80	6.5
160	16

Failure of low communication range is due to not enough information being exchanged between particles; particles end up almost exclusively using their own personal best position for learning, which causes extremely slow convergence. In the case of very high communication range, the initial convergence of the population was faster than with the shorter communication ranges, but it would often prematurely converge on a solution which did not have particularly high performance. This indicates that a global neighborhood is actually detrimental to finding very good solutions, and we therefore gain no benefit whatsoever by expanding our communication range beyond a certain point.

Both communication ranges of 40 cm and 80 cm (corresponding to average neighborhood sizes of 2.0 and 6.5 particles respectively) achieved very high fitness. Even a communication range of 20 cm, corresponding to 0.54 neighbors on average, achieved good fitness. The success of all these suggests that the effectiveness of the algorithm is not highly dependent on choosing an exact neighborhood size, making the algorithm parameters quite flexible. This is an important feature, as the communication range with real robots can vary due to obstruction and environmental effects.

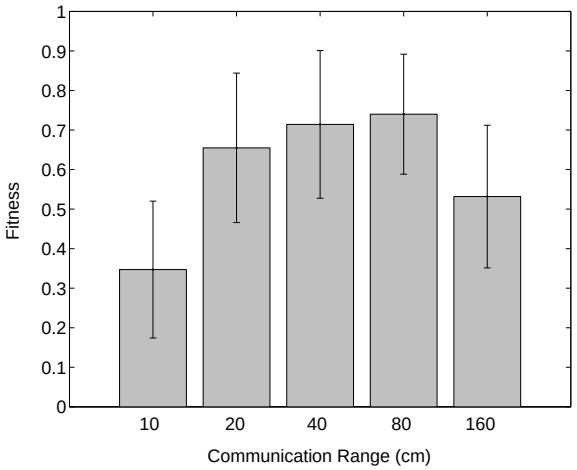

Figure 6: Average of final best performances over 20 evolutions for different communication ranges in Model 2. Error bars represent standard deviation across evolutionary runs.

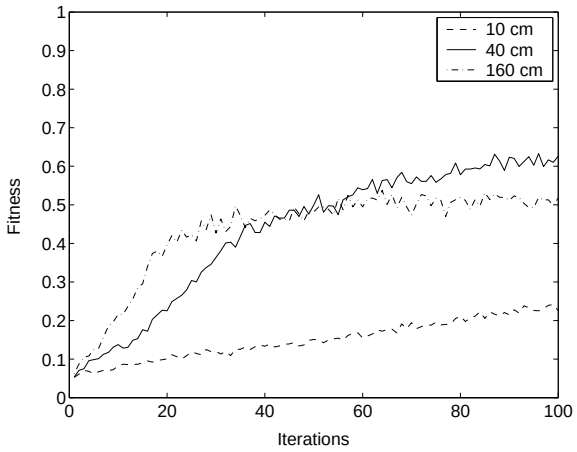

Figure 7: Average performance of population over 20 evolutions for 10 cm, 40 cm, and 160 cm communication range in Model 2.

6. GROUP LEARNING AND CREDIT ASSIGNMENT

Obstacle avoidance is a largely single-robot behavior. The observations and actions of other robots do not impact a robot's performance, except in having to avoid robots which move into its path. We wish to explore how susceptible our algorithms are to the credit assignment problem by evolving aggregation, a behavior whose success is highly dependent on the coordinated actions of many agents in the group.

6.1 Experimental Setup

We endow the Khepera robots with the ability to detect the relative positions of other nearby robots. This measurement is completely independent of any global coordinate system, and is given solely by where other robots are from the detecting robot's point of view (for example, range, the distance to the other robot, and bearing, the angular offset from the detecting robot's forward direction). This is a capability common to many robots working in collective scenarios, and can be accomplished with fairly simple systems (e.g., [19]). We add zero-mean Gaussian noise to the range and bearing, with range noise standard deviation equal to 10% of the range value and bearing noise standard deviation equal to 0.1 radians. We assume our relative positioning system is not susceptible to occlusions.

We expand the inputs to our artificial neurons to include relative positioning information. Because the number of robots within relative positioning range may vary, we use the center of mass of all detected robots as the input values. This is represented as x and y, where x is the forward-back displacement of the center of mass and y is the left-right displacement from the robot's point of view. This increases our total neural weights to 26.

The fitness value we use for this scenario is given by

$$F(i) = \frac{rob_{RP}(i)}{rob_{tot}}$$

where $F(i)$ is the fitness of robot i, $rob_{RP}(i)$ is the number of robots within relative positioning range of i, and rob_{tot} is the total number of robots. Therefore, a robot is rewarded for having the maximum number of other robots within relative proximity range at the end of a run.

The progress of evolving aggregation behavior may be susceptible to the first type of credit assignment problem described in Section 2, where robots use individual fitness values which can be impacted by the actions of other robots in the group, causing inaccurate evaluations. We therefore wish to compare the performance of our normal heterogeneous algorithms to homogenous algorithms, an established method of overcoming the credit assignment problem where all robots use the same controller at each evaluation. We generate a group fitness for each run by averaging all the individual fitness values obtained:

$$F_g = \frac{1}{rob_{tot}} \sum_i F(i)$$

Because the individual and group fitness functions are well-aligned, this allows us to compare their performances in a very fair manner. While homogenous learning will drastically slow the algorithm speed since we can no longer evaluate controllers in parallel, it will immediately provide a very noise-free estimation of the effectiveness of the solution, something which may not be available in the heterogeneous case (e.g., a robot may have a very good controller, but achieves poor performance because no other robot is aggregating well).

We use an unbounded arena with 20 Khepera robots for our setup. At each evaluative run, the Kheperas are distributed randomly in a 2m x 2m square. The evaluation lasts 10 simulated seconds, and the fitness is measured at the end. Robots are capable of sensing other robots within 80 cm of them. The arena can be seen in Fig. 8.

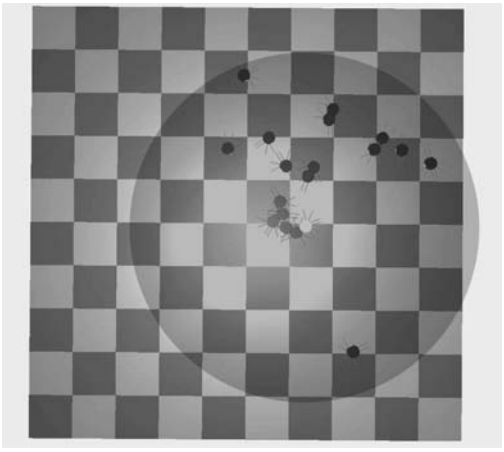

Figure 8: Aggregation arena with Khepera robots aggregating. The dimmed circle represents the relative positioning range of the white robot. All robots within this range are detectable.

We use our noise-resistant GA and PSO (with ring topology) algorithms and homogenous versions of these algorithms (HGA and HPSO, respectively), as well as the Model 1 and Model 2 neighborhood versions of the PSO algorithm. All algorithms have the same parameters used previously. Model 2 uses $r = 40$ cm. We run 100 iterations of the heterogeneous algorithms. Because we are using 20 robots, homogenous versions of the algorithms progress 20 times slower than the heterogeneous versions. We therefore run only 5 iterations

of these algorithms to match the number of evaluative runs.

6.2 Results

The final performance of all algorithms can be seen in Fig. 9. The progression of GA, PSO, HGA, and HPSO over the evolution can be seen in Fig. 10. All algorithms achieved good results in this scenario. For GA, the heterogeneous algorithm performed slightly worse than the homogenous version, while heterogeneous PSO performed as well as homogenous PSO on average, though with a higher standard deviation. This suggests that PSO may be less susceptible to the credit assignment problem than GA. However, as very few iterations were performed with the homogenous algorithms, it is likely HPSO would be able to achieve superior performance in longer runs. If we observe the progression of the algorithms throughout the learning process, GA initially improves more quickly, but levels off, while PSO continues to improve throughout. GA could therefore be preferable to PSO if we are only able to run very few iterations.

While the best final solutions from homogenous GA and PSO achieved very similar performances, the average population fitness for HGA was much higher than the average population fitness for HPSO throughout the learning process. This was observed in [18] and is likely due to the GA population containing much less variation than the PSO population, as the local neighborhood in PSO maintains diversity and no mechanism is present in GA to accomplish this. This diversity is likely what allows PSO to continue improving after the GA population converges on some solution.

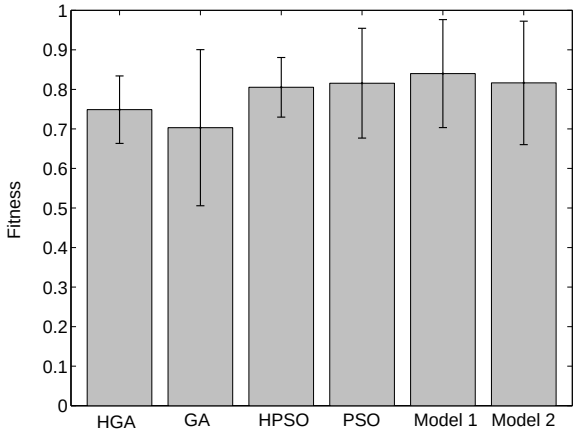

Figure 9: Average of final best performances in aggregation over 20 evolutions. HGA and HPSO are homogenous versions of the GA and PSO algorithms. Model 1 and Model 2 are PSO with neighborhoods described in Section 4. Error bars represent standard deviation across evolutionary runs.

Model 1 and Model 2 neighborhoods again achieved performances comparable to the standard ring topology, in spite of the very different distribution of robots in aggregation (high performing robots will be clustered together, while low performing robots may have traveled very far from the group center). The fact that these models continue to perform well is a good indication that neighborhoods based on limited communication capabilities of real robots can continue to function in a variety of scenarios.

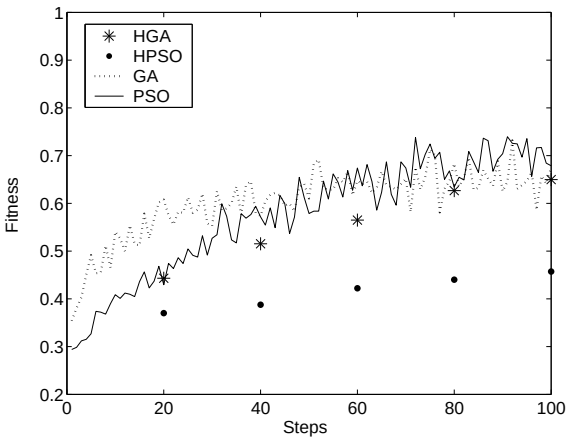

Figure 10: Average performance of population in aggregation over 20 evolutions. HGA and HPSO are the homogenous versions of the GA and PSO algorithms.

7. DISCUSSION AND OUTLOOK

Although PSO far outperformed GA in Section 2 of this paper, we suspect this is due almost exclusively to the small population size used. Indeed, the good performance of GA in Section 6 indicates that it can perform comparatively to PSO, and even better for fewer iterations. However, because of the different ways in which the population is managed, we would need to modify GA much more heavily in order to allow it to function distributedly with limited communication. Although this is certainly possible (e.g., as was done in [17]), the fundamental changes to the algorithm structure make it much more likely that we will lose the useful dynamics of the algorithm, as compared to PSO, where very few modifications are needed.

By increasing the robot group size from 1 to 20 robots, we were able to decrease the behavior learning time by a factor of 20. However, using a particle population size of 20, there is no easy to further decrease the time while maintaining only local interactions. It may be possible to use 40 robots to simultaneously evaluate the 20 new particles and reevaluate 20 previous best particles, but this would require a global supervisor to manage the assignments of candidate solutions to different robots, as each robot is no longer fully in charge of a particle. Therefore, further increasing the number of robots using only local interactions would only allow us to increase the size of the population. It has yet to be explored how increasing the population size could effect the convergence time.

In our model, the progress of all the robots was synchronized (i.e., fitness evaluations began and ended at the same time). In real-world multi-robot scenarios, this often isn't the case. Therefore, it would not make sense to exchange particle information only at the end of an evaluation, as the difference in time between robots could cause major delays. A simple alternative would be to exchange particle information on the previous evaluation during the evaluation itself. This is a rather minor modification to the algorithm, and we predict it will not significantly impact the performance. In fact, robots moving about during the evaluation would likely be exposed to more robots in close proximity, which

may allow them to further decrease their communication range while maintaining the same number of neighbors.

The model we use for communication in this paper is omnidirectional, immune to obstruction and error free. This corresponds to using radio transmissions in an open noiseless environment. In the real world, many other communication methods may be preferred or required. Infrared transmissions are often directional and could be blocked by other robots or by environmental obstacles. Radio could be blocked by large obstacles in some environments. Many types of communications may be susceptible to errors in noisy environments. The performance of the algorithm in these scenarios is thus far unexamined.

The scenario we used for testing susceptibility to the credit assignment problem only explored a small portion of the problem. It would be interesting to apply the algorithms to other scenarios, such those requiring specialization amongst robots or having less well-aligned group and individual fitness functions.

8. CONCLUSION

A modified version of the Particle Swarm Optimization algorithm was tested for unsupervised learning in groups of robots. The algorithm maintained good performance for groups of robots of various sizes. In the case of assigning a single unique particle to each robot, the performance was further improved by using PSO neighborhoods based on the limited communication abilities of real-world robots. Varying the communication range demonstrated that there is no benefit to communicating farther than a certain distance, and that the algorithm maintains high performance over a large variation of range. Applying the algorithm to a group learning task showed that it is able to overcome the credit assignment problem and that communication-based neighborhoods can perform well for non-uniform robot distributions. Implications of the results are examined and future research is suggested.

ABSTRACT

Autonomous robots need to track objects. Object tracking relies on predefined robot motion and sensory models. Tracking is particularly challenging if the robots can actuate on the object to be tracked, as the motion can become highly discontinuous and nonlinear. We have previously developed a successful tracking approach that switches among target motion models as a function of one robot's actions. In this paper, we consider the object to be effected by a team of agents. We contribute on our team-based tracking method that can use a dynamic multi-motion model based on a team coordination plan. We present the multi-target multi-model probabilistic tracking algorithm in detail and present empirical results both in simulation and in a human-robot Segway soccer team. The team coordination plan allows the robot to much more effectively track mobile targets.

1. INTRODUCTION

Autonomous robot agents need to be able to track moving objects. (e.g. [11]). When tracking is performed by a robot executing specific tasks acting over the target being tracked, such as a Segway RMP soccer robot grabbing and kicking a ball, the motion model of the target becomes dependent on the robot's actions [9]. The robot's tactic provides valuable information in terms of the target behavior. A tactic-based motion modeling and tracking in such scenarios has been introduced in [7].

However, the Segway RMP soccer robot operates in such a environment that all the players on the field can actuate over the ball, namely grab and kick the ball according to the rules, which makes the motion model of the ball even more complex. When the robot is joining a game as a member of a human-robot team, the team coordination knowledge provides further information that can be incorporated into the motion modeling and tracking process. Furthermore, the approach in [7] does not perform well once incorrect measurements originating from clutter or false alarms exist, which causes multiple hypothesis of the tracked target. Recently, a hybrid approach for online joint detection and tracking for multiple targets was proposed [10]. This approach does not assume the knowledge of true targets (without clutter) is given. It first uses a deterministic clustering method that searches for regions of interest (ROIs) based on the observations and monitors these ROIs for target detection, then performs multi-target tracking by Sequential Monte Carlo (SMC) methods. In this paper, based on their approach, we present an extension to the tactic-based tracking scheme introduced in [7] to solve a plan-dependent multi-target multi-hypothesis tracking problem.

The paper is organized as follows. We first give a brief description of the Segway RMP soccer robot. Next we show the system dynamics. We introduce play-based motion model which incorporates the team coordination knowledge. We then describe the multi-target multi-model tracking algorithm, leading to our experimental results, related work, and conclusions.

2. SEGWAY RMP SOCCER ROBOT

The Segway platform is unique due to its combination of wheel actuators and dynamic balancing [5]. Segway RMP, or Robot Mobility Platform, provides an extensible control platform for robotics research. It imbues the robot with the novel characteristics of a fast platform and travel long ranges, able to carry significant payloads, able to navigate in relatively tight spaces for its size, and provides the opportunity to mount sensors at a height comparable to human eye level [12].

In our previous work, we have developed a Segway RMP robot base capable of playing Segway soccer. We briefly describe the two major components of the control architecture, the sensor and the robot cognition, which are highly related to our multi-model motion tracking.

2.1 Vision Sensor and Infrared Sensors

The goal of vision is to provide as many valid estimates of targets as possible. Tracking then fuses this information to track the most interesting targets (the ball and the team member, in this paper) of relevance to the robot. We use one pan-tilt camera as the vision sensor. We do not discuss the localization of the robot in the sense that a lot of soccer tasks (known as tactics and plays described in section 2.2) can be done by the Segway RMP robot without localization knowledge. Also we use global reference for position and velocity in this paper which means it is relative to the reference point where the robot starts to do dead reckoning.

We have equipped each robot with infrared sensors to reliably detect the objects located in the catchable area of the robot. Its measurement is a binary value indicating whether or not an object is there. In most cases, this is the blind area of the pan-tilt camera. Therefore, the infrared sensor is particularly useful when the robot is grabbing the ball.

2.2 Robot Cognition

A control architecture, called Skills-Tactics-Plays, was proposed in [4] to achieve the goals of responsive, adversarial team control. The key component of STP is the division between single robot behavior and team behavior.

A play, P, is a fixed team plan consisting of a set of applicability conditions, termination conditions, and N roles, one for each team member. Each role defines a sequence of tactics $T_1, T_2, \cdots$ and associated parameters to be performed by that role in the ordered sequence. Assignment of roles to team members is performed dynamically at run time. Upon role assignment, each robot i is assigned its tactic T_i from the current step of the sequence for that role.

A tactic, T, encapsulates a single robot behavior. Each robot i executes its own tactic as created by the current play P. A tactic T_i determines the skill state machine SSM_i to be executed by the robot i.

A skill, S, is a focused control policy for performing some complex action. Each skill is a member of one, or more, skill state machines $SSM_1, SSM_2, \cdots$. Each skill S determines what skill it transitions to S' based upon the world state, the time skill S has been executing for, and the executing tactic for that robot.

We construct the robot cognition using a similar architecture. Plays, tactics, and skills, form a hierarchy for team control. Plays control the team behavior through tactics, while tactics encapsulate individual robot behavior and instantiate actions through sequences of skills. Skills implement the focused control policy for actually generating useful actions. Figure 1 shows the $SSMs$ and transitions for an example tactic: *CatchKickToGoal*, which contains six skills. Each node in the figure is a skill and the edges show the transition between skills.

Segway soccer is a team sport, and therefore the building of our game strategy required not only execution of single robot behavior , but also coordination with the team member, the human player. The current coordination is simple and basically based upon two fixed plays for offensive and defensive situation respectively. Our offensive play is shown as follows, in which the termination condition is either play aborted or the situation changed (a turn-over of ball possession announced by the referee). There are two roles in this play, one passes the ball to the other who positions down field and waits for receiving a pass. Once the positioning

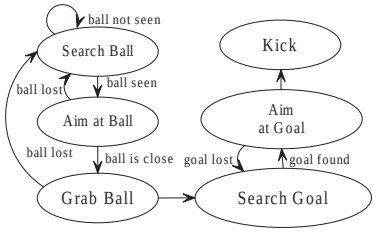

Figure 1: Skill state machines (SSMs) for an example tactic: *CatchKickToGoal*.

is done (e.g the other is closer to the opponent goal), the passing is performed.

```
PLAY Naive Offense
APPLICABLE offense
DONE aborted OR !offense
ROLE 1
  pass 2
  none
ROLE 2
  position_down_field
  receive_pass
  none
```

Our current coordination is purely observation based. Each player assigns role from his own eyeshot without communication. For example, should the robot think the team member is closer to the ball, the robot (ROLE 2) would choose to position and receive the ball from its team member (ROLE 1). Furthermore, the robot knows which side gains possession of the ball from the referee announcement, therefore it tells offensive from defensive situation clearly and thus it has deterministic idea of which play the team is using. The robot makes an assumption that its team member is performing the same game play as itself. The robot infers what tactic the team member is executing from the team play. For example, after receiving the ball from the team member, as a passer the robot would assume the team member go forward to a tactically advantageous position to receive a pass. The predefined play for team coordination helps motion modeling, which will be further discussed in section 3.

3. PLAY-BASED MOTION MODELING

In this section, we take a multi-target tracking problem as a detailed example to show the extension of the tactic-based motion modeling method in general when the team coordination knowledge (play) is incorporated. First we give an introduction of the environment and targets under the Segway soccer setup. Second, we describe detailed motion models for both the ball and the team member. Third, we extend the tactic-based motion modeling to the play level when both the ball and the team member are included into the tracking. We show how we model the play-dependent interactions between the team member, the robot and the ball and set up a base for giving the multi-model tracking algorithm in the next section. Although we present the Segway soccer domain as an example, the formalism is general.

3.1 Tracking Scenario

Many tracking scenarios involve multiple moving targets. In a Segway soccer game, we need to track the ball, the hu-

man team member and the two opponents. Each team is identified by their distinct color. The ball is orange [13]. An observation from the sensors might consist of multiple measurements due to the moving objects and the clutter. Generally the clutter has similar color as the targets we are interested in and it causes multiple hypothesis for the true targets. Therefore, we construct two multi-target trackers in the system, for the ball and the team member respectively. We use two separate trackers instead of one because we can differentiate the ball with the team member thanks to the color-based vision system. We use multi-target tracker instead of single target tracker because we can keep track of the true target and the false positive at the same time without losing any of them and perform ball(or team member) recognition from a pool of tracked objects later.

3.2 State Space and Dynamics

Let $\mathbf{x}_t = [\mathbf{x}_{1,t}^T, \mathbf{x}_{2,t}^T, \cdots, \mathbf{x}_{K_t,t}^T]^T$, denote a combined target state vector for K_t unknown and time-varying number of targets. The general parameterized system process for the kth target $\mathbf{x}_{k,t}$ at time t is given by:

$$\mathbf{x}_{k,t} \quad = \quad \mathbf{f}_k(\mathbf{x}_{k,t-1}, \mathbf{u}_{k,t-1}, \mathbf{v}_{k,t-1}) \tag{1}$$

where f_k is the parameterized state transition functions for the kth target; $\mathbf{x}, \mathbf{u}$ are the state and input vectors; $\mathbf{v}$ is the process noise vectors of known statistics. Given the number of targets at $t-1$ and t, the state transition can be represented as follows:

$$p(\mathbf{x}_t|\mathbf{x}_{t-1}, K_t, K_{t-1})$$

$$= \begin{cases} p_0(\mathbf{x}_{K_t,t}) \prod_{k=1}^{K_{t-1}} p(\mathbf{x}_{k,t}|\mathbf{x}_{k,t-1}), if\ K_t = K_{t-1}+1 \\ \prod_{k=1}^{K_t} p(\mathbf{x}_{k,t}|\mathbf{x}_{k,t-1}), if\ K_t = K_{t-1} \\ \prod_{k=1,k\neq k^*}^{K_{t-1}} p(\mathbf{x}_{k,t}|\mathbf{x}_{k,t-1}), if\ K_t = K_{t-1}-1 \\ 0,\ otherwise \end{cases} \tag{2}$$

The prior $p(\mathbf{x}_{k,t}|\mathbf{x}_{k,t-1})$ can be evaluated from (1). The function $p_0(\mathbf{x}_{K_t,t})$ is the initial distribution of a new target state and k^* is a target that vanishes at t. We assume at most one target appears or vanishes in each time step. The number of targets is obtained deterministically (see section 4.1 for the details).

3.3 Observation Model

We assume that measurements are independent of each other and either originate from true targets or clutter. Furthermore, each target generates at most one measurement in each time step but may not be detected by the sensor.

Let $\mathbf{z}_t = [\mathbf{z}_{1,t}^T, \mathbf{z}_{2,t}^T, \ldots, \mathbf{z}_{M_t,t}^T]$ denote an observation vector for M_t measurements. The observation equation for modeling the cth measurement originating from the kth target is given as:

$$\mathbf{z}_{c,t} \quad = \quad \mathbf{h}_k(\mathbf{x}_{k,t}, \mathbf{n}_{c,t}) \tag{3}$$

where $\mathbf{n}_{c,t}$ is a zero-mean observation noise with a known covariance Σ_n. The measurement originating from a clutter is modelled to be uniformly distributed within the entire visible region (observation volume V) of the camera. We use a deterministic method to perform measurement-to-target association. Let α_t denote the association vector which indicate the measurement-to-target assignment, whose ith element $\alpha_{i,t}$ is set to j if the ith measurement originates from the jth target, or zero if it originates from clutter. Let N_{C_t} denote the number of clutter points, and Ω_D denote the set of measurements indices corresponding to the detected targets, the likelihood function for measurement $\mathbf{z}_t$ can be written as:

$$p(\mathbf{z}_t|\mathbf{x}_t, K_t, \alpha_t) = (\frac{1}{V})^{N_{C_t}} \prod_{l\in\Omega_D} p(\mathbf{z}_{l,t}|\mathbf{x}_{\alpha_{l,t},t}) \tag{4}$$

where $p(\mathbf{z}_{l,t}|\mathbf{x}_{\alpha_{l,t},t})$ is evaluated from (3).

3.4 Ball Motion Modeling

In our Segway RMP soccer robot environment, we define five models to model the ball motion (for the rest of this paper, for simplicity, we use $\mathbf{x}_t$ to represent the ball state, and use $\mathbf{x}'_t$ to represent the team member state).

- *Free-Ball*, *Robot-Grab-Ball*, *Robot-Kick-Ball*. We use the same models as *Free-Ball*, *Grab-Ball* and *Kick-Ball* introduced in [7] respectively.
- *Human-Grab-Ball*. The ball is held by the team member. we can infer the ball position similarly if we know the team member position well.
- *Human-Kick-Ball*. The ball is kicked by the team member and it is supposed to be either a pass to the robot or a shoot at the goal .

In general, we will have n motion models $m_1, m_2, \cdots, m_n$.

3.5 Team Member Motion Modeling

We define four models to model the human team member's motion.

- *Random Walk*. The team member is wondering in the field. So the state at the new time is the state at the current time with some additive zero-mean (assumed Gaussian) noise.
- *Holding Ball*. The team member is holding the ball without moving and waiting for the robot to receive the ball. Should the robot know the ball position well, it can infer the team member position by the ball position in a similar way as *Robot-Grab-Ball* for ball motion modeling.
- *Accelerating (Decelerating)*. The team member dashes (stops) to obtain (lose) a velocity in a short time.
- *Positioning*. The team member is going to a predefined tactical position with a constant speed. This case happens mostly after the team member passing the ball to the robot and moving down the field toward opponent's goal.

3.6 Play Based Model Transitions

Given the knowledge of the team coordination plan (the play P_{t-1} at time $t-1$), the robot can infer what tactic the team member is executing (T'_{t-1}), which provides valuable information about the motion model of the team member (m'_t). Both the robot and the team member act over the ball in a Segway soccer game. The motion model of the ball (m_t) is therefore affected by what tactic the robot (T_{t-1}) and the team member (T'_{t-1}) are executing.

From the previous subsection, we know that the model index m determines the present model being used. For our team member tracking example, $m'_t = i, i = 1, \cdots, 4$. In our

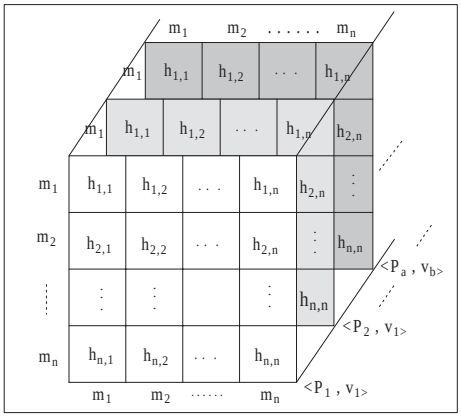

Figure 2: Play-Based motion modeling, where $m_1, m_2, \cdots, m_n$ are n models, P_a is the team play, v_b is the additional information. $h_{i,j}$ is the transition probability from model m_i to model m_j given m_i, and $\langle P_a, v_b \rangle$. Each layer in the graph is conditioned on a particular combination of the play executed and the additional information obtained.

approach, it is assumed that the team member motion model index, m'_t, conditioned on the previous tactic executed T'_{t-1} by the team member, and other useful information v'_t (such as ball state), is governed by an underlying Markov process, such that, the conditioning parameter can branch at the next time-step with probability.

$$p(m'_t = i | m'_{t-1} = j, T'_{t-1}, v'_t) = h'_{i,j} \tag{5}$$

where $i, j = 1, \cdots, N_{m'}$. Since T'_{t-1} can be determined by P_{t-1}, we get

$$h'_{i,j} = p(m'_t = i | m'_{t-1} = j, P_{t-1}, v'_t) \tag{6}$$

Since we can draw $p(m'_t = i | m'_{t-1} = j)$ in an $N_{m'} \times N_{m'}$ table, we can create a table for Equation 6 with a third axis which is defined by the tuple $\langle P_a, v_b \rangle$ as shown in Figure 2. Here the play P_a, is the primary factor that determines whether m_i transits to m_j and what the transition probability is, while the information v_b determines the prior condition of the transition. Each layer in the graph is conditioned on a particular combination of the tactic executed and the additional information obtained.

For our ball tracking example, $m_t = i, i = 1, \cdots, 5$. Similarly,

$$h_{i,j} = p(m_t = i | m_{t-1} = j, T_{t-1}, T'_{t-1}, v_t) \tag{7}$$

where $i, j = 1, \cdots, N_m$. Since T_{t-1}, T'_{t-1} can be determined by P_{t-1}, we get

$$h_{i,j} = p(m_t = i | m_{t-1} = j, P_{t-1}, v_t) \tag{8}$$

Suppose the current team play is the *Naive Offense* in Section 2.2, we can obtain the corresponding motion model transitions for both the ball and the team member using the play-based method (Figure 3).

4. MULTI-MODEL MOTION TRACKING

In this section, we first describe the clustering algorithm we used to continuously monitor the appearance and disappearance of regions of interest (ROIs) on the field. We then

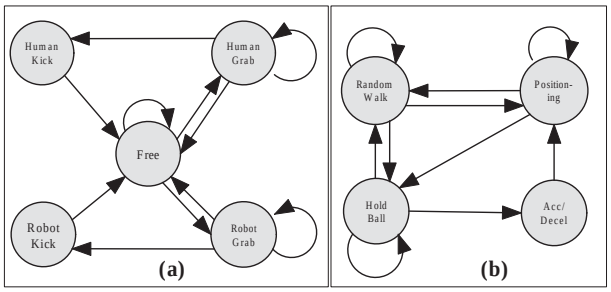

Figure 3: Object motion modeling based on the play: *Naive Offense*. Each node is a model. Models transit to one another according to the predefined probabilities (not shown in the figure). (a) Ball motion model. (b) Human team member motion model.

use dynamic Bayesian networks to represent the whole system. We give the detailed sequential Monte Carlo methods of tracking in a multi-model multi-hypothesis scheme finally.

4.1 Clustering Algorithm

The idea of this algorithm is to group a set of ROIs, $\mathcal{S}_t = \{S_t^{(j)}\}_{j=1}^{J_t}$, within a buffer of observations $\mathcal{Z}_t = \{\mathbf{z}_{t'}\}_{t-\tau}^{t}$, where τ is the length of the sliding window [10]. If the current targets are widely separated, the measurements originating from them will be clustered in the locations where the targets had visited from $t - \tau$ to t. Therefore the distance between two measurements within two successive time steps can be taken as the clustering criteria. Let $d_{c,l}(t'+1, t')$ denote the normalized distance between the cth and lth measurements of $\mathbf{z}_{t'+1}$ and $\mathbf{z}_{t'}$.

$$d_{c,l}(t'+1, t') = e_{c,l}^T(t'+1, t')\Sigma_e^{-1} e_{c,l}(t'+1, t') \tag{9}$$

where $c \in \{1, \ldots, M_{t'+1}\}$ and $l \in \{1, \ldots, M_{t'}\}$, $e_{c,l}(t'+1, t') = \mathbf{z}_{c,t'+1} - \mathbf{z}_{l,t'}$ and $\Sigma_e = 2\Sigma_n$. For all measurements of $\mathbf{z}_{t'+1}$, we have a set of normalized distances $\{d_{c,l}(t'+1, t')\}_{c=1}^{M_{t'+1}}$. The c^*th measurement $\mathbf{z}_{c^*,t'+1}$ will be grouped with $\mathbf{z}_{l,t'}$ in the same cluster $S_t^{(j)}$ if

$$d_{c^*,l}(t'+1, t') = argmin\{d_{c,l}(t'+1, t')\}_{c=1}^{M_{t'+1}} \tag{10}$$

and

$$d_{c^*,l}(t'+1, t') \leq \epsilon_z \tag{11}$$

where ϵ_z is a threshold. If none of the measurements of $\mathbf{z}_{t'+1}$ can be grouped with $\mathbf{z}_{l,t'}$, the search procedure continues and uses $\mathbf{z}_{t'+b}, 1 < b \leq \tau$ until (10) and (11) are both satisfied. Meanwhile the algorithm propagates through time to group other measurements in the remaining observations. Since the detected regions obtained via (10) and (11) possibly arise from clutter points, another threshold is set to examine the number of measurements in the region to eliminate the false positives. That is, if the number of measurements in the jth region $S_t^{(j)}$ is less than τ_{min}, defined as the minimum number of clustered measurements in a region required to identify a target, it is discarded; otherwise, the jth region is classified as originating from a target. Once a set of ROIs $\mathcal{S}_t = \{S_t^{(j)}\}_{j=1}^{J_t}$ is obtained, it is necessary to determine which region belongs to which existing active track or a

new track deterministically. Let $\gamma_t = [\gamma_{1,t}, \gamma_{2,t}, \cdots, \gamma_{K_t,t},]^T$ denote the track-to-region association vector. $\gamma_{k,t}$ is used to indicate the association between the ROIs and the active tracks. $\gamma_{k,t}$ is evaluated as j if track k can be associated with $S_t^{(j)}$, otherwise it is zero. Refer to [10] for more details of the clustering algorithm.

4.2 DBN Representation

Following the play-based motion model, we can use dynamic Bayesian networks (DBNs) to represent the whole system for team member and ball tracking in a natural and compact way as shown in Figure 4 and Figure 5 respectively. In the two graphs, the system state is represented by variables (play P, tactic T, infrared sensor measurement s, ball state $\mathbf{x}$, ball motion model index m, vision sensor measurement of ball $\mathbf{z}$, team member state $\mathbf{x}'$, team member motion model index m', vision sensor measurement of team member $\mathbf{z}'$), where each variable takes on values in some space. The variables change over time in discrete intervals, so that e.g. $\mathbf{x}_t$ is the ball state at time t.

Furthermore, the edges indicate dependencies between the variables. For instance, in Figure 5 the ball motion model index m_t depends on $m_{t-1}, T_{t-1}, T'_{t-1}, s_t$ and $\mathbf{x}_{t-1}$, hence there are edges coming from the latter five variables to m_t. For the rest of this section, we give the ball-tracking algorithm following Figure 5. The team-member-tracking algorithm can be obtained similarly following Figure 4.

4.3 Importance Sampling Function

We use the sequential Monte Carlo method to track the motion model m and the multi-target state $\mathbf{x}$. Particle filtering is a general purpose Monte Carlo scheme for tracking in a dynamic system [6]. It maintains the belief state at time t as a set of particles $p_t^{(1)}, p_t^{(2)}, \cdots, p_t^{(N_s)}$, where each $p_t^{(i)}$ is a full instantiation of the tracked variables $\{p_t^{(i)}, w_t^{(i)}\}$, $w_t^{(i)}$ is the weight of particle $p_t^{(i)}$ and N_s is the number of particles. In our case, $p_t^{(i)} = \langle \mathbf{x}_t^{(i)}, m_t^{(i)} \rangle$. To make our notation more concrete, a particular particle $p_t^{(i)}$, which is tracking K_t multi-target state vector $\mathbf{x}_t$ and motion model m_t, is given as [8]:

$$p_t^{(i)} = \begin{pmatrix} m_{1,t}^{(i)} & m_{2,t}^{(i)} & \cdots & m_{K_t,t}^{(i)} \\ x_{1,t}^{(i)} & x_{2,t}^{(i)} & \cdots & x_{K_t,t}^{(i)} \\ y_{1,t}^{(i)} & y_{2,t}^{(i)} & \cdots & y_{K_t,t}^{(i)} \\ \dot{x}_{1,t}^{(i)} & \dot{x}_{2,t}^{(i)} & \cdots & \dot{x}_{K_t,t}^{(i)} \\ \dot{y}_{1,t}^{(i)} & \dot{y}_{2,t}^{(i)} & \cdots & \dot{y}_{K_t,t}^{(i)} \end{pmatrix} \tag{12}$$

We sample the ball motion model following the ball-tracking DBN as below:

$$m_{k,t}^{(i)} \sim p(m_{k,t} | m_{k,t-1}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, s_t, T_{t-1}, T'_{t-1}) \tag{13}$$

Note that T_{t-1} and T'_{t-1} are inferred deterministically from P_{t-1} instead of sampling. Conditioned on the ball motion model $m_{k,t}^{(i)}$, we then use the importance function introduced in [10] to sample ball state $\mathbf{x}_{k,t}^{(i)}$:

$$\mathbf{x}_{k,t}^{(i)} \sim \begin{cases} q_D(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}), & k \notin \mathcal{K}_{S_t} \\ q_{DS}(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, S_t^{(j)}), & k \in \mathcal{K}_{S_t} \end{cases} \tag{14}$$

where $k \in \mathcal{K}_{S_t}$ are those tracks with $\gamma_{k,t} = j$ and $j \in \Omega_D$, and $q_D(\cdot)$ and $q_{DS}(\cdot)$ are the proposal functions for $x_{k,t}$

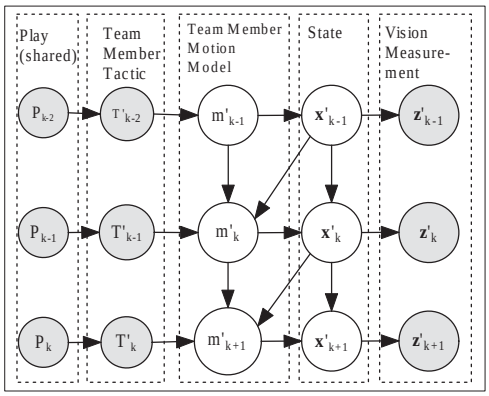

Figure 4: A dynamic Bayesian network for team member tracking with a Segway RMP robot. Filled circles represent deterministic variables which are observable or are known as the tactic or the play that the robot is executing.

without and with an associated ROI $S_t^{(j)}$, given as follows, repectively,

$$q_D(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}) = p(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}) \tag{15}$$

$$q_{DS}(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, S_t^{(j)}) =$$

$$\mu p(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}) + (1-\mu) q(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, S_t^{(j)}) \tag{16}$$

where $0 \le \mu \le 1$ and $q(\cdot)$ is a uniform sampling from the associated ROI $S_t^{(j)}$. If $\mu = 1$, the importance sampling function is reduced back to the dynamic prior. If $\mu = 0$, all particles are generated from the data-dependent importance function. If $0 < \mu < 1$, this proposal combines the dynamic prior and the current ROIs to generate representative particles.

4.4 Birth, Death and Update Moves

Assuming that there are K_t^b ROIs that cannot be associated with any existing track, we will initiate a new track in each time step from one of these regions instead of initiating K_t^b tracks simultaneously in order to fit the birth move with the assumed system process model in (2). When an existing track cannot be associated with a region at a given time, the target being tracked by the tracker may have disappeared or temporarily experience a short period of data loss. Thus we may remove the track for the target only if it has failed to associate with any ROI with τ_d time steps. Refer to [10] for the detailed algorithm of birth move and death move.

In the update move, there is no change in terms of the number of ROIs. We only need to update the target states with a common value of number of targets $K_t^{(i)} = K_{t-1}^{(i)}$, using the sequential importance sampling method as follows:

$$[\{\mathbf{x}_t^{(i)}, m_t^{(i)}, w_t^{(i)}\}_{i=1}^{N_s}] =$$
$$\boldsymbol{SIS}[\{\mathbf{x}_{t-1}^{(i)}, m_{t-1}^{(i)}, w_{t-1}^{(i)}\}_{i=1}^{N_s}, \mathbf{z}_t, s_t, T_{t-1}, T'_{t-1}]$$

01 **for** $i = 1 : N_s$
02 **for** $k = 1 : K_t$
03 draw $m_{k,t}^{(i)} \sim p(m_{k,t} | m_{k,t-1}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, s_t, T_{t-1}, T'_{t-1})$.
04 **if** track k has corresponding ROI $S_t^{(j)}$
05 draw $\mathbf{x}_{k,t}^{(i)} \sim q_{DS}(\mathbf{x}_{k,t} | m_{k,t}^{(i)}, \mathbf{x}_{k,t-1}^{(i)}, S_t^{(j)})$

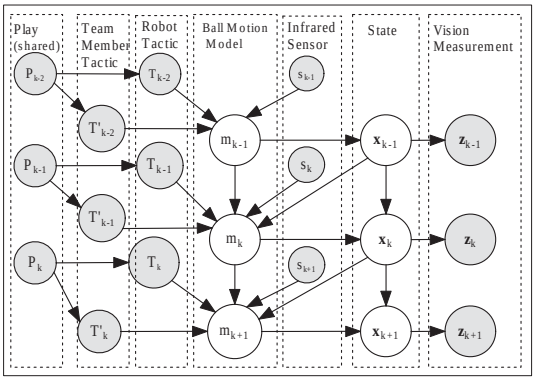

Figure 5: A dynamic Bayesian network for ball tracking with a Segway RMP robot.

```
06        else
07          draw x_{k,t}^{(i)} ~ q_D(x_{k,t} | m_{k,t}^{(i)}, x_{k,t-1}^{(i)})
08        end if
09      end for
10      set w_t^{(i)} = w_{t-1}^{(i)} · p(z_t | x_t, K_t, α_t)
11    end for
12    Calculate total weight: w = Σ[{w_t^i}_{i=1}^{N_s}]
13    for i = 1 : N_s
14      Normalize: w_t^i = w_t^i / w
15    end for
16    Resample.
```

The inputs of the algorithm are samples drawn from the previous posterior $\langle \mathbf{x}_{t-1}^{(i)}, m_{t-1}^{(i)}, w_{t-1}^{(i)} \rangle$, the present vision and infrared sensory measurement $\mathbf{z}_t, s_t$, the robot's tactic T_{t-1}, and the team member's tactic T'_{t-1}. The outputs are the updated weighted samples $\langle \mathbf{x}_t^{(i)}, m_t^{(i)}, w_t^{(i)} \rangle$. In the sampling algorithm, first, a new ball motion model index, $m_t^{(i)}$, is sampled according to (13) at line 03. Then given the model index, and previous ball state, a new ball state is sampled according to (14) at line 05/07. According to (4), the importance weight of each sample is given by the likelihood of the vision measurement given the predicted new ball state at line 10. Finally, each weight is normalized and the samples are resampled. Then we can estimate the ball state based on the mean of all the $\mathbf{x}_t^{(i)}$. Though we are trying to eliminate the clutter from the beginning of tracking (clustering algorithm), due to the property of the multi-target tracker, further recognition process might be done in order to figure out which tracked target is the true ball. Similarly the state of the team member $\mathbf{x}'_t$ can be obtained from the team member tracker.

5. EXPERIMENTAL RESULTS

From previous work we knew the initial speed and accuracy of the ball velocity after a kick motion. We profiled the system and measurement noise as well. In this section, we evaluate the effectiveness of our tracking system in both simulated and real-world tests.

5.1 Simulation Experiments

Because it is difficult to know the ground truth of the target's position and velocity in the real robot test, we do the simulation experiments to evaluate the precision of tracking.

Table 1: The average RMS error of position estimation and velocity estimation from human trackers and ball trackers.

Motion Model	Single Model	Multiple Model
Human Position Est RMS (m)	0.0030	0.0014
Human Velocity Est RMS (m/s)	0.42	0.025
Ball Position Est RMS (m)	0.0028	0.0017
Ball Velocity Est RMS (m/s)	0.4218	0.0597

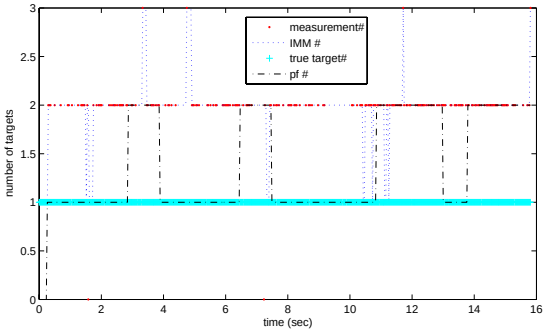

Figure 6: A comparison of the target detection performance between the proposed method and the IMM tracker when only one target exists with surrounding clutters.

Experiments are done following the *Naive Offense* play, in which the robot acts as the receiver and the human team member acts as the passer. Noises are simulated according to the model we profiled in previous work. In the beginning, the team member holds the ball. After a fixed amount of time, the ball is kicked towards the robot, and the team member moves forward to a predefined location.

We implement both a single model tracker and a play-based multi-model tracker for the ball and the team member. We simulate the experiment for 50 runs, and then compare the performance of the two trackers with different implementations. The average RMS error of position estimation and velocity estimation are shown in Table 1. The results show that the play-based multi-model scheme performs much better than the single model especially in terms of velocity estimation. Because with the play-based motion model, when the ball is being kicked, most particles evolving using the transition model determined by the play will change its motion model $m_t^{(i)}$ from *Free-Ball* to *Human-Kick-Ball*, and a velocity will be added to the ball accordingly.

5.2 Multi-Target Tracking Test

In this test, one Segway RMP robot is tracking one or more balls on the field with *SearchBall* tactic. We would like to compare solely the target detection performance between the proposed method and the IMM tracker. A scenario with K_t $(0 \leq K_t \leq 3)$ balls appearing and disappearing at different times and there are a set of false positives at fixed position in the surroundings.

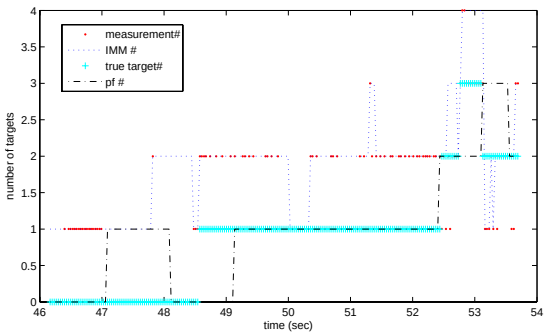

Figure 7: A comparison of the target detection performance between the proposed method and the IMM tracker when multiple targets exist with surrounding clutters.

When estimating the number of targets, 3600 particles are used in the proposed method. Figures 6-7 summarize the results. In both figures, the dots show the number of measurements at a given time. The dotted line represents the number of the targets tracked by the IMM tracker. The dashdotted line represents the number of targets tracked by the multi-model multi-target tracker proposed in this paper. The crosses show the true number of the targets at any given time. As shown in the figure, the IMM tracker is sensitive to the number of measurements, while our approach is more robust and consistent to high clutter density. Since the detection is basically performed on the clustering of the observations and the association between the detected ROIs and the existing tracks, it is computational low-cost. Therefore it is also practical for real-time multi-target detection and tracking.

5.3 Team Cooperation Test

We do experiments on the Segway RMP soccer robot executing the offensive play and coordinating with the human team member. The test setup is demonstrated in Figure 8, in which the digits along the lines show the sequence of the whole strategy, the filled circle at position B represents the robot, the unfilled circle at position E represent an opponent player, and the shaded circle represent the human team member.

When each run begins, the human team member is at position A . With this team cooperation plan (play), the robot chooses the tactic *CatchKickToTeammember* to execute, in which the robot starts with the skill *Search-Ball*. When the robot finds the ball, the team member passes the ball directly to the robot and chooses a positioning point to go to either at C or D. The robot grabs the ball after the ball is in the catchable area and is detected by the infrared sensor (skill *Grab-Ball*). Next the robot searches for the team member holding the ball with its catcher (skill *Search-Teammember*). After the robot finds the team member, the robot kicks the ball to its team member (skill *KickToTeammember*) and the team member shoots at the goal, completing the whole offensive play. Each run ends in one of the following conditions.

- succeed if the human receives the ball from the robot or the human does not receiver the ball but the pass can be considered as a "good" one.
- fail if the robot is in searching for the ball or the team member for more than 30 seconds.
- fail if the ball is outside the field before the robot catches it.

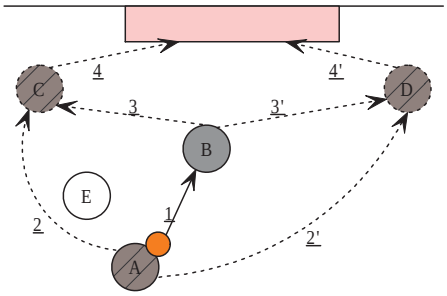

Figure 8: A demonstration of a naive team cooperation plan in offensive scenario. The digits along the lines show the sequence of the whole plan. The filled circle at position B represents the robot. The unfilled circle at position E represent an opponent player. The shaded circle represent the human team member.

Table 2: The average time taken over all the successful runs.

Motion Model	Single Model	Multi-Model
Mean Time (sec)	33.4	22.6

In the experiment over 15 runs, the robot with single model trackers fails 5 of the total. While the robot with play-based multi-model trackers fails 2 of the total. We also keep track of the mean time taken in all the successful runs. We list the result in Table 2. Using play-based multi-model tracking saves 32.3% time in terms of completing the whole play over single model tracking. During the experiment, we note that when using the single model tracking, most time were spent on searching the team member. Incorporating the team cooperation knowledge known as play into the team member motion modeling greatly improves the accuracy of the team member motion model and therefore avoids taking time in searching a lost target from scratch.

6. RELATED WORK

Tracking moving targets using a Kalman filter is the optional solution if the system follows a single model, **f** and **h** in Equation 1 and 3 are known linear functions and the noise **v** and **n** are Gaussians [1]. Multiple model Kalman filters such as Interacting Multiple Model (IMM) are known to be superior to the single Kalman filter when the tracked target is maneuvering [3]. For nonlinear systems or systems with non-Gaussian noises, a further approximation is introduced, but the posterior densities are therefore only locally accurate and do not reflect the actual system densities.

Since the particle filter is not restricted to Gaussian densities, a tactic-based motion modeling method is proposed

in [7]. Based on that approach, we further introduce the play-based motion modeling method when team coordination knowledge is available. Another related approach was proposed to track a moving target using Rao-Blackwellised particle filter [9], in which a fixed transition table was used between different models. Our transition model is dependent on the play that the robot is executing and the additional information that matters. This model can be flexibly integrated into our existing STP architecture.

There have been different strategies in multi-target tracking. In order to handle the data association and tracking problem, the classical Joint Probabilistic Data Association Filter (JPDAF) adopts the methods like the extended Kalman Filter (EKF) for multi-target state estimation, whose tracking performance is known to be limited by the linearity of the data models [2]. Another approach known as sequential Monte Carlo methods are able to perform well even when the data models are nonlinear and non-Gaussian. However, almost all of these methods assume that the knowledge of true targets (without clutter) is given, which is not applicable in the field that Segway RMP soccer robots operates in.

Recently, a hybrid approach for online joint detection and tracking for multiple targets was proposed [10]. This approach does not rely on the clutter-free assumption. In this paper, based on their approach, we present a play-based multi-target tracking algorithm, which incorporates tactic information to eliminate the false alarms and to improve resampling efficiency. Compared to our method, first, existing techniques consider less complex dynamic systems where only one part of the state space is non-linear. In contrast, our approach estimate a system where multiple components are highly non-linear (Segway RMP robot motion, ball motion, team member motion). Second, most existing techniques examine their performance with simulated experiments, while we test our approach in real robot experiments. Third, our approach goes beyond existing techniques by incorporating team coorperation information into the tracking process which further improves the performance.

7. CONCLUSIONS AND FUTURE WORK

Motivated by the interactions between a team and the tracked target, we contribute a method to achieve efficient tracking through using a play-based motion model and combined vision and infrared sensory information. This method gives the robot a more exact task-specific motion model when executing different tactics over the tracked target (e.g. the ball) or collaborating with the tracked target (e.g. the team member). Then we represent the system in a compact dynamic Bayesian network and use particle filter to keep track of the motion model and target state through sampling. The empirical results from the simulated and using the real robot agent show the efficiency of the multi-model tracking over single model tracking.

If the teammate is a human, not a robot, the certainty that the teammate is executing the expected play or tactic could be reduced. That is, the human teammate could fail to execute the desired play or tactic. Future work will take such uncertainty into account. A better human team member modeling (for example, include intercepting the moving ball, mark a player, covering the goal) will also help. Another interesting work is to know how the performance of the presented method is affected by the presence of tactics of the team member that are not exactly determined in the team coordination plan.

8. ACKNOWLEDGMENTS

We would like to thank the members of the CMBalance Segway soccer team for their help with developing the infrastructure for the Segway robots. In particular, we thank Brett Browning for the vision and initial control systems and Brenna Argall for the game skills.

ABSTRACT

This paper presents an algorithm for multi-agent strategic modeling (MASM) applied in a robotic soccer domain. It transforms a multi-agent action sequence into a set of strategic action descriptions in a graphical and symbolic form. By using hierarchically ordered domain knowledge, the algorithm is able to generate graphic and symbolic strategic action descriptions together with corresponding rules at different levels of abstraction. The method was evaluated on the RoboCup Soccer Server Internet League data.

Keywords

Multi-agent strategic modeling, strategy, RoboCup.

1. INTRODUCTION

Multi-agent modeling deals with the following task[15]: How can external observations of multi-agent systems be used to analyze, model, and direct agent behavior? Analysis of such systems must thus capture complex world state representation and asynchronous agent activities. Instead of studying pure numerical data researchers often use knowledge-level structures, such as rules and decision trees. Although being extremely useful when characterizing state space, they lack the ability to clearly represent temporal state changes occurred by agent actions. To comprehend simultaneous agent actions and complex changes of state space, most often a combination of graphical and symbolical representation performs better in terms of human understanding.

Multi-agent strategic modeling (MASM) is a process that is able to discover a strategic activity from raw multi-agent action data. A strategic activity is a time-limited multi-agent activity that exhibits some important or unique domain-dependant characteristics.

This paper addresses the problem of graphically and symbolically representing strategies of multi-agent systems (MAS). Our goal was to create an algorithm that would discover strategic agent behavior and enable humans to understand and study the underlying behavioral principles. The task is to translate multi-agent action sequence and observations of a noisy, dynamic, complex and multivariate world state into a graph-based and rule-based representation. By using hierarchically ordered domain knowledge the algorithm should be able to generate strategic action descriptions and corresponding rules at different levels of abstraction. More abstract descriptions also tend to be more noise resistant.

Our approach is applied in a Multi-Agent Strategy Discovering Algorithm (MASDA) and tested on a RoboCup Simulated League domain (RoboCup) [12], a multi-agent domain where two teams of 11 agents play simulated soccer games. The physical 2D soccer is simulated with additional noise when calculating forces on objects. Continuous time is approximated with discrete cycles. All agents can move and act independently as long as they comply with soccer rules. Agents can freely communicate with each other, but as in real world their visual and hearing perception is distance-limited. The domain is at the same time a complex MAS and easily understandable by humans due to its soccer-related content.

An example of a sequence of RoboCup actions is presented in Figure 1. The four frames show a successful direct-attack action. The players are presented as filled circles with a pointer indicating body direction. The attacking team is black while the defending team is gray. The ball is a white circle with black border; its trace is drawn throughout the sequence. Lines represent traces of movement. The action sequence in Figure 1 is typically described by humans as: "The left team's left forward player dribbles from the left half of the middle third into the penalty box. He then passes a ball to the center forward in the center of the penalty box, where the receiver successfully shoots into the right part of the goal." This sequence is graphically presented in Figure 2 consisting of **player roles,** player actions and factual ***domain-related descriptions***, such as positions of involved players.

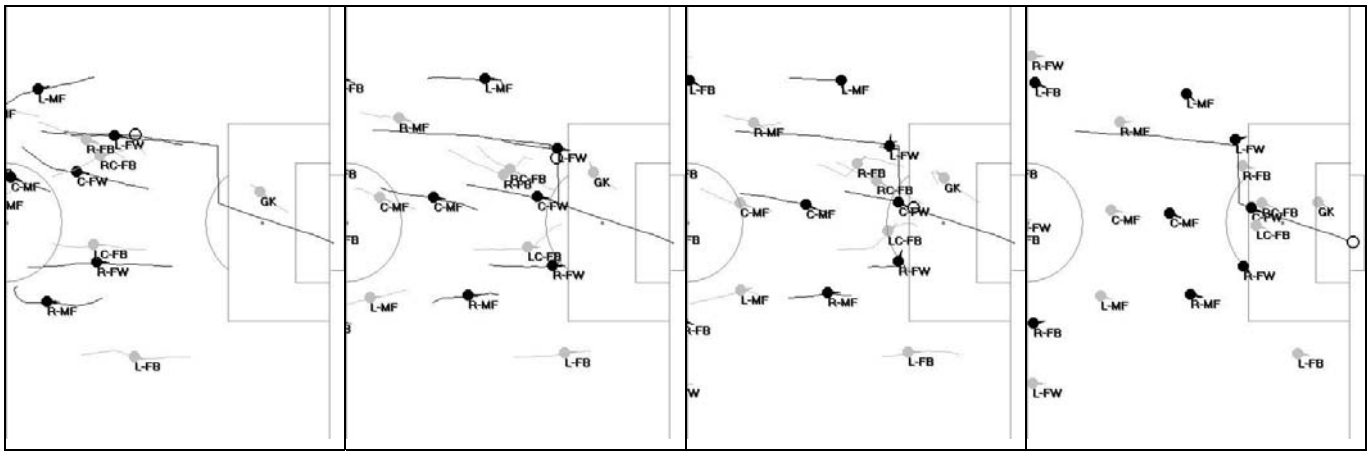

Figure 1: Four frames from a RoboCup game showing a successful direct-attack action sequence.

The diagrammatic action representation is commonly used to help understanding spatial and temporal activity, as shown in Figure 2. Since the aim of MASM is to discover strategic activity and to describe this activity in a human-understandable form, MASDA uses a similar representation, with a diagram, action sequence and rules that describe factual domain features.

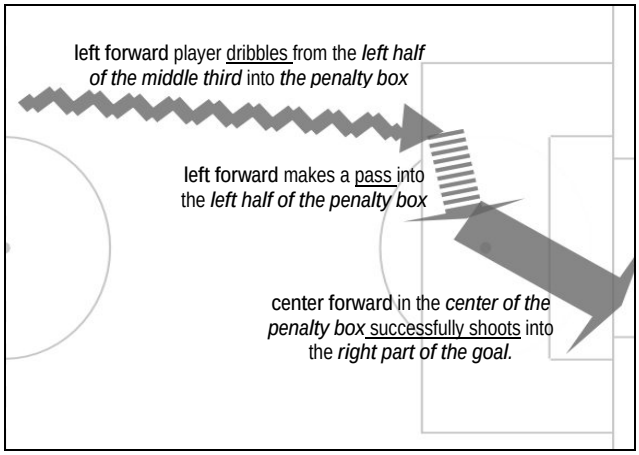

Figure 2: An example of a soccer strategy: a left side direct attack.

This paper is organized as follows. Section 2 reviews the related work. Section 3 presents MASDA. Section 4 describes an example of a generated strategy. In Section 5 an evaluation of the described method is given, followed by discussion in Section 6.

2. RELATED WORK

The task of graphically representing agent actions has been addressed by several multi-agent graphical models, most notably by multi-agent influence diagrams [8] and influence diagram networks [15]. However, all these are concerned with agent decision making, and not agent modeling, and are therefore not suitable for representing observed strategic agent behavior.

The work [11] from Intille deals with the related task of recognizing multi-agent actions in the American football domain. However, the focus in that work is on recognition, using a database of plans, knowledge about football, computation of perceptual features from the trajectories, and propagation of uncertain reasoning, the recognition system developed can determine if the example of a game play is in fact an example of a "p51curl" play. The drawback with their approach is that they explicitly make use of a database of plans and cannot discover new behavior. The paper [5] from Hirano and Tsumoto presents a novel method for finding interesting pass patterns from soccer game records. Taking two features of the pass sequence – temporal irregularity and requirements for multiscale observation – into account, they have developed a comparison method of the sequences based on multiscale matching. The method is used with hierarchical clustering to produce clusters of spatial pass patterns. Experimental results soccer game records demonstrate that the method is able to discover some interesting pass patterns that may be associated with successful goals. This work is concerned primarily with spatial pass patterns while out process also captures important domain-specific knowledge.

There has been extensive research about quantitative modeling in the RoboCup domain. Unfortunately, the problem of constructing human-readable representations of multi-agent activity has received little interest. The work from Raines et al. [13] focused on an automated assistant for analyzing agent teams. Their system ISAAC performs post-hoc, off-line analysis of teams using agent-behavior traces in the domain. The analysis is performed bottom-up, using data mining and inductive learning techniques. ISAAC is able to discover interesting patterns based on user provided features, thus combining the analytical capabilities of the machine with the domain knowledge of the user. Their system is similar to ours in terms of domain knowledge and rule induction. However, our approach explicitly exploits abstraction and provides graphic representation for detected strategies. Work from Kuhlmann et al. [9] deals with the problem of formulating advice-giving as a learning problem. They are able to learn and predict agent behavior from past observations and automatically generate advice to improve its team performance. Although their work concentrates on advice giving task, they successfully construct rules that predict the next significant action events. Our work is

similar in terms of rule induction; however we focus towards increased human comprehension and visual representation as opposed to purely classification accuracy. Work from Kaminka et al. [7] addresses the problem of unsupervised autonomous learning of the sequential behaviors of agents. They translate observations of the complex world state into a time-series of recognized atomic behaviors. The time series are then analyzed to find repeating or statistically significant subsequences characterizing each team. Their work addresses only frequent action subsequence matching while we construct graph-based action model that provides spatial, sequential, and temporal information about agent actions. Kaminka et al. [6] later introduced a behavior-based approach to plan recognition, in which hierarchical behaviors are used to model the observed robots. Efficient symbolic algorithms for answering key queries about observed robots are also presented. However, their approach explicitly utilizes a hierarchical behavior library while our process creates graph-based action models on-the-fly. The work from Sukthankar and Sycara [16] presents a cost minimization approach to the problem of human behavior recognition in a military domain. Using full-body motion-capture data acquired from human subjects, the system is able to recognize the behaviors that a human subject is performing. Low-level motion classification is performed using support vector machines (SVMs) and a hidden Markov Model (HMM); output from the classifier is used as an input feature for the behavior recognizer. Given the dynamic and highly reactive nature of the domain, their system is able to handle behavior sequences that are frequently interrupted and often interleaved. While their approach can identify different behaviors using behavior library our approach detects strategic activity without prior strategic knowledge.

3. THE ALGORITHM

In this section we present MASDA, which is capable of discovering strategic multi-agent activity and describe it graphically and symbolically. The algorithm can be presented as a three-step process: a preprocessing step, a graphical-description generation step and a symbolic-description generation step. Each step is further split into smaller tasks, as presented here, with data structures in parenthesis:

- Step 1: Data preprocessing:
  - Detection of actions in raw data (attributes)
  - Action sequence generation (symbolic sequence)
  - Introduction of domain knowledge (hierarchical concepts)
- Step 2: Graphical description creating:
  - Action graph creation (action graph)
  - Abstraction process (abstract action graph)
  - Strategy selection (graph path)
- Step 3: Symbolic description learning:
  - Action description generation (action description)
  - Rule data generation (set-valued attributes)
  - Rule induction (rules)

The output from each step is the input for the next one. In the first two tasks of the first step MASDA detects actions in raw multi-agent data and generates corresponding action sequences. Detailed description of preprocessing [1] is omitted due to lack of space. The domain knowledge is introduced (task 3 of step 1) in Section 3.1. The process of generating graphical descriptions (step 2) is described in Section 3.2. In Section 3.3 we describe the process of symbolic descriptions generation (step 3).

3.1. Introduction of Domain Knowledge

MASDA exploits domain knowledge through taxonomies of domain concepts. *Taxonomy T* is a hierarchical representation of domain concepts. A concept $x \in T$ is an ancestor of a concept $y \in T$, $x \leftarrow y$, if it denotes a more general concept than the concept y. Hierarchically ordered domain knowledge allows MASDA to travel up and down in the hierarchy to produce more or less abstract descriptions. Specifically, MASDA makes use of:

- a taxonomy of agent roles (T_{roles}), shown in Figure 4
- a taxonomy of agent actions ($T_{actions}$)
- taxonomies of binary domain features ($T_{features}$)

Given a hierarchically ordered structure, we can define the *depth of a concept*. It is the length of the shortest path from the root to the given concept. Consequently, the smaller the depth is, the more abstract the concept is. The root concept has a depth 0.

As agents in MAS can change roles and thus change their behavior [10], agent roles are assigned dynamically during agent activity. Similarly, each detected agent action is assigned its corresponding hierarchical representation. While agent roles and actions are used to describe the activity of agents the domain features are used to describe the truth of some particular domain feature in a domain state space. In our case, domain features are only defined for moving entities - the ball or an agent. They are used to describe agent positions, their relation to the ball and their states. For example, in a RoboCup domain, the feature *HasBall* is true only for the agent that controls the ball (E.g.: *agent1:HasBall*=true) and is false for all other agents (E.g.: *agent2:HasBall*=false). A part of ball-related domain feature taxonomy is shown in Figure 3.

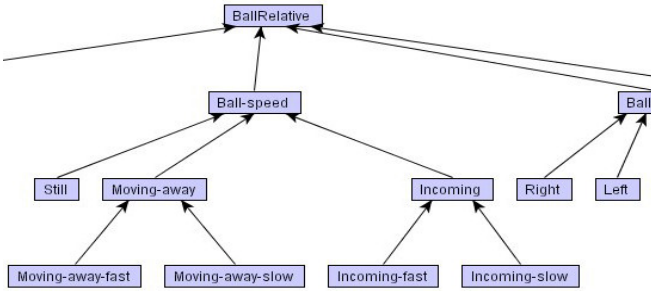

Figure 3: A part of ball-related soccer domain features.

We defined the following three domain taxonomies:

- Position-related taxonomy defines concepts describing whether the ball or an agent is in certain spatial region of the playing field. For example: *left-wing, center-of-the-field, right-wing, left-half, right-half, defending-third, defending-third-danger-zone, defending-third-penalty-box, defending-third-goal-box, middle-third, center-circle, attacking-third, attacking-third-danger-zone,* , etc.
- Speed-related taxonomy defines the speed of an agent and ball: *stationary, moving, fast*, *medium*, and *slow*.

- Ball-related taxonomy defines relations of players regarding the ball, as shown in Figure 3. For example: *has-ball*, *left, right, front, back, incoming, moving-away, incoming-fast, incoming-slow*, *moving-away-fast, moving-away-slow, still, immediate, near, far*, etc.

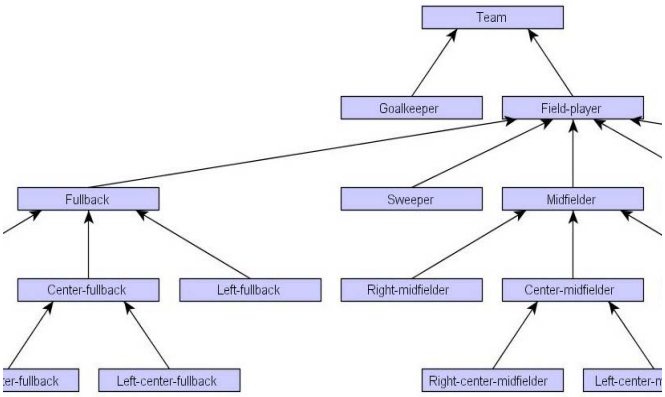

Figure 4: A part of role concept taxonomy.

3.2. Graphical representation

In this section, we describe the process of constructing graphical action representation from the observed action sequence that was generated in the preprocessing step.

3.2.1 Action Graph Representation

An *action graph* (AG) is a directed graph, where connections correspond to actions and nodes represent state space at the beginning of each action. Terminal actions (i.e. the last actions in action sequences) are represented as connections to terminal nodes, which are nodes with no outgoing connections and define the state space at the end of action For example, an action sequence (α, β, γ) is represented as an AG:

$$a \xrightarrow{\alpha} b \xrightarrow{\beta} c \xrightarrow{\gamma} c_{terminal}$$

Node positions correspond to agent positions in a domain space. Each node is also assigned a common action- and role-parent (see Table 1) of outgoing actions from action and role taxonomies. This enables MASDA to generate abstract descriptions of agent role and actions. Each connection also holds start times and durations of the represented actions.

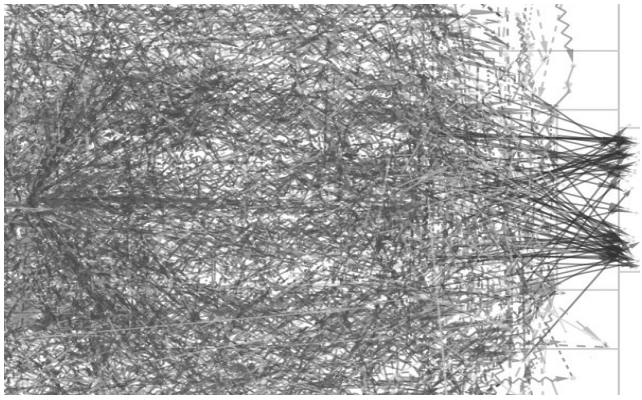

Figure 5: An example action graph.

A more detailed description of action graphs and the construction process is given in [1]. An example action graph, obtained from actions in 10 RoboCup games, is presented in Figure 5.

3.2.2 The Abstraction Process

Complex action graphs with many nodes are difficult to visualize, and are thus difficult to comprehend by humans. An approach to overcome this problem is to reduce the number of nodes. However, one would like to reduce action graph nodes in a manner consistent with captured action concepts.

This can be accomplished with hierarchical clustering of graph nodes. By merging the nearest two graph nodes, we generate a new node that represents common role and action concepts (i.e. the most specific common ancestor of both concepts). The rationale behind the merge process is that actions, frequently occurring near in domain space, define some important strategic concepts. The definition of 'near' thus solely governs how the abstraction process combines action descriptions. Although the distance function is strictly domain-dependent it must utilize conceptual distance between actions, agent roles, and domain positions. Formally, the distance between nodes a and b is a function *distance*(a, b), which must comply with the following three distance axioms [3]:

1. Non-negative definiteness: $\forall$ a, b:
   $dist(a, b) \geq 0 \wedge dist(a, b) = 0$ iff a = b
2. Symmetry: $dist(a, b) = dist(b, a)$
3. Triangular inequality:
   $\forall$ a, b, c: $dist(a, b) \leq dist(a, c) + dist(c, b)$

We defined the distance between graph nodes as a weighted sum of distances between node positions and graph distances between role and action concepts. The weights were assigned by trial and error to produce meaningful results. A more in depth description of the distance function and the whole abstraction process is described in [2].

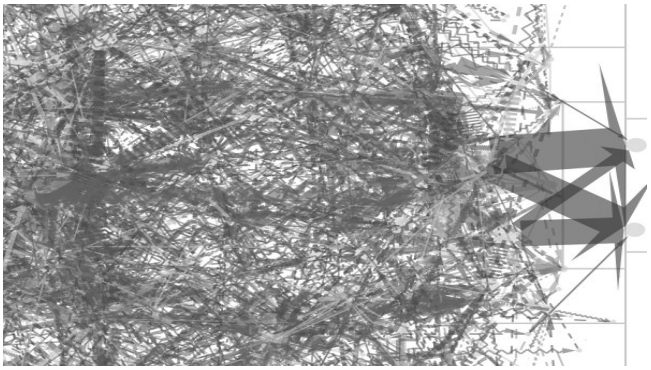

Figure 6: An abstract action graph (AAG_8).

The clustering process results in an *abstract action graph* (AAG), which is an action graph where graph nodes represent more than one agent action. Abstract action graph describes agent behavior in a more abstract way than the original action graph. An abstract action graph, where minimal distance between nodes is greater or equal than some value *dist*, is labeled AAG_{dist}. Such graph can be created with repeated merging of nearest nodes until the minimal distance between nodes is grater than *dist*. An *action description*

of a node in AAG_{dist} is a combination of a node position, corresponding action, and role concepts and a parameter *dist*. AAGs with greater value *dist* represent actions in a more abstract way than AAGs with a lower *dist* value. Therefore, the value of parameter *dist* can be regarded as the degree of abstraction of an AAG. An example abstract action graph AAG_8 is presented in Figure 6. The abstraction process can be stated in a pseudo-code as follows:

```
Input:
- action graph: G
- node distance function: distance(n1, n2)
- target abstraction value: dist

Algorithm:
while (true) { // repeat forever
  //find the nearest nodes
  find nodes a,b ∈ G: min(distance(a, b))
  // check if nodes are near enough
  if (distance(a, b) < dist) { // merge nodes
    create new node c ∈ G
    c.action = common_parent(a.action, b.action)
    c.role = common_parent(a.role, b.role)
    c.instances = a.instances ∪ b.instances
    c.pos = avg(position of agents in
                c.instances)
    remove a, b from G
  }
  else {
    break // stop the abstraction process
  }
}

Output:
- abstract action graph: Gdist
```

3.2.3 Detection of Strategies

When dealing with the observed multi-agent activity it is difficult to decide whether the observed activity represents an instance of a strategic plan or is it simply a result of agent activity based on some local agent decisions. However, multiple and similar agent activities observed over a longer time period tend to be more strategic than those emerged as local decisions, which can be regarded as noise. Therefore we consider repeated and similar action activity as a strategic activity.

In MASDA, similar actions are represented as a single node in an abstract action graph. The amount of similarity is regulated with the value of abstraction parameter *dist*. Multi-agent activity is represented as a path in an AAG. Hence, repeated activity can be discovered by finding adequate number of complete action instance sequences in an AAG path.

An example of a discovered path, together with traces of its action instances, is shown in Figure 7. Although not all actions continue throughout the whole path, there are three action sequences in this example that span the whole path. As this path exhibits repeated and similar agent activity, it is therefore considered as a representation of a strategic activity.

3.3. Symbolic description generation

This section describes the process of generating symbolic description from the obtained graphic representation of strategic activity.

3.3.1 Action Description Generation

We showed that path nodes from the obtained graphic representation of strategic activity represent a sequence of strategic actions. A symbolic action description is generated by visiting the nodes in a path and extracting role and action concepts together with node position and abstraction value. For example, an obtained strategic action description sequence presented in Table 1 corresponds to AAG_8 path shown in Figure 7. The sequence is strategic because it describes a strategic soccer situation - a successful shot. Again, it is expected that a strategy generated from AAG_{dist} with a greater *dist* value is more abstract that the one generated from AAG_{dist} with lower *dist* value.

Action descriptions can be used to create a pattern to detect strategic activity. This is particularly useful when observing unseen agent activity. Namely, if opponent activity matches a starting part of previously constructed strategic action description, it is reasonable to conclude that agents will follow this strategic activity. Consequently, agents can anticipate further opponent actions and devise a suitable counter-activity.

LTeam.FW: Long-dribble	LTeam.FW: Pass-to-player	LTeam.FW: Succesful-shoot	LTeam.FW: Succesful-shoot (End)
(x: 2.3, y: -11.9) *dist*: 8	(x: 39.2,y: -10.8) *dist*: 8	(x: 41.0, y: -4.9) *dist*: 8	(x: 53.6, y:4.5) *dist*: 8

Table 1: A strategic action description from AAG_8

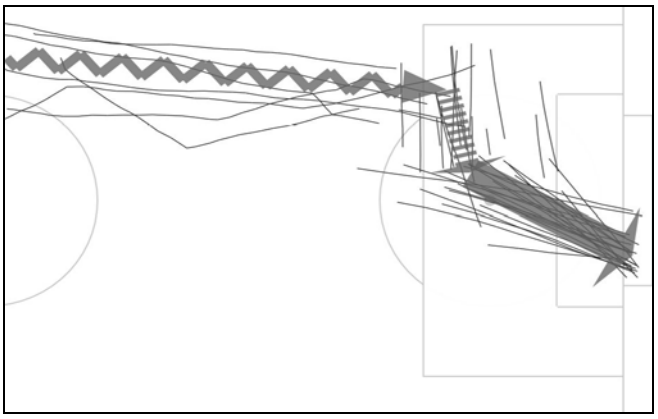

Figure 7: Graphical representation of strategic activity.

3.3.2 Dataset Generation and Rule Induction

As each node defines unique action concept it can be used to generate rules that describe this specific agent action. We generate data suitable for rule induction algorithms as follows. Positive examples are action instances in the target node and negative examples are instances in nearby nodes (i.e. near misses). For each time step we generate all pairs (*agent role, domain feature*), written as *role:feature*, and store only the true ones. However, the standard attribute-value approach is not suitable here. Namely, agents dynamically change roles, and thus it is impossible to generate all *role:feature* pairs for all time steps. Consider an example with only positive examples describing an action X. Internal data representation is presented in Table 2 with its corresponding attribute-value representation shown in Table 3.

	agentA			agentB		
time	role	feature1	feature2	role	feature1	feature2
1	L-FW	T	T	C-MF	F	T
2	L-FW	T	F	C-MF	T	T
3	C-MF	F	T	R-FW	T	T
4	C-MF	F	T	R-FW	T	F

Table 2: Internal data representation

	L-FW		R-FW		C-MF	
time	feature1	feature2	feature1	feature2	feature2	feature2
1	T	T	/	/	F	T
2	T	F	/	/	T	T
3	/	/	T	T	F	T
4	/	/	T	F	F	T

Table 3: Attribute-value data representation with roles instead of agent names

Because *role:feature* pairs are not defined for all times, this representation suffers from poor expressiveness. A more appropriate approach is to define *set-valued attributes* that are attributes whose domains are sets instead of single values. With this approach, each feature corresponds to one set-valued attribute while the values are sets of agent roles, whose corresponding *agent:feature* pair is true. The example data is presented in Table 4.

time	feature1	feature2
1	{L-FW}	{L-FW, C-MF}
2	{L-FW, C-MF}	{C-MF}
3	{R-FW}	{R-FW, C-MF}
4	{R-FW}	{C-MF}

Table 4: Set-valued attribute data representation

Due to hierarchically ordered nature of role concepts, it is possible to automatically generate common parent role concepts, as shown in Table 5. This allows rule inducer to induce rules that describe agent activity in a stricter and more abstract manner. Namely, a rule generated from example shown in Table 4 is *IF (C-MF:feature2)* $\Rightarrow$ *X* while rule generated from example in Table 5 is *IF (FW:feature1* $\wedge$ *C-MF:feature2)* $\Rightarrow$ *X*. The latter rule exhibits more abstract role concept (FW instead of L-FW and R-FW) and is more specific, as it has two features instead of only one as in the previous rule.

time	feature1	feature2
1	{L-FW, FW}	{L-FW, C-MF}
2	{L-FW, C-MF, FW}	{C-MF}
3	{R-FW, FW}	{R-FW, C-MF}
4	{R-FW, FW}	{C-MF}

Table 5: Set-valued attribute data representation with generated common parent role concepts (FW)

4. OBTAINED RESULTS

We generated data for each action obtained from nodes in a discovered strategic path. We used SLIPPER [4], a set-valued rule inducer, with fixed values of parameters to generate corresponding rules. In a typical experiment, 10 games were given as input and several tens of strategic action descriptions were constructed each time. For a chosen description we constructed rules for AAG_1 to AAG_{20}.

The example in Table 6 presents automatically constructed rules generated from AAG_8 action description (see Figure 8).

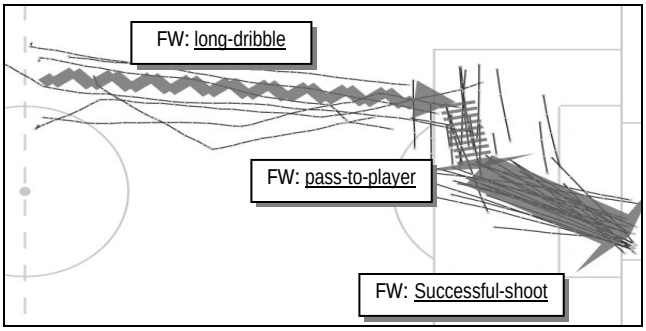

Figure 8: Discovered strategic action description (thick arrows) and original action sequence instances (thin lines).

LTeam.FW:Long-dribble (First frame in Figure 1): RTeam.C-MF:Moving-away-slow $\wedge$ RTeam.L-FB:Still $\wedge$ RTeam.R-FB:Short-distance
LTeam.FW:To-player (Second frame in Figure 1): RTeam.R-FB:Immediate
LTeam.FW:Successful-shoot (Third frame in Figure 1): RTeam.C-FW:Moving-away $\wedge$ LTeam.R-FW:Short-distance
LTeam.FW:Successful-shoot-END (Last frame in Figure 1): RTeam.RC-FB:Left $\wedge$ RTeam.RC-FB:Moving-away-fast $\wedge$ RTeam.R-FB:Long-distance

Table 6: Rules describing discovered strategy

At a first glance the rules seem a bit uninformative. However, expert analysis revealed that the rules do describe important strategic information:

- LTeam.FW:Long-dribble

RTeam.C-MF:Moving-away-slow: The right team's center-midfielder was occupied with previous ball owner and was for a while moving away from the ball. Consequently, he stayed behind the action.

RTeam.L-FB:Still: This player is at the bottom of the first frame in Figure 1 moving adjacent to the ball. In terms of relative movement to the ball he appears still. His movement is defensive, but he fails to aim to directly intercept or cover any of the attackers.

RTeam.R-FB:Short-distance: The right team's right fullback player unsuccessfully tried to intercept the dribbler. He consequently stayed at short distance behind the ball. Humans would probably favor the equivalent *RTeam.R-FB:behind* feature.

The three clauses successfully point out three main reasons for the success of the attack.

- LTeam.FW:To-player

RTeam.R-FB:Immediate: This rule essentially states that a pass occurred because right team's right fullback came too close to the ball. A ball owner was threatened by the opponent so he passed the ball to the teammate, who was left uncovered.

- LTeam.FW:Successful-shoot

RTeam.C-FW:Moving-away: Since shots represent a very fast ball movement, players are moving away from the ball. The rule inducer therefore just picked one feature among many equivalents. This is essentially the same as *ball:fast* which would have been far more intuitive.

LTeam.R-FW:Short-distance: there are many agents at short ball distance (*LTeam.L-FW, LTeam.R-FW, RTeam.L-FB, RTeam.LC-FB, RTeam.RC-FB, and RTeam.R-FB*). As rule inducer considers shorter rules to be better than longer, it only included one such feature instead of more, as would be expected by humans.

It is evident that rule inducer is not able to choose the most appropriate human-favored features. One reason for this is in a small number of learning examples and consequently substantial number of equivalent *agent:feature* pairs for each situation. As rule inducer has no meanings to favor one feature over another, it simply picks one. However, expert analysis showed that this nevertheless results in meaningful rules describing actual causal strategic relations. In terms of human comprehension, it appears that rule inducer would greatly benefit from some sort of domain-dependent knowledge about features. We consider the construction of such feature rating mechanism as our future work.

5. EXPERIMENTAL EVALUATION

We evaluated MASDA on 10 RoboCup games played during SSIL [14]. A leave-one-out strategy was used to generate 10 learning tasks. A pre-determined 3-action strategy, shown in Table 1 and in Figure 7, was used as a reference and was generated from all 10 games, for abstractions AAG_1 to AAG_{20}. For each learning task, a strategy was generated on 9 games and tested on the remaining game, again for AAG_1 to AAG_{20}. Tests measured the difference between action descriptions, the quality of generated rules for all three actions and joint use of rules together with action descriptions. One learning or test example is one 3-action sequence which is positive if it fits the reference strategy description. If the positive test example fits the learned strategy then this example is considered a true positive, otherwise it is considered a false negative. The results presented in Table 8 are averaged over 10 tests where the x-axis is the level of abstraction (parameter *dist* for AAG_{dist}).

The results in Table 8a indicate that the accuracy of action descriptions is approximately constant with the abstraction. However, the accuracy of rules quickly increases until it peaks at *dist*=4 and then slowly decreases.

This is expected because for lower abstractions, nodes represent only a few action instances, which is insufficient for rule inducer to generate good rules. This is different with high *dist* values where nodes represent quite different action concepts, thus producing more abstract and less accurate rules. Accuracy when using both rules and description follows rule accuracy for lower abstraction values, since rules are too specific. With higher abstraction values (>14) overall accuracy follows description accuracy since rules become too general.

When measuring recall, all the three test scenarios give similar results as shown in Table 8b. That is, the quality of classifying true cases increases to *dist*=3 then remains steady until *dist*=14 when it quickly drops. The similar phenomenon is observed when measuring precision, shown in Table 8c. This can be explained by the generated agent behavior being too abstract.

The last test was performed to verify if the abstraction process really generates more abstract descriptions. For this test we measured the abstraction of generated rules, defined as an average feature depth in feature taxonomy for features used in rules. The lower the depth, the more abstract the rule is. The results, presented in Table 7, clearly show that average feature depth is negatively correlated with the abstraction parameter *dist*. This confirms that as abstraction value increases the rules contain more abstract features. Since rules were generated from node data, we can safely conclude that generated strategies and AAGs exhibit the same principle: that the AAG with higher *dist* value presents more abstract action activity than the one with lower *dist* value.

a) Accuracy

b) Recall

c) Precision

Table 8: Results. The x-axis is the degree of abstraction (parameter *dist*).

6. DISCUSSION

We have designed and implemented MASDA as a general domain-independent framework for discovering strategic behavior of multi-agent systems. Domain-specific knowledge was introduced in the form of role, action and domain feature taxonomies. We assume that changing a domain is a straightforward task that would require changing specific domain-knowledge of a similar form. We believe that there is a wide range of possible domains that can be exploited by MASDA since its essence is stepwise abstraction in the domain-space.

The experiments indicate that the approach is practically useful in terms of accuracy, recall and precision. Our tests also confirm that the abstraction process in fact generates more abstract descriptions of agent activity.

There are some open questions that need to be addressed. First, MASDA was evaluated only on the RoboCup domain. Although the authors believe that no major problem should emerge when introducing another domain, this should be verified in practice. Second, while the discovered rules seemed sensible to the soccer expert, they were rather unintuitive for non-experts to comprehend. The rule discovery process would greatly benefit from some sort of feature relevance function, based on domain-knowledge that would favor human-desired features. This kind of knowledge should be provided by a domain expert.

7. ACKNOWLEDGEMENT

The authors would like to thank Gal Kaminka for helpful discussion and thoughtful comments.

ABSTRACT

A novel control mechanism was recently introduced based on Extended Markov Tracking (EMT) [9, 10]. In this paper, we present a study of its response to multiple interacting control goals. We show a simple extension that can be integrated into EMT-based control, and which provides it with the ability to handle several behavioral targets. Experimental support for the validity of this extension is provided. We also describe an experiment with a simulated robot, where EMT-based controllers interact and interfere indirectly via the environment. Experiments support the resilience of multiagent EMT-based team control to potential conflicts that may appear within a team.

1. INTRODUCTION

Imagine a car moving quickly along a highway; a bend in the road approaches, and the car's autopilot considers possible actions. It faces two interacting and potentially interfering considerations: first, the car has to turn fast enough to fit the road's curvature, or it will run off the road; second, a car has to turn slowly enough to maintain its grip on the road, or it will spin out of control. Furthermore, not only its radial speed, but also its linear speed affects the car's successful negotiation of the bend in the road, and the autopilot has to consider (or at least respond to) the environment-enforced interaction between these two motion parameters. That is, the autopilot faces both explicit and implicit multi-objective control problems.

These can be solved using a variety of methods. For example, proper control strategy can be achieved through learning (as, for instance, in [5]). Depending on the controller representation, and if some basic control capabilities are available, behavior-based (e.g., [1, 2]) or expert-based (e.g., [4, 12, 8]) approaches can also be used to achieve the required balance. Both, however, have their limitations. For example, the expert-based approach provides a fluent merger of basic advice from multiple sources, but concerns itself only with this merger and does not dictate how the basic advice is produced. The behavior-based approach, on the other hand, explicitly states different basic behaviors and their interrelationships with respect to action selection, and is capable of complex behavior composition. Unfortunately, each basic behavior is usually obtained by specific controller design and specialization. This results in explicit and simple controllers, but sacrifices the controller's universality and reuse, in case another behavior has to be included.

In this paper we consider the multi-criteria problem when basic control is performed using a control scheme based on Extended Markov Tracking (EMT) [9, 10]. EMT-based control provides a means to achieve a complex behavioral goal. We use a scaled additive mechanism directly integrated into EMT-based control to combine rationales for action with respect to multiple behavioral targets. This creates a fluent merger out of a well-defined underlying action choice mechanism, and we carry out experiments to test this new multi-target EMT control in an explicit multi-objective control scenario.

We then applied EMT-based control to implicit multi-objective control. We created a simulated robot setting using the Player/Stage simulator [6], in which an EMT-controlled robot had to follow a target. In this experiment, linear and radial speeds of the robot were controlled by two independent EMT-based controllers, which forced them to solve an implicit multi-objective problem, since the robot's motion correlates the two speeds, and thus the two controllers. In addition, we complicated the setting by providing controllers with inexact environment models. EMT-based control demonstrated strong resistance to multiple sources of system noise, and successfully handled the scenario.

The rest of the paper is organized as follows. Section 2 briefly describes the formal setting of Extended Markov tracking and a control scheme based on it, with Subsection 2.1 describing our extension of the additive combination mechanism to EMT-based control. We proceed in Section 3 to the experiments and experimental results of a simple multi-target problem. Section 4 describes our

experiment with the simulated robot scenario of target following. We discuss in Section 5 our results and future work.

2. EXTENDED MARKOV TRACKING AND CONTROL

EMT-based control [9, 10] is a recently introduced framework for control of a stochastic environment. It relies on the fact that the system environment has a Markovian model of the form $< S, s_0, A, T, O, \Omega >$, where

- S is the set of all possible environment states;
- s_0 is the initial state of the environment (which can also be viewed as a distribution over S);
- A is the set of all possible actions applicable in the environment;
- T is the environment's probabilistic transition function: a mapping $T : S \times A \rightarrow \Pi(S)$. That is, $T(s'|a, s)$ is the probability that the environment will move from state s to state s' under action a;
- O is the set of all possible observations. This is what the sensor input would look like for an outside observer;
- Ω is the observation probability function: a mapping $\Omega : S \times A \times S \rightarrow \Pi(O)$. That is, $\Omega(o|s', a, s)$ is the probability that one will observe o given that the environment has moved from state s to state s' under action a.

Extended Markov Tracking (or EMT for short) then uses this environment model to follow the system development, and maintains two estimators. First is the regular estimator for this type of environment — the state estimator, or state beliefs, expressed by a distribution vector over the system states $p_t \in \Pi(S)$. The second is the system dynamics estimator $PD : S \rightarrow \Pi(S)$, which can be seen as a stochastic function that "explains away" the changes in the system state beliefs seen so far.

To keep track of the actual system development, EMT dictates that its estimators be updated as follows:

- For state beliefs a Bayesian update is used. If at time t an action $a \in A$ was taken and then an observation $o \in O$ received, the new state beliefs p_{t+1} would be expressed by the formula:

$$p_{t+1}(s) \propto \Omega(o|s, a) \sum_{s'} T(s|a, s')p_t(s')$$

- For the system dynamics estimate EMT uses the Kullback-Leibler distance [3]

$$D_{KL}(p\|q) = \sum_x p(x) \log \frac{p(x)}{q(x)}$$

to perform a conservative update based on the following convex optimization problem:

$$PD_{t+1}(\cdot|s) = \arg \min_{Q(\cdot|s)} \langle D_{KL}(Q(\cdot|s)\|PD_t(\cdot|s))\rangle_{p_t(s)}$$

$$s.t.$$

$$\forall s' \;\; p_{t+1}(s') = \sum_s Q(s'|s)p_t(s)$$

$$\forall s \;\; \sum_{s'} Q(s'|s) = 1$$

That is, an explanation is sought for the change in system state beliefs from p_t to p_{t+1}, similar (as much as possible) to the old dynamics estimate PD_t. This update is denoted for short as $PD_{t+1} = H(p_{t+1}, p_t, PD_t)$.

Despite the fact that the optimization problem contained within the dynamics estimate update looks difficult, it has rather attractive properties. First, it is a convex optimization problem over a convex domain, which means that it can be solved efficiently. Second, a numerical iterative solution exists, tailored specifically for this type of optimization problem — iterative proportional fitting [7].

EMT-based control's approach to estimation has been embedded within a simple greedy control algorithm that is summarized below. The algorithm employs a reference system dynamics $r : S \rightarrow \Pi(S)$, termed the *ideal system dynamics* or *tactical target*; the control algorithm greedily selects actions so as to modify the estimated system dynamics to concur with the reference. This approach is similar to closed-loop differential control [11].

0. Initialize estimators:
   - the system state estimator $p_0(s) = s_0 \in \Pi(S)$,
   - system dynamics estimator
   $$PD_0(\bar{s}|s) = prior(\bar{s}|s)$$
   Set time to $t = 0$.
1. Select action a^* to apply using the following computation:
   - For each action $a \in A$ predict the future state distribution $\bar{p}^a_{t+1} = T_a * p_t$;
   - For each action, compute
   $$D_a = H(\bar{p}^a_{t+1}, p_t, PD_t)$$
   - Select $a^* = \arg\min_a \langle D_{KL}\left(D_a\|r\right)\rangle_{p_t}$
2. Apply the selected action a^* and receive an observation $o \in O$.
3. Compute p_{t+1} due to the Bayesian update.
4. Compute $PD_{t+1} = H(p_{t+1}, p_t, PD_t)$.
5. Set $t := t + 1$, goto 1.

2.1 Multi-Target EMT-based Control

At times, there may be several behavioral preferences. For example, in the case of multi-robot movement in formation, two preferences on motion direction exist — one dictated by keeping in formation, the other by obstacle collision avoidance. Successful formation navigation requires a robot to adhere to, and balance, both of these behaviors. For EMT-based control, this would mean facing several tactical targets $\{r_k\}_{k=1}^K$, and the question becomes how to merge and balance them. A balancing mechanism can be applied to resolve this issue.

Note that EMT-based control, while selecting an action, creates a preference vector over the set of actions based on their predicted performance with respect to a given target. If these preference vectors are normalized, they can be combined into a single unified preference. We thus replace stage 1 of EMT-based control (the action selection stage) by the following:

1. Given a set of tactical targets $\{r_k\}_{k=1}^K$, and their corresponding weights $w(k)$, select action a^* based on the following computations:
   - For each action $a \in A$ predict the future state distribution $\bar{p}^a_{t+1} = T_a * p_t$;

- For each action, compute
$$D_a = H(\bar{p}^a_{t+1}, p_t, PD_t)$$
- For each $a \in A$ and r_k tactical target, denote
$$V(a,k) = \langle D_{KL}\left(D_a \| r_k\right)\rangle_{p_t}.$$
Let $V_k(a) = \frac{1}{Z_k} V(a,k)$, where $Z_k = \sum_{a \in A} V(a,k)$ is a normalization factor.
- Select $a^* = \arg\min_a \sum_{k=1}^{k} w(k) V_k(a)$

The weight vector $\vec{w} = (w_1, ..., w_K)$ allows the additional "tuning of importance" among tactical targets without the need to redesign the targets themselves. This balancing method is also seamlessly integrated into the EMT-based control flow of operation, and is compatible with its multi-agent extension, as explored in [10]. This compatibility makes possible the following experiment.

3. MULTIPLE TARGETS IN A SCALE BALANCING EXPERIMENT

Originally, EMT-based multi-agent control was tested for its team coordination capabilities over a small balancing problem involving two agents. In this problem, two agents of equal mass are standing on a long bar resting with its ends on two equal springs (Figure 1).

At each time step of the system, each agent has the choice of three actions: moving left one step, moving right one step, or staying put. Every movement of an agent has a non-zero probability of failing, and the probability is biased by the inclination of the bar. That is, an uphill motion will have less probability of succeeding than if the bar were level, and downhill motion will have greater probability of succeeding than if the bar were level. Notice that bar inclination depends on the current agent positions on the bar, thus creating a correlation between the effects of the agent actions, and providing for implicit information transfer between the agents.

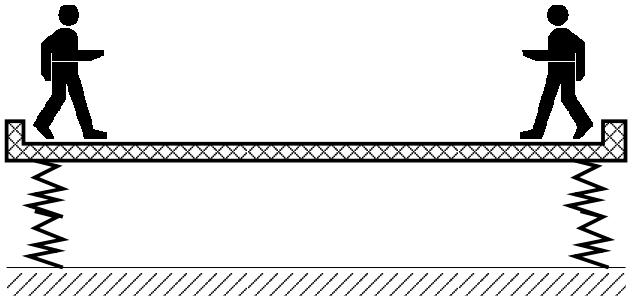

Figure 1: Springed bar setting

Formally, the system state is described by the positions of the two agents on the bar, $S = [1 : d_{max}]^2$, where d_{max} is the length of the bar in "steps", and the initial state is an unbalanced one, so that $s_0 = (1, \frac{d_{max}}{2} + 1)$. The action sets are $A_i = \{left, stay, right\}$, and the transition probability is built according to the physics of motion as previously described.

In this paper, we consider only one observation scenario among the original two: both agents receive independent noisy observations about their joint position. That is, $O_i = S = \{$all positions of the two agents$\}$, $\Omega_1 = \Omega_2$ and creates uniform noise over the immediate neighborhood of the real joint position of agents.

However, unlike the original paper [10], we have modified action selection to accommodate multiple targets, as described in Section 2.1. We then set the agents two conflicting targets. One is to balance the springed bar, while the other is to maintain a preset distance between themselves. Note that these targets are not requirements of the system state, but of the laws governing its behavior. For instance, distance maintenance is expressed by a dynamics matrix, that shifts any given state into one that possesses the correct distance property, and EMT-based control sets out to achieve this kind of law within the system.

Although the two behavioral targets we have chosen are compatible, that is, there exists a position of agents on the bar that satisfies both, the targets are indeed conflicting and interfering. For example, assume that we want agents to be at a distance of 4 from each other. Denote by 0 the coordinate line at the center of the bar, and assume that the system's noisy response forced the agents into positions -2 and $+3$. In this case, the balancing target can encourage the motion of the left agent from -2 to -3 thus balancing the bar, but violating the distance constraint. On the other hand, the distancing target could be satisfied by the same agent moving right to -1, violating bar balancing even further.

In our experiment sets, we tested both the reaction of EMT-control to multiple targets, and to their balancing by weight vector $\vec{w}$. The bar length was set to 14, so that the leftmost position on the bar would have coordinate 1 and the rightmost position would have coordinate 15, and the agents were also required by the second target to keep the distance between them at 4 steps.

Despite the constant conflict between the two targets, multiagent EMT-based control equipped with our multi-target action selection approach managed to maintain both targets quite closely. Although relentless system noise caused fluctuations, as seen from an example run at Figure 2, these fluctuations occurred around the only common position that satisfies the demands of both targets. In fact, the mean values of distance between agents and the position of the center of mass almost perfectly matches the ideal, as can be seen from the value distributions in Figure 3, which in our experiments would be 4 and 8 respectively.

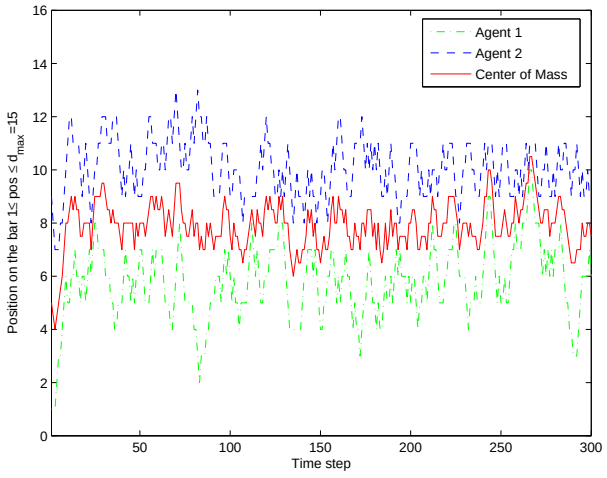

Figure 2: Example Run of Dual-Target Springed-Bar Problem

As was mentioned above, our experiments included different balancing vectors $\vec{w}$, e.g., the distribution in Figure 3 was obtained from the weight vector $\vec{w} = (0.2, 0.8)$, that is, setting the balancing target at 0.2 and the distancing target at 0.8. Changing the weights vector to be $\vec{w} = (0.4, 0.6)$ exposes an interesting property of multi-target EMT-based control. Since the targets were weakly

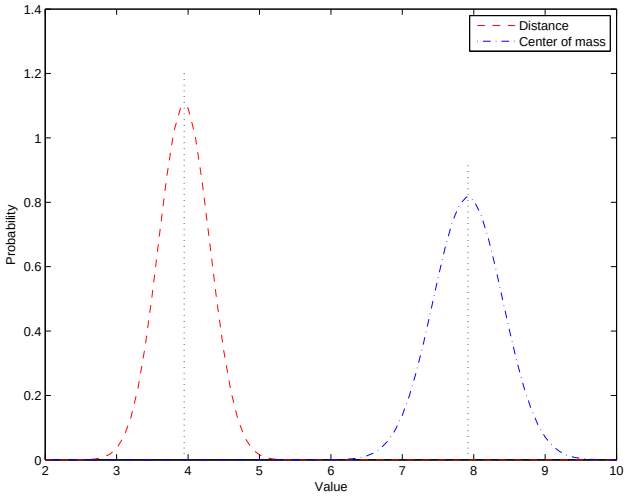

Figure 3: (Fitted normal) Distribution of distance and center of mass in dual-target springed-bar problem with (0.2, 0.8) balancing

compatible, the algorithm maintained both targets with the new balancing vector, as it did with the old one. The difference occurred when the control algorithm had to correct system behavior in response to noise — the algorithm was more ready to briefly deviate from the distancing target than the balancing one, as shown by the distributions in Figure 4.

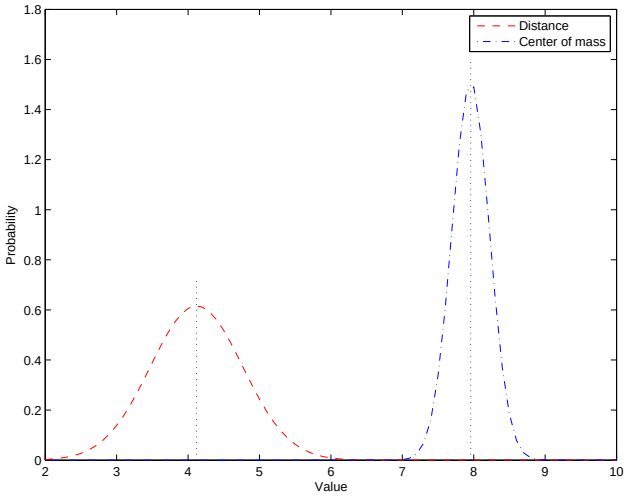

Figure 4: (Fitted normal) Distribution of distance and center of mass in dual-target springed-bar problem with (0.4, 0.6) balancing

However, as the weight of the the balancing target increased, not only the variance of the distance between the agents changed, but also the mean. EMT-based control began to lean strongly towards the balancing target, almost abandoning the distancing target. This can be seen clearly from Figure 5, which depicts changes of the distance and center of mass distributions mean, as a function of weight of the target.

Note that the balancing target had a very strong presence at the weight 0.4, as expressed by the mean and variance of the center

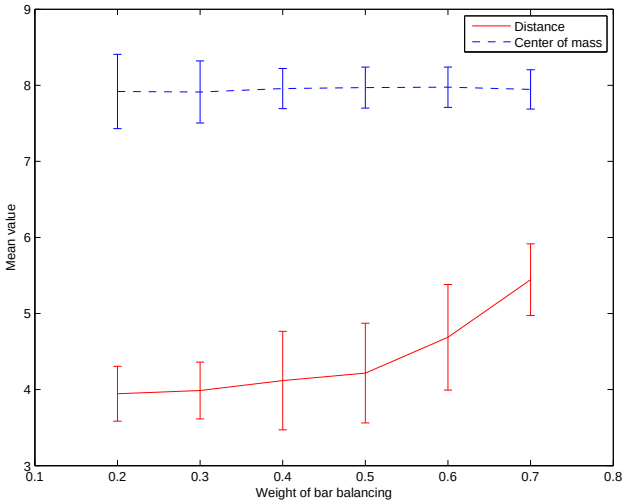

Figure 5: Means of distributions with respect to the weight of the balancing target. Error bars depict variance.

of mass distribution. On the other hand, the distancing target at the weight of 0.4 had much less attention from EMT-based control. This inequality in attention to targets with respect to symmetric weight vectors was at first surprising, but can be explained. It has to do with the strength of preference as expressed by the two targets used.

While constructing the targets for the EMT-based controller, a simple inverse exponential scheme was selected to produce the preferences. The balancing target was constructed to have inverse exponential preference over the center of mass deviation from an ideal, while the distancing target was composed based on deviation from the distance ideal. However, simple parameter selection for this scheme produced two targets with different *strength* of preference. While the balancing target included preferential differences of dozens of orders of magnitude, the distancing target featured preference differences of only 2–4 orders of magnitude.

As a result, any change in system dynamics had much higher impact with respect to the balancing behavioral preference, which thus had a stronger effect on proper system behavior. The distance tactical target was very mild in comparison, and thus had less influence on action choices.

4. SIMULATED OBJECT TRACKING EXPERIMENTS

The experiments above with multiple targets were the first step in testing EMT-based controllers for inter-controller interference. It is possible and even necessary to consider situations where separate controllers interact via the environment, interfering with one another. This situation often occurs naturally in robotics, and we chose to test EMT-based control in that domain.

4.1 Robot Motion with EMT Control

Computerized algorithmic control of a robot, unlike low-level reactive control, requires a discretization of sensory information received by the robot, and later the carrying out, by the robot's actuators, of a discrete action description. In effect, the actual robot serves as an interface between the real world and a discrete controller, transforming sensory information to fit the internal environment model used to make decisions.

Two adjustments are required, in order to apply EMT control to robotic motion.

If the internal model is chosen to be a Markovian model, $< S, A, T, O, \Omega, s_0 >$, then sensory discretization requires mapping real world sensations onto the observation set O. This makes the set of states S abstract — it is only indirectly connected to the real world, and all $s \in S$ gain meaning through the observation probability function Ω.

Abstraction of S has several consequences. First, a control algorithm based on a Markovian model would usually require the transition function $T : S \times A \rightarrow \Pi(S)$, also called the "action model," to be strongly coherent with the environmental dynamics of the system state's *meanings*, determined by O and Ω. However, the EMT Controller manages to achieve reasonable, though not optimal, results even with an inaccurate action model (Section 4.2).

Second, if EMT Control is to be applied, its strategic layer has to create a tactical target by "reverse engineering" — a high-level target is described by limitations on *observations*, and the strategic layer uses Ω to convert it into system state dynamics, $r : S \rightarrow \Pi(S)$.

Other than the two adjustments above, the basic EMT Controller remains unchanged for robot control.

4.2 Target-Following Experiment

We designed a straightforward simulation experiment, within the Player/Stage simulation environment [6], to see whether EMT Control would be effective for robot control, and whether it would be able to cope with implicit controller interference and an inaccurate environment model.

In the experiment, two independent EMT Controllers, $EMTC_1$ and $EMTC_2$, were applied to linear and rotation speed modulation of a single (simulated) Pioneer-2X robot, with the task of following another robot's motion. The sensory information was received through a *blob finder* — an on-robot camera with basic image analysis that makes possible the detection of color blobs within the picture. Camera information was approximately mapped onto the observation sets: color blob relative area and centering within the picture. Thus, the observation distributions provided state meanings of linear distance for $EMTC_1$, and angular distance for $EMTC_2$.

To follow (but not capture) an object, a robot must solve two balancing problems: stay within a certain distance from the object, and stay directed straight at it.

A well-studied formal balancing problem exists that can easily be adopted for robotic controllers: the Drunk Man Walk (DMW). This problem concerns a weakly-controlled random walk over a linear graph, as depicted in Figure 6. The actions in this model tilt the probability of left and right steps, while the observation distribution blurs the current position.

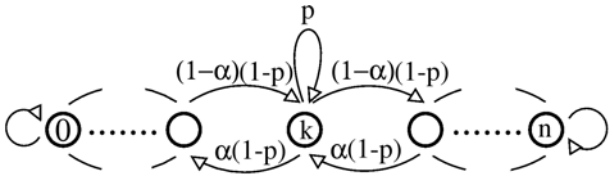

Figure 6: Drunk Man state transition diagram. α is subject to action effect.

Since EMT-based control was shown to be successful at solving this problem [9], we chose to use the DMW as the internal model for the $EMTC_1$ and $EMTC_2$ controllers. Their balancing acts translated into a tactical target in a natural way, essentially projecting all states in S_i onto $s = \frac{|S_i|}{2}$.

Notice, however, that the transition function of a DMW (our action model) is not entirely coherent with the real world's reactions, and with the meaning of system states. This incoherence actually serves our purposes, since we want to verify the performance of EMT-control with respect to an imperfect model. For example, $EMTC_1$ uses system states S_1 to represent distance from a followed object, and since their meaning is based on the camera picture, they represent an irregular set of distances. This lack of regularity would dictate uneven transition probabilities from different states under the same action, but this is not the case in the DMW model, where all system states are symmetric. A similar problem exists within $EMTC_2$, because change in the visible angle of an object may depend on its linear speed as well as on its angular speed. However, this is not accounted for by the DMW model within $EMTC_2$.

This incoherence indeed influences the EMT Controller's performance; however, it was still able to successfully perform the tracking task. A sample run of the EMT-controlled robot can be seen in Figure 7, depicting three positions of the robots at different times. In this run, the followed robot (which we shall call the *prey*) performed a constant loop, and the EMT-controlled robot that followed it (the *predator*) managed to capture this motion.[1] The predator traces a smaller loop, concentric with the one traced by the prey. However, due to action model incoherence, the predator did not perform optimally and reacted to the change in the prey's position with insufficient correcting actions. Effectively, it resulted in the predator being significantly further away from the prey than was required by the tactical target.

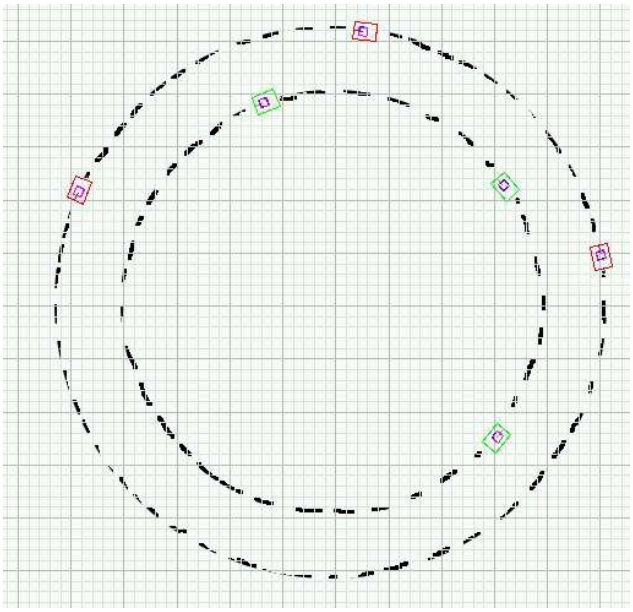

Figure 7: Target Following with a Weakly Coherent Model

5. DISCUSSION AND FUTURE WORK

In this research we explored the performance of EMT-based control in response to multiple interacting targets, as well as interacting environment models. In the latter, EMT-based control was applied

[1]Predator/Prey terminology is used here for naming convenience only, since there is no actual 'capture' intended.

in an experimental setting with the additional complication of an incoherent environment model.

For EMT to handle explicit multiple objectives, we introduced an additive weighing scheme that integrated directly into EMT operations, and allowed it to select actions in a well-balanced way. In fact, in our experiments EMT control managed in many situations to achieve both targets, despite their interference and, at times, conflict with one another.

Our results also showed that EMT-based control is sensitive to the strength of its tactical targets, and actions are selected in correspondence to that strength. As the proposed weighing scheme affects EMT's attention to targets as well, we conclude that it can and should become a part of an overall target design process, allowing for finer tuning of the combined behavior.

The simplicity with which tactical behavioral targets can be balanced within EMT-based control suggests further development of dynamic balancing schemes, guided, perhaps, by some external global system behavior evaluation. For example, in our car driving scenario above, it might be the successful passing of a bend in the road.

As our weighted balancing scheme is closely related to other multi-objective algorithms, it is important to continue research into the possibility of their integration. Since EMT-based control includes a prediction mechanism, expert-based balancing approaches (such as [4, 12, 8]) would be of particular interest. Insights from multi-objective reinforcement learning (e.g., [5, 2]) could also be used.

EMT sensitivity to preference strength can be further exploited by introducing non-linear balancing and weight schemes, in effect amplifying preferences as needed, without complicating tactical target design.

The proposed multi-target approach, combined with the natural abilities of EMT control with respect to implicit interference of multiple controllers, can be readily used in a multi-robot setting, quickly providing a sustainable behavior of a team. Formation restricted navigation, multi-featured manipulator control, multi-robot sweeping, and many other tasks become susceptible to the use of EMT with the aid of our multi-target approach, and we plan to explore these applications in the future.

ABSTRACT

A multiple UAV search and attack mission involves searching for targets in an unknown region, followed by attack on the detected targets. An effective mission involves assigning the tasks to UAVs efficiently. Task allocation becomes difficult when the UAVs have limited range to detect the targets and neighbouring UAVs. The UAVs are also subject to limited communication range. With these constraints, allocating tasks efficiently to UAVs become difficult. In this paper, we propose a negotiation scheme that efficiently allocates tasks for multiple UAVs. The performance of the negotiation based task allocation is studied on a battle field scenario. We study the effect of sensor ranges on the task allocation and compare the results with that of greedy strategy and a variation of the negotiation mechanism. The results show that the negotiation based task allocation mechanism performs far better than the greedy strategy. Negotiation with target information exchange between neighbours performs better than without target information exchange, when the sensor radius is low.

Task allocation, Negotiation, Multiple agents, UAV search and attack tasks

1. INTRODUCTION

Unmanned aerial vehicles (UAVs) are being extensively used for military purposes, like search, surveillance and as munitions in the battlefield [1] - [10]. They play a crucial role in information gathering from hostile and unknown regions. These UAVs can also be used as munitions to search, attack and destroy targets in the unknown region. The UAVs used for these applications may have limited capabilities and may not have the required stealth capability and ammunition payload to complete the task single-handedly. Hence, there is a necessity for such UAVs to be deployed in swarms. A desirable feature for these UAV swarms is to have autonomous decision making and coordinating capability. As the UAVs perform search, they may find several targets in the search region. The number of UAVs may be more than the number of targets available or the number of targets available may be more than the number of UAVs. In either case, we need an efficient task allocation method for assigning the UAVs to the targets. The classical solution for task allocation problem is to have a centralized task allocation system that generates the necessary commands for the UAVs. But, centralized task allocation system have well known limitations and do not address scalability issues well. Hence, there is a necessity to develop a decentralized task allocation algorithm. This algorithm must be suitable for implementation in a multiple agent UAV swarm. It should also be scalable, and consume low computational overhead. An efficient task allocation strategy should have the ultimate objective to complete the mission (that is, destroy all targets) in minimum time by cooperating and coordinating with other UAVs [1]. Cooperation can be achieved by communication with neighbouring UAVs, explicitly or implicitly. Here, we use negotiation mechanism to develop such a decentralized task allocation algorithm for multiple UAVs that communicate with each other for decision-making while performing search and attack tasks in an unknown region.

The UAVs that we consider are small in size, have limited fuel capacity (limited flight time), and limited sensing capabilities. The UAVs can detect the presence of neighbouring UAVs and targets within its sensor range only. The UAVs communicate with their neighbours and make their decisions based only on the information they receive from their sensors. All the UAVs are assumed to be homogeneous, have constant speed, and have no turn radius constraints. The UAVs have to carry out the mission within the given flight time. Collision avoidance between UAVs is also not an issue.

The UAVs can perform search, attack, and speculative tasks. Search task refers to searching for targets in the unknown region. Once a target is found by the UAV, it executes a speculative task to ensure that the target is a real target and not a false target. The target that has been verified as a real target is attacked by the UAV. We assume that once a target is attacked, it is destroyed and hence battle damage assessment task on the target is not necessary to be performed. However, it can be incorporated in the formulation fairly easily.

The speculative task is performed in the following way: Once a UAV finds a target, it estimates the value of the target. This value is used for negotiating with the neighbouring UAVs for assignment of the target.

Each UAV performs decision-making independently, based

on the estimate of the target status. The decision taken by the UAV also depends on the number of neighbouring UAVs. Here, we assume that the UAVs do not have sufficient memory to remember the path it has travelled.

1.1 Literature

Task allocation of UAVs is an active research area for the past few years. Nygard et al. [1], propose a network flow optimization model for allocating UAVs to targets. The network optimization problem is formulated as a linear programming problem to obtain decisions for allocating the UAVs. The authors assume that global communication between UAVs exists. The network flow model has been further extensively studied by Schumacher [2, 3, 4] for wide area search munitions with variable path lengths, assignment with timing constraints and path planning. Chandler et al. [5, 6], explore various other techniques like iterative network flow, auctions, linear programming, and mixed integer linear programming, for multi-UAV task allocation. The effect of communication delays on the task allocation using the iterative network flow model is dealt with in Mitchell [7]. Curtis [8] presents a task allocation methodology for simultaneous search and target assignment, where the search and task assignments are posed as a single optimization problem. Turra et al. [9] present a task allocation algorithm for multiple UAVs performing search, identification, attack, and verification tasks in an unknown region for targets that move in real time. These authors also address the problem of obstacle avoidance. Jin et al. [10] propose a probabilistic task allocation scheme for the scenario presented in [5, 6].

In most of the algorithms presented in the papers cited above, global communication between agents is assumed. So, information obtained by an agent is assumed to be communicated to all the other agents. However, the task allocation decision algorithm is autonomously executed by the agents. Sujit et al. [11] present a team theoretic approach that allows the UAVs to perform decision-making independently when there is no communication between UAVs. The UAVs can only sense the location of their neighbours and targets. The task allocation is performed based on a linear programming formulation, where the cost associated with each target is estimated with some probability. Rajnarayan and Ghose [12] pose a multiple agent search problem as a problem in the team theory framework and propose optimal solution to the problem of determination of search regions.

Recently, market based approaches have shown some considerable increase in performance of task allocation strategies for multiple agent applications. Dias and Stenz [13, 14, 15] introduce a novel approach for coordinating robots based on the free market architecture in economics. The approach defines revenues and cost functions across the possible plans for executing a specified task. The task is accomplished by decomposing it into sub-tasks and allowing the robots to bid and negotiate to carry out these sub-tasks. Gerkey and Mataric [16] use an auction mechanism for multi-robot coordination. Although there are many cooperative strategy algorithms available for multiple agents, very little attention has been paid to the role of communication which plays a vital role in the development and performance of a search strategy. Usually, the communication between agents is quantified by the amount of information that flows between them. The communication and computational complexity involved in multi-robot task allocation are analyzed in [17]. Mataric et al. [18] develop various task allocation strategies and study their performance on a multi robot application with sensor noise. The simulation study is compared with the results obtained using experiments. Gurfil [19] also uses auctions mechanism for task allocation among multiple UAVs performing search and destroy mission. Lagoudakis et al. [20] uses auction algorithm for assigning unexplored tasks to group of mobile robots. The paper also provides some theoretical bounds on the computational complexity of the proposed algorithm.

In this paper, we present a task allocation algorithm for multiple UAVs performing search and attack tasks in an unknown region using negotiation scheme for the scenario given in the next section. This is one of the very few applications available that exploits the use of negotiation for a network of UAVs involved in a practical problem of decision-making.

1.2 Problem Scenario

Consider a planar search space consisting of an unknown number of targets. The location of the targets are not known *a priori* to the UAVs. A search and destroy mission would be undertaken by sending a fleet of UAVs to search a region and destroy as many targets as possible within the flight endurance time of the UAVs. The task involved in such missions are search and attack. A search task is to search the environment for targets and, if found, engage a UAV to attack the target. The UAVs have to coordinate among each other so as to accomplish the mission efficiently and in minimum time. The UAVs have limited sensor and communication range. The UAVs can sense the exact position of all the targets and its value within its sensor range. The location of all the neighbouring UAVs within a UAV's sensor region are also assumed to be detected. The UAVs should perform task allocation so that as much of the mission as possible is completed. The task allocation mechanism we use is based on negotiation.

2. PROBLEM FORMULATION

Consider N UAVs/agents performing a search and destroy operation on a bounded region consisting of M targets whose exact positions are not known *a priori*. The basic problem of task allocation is to assign agent $A_i \in N$, to target $m_i \in M$, efficiently such that the mission is completed as fast as possible. The task allocation problem can be solved either using a centralized controller or a decentralized controller. In the former case each agent communicates the information it has to the centralized controller that solves a task allocation algorithm and assigns each agent to a particular task. However, implementing this task allocation strategy in real-time requires large communication overhead and may not be scalable with increase in number of agents and targets. Also, these strategies are not robust to failures. Hence, a decentralized task allocation strategy is necessary for implementing on a multi-agent system. The decentralized task allocation can be performed by any one agent in the multiple agent system. This agent receives the necessary information from all the agents and solves a task allocation algorithm and broadcasts the assignments to the agents. Another way of implementing a decentralized task allocation would be that, each agent broadcasts its information to all the other agents and hence each agent has the required information to solve the task allocation problem independently and assign a task for itself. The implementation of this task allocation

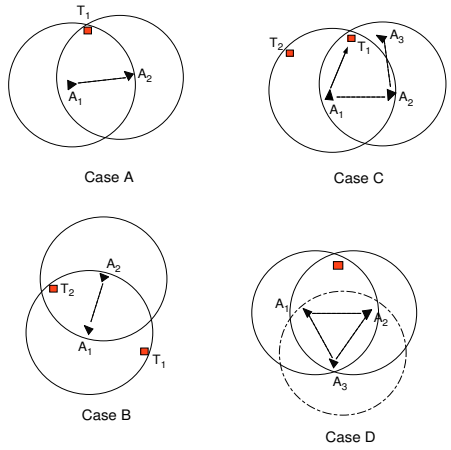

Figure 1: Some scenarios for decision-making

strategy requires large amount of communication among the agents.

The implementation of decentralized task allocation with finite communication range poses some challenging problems. For instance, consider Case A from Figure 1 where agent A_1 and A_2 have target T_1 in their sensor range and an allocation has to take place as to which agent should be assigned to the target. The task allocation can be done using a greedy strategy, in which case both the agents would move towards the same target which is not desirable. Another task allocation mechanism used in multi-robot literature is based on auctions. But in this case since the system is decentralized then each agent would become am auctioneer and hence both the agents auction the same target. A modification to the standard auction algorithm may eliminate some of the difficult issues, however this would complicate the decision-making rules for multiple agents using auction mechanism locally.

Consider Case B, wherein A_1 has T_1 and T_2 in its sensor range while A_2 has T_2 only. Auction requires broadcast of all the target and their associate costs. Resolving conflicts using auctions is a difficult task. In Case C, we can see that A_1 sees T_1 while A_3 is already on its way to attack T_1. So, A_1 wastes some resource in moving towards a target that is already assigned, Since the communication is limited it does not have access to the assignment of other agents. Instead of T_1 it could have attacked T_2. Here also greedy and auction algorithm would not yield good performance. In Case D, agent A_3 gets the auction information from A_1 and A_2 about T_1, now A_3 does not know to which agent it has to send the bid. These complications in using auctions for limited communication cases, give rise to the use of negotiation as a tool that can handle these situations efficiently. In cases A, A_1 and A_2 can negotiate which agent would be assigned to target T_1. While in case B, A_1 and A_2 can negotiate such that one agent attacks T_1 and the other moves towards T_2. In case C, A_2 can detect a conflict between A_1 and A_3 and send decisions such that A_1 or A_3 moves towards T_1. However in Case D, A_3 actually negotiates between A_1 and A_2 which are not neighbours and detects an early conflict and hence provides an efficient task allocation decision and has better fuel usage as only one agent can continue search to select other targets instead of moving to T_1.

However, the implementation of negotiation scheme involves designing of negotiation rules over which the process of decision-making takes place. In the next section we describe the negotiation scheme employed in decision-making.

At every time step each agent has to perform a task. The task can be search or attack a target. Each agent senses its environment consisting of other agents and targets. An agents' assignment for a task depends on four different situations. These situations are dependent on the availability of neighbouring agents and targets. The four situations, in which agent A_i has to perform a task and make a decision are:

1. No targets and no neighbours

   Task: Search

   Decision: Continue to move in the same direction

2. No targets but has neighbours

   Task: Perform search or attack. The target information may be provided by the neighbouring agents.

   Decision: Acts as a negotiator for neighbouring agents

3. Targets are present but no neighbours

   Task: Attack

   Decision: Select a target that yields maximum value

4. Target as well as neighbours are present

   Task: Search or attack

   Decision: Negotiate with neighbours

Once an agent A_i is present within a distance d from the target, we assume that the target is destroyed. The agents have to negotiate with its neighbouring agents for an efficient task allocation. The agents are not subjected to any turn radius constraints and hence can move in any direction. The agents have to maximize the number of targets destroyed in the search space by coordinating with its neighbouring agents through negotiation.

3. DECISION-MAKING

3.1 Negotiation as a tool to handle uncertainty in agent actions

In general, negotiation refers to the communication process that facilitates coordination and cooperation among a group of agents [22]. In multi-agent systems, its aim is to resolve problems related to resource allocation and task assignments between various agents in a decentralized setting.

Our approach is somewhat similar to Rubinstein's model of strategic negotiation [21] where agents make proposals that are either accepted or rejected by other agents; and whether an agent implements its proposal or not depends on what other agents do. However, our approach is different from Rubinstein's model on many counts due to the nature of the task allocation problem. Unlike most negotiation models we do not have a situation where each proposal is vetted by all the other agents. In fact, due to the connectivity restrictions we have a network of agents where an agent is not necessarily directly connected to all other agents. So, each agents decision is based on the response of

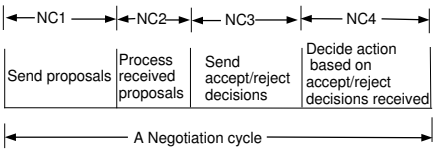

Figure 2: Negotiation cycle

only those agents that are connected to it. Moreover, unlike in Rubinstein's model, agents make simultaneous offers at pre-defined decision epochs and the actions are accordingly distributed between agents. Another way in which our model differs from Rubinstein's model is due to the fact that, in a task allocation problem the need for negotiation arises mainly because of lack of information about the action of other agents. So, the whole process of negotiation is geared towards determining the action of an agent in a coordinated autonomous fashion without assuming any kind of hierarchy or priority among agents.

A coordinated decision by an agent would be one that is not in conflict with the decision of its neighbors. There is no conflict except that which arises due to uncertainty of agent actions. For example, it occurs when more than one agent is planning to attack the same target, thus decreasing the effectiveness of the mission. Resolution of such conflicts can be effected either by

(i) Direct communication/negotiation as in the case when an Agent A_i and another agent A_j are within communication range.

(ii) Indirect negotiation when an Agent A_i and another agent A_j, $A_j \notin \mathcal{N}(A_i)$ want to attack the same target T, and A_i and A_j are connected through a sequence of communication links through other agents. For instance, they may be connected through a third agent A_k with $A_j \in \mathcal{N}(A_k))$ and $A_k \in \mathcal{N}(A_i)$.

In the first case, since A_j is within the communication range of A_i, it can exchange information with A_j and resolve the conflict. While, in the second case, A_i does not know about the existence of A_j, and so direct communication is not feasible. So, the intermediate agents are important in the negotiation process. In the negotiation scheme developed next, we will show that it is the neighboring agents who contribute to the decision-making of agent A_i.

3.2 Negotiation scheme

Each agent A_i performs the following actions during decision-making: (i) Sends/receives proposals (ii) Processes received proposals and sends Accept/Reject decisions to proposing agents (iii) Computes own route decision (iv) Implements decision. All these actions happen within each negotiation cycle. This is shown in Figure 2. Note that an agent A_i that has no targets will have the second segment only, while the agents that have targets as well as neighbouring agents will have all the four segments of decision-making.

The different segments of the negotiation cycle are described below:

3.2.1 Send/receive proposals (NC1)

Each agent evaluates the benefit associated with each target. Let $b_i(T_j)$ be the expected benefit A_i gets by attacking target T_j, which is given by

$$b_i(T_j) = V_{T_j} w_r \ - \ S_t \tag{1}$$

where, V_{T_j} = value of target T_j, w_r = the weight given to search task over the task of attacking a target, S_t = (time to reach the target T_j)/(total flight time). The benefit set $\mathcal{B}_i$ of A_i consists of benefits for all the tasks an agent has. Let $\mathcal{T}_i$ be the set of all targets. The benefit set for agent A_i is represented as:

$$\mathcal{B}_i = \{b_i(T_j) \mid T_j \in \mathcal{T}_j\} \tag{2}$$

Agent A_i chooses a target T_{S_i} for which A_i gets the maximum value, as

$$S_i \ = \ \arg\max_j \{b_i(T_j) \in \mathcal{B}_i\} \tag{3}$$

The proposal of agent A_i, sent to its neighboring agents, is of the form $Q_i = (A_i, T_{S_i}, b_i(T_{S_i}))$, containing the proposer agent's identification, proposed target, and the value associated with T_{S_i}.

3.2.2 Processing received proposals (NC2) and send decisions (NC3)

Let $\mathcal{Q}_i$ be the set of proposals received by agent A_i from its neighbors A_j, including its own proposal.

$$\mathcal{Q}_i = \{(A_j, C_{S_j}, \beta_j); L(A_j) \in \mathcal{N}(L(A_i), q_c)\}$$

Let T_k^i be a target that appears in at least one of the proposals received by A_i. That is, $T_k^i = T_{S_j}$ for some $Q_j \in \mathcal{Q}_i$. For each such T_k^i, define $\mathcal{A}(T_k^i)$ as the set of agents that have proposed T_k^i, and $\mathcal{B}(T_k^i)$ as the set of values associated with agents in $\mathcal{A}(T_k^i)$. So,

$$\begin{aligned} \mathcal{A}(T_k^i) &= \{A_j \mid Q_j \in \mathcal{Q}_i, T_{S_j} = T_k^i\} \\ \mathcal{B}(T_k^i) &= \{b_i(T_j) \mid A_j \in \mathcal{A}(T_k^i))\} \end{aligned} \tag{4}$$

Using the above two sets ($\mathcal{A}(T_k^i)$) and $\mathcal{B}(T_k^i)$, agent A_i sends *accept* or *reject* decision to its neighbors using the following rules:

Rule 1: An agent A_i sends *accept* to agent A_j, if

$$\mathcal{A}(T_k^i) = \{A_j\} \tag{5}$$

That is, $\mathcal{A}(T_k^i)$ is a singleton containing only agent A_j (note that A_j could be A_i itself).

Rule 2: If $\mathcal{A}(T_k^i)$ is not a singleton then agent A_i sends *accept* to that agent in $\mathcal{A}(T_k^i)$ which has the maximum value by attacking target T_k^i and *reject* to all other agents in $\mathcal{A}(T_k^i)$. That is, *accept* is sent to $A_{j'} \in \mathcal{A}(T_k^i)$ if,

$$j' = \arg\max_j \{b_i(T_j) \in \mathcal{B}(T_k^i)\} \tag{6}$$

Note that Rule 2 subsumes Rule 1. But they are stated separately for clarity. Again $A_{j'}$ can be A_i itself.

Rule 3: An agent can send only one *accept* for one target. If there are more than one j' then the agent selects one of them.

Rule 4: For A_i to decide on its action at the current search step it has to get *accept* from all its neighboring agents to which it had sent its proposals.

Rule 1 implies that when an agents' proposal is not in conflict with other agents' proposals an *accept* can be sent

without considering other agents' decision. When more than one agent proposes to attack T_k then there is a conflict between the proposing agents which A_i has to resolve. The conflict can be resolved by comparing the benfits' proposed by the agents. Agent A_i compares the $b_i(T_j)$ received for target T_k and sends *accept* decision to an agent A_k which has the highest $b_i(T_j)$ and *reject* decisions to the remaining agents. An agent A_i can receive a mix of *accept* and *reject* decisions from its neighbors. If we allow the agent to attack a target T_k, since it has got acceptance from some of the agents, this assignment would cause ineffective performance as multiple agents will get assigned to the same target. Hence, *Rule 4* guards against agents getting multiple assignment. The Rules 1-4 are the key to the negotiation scheme. While implementing *Rule 3*, we may encounter situations where more than one agent has the same $b_i(T_j)$, in which case we use a deadlock resolution scheme that resolves such deadlocks.

3.2.3 Computing route decision (NC4)

Agent A_i decides whether to implement or discard its proposed task based on the *accept* or *reject* decisions received from its neighbors. The agent implements its proposal if it receives *accept* decisions from all its neighbors and discards it if the agent receives a *reject* from even one of its neighbors. An agent that received a *reject* for its proposal from at least one neighbor will go on to the next negotiation cycle and this process will continue till it receives all *accept* decisions. An agent that has arrived at a decision (after receiving accept from all its neighbors) will not send any more proposals during subsequent negotiation cycles. The sequence of negotiation cycles will terminate automatically when all the cycles have converged to a decision. Later we will prove that only a finite number of negotiation cycles are necessary.

When an agent A_i receives reject for all its proposals, it adopts the search task.

3.3 Additional target information exchange

The agents that have received acceptance to their proposal may have other targets within its sensor range. An agent A_i can send this information to its neighbouring agents who can use it. The information that an agents sends is the target location and its value as perceived by A_i. This information will be more useful for those agents that may not have decided any targets but are neighbours of A_i. The target information broadcast by A_i can also be useful if all the proposals of agent $A_j \in \mathcal{N}(A_i)$ are rejected.

Once an agent receives the available targets from agent A_i, it can make assignment to any of the targets based on random number generation, greedy strategy, or start a negotiation with its neighbouring agents for obtaining an assignment. In this paper we use greedy strategy for simplicity.

3.4 Deadlock resolution mechanism

We define a deadlock, when an agent A_i is unable to decide to whom it has to send an acceptance. This situation can happen when more than one agent, with the same $b_i(T_j)$ value, seeks target T_j to attack. Since the $b_i(T_j)$ values are same, use of *Rule 2* is not possible and agent A_i cannot send acceptance to all the agents as that will violate *Rule 3*. There are two possible ways of resolving deadlock: loss information and token algorithm.

Loss information: In this scheme, agent A_i requests for more information from agents in $\mathcal{A}(T_k^i)$. This additional information will aid in effective decision-making. The additional information that an agent requests is the value of possible loss that each proposing agent suffers if it chooses the next best action instead of the proposed action. Let the new benefit vector for agent A_k be $\hat{\mathcal{B}}_k$ and the loss λ_k be evaluated using (7) as,

$$\hat{\mathcal{B}}_k = \{\mathcal{B}_k \setminus b_i(C_{S_K})\}$$
$$\lambda_k = \max \mathcal{B}_k - \max \hat{\mathcal{B}}_k \quad (7)$$

where, $'\setminus'$ denotes set difference. When agent A_i requests for loss information, the loss λ_k is sent to agent A_i. Let Λ_i represent the set of loss information received from all the agents in $\mathcal{A}(T_k^i)$. An *accept* is sent to an agent A_j that satisfies the condition in (8) and *reject* is sent to the remaining agents.

$$A_j = \arg\max_i(\Lambda_i) \quad (8)$$

Suppose there are multiple $b_i(T_j)$'s that are at the next highest level, then the same procedure needs to be repeated. Using the loss information does not guarantee that the deadlock will be resolved. This situation can arise when multiple agents have the same loss value. In that case, we use a token algorithm as given below.

Token Algorithm: Every agent A_i carries a unique token number K_i. Whenever the above situation (of the loss being equal) occurs wherein the agent is unable to decide to whom it has to send acceptance, the agent requests for token number of the agents $A_k, A_k \in \mathcal{A}(T_k^i)$. Let $\mathcal{K}_i$ be the set of token numbers received by agent A_i. Agent A_i compares these token numbers and chooses an agent A_j with the least token number.

The token number K_j is increased by a number $\hat{N}$, where $\hat{N}$ is an arbitrary large number greater than N. Agent A_j updates its token number to $K_j + \hat{N}$, after receiving the acceptance from agent A_i. This scheme ensures that an agent that has been selected earlier in this situation, will not be selected again in a similar situation if there is at least one other agent which has not been selected before.

Whenever a situation occurs when many agents are proposing for the same target, using the rules specified and the deadlock resolution mechanisms, it is guaranteed that there would be at least one agent that gets acceptance from all its neighboring agents.

3.5 Some theoretical results

THEOREM 1. *If more than one agent is proposing a target T_j, then at least one of the agents will receive all acceptances from its neighbors.*

Proof: Let $\mathcal{A}(T_j^i)$ be the set of agents proposing target T_j as their proposal. Then, by *Rule* 2, agent A_i sends an *accept* decision to agent A_j which has the maximum $b_i(T_j)$. If there are multiple agents with same $b_i(T_j)$ then A_i invokes the deadlock resolution mechanism by which one agent would receive an *accept*. □

THEOREM 2. *The negotiation terminates in a finite number of negotiation cycles.*

Proof: From Theorem 1 we observe that, at each negotiation cycle, at least one of the agents gets all *accept* and so decides

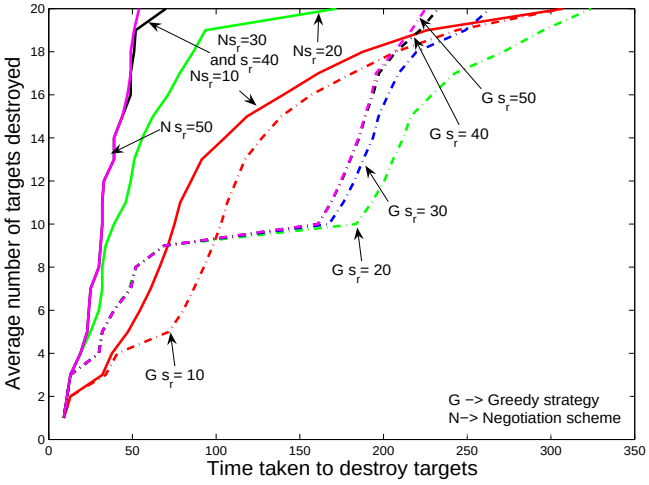

Figure 3: Average number of target hits for 100 different target positions

upon a target for its next step. Since there are a finite number of agents, in a finite number of negotiation cycles each agent would decide upon a target to attack. And if the target are not available then they choose search task. Hence, all the agents would decide upon a task in a finite number of negotiation cycles. The maximum number of negotiation cycles an agent can go through is N. □

4. SIMULATION RESULTS

A simulation study is conducted on a battle field scenario of size 100×100. Through these simulations we show that the negotiation scheme performs better than greedy strategy in terms of average number of targets destroyed. The simulation is carried out using 7 UAVs for 100 different sets of target positions with each set having 20 targets. The *a priori* knowledge about number of targets present in the space and their initial positions are not available to the UAVs. We also study the performance of negotiation and greedy schemes for various sensor radius.

From Figure 3 we can see that the negotiation scheme outperforms the greedy strategy. The number of targets using negotiation scheme is higher and also the time taken to accomplish the mission is comparatively low. An expected result of increase in performance with increase in sensor range can be seen for the performance curves of negotiation scheme in the figure. However, this intuitive result is not true for greedy strategy for all the sensor radius.

As we can see from the figure the performance of greedy strategy with sensor radius $s_r = 10$, fares better than higher sensor radius $s_r = 20$ to $s_r = 50$. This is due to the fact with low sensor radius, the UAVs are unable to the sense the targets initially and hence move in the initial heading direction (spreading out). But, with higher sensor radius the agents are able to sense the target from their initial positions and hence all the UAVs move in the direction of sensed target as a swarm. Hence, the performance is worse when compared to lower sensor radius.

We carried out another set of simulations to study the performance of task allocation algorithm for different target

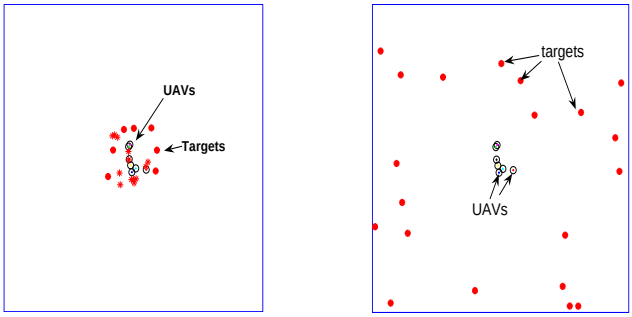

Figure 4: Battle field with 20 targets for proximity factors $\rho = 0.625$ and $\rho = 0.11$, while the sensor radius $s_r = 10$.

distributions on the search space. In order to conduct these experiments we define a proximity factor that determines the nature of the distribution or spread of targets in the search space. The proximity factor is defined as:

$$\rho = \frac{S_r}{\frac{1}{N}\sum_{i=1}^{N}\sqrt{(x_i - x_c)^2 + (y_i - y_c)^2}} \quad (9)$$

where N is number of targets, (x_i, y_i) represents the position of the ith target location, (x_c, y_c) the mean of all the target positions and S_r the sensor radius. Low proximity factor implies well separated targets compared to the sensor radius. While higher proximity factor ensures that the targets are placed very closely. Figures 4 show different target distributions in the search space.

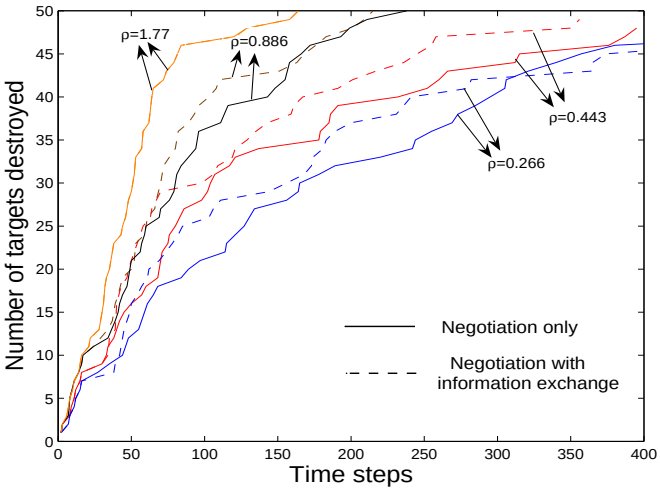

Figure 5: Number of targets destroyed for different proximity factors

The simulation is carried out using 7 UAVs for a search space consisting of 50 targets, with different proximity factors. Figure 5 shows the performance of negotiation and negotiation with target information based task allocation schemes. From the figure we can see that for lower proximity factors the number of targets destroyed are low as

compared to the number of targets destroyed in the higher proximity factor case. When the proximity factor is small, the effect of target information sharing during decision making by the agents that have targets in their sensor range is significant. For $\rho = 0.266$, we can see from the figure that the performance of negotiation with target information based task allocation is better than that using negotiation only. Here, the target information broadcast plays a crucial role in enhancing the performance. Similar kind of effect can be seen for $\rho = 0.443$. However, for $\sigma = 0.886$, the negotiation based task allocation is better than that of with target information exchange. This is due to the fact that the additional information about distant targets makes the agent choose targets to attack rather than perform search in its own neighborhood. This causes it to miss nearer targets outside its sensor range. For $\rho = 1.77$, the performance is same for both the negotiation schemes. Since the proximity factor is high, all the agents can sense all the targets hence there is no improvement in performance with information exchange. It should be noted that the amount of information broadcasted also plays a crucial role in the performance of the task allocation. Hence, there is always a tarde off between how much of information should be broadcast and the performance.

5. CONCLUSIONS

In this paper, we demonstrate an efficient task allocation scheme using negotiation for multiple UAVs performing search and destroy mission on an unknown region. The performance achieved using negotiation based task allocation is compared with greedy strategy for various sensor ranges and it is found that negotiation based task allocation is significantly better. We also studied the effect of task allocation mechanism on the spread of targets in the search space. The results show that with lower proximity factor the number of targets destroyed is low while with higher proximity factor the number of targets destroyed is high. We also studied the performance of negotiation scheme when agent communicate additional information to its neighbouring agents about the availability of targets. It is found that with lower sensor radius this information yield better results.

pdasgupta@mail.unomaha.edu

ABSTRACT

In modern day warfare, reconnaissance operations such as automatic target recognition(ATR) using unmanned aerial vehicles(UAVs) constitute a strategic war tactic. Traditionally, ATR is performed by UAVs that fly within the reconnaissance area to collect image data through sensors and upload the data to a central base station for analyzing and identifying potential targets. The centralized approach to ATR introduces several problems including scalability with the number of UAVs, network delays in communicating with the central location, and, susceptibility of the system to malicious attacks on the central location. These challenges can be addressed using a distributed system for performing ATR. In this paper, we describe a multi-agent system called COMSTAR-UAV (COoperative Multi-agent System for automatic TArget Recognition using Unmanned Aerial Vehicles) that uses swarming techniques inspired from insect colonies to perform ATR in a distributed manner.

Categories and Subject Descriptors: I.2.11 Distributed Artificial Intelligence: Multi-agent Systems
General Terms: Experimentation.
Keywords: Collective and Emergent Behavior, Simulation and Modeling, Distributed automatic target recognition.

1. INTRODUCTION

Automatic target recognition (ATR) involves determining the visual and other distinguishing features of an object, usually from a distance, and using this signature to automatically identify the object as a potential target. Traditionally this is achieved using unmanned aerial vehicles(UAVs) that obtain image data through their sensors from objects within a reconnaissance area and uploaded the data to a central location such as a base station, where potential targets are identified using image analysis algorithms [2, 4, 6]. However, this centralized model for ATR introduces several problems such as scalability and network delays in communication with the central location.

With the advancement of technology, the computation power of processors on UAVs has improved significantly and mini-UAVs can perform moderate computation beyond the trivial image data acquisition. However, the processors on UAVs are still not sophisticated enough to perform image identification solitarily on-board the UAV itself. We envisage that swarming[1, 3] provides a suitable mechanism to assimilate the capabilities of individual UAVs into a group of coordinating UAVs that perform ATR in a distributed manner. In a swarmed system, multiple mobile entities are directed to converge on a single point of interest, disperse and regroup again. To achieve distributed ATR using swarming, each UAV individually searches for potential targets within an area of interest using its image sensor. As soon as the image of an object is sensed to be a possible target by a UAV, other UAVs cooperate with it by swarming towards the potential target to collectively perform ATR and confirm the object as a target. In contrast to a centralized model for ATR, a distributed ATR model can: (1) scale up efficiently in the number of UAVs deployed and in the amount of data collected and processed for ATR, (2) improve the efficiency of the system because most computation is done locally within each UAV, which in turn reduces the time required to upload every image data from different UAVs onto the central location, and, (3) reduce the communication between the central location and individual UAVs so that the system is less susceptible to loss of data and failures due to wireless communication problems between an individual UAV and the central location. In this paper, we describe a multi-agent system called COMSTAR(Co-Operative Multi-agent Swarm for automatic TArget Recognition) that enables a group of UAVs deployed within a reconnaissance area to behave collectively as a swarm and perform ATR in a distributed manner.

Our swarming mechanism for ATR is based on the *stigmergetic* activity of social insects such as ants [1] to locate food. Stigmergy is a reinforcement learning mechanism that enables ants to indirectly communicate with each other about their environment using a chemical substance called pheromone. For example, while searching for food ants start from their nest and leave behind a pheromone trail along the path they traverse. The path leading from the nest to the food receives the highest amount of pheromone. Pheromone provides positive reinforcement to future ants, and, ants searching for the food later on use the trail as a positive reinforcement to reach the location of the food. To enable the ant algorithm in our system, we use pheromone to indicate potential targets while ants are implemented through software agents located within the computers on the UAVs. Software agents are characterized by a small footprint (few kilobytes) and are suitable for execution on computers within UAVs with limited computation power.

2. UAV OPERATION

We consider a battlefield scenario where UAVs are deployed from the base station into the area of interest(AOI). The AOI is logically divided into smaller sub-areas and a group of UAVs is deployed by the base station into each of these *home-areas*. We

assume that each UAV is provided with the following equipment to enable it to perform ATR: (1) Wireless communication capability for sending and receiving messages from other UAVs and the base station. (2) One or more image sensors capable of capturing snapshots of the area over which the UAV flies. (3) Processor with limited computing capability. (4) Rudimentary image processing software that enables the UAV to identify objects obtained by its image sensors as potential targets. (5) A global positioning system(GPS) that returns the 3-d coordinates (latitude, longitude, altitude) of the UAV's current location. Because of limited computational resources available on a single UAV, we assume that for definite target identification, $(n-1)$ other UAVs need to visit the location of a potential target reported by a single UAV to observe and confirm it as a definitive target.

After being deployed within its home-area, each UAV uses a deterministic foraging algorithm to navigate within its home area while searching for potential targets. When a UAV locates a potential target it associates a particular amount of pheromone with the target. Each UAV continuously exchanges information about targets it is aware of with other UAVs within its communication range using a gossip mechanism. The local map for potential targets that a UAV is aware of is maintained within it on a *pheromone landscape*. A UAV's task is to plan a navigation route by prioritizing the points on its pheromone landscape. The individual behavior of each UAV results in the movement of multiple UAVs towards the most prominent unconfirmed potential target in their vicinity, thereby manifesting the swarming behavior of the system. Because the computations on a UAV are performed by the agent located on it, we have used the terms agent and UAV interchangeably in the rest of the paper.

3. MODEL

We consider a set of $\mathcal{A}$ agents. Each agent $i \in \mathcal{A}$ maintains two sets: Ψ_i: Pheromone landscape of agent i comprising the set of potential targets agent i received through gossip or discovered through its sensors, and, Γ_i: set of tasks corresponding to the targets agent i is aware of. Each point $\psi \in \Psi_i$ corresponds to a potential target and is defined as $\psi = \{pher, loc, hops, time, vel, bearing\}$, where $pher \in [0,1]$ is the amount of pheromone associated with the potential target, $loc \in L \subset \Re^3$ is the location of the potential target in 3-d coordinates (latitude, longitude, altitude) obtained through the UAV's GPS, $hops$ is the number of agents that have forwarded the pheromone point ψ using the gossip mechanism before it reached agent i, and $time$ is the time at which this pheromone was last updated. The parameters vel and $bearing$ are used for mobile target tracking. In our system, time is measured in logical units called *ticks*. Every entity receives the current time measured in ticks from a globally available clock in the COMSTAR simulator. The availability of globally available clock avoids synchronization problems between different UAVs. Each task $\gamma \in \Gamma_i$ corresponds to a pheromone-point on the pheromone landscape Ψ_i of agent i and is defined as $\gamma = \{\psi, prio, status\}$ where $\psi \in \Psi_i$ is the pheromone corresponding to the task, $prio \in [0,1]$ is the priority of task γ, and, $status = \{Potential, Definite\}$ gives the identification status of the target. The priority of each task $\gamma \in \Gamma_i$ is recalculated every time the pheromone landscape of agent i gets updated. An agent's set of actions is given by: (i) *Navigate* to the location of the highest priority task within its task set, (ii) *Gossip* pheromone values that it is aware of, and, (iii) *Forage* deterministically to explore the AOI when the task set is empty.

Deterministic Foraging: When an agent is not swarming towards a pheromone point, it uses the deterministic foraging algorithm to navigate itself while avoiding flight-path conflicts with other agents. The deterministic foraging algorithm divides the immediate vicinity of an agent into sectors and then selects the least dense sector to move to. This ensures that each agent moves in a direction away from its neighboring areas that have higher concentration of agents.

Pheromone Landscape Update: The pheromone update equation used by agent i for pheromone point ψ is given by:

$$\begin{aligned} \psi.pher \leftarrow \lambda\psi.pher + (1-\lambda)(w_1 s + w_2 c) \\ \psi.time = currentTime; \\ \psi.loc = currentLocation, \end{aligned} \quad (1)$$

Parameters $s \in \Re$ and $c \in \Re$ in Equation 2 represent the severity of the potential target and the confidence in identifying the image from the sensor as a potential target. Weights w_1 and w_2 represent agent i's belief in the parameters s and c, while the parameter λ controls the preference between agent i's own perception and other agents' perception (pheromone value) of the potential target. The pheromone decay equation used by agent i is given by:

$$\begin{aligned} \epsilon = \text{currentTime} + \text{time to reach } \psi.loc - \psi.time, \\ \psi.pher \leftarrow \psi.pher.e^{-\beta\epsilon} \end{aligned} \quad (2)$$

where β is a control parameter, and, ϵ gives the time required by a UAV to reach the location $\psi.loc$ corresponding to pheromone point ψ that was last updated at $\psi.time$.

Gossip mechanism: Each agent employs a gossip mechanism[5] to exchange pheromone information with other agents. To set up a communication channel with other agents for sending the pheromone information, an agent broadcasts a *ping* message at regular intervals. Other agents that are within communication range of the agent originating the ping message respond with a *ping-ack* message that sets up the wireless communication channel. To disseminate gossip information across the system, each agent forwards gossip information it receives using a controlled flooding mechanism.

Task Prioritization: We consider two task prioritization strategies: ***(1) Myopic Strategy:*** For a myopic agent, the priority of its tasks is determined from the pheromone value of a point on its pheromone landscape perceived by itself only. The priority function of a myopic agent gives a higher preference to pheromone points that are significantly prominent than the agent's current destination, or, are en-route to the agent's current destination. ***(2) Look-Ahead Strategy:*** In the lookahead strategy, before prioritizing a new task, an agent takes into account the intention of other agents to perform that task. If the agent discovers that $(n-1)$ other agents (n agents are required to confirm a target) are already performing or planning to perform the task, it continues with its current mission and does not consider the new task for prioritization.

Mobile Target-Tracking With Anti-Pheromone: In our mobile target identification algorithm, the most recently observed location of a mobile target is marked with pheromone as before while the previous locations of the target are marked with anti-pheromone. Unlike pheromone, anti-pheromone provides negative reinforcement and prevents an agent from visting the point marked with anti-pheromone on its pheromone landscape. Our anti-pheromone based target tracking mechanism directs the UAV swarm towards the estimated location of a mobile target based on the target's most recently observed location and dynamics, and, is capable of tracking targets that are both continously and intermittently mobile.

4. SIMULATION RESULTS

For all our experiments we have considered the time (measured in no. of ticks) required to confirm all targets within an AOI as

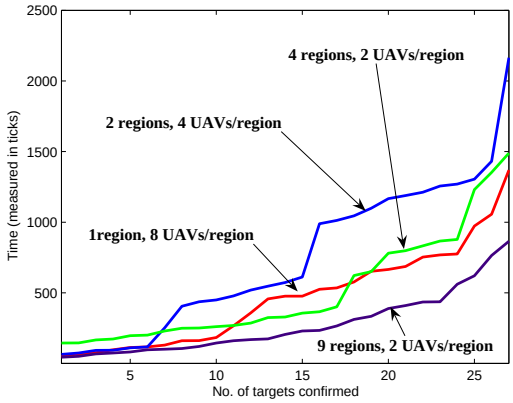

Figure 1: Time required to confirm targets in an AOI for different number of home-areas(regions) into which the AOI is sub-divided.

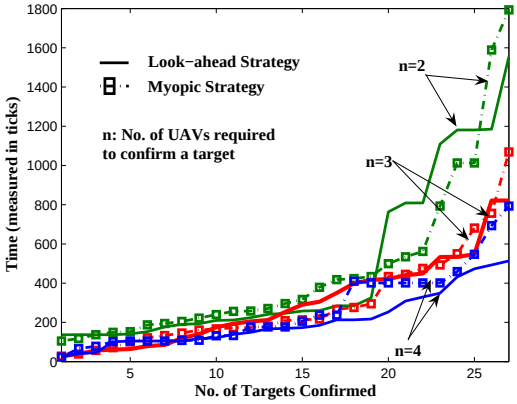

Figure 2: Time required to confirm targets in an AOI with myopic and lookahead strategies for different initial UAV densities per region.

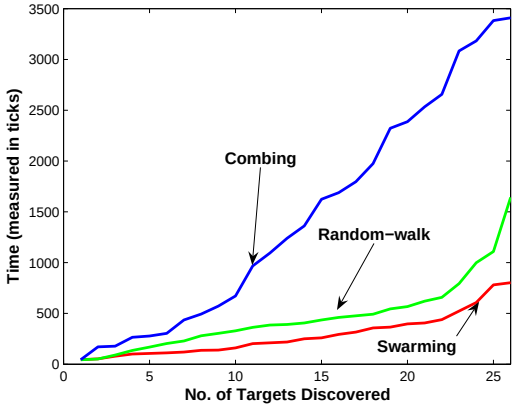

Figure 3: Time required to cover a square AOI using three different coverage strategies.

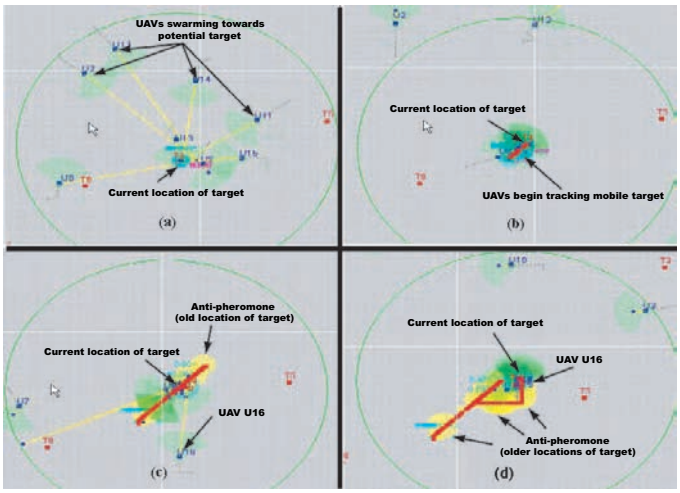

Figure 4: Snapshots illustrating the anti-pheromone update by different UAVs while tracking a mobile target.

the metric for quantifying system performance. The AOI is considered to be an invariant square region. However, the number of regions or home-areas into which the AOI is subdivided is varied to measure the effect of the size and number of home-areas on system performance. Targets are assumed to distributed randomly within the AOI. The communication range of each UAV is assumed to be $1/3$ of one side of the square AOI. The pheromone decay rate is set at $1/200$ per tick. Our experimental results are reported in Figures 1 through 4.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we have reported the results from software based simulations for a swarmed model of ATR and shown that is compares favorably with existing ATR strategies. In the future, we are investigating mechanisms to improve the lookahead strategy using a temporal inference technique, improve the communication protocol using a a decision theoretic mechanism, and, address issues related to security and fault tolerance in the system.

ABSTRACT

As agent systems are solving more and more complex tasks in increasingly challenging domains, the systems themselves are becoming more complex too, often compromising their adaptivity and robustness. A promising approach to solve this problem is to provide agents with reflective capabilities. Agents that can reflect on the effects and expected performance of their actions, are more aware and knowledgeable of their capabilities and shortcomings.

In this paper, we introduce a computational model for what we call *action awareness*. To achieve this awareness, agents learn predictive action models from observed experience. This knowledge is then used to optimize, transform and coordinate plans. We apply this computational model to a number of typical scenarios from robotic soccer. Various experiments on real robots demonstrate that action awareness enables the robots to improve the performance of their plans substantially.

1. INTRODUCTION

Improvements in agent technology allows agent systems to solve more and more complex tasks. As the tasks and environments become more complex, so do the agent systems themselves. This often compromises the robustness and adaptivity of the system, leading to a shorter operational life-time. A promising approach to solve this problem is to provide the agents with reflective capabilities [2]. When the agents are aware of what they are doing, and why, they become more robust, and can adapt to new situations. We call this *action awareness*.

We investigate the issues of action awareness and its applications in the context of multi-robot control. Robotic soccer is a good example of a domain in which the agent's interactions with the environment are often very complex. Therefore, hand-coding the controller is intractable and failure-prone. However, by reasoning about their actions, robots are able to choose the appropriate action, and optimize its parameterization on-line themselves.

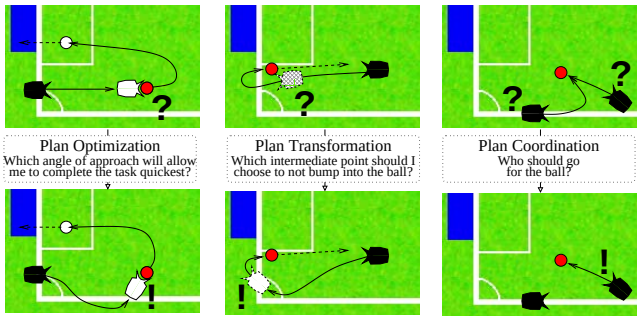

Figure 1: Three typical robotic soccer scenarios including control tasks requiring action awareness.

In this paper, we will propose a novel **computational model** for the acquisition and application of action awareness. It shows how action awareness can be acquired by **learning predictive action models** from observed experience (Section 2). We then explain how action awareness can be used to **optimize** (Section 3.1), **transform** (Section 3.2), and **coordinate** (Section 3.3) underspecified plans with highly parameterizable actions in the context of robotic soccer. While the individual contributions are not new, we do not know of a system implementing this as a comprehensive computational model, and applying it to autonomous robot control.

The computational model is depicted in Figure 2. To the left are the more or less 'traditional' action selection modules, and to the right are the novel modules that generate and exploit action awareness. When the robot has idle time, it learns prediction models for the actions in the ac-

tion library. During operation time, action chains are generated. Three modules then take these chains, and optimize, transform, and coordinate them using the pre- and post-conditions, as well as the prediction models. The modified chains then simply replace the original ones, and are executed.

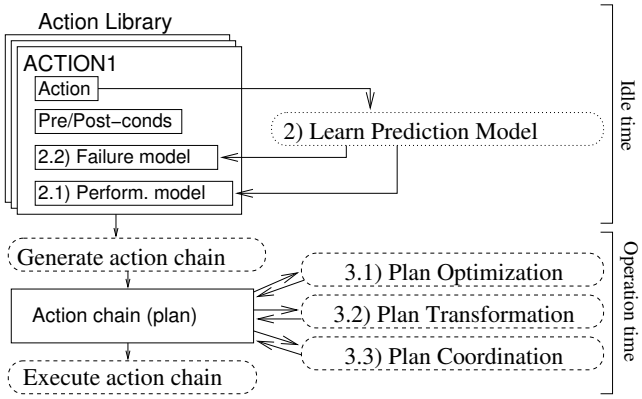

Figure 2: Computational Model

2. BECOMING ACTION AWARE: LEARNING PREDICTION MODELS

The robots achieve action awareness by learning action prediction models from observed experience. Given a specific scenario, these models should predict whether an action is likely to succeed, and what its expected performance will be. In this section, we will explain how temporal and failure prediction models were learned. The experiments in this paper were conducted with three customized Pioneer I robots of our RoboCup mid-size team the Agilo RoboCuppers. The robots use differential drive for locomotion, and a single forward facing CCD camera for state estimation.

2.1 Action Performance Prediction

Being aware of an action's expected performance is valuable knowledge. In many robotic domains, execution time is an important performance measure. Therefore we learn temporal prediction models. For our actions `goToPose` and `dribbleBall`, the model should predict the expected time of navigating from a start to a goal pose with this action. This model is acquired by training a model tree with data acquired on real robots. The training examples for the model tree were acquired by randomly choosing goal destination on the field, executing the `goToPose` or `dribbleBall` action, and measuring the time it took for the approach. In [6] we determined that 40 minutes operation time on a real robot yields enough examples to acquire an accurate temporal prediction model. The mean absolute error between the actual an predicted approach time for the `goToPose` and `dribbleBall` actions are 0.18s and 0.22s respectively.

2.2 Action Failure Prediction

The `goToPose` action can often be used well to approach the ball. However, in some situations it will bump into the ball before achieving the desired orientation, as can be seen in Figure 1. The second performance model we have learned predicts whether executing `goToPose` will lead to a collision with the ball or not. This model was learned by training a decision tree on data acquired in simulation. The training examples for this tree were acquired by having the robot executed `goToPose` a thousand times, with random initial and destination poses, the ball always positioned at the destination pose. For each run, we record if the robot had a `Collision` with the ball before reaching its desired position and orientation. If not, the run was a `Success`. On a test set, the learned decision tree predicts collisions correctly in almost 90%.

3. APPLYING PREDICTION MODELS TO AGENT CONTROL

In this section we will show how prediction models can be used to optimize, transform and coordinate plans.

3.1 Plan Optimization

Actions and action chains are often underspecified in plans. Take the example in Figure 3. The robot's plan is to approach the ball, and dribble it to the specified point. If it approached the ball as fast as possible, it would end up in the position on the top field in the image. This is an unfortunate position from which to start dribbling towards the goal. The problem is that, according to the planner, being at the ball is considered sufficient for dribbling the ball, and the angle of approach is considered to be irrelevant for the consecutive dribbling action. So, the intermediate state is under-specified, and we are allowed to choose any state from the set of intermediate states that the conditions deem valid.

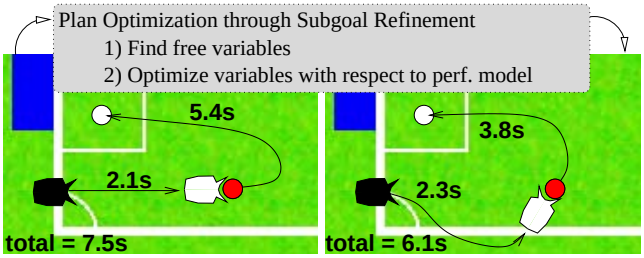

Figure 3: Overview of plan optimization.

What we would like the robot to do is to go to the ball *in order* to dribble it towards the goal afterwards. The robot should, as depicted in the right field in Figure 3, perform the first action sub-optimally in order to achieve a much better position for executing the second plan step. Our action-aware plan execution system can determine optimal intermediate states on the fly, using predictive models. We call this *subgoal refinement*.

First of all, the agent has to determine which variables can be used for optimization. That is, which variables are not bound by the plan. In this example, the only free variable is the angle of approach. For an explanation of how free variables are determined automatically, we refer to [4]. To optimize the action chain, we will have to find those values for the free variables for which the performance of the action chain is the highest. This overall performance is estimated by summing over the temporal prediction models of all actions that constitute the action chain. In Figure 3,

the predicted execution time of the first action in the left situation is 2.1s. However, the total time is 7.5s, because the second action takes 5.4s for this angle. Although the first action is executed very fast, this is not the optimum *overall* performance. By performing the first action suboptimally, an minimum overall predicted performance of 6.1s can be achieved, for an angle of 59°. This particular example yields a performance increase of 38%. The mean increase over a 1000 examples with random robot, ball and final goal positions was 12%.

Without subgoal refinement, the transitions between actions were very abrupt. In general, these motion patterns are so characteristic for robots that people trying to imitate robotic behavior will do so by making abrupt movements between actions. In contrast, one of the impressive capabilities of animals and humans is their capability to perform chains of actions in optimal ways and with seamless transitions between subsequent actions. It is interesting to see that requiring optimal performance can implicitly yield smooth transitions in robotic and natural domains, even though smoothness in itself is not an explicit goal in either domain.

3.2 Plan Transformation

In planning systems, the pre-conditions determine a set of states in which the action can be executed. Frequently, actions can be reused to perform other tasks than those they were originally designed for. For instance, the `goToPose` action can also be used to approach the ball. However, since `goToPose` does not consider the ball, it will sometimes bump into it before achieving the goal pose. In Section 2.2 we saw that a decision tree could be learned to accurately predict when this happens. In a sense, this decision tree can be seen as a learned pre-condition for a new `approachBall` action. This pre-condition can be used to determine when a plan to approach the ball will fail, and transform it so that a collision is avoided. Exactly how this is done is discussed in more detail in [5].

3.3 Plan Coordination

Many complex application tasks require two or more agents to cooperate in order to solve the task. A key aspect of these systems is that multiple agents share the same workspace, and can therefore not abstract away from the actions of other robots. Therefore, agents must not only be aware of their own actions, but also of those of others. Humans are very good at performing joint actions in shared workspaces, because they are very aware of the actions of others. Humans achieve this by inferring the intentions of others. Once the beliefs and desires of the cooperating party are known, we imagine what we would do in that situation. In contrast, coordination in multi-agent systems is usually achieved by extensive communication of intentions or utilities [3].

We believe that there are many domains in which implicit coordination is essential. Rescue robotics and autonomous vehicles operating in traffic are examples of domains in which robust communication is not guaranteed, but where correct coordination and action anticipation is a matter of life and death. We also consider implicit coordination to be essential for natural interaction between robots and humans. It cannot be expected of humans to continuously communicate their intentions. Instead, the robot must be able to anticipate a human's intentions, based on predictive models of human behavior.

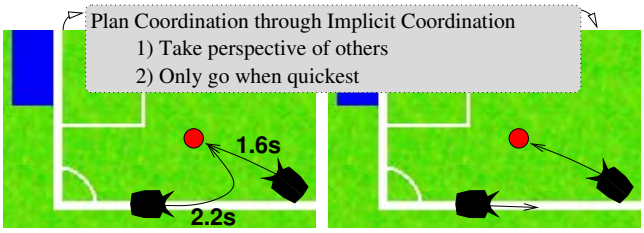

Figure 4: Overview of plan coordination.

A typical coordination task from the robotic soccer domain is to regain ball possession. Acquiring ball possession is a goal for the team as a whole, but it can be achieved by only one of the field players. Of course, the robots must agree upon which robot will approach the ball. The intuitive underlying rule is that only the robot who is quickest to the ball should approach it. The key to achieving implicit coordination is *perspective taking*. If the robots have estimates of each other's states, they can predict ball approach time for the others just as well as for themselves. In a sense, the awareness of their own action also provides them with awareness of actions of others. Once each robot has computed each robot's predicted ball approach time, each robot can determine if it is the fastest or not.

Our experiments have shown that the robots reach almost perfect agreement on this (99%), without communication [6]. The robot on which agreement is reached is indeed the quickest in 96% of the experiments.

ABSTRACT

Modular robots represent a perfect application scenario for multiagent coordination. The autonomous modules composing the robot must coordinate their respective activities to enforce a specific global shape or a coherent motion gait. Here we show how the TOTA ("Tuples On The Air") middleware can be effectively exploited to support agents' coordination in this context. The key idea in TOTA is to rely on spatially distributed tuples, spread across the robot, to guide the agents' activities in moving and reshaping the robot. Three simulated examples are presented to support our claims.

1. INTRODUCTION

A modular (or self-reconfigurable) robot is a flexible robot made up of a collection of (typically simple) autonomous elements connected with each other with some degree of freedom in their relative movements [2, 3].

The key idea underlying a modular robot is to have its components execute distributed control algorithms so as to coordinate their actions and let the robot assume a specific shape or move according to some specific motion pattern (i.e., gait).

Modular robots represent a perfect application scenario for multiagent systems. On the one hand, the modules constituting the modular robot should be autonomous and running agent applications. This, in fact, avoids single point of failure and bottlenecks. If one module breaks down the other can reorganize their activities leaving the broken element behind. Autonomy enables also disconnected operations: modules can disassemble, move along different paths and reassemble subsequently. On the other hand, the main task the modules have to undertake is *coordination*. The agents governing the modules must coordinate their respective activities to enforce a specific global shape or a coherent motion gait in the whole robot (i.e., multiagent system).

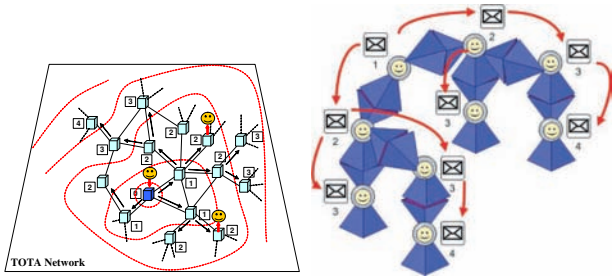

Figure 1: (left) The general scenario of TOTA. (right) TOTA in modular robots.

For the purpose of supporting agent coordination, in our research, we developed a general middleware called "Tuples On The Air" (TOTA). TOTA supports the creation of distributed overlay data structures spread across a distributed network. In this paper, we want to test the TOTA's generality by implementing some advanced mechanisms required for the control of a modular robot. In particular, our goal is to show that TOTA enables to easily and flexibly express and program biologically-inspired control algorithms (i.e. hormone-based [3]) for modular robots' coordination.

2. THE TUPLES ON THE AIR APPROACH

TOTA is a general-purpose middleware for multiagent coordination, in distributed computing scenarios. In TOTA we assume the presence of a network of possibly mobile nodes, each running an agent application. Each agent is supported by a local version of the TOTA middleware. Nodes are connected by only short-range network links. Each agent has only a local (one-hop) perception of its environment. Long range interactions must be mediated by other agents. Upon the distributed space identified by the dynamic network of TOTA nodes, each agent is capable of locally storing tuples

and letting them diffuse through the network. Tuples are injected in the system from a particular node, and spread hop-by-hop accordingly to a specified propagation rule (see Fig. 1(left)). In the modular robot scenario, this reflects in having each agent installed in a module of the robot. The modules (and thus the agents) are connected according to the topology of the robot. Tuples are injected and propagate across the robot's body (see Fig. 1(right)).

In TOTA, distributed tuples **T=(C,P,M)** are characterized by a content **C**, a propagation rule **P** and a maintenance rule **M**. The content **C** is an ordered set of typed fields representing the information carried on by the tuple. The propagation rule **P** determines how the tuple should be distributed and propagated in the network, and how the tuple content should change during propagation. The maintenance rule **M** determines how a tuple's distributed structure should react to events occurring in the environment.

We developed a first prototype of TOTA running on Linux IPAQs equipped with 802.11b WLAN and Java (J2ME, CDC, Personal profile). Moreover, we have implemented an emulator to analyze TOTA behavior in presence of hundreds of nodes [1]. To perform experiments with modular robots, we connected our TOTA simulator with the Polybot modular robot simulator [2]. This program can simulate the behavior of various types of modular robots, taking into account both the characteristics of the joints connecting different parts of the robot and the physical forces acting on the robot (e.g., gravitation), and offers a 3D view of the robot's actual configuration and movements.

3. MULTIAGENT COORDINATION IN MODULAR ROBOTS

From a multiagent perspective, the main challenge in modular robots is the design of decentralized coordination mechanisms enabling autonomous agents (i.e., modules) to coordinate their actions to achieve a specific global shape, or a specific motion gait. Some of the most innovative approaches to control a modular robot adopt the biologically inspired idea of hormones [3]. Hormone signals are actually sort of messages, spread across the robot and triggering the individual actuator's bending. A motion gait would be encoded by means of a specific sequence of hormones to be injected in the robot and by means of specific reactions triggered by these hormones, changing the bending angles.

The idea of hormones is a perfect match for TOTA distributed tuples and our approach has been to re-implement hormones with the support of our middleware. With this regard, it is fair to remark that we do not propose a novel approach for modular robot coordination. We just take advantage of the TOTA middleware to implement (with some changes) the hormone-based approach [3]. In our opinion, the importance of how to actually program such systems should not be overlooked and the proposed approach is valuable with regard to this topic.

In particular, the main subject of our research has been chain-type modular robots. This kind of robots is characterized by the fact modules are connected in a line configuration (e.g., snake-like), or - eventually - in a tree-like configuration (e.g., robot with legs), see the figures in next pages. In our experiments, we assumed that the robot is composed of very simple equal modules (i.e., joint actuators). Each module has a "front" side and a "back" side. On each side there is an infrared (IR) network link. Each module runs the TOTA middleware and an agent in charge of driving the module joint. The agent, looking at the active IR links, is able to infer whether it is the "head," the "tail," or a part of the "body" of the robot. Specifically, the "head" agent is the one with only the back IR link active, the "tail" agent is the one with only the front IR link active, a "body" agent is one having both the IR links active. The process of assessing whether an IR link is active or not can be based on "ping" messages and can be executed iteratively to take into account topological reconfigurations and module breakdown.

From a methodology point of view and in very general terms, the proposed approach consists in codifying a motion gait by means of a *Gait* tuple (examples are in the next section). Once this tuple is injected in the modular robot, it propagates hop by hop across all the modules changing its content to the desired gait. When an agent installed on a module senses the income of a tuple of this kind, it reacts by bending the module joint by the angle specified in the tuple. So, for example, if in a robot composed of N modules a tuple having in its content a fixed angle of about $(360/N)^\circ$ is spread, the robot closes into a loop.

4. EXPERIMENTS

In the rest of this section we will use TOTA to support three motion gaits in modular robot: the "caterpillar gait" (that lets the robot proceed by mimicking the motion of a snake) and the "rolling gait" (that lets the robot close in a loop, and then roll). Finally, we will present a gait for legged robots where agents coordinate legs' movements to proceed forward. It is worth noting that while the mechanisms underlying the former two gaits are well known in modular robot research [3], the latter one has been designed from scratch.

4.1 Caterpillar Gait

To implement the caterpillar gait, the head agent injects a caterpillar tuple (i.e., a TOTA tuple of the class *Caterpillar Gait Tuple*). The general structure of such a tuple is depicted below it propagates across the robot letting it bend accordingly. Once the tail agent receives the tuple, according to the general description given above, it injects another tuple to notify the head that a new step is ready to be executed. At this point, the head agent repropagates the tuple. This process is iterated letting the whole robot move performing the caterpillar gait (see Fig. 2).

Caterpillar Gait Tuple
C = (state, angle)
P = (propagate hop-by-hop, storing on intermediate nodes changing the content accordingly to the following table)

Current State	New State	New Angle
INIT	A	$+45^\circ$
A	B	$+45^\circ$
B	C	-45°
C	D	-45°
D	A	$+45^\circ$

M = (If on the head node and upon the receipt of a gait-tuple, re-apply propagation)

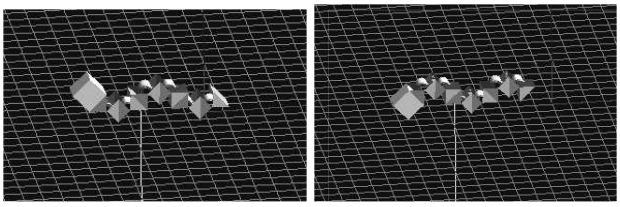

Figure 2: Some stages of a caterpillar gait, in a chain-typed modular robot, composed of six actuators

4.2 Rolling Gait

The idea of this gait is to let the robot close in a loop and then roll. Unfortunately, the modular robot simulator we employed does not allow structures with loops. Structures with loops are overconstrained. The simulation does not solve the constraint satisfaction problem. To overcome this problem, we let the robot bend in an open loop (something like a 'C' shape) and then roll. Although this complicates the rolling procedure, it allows us to maintain the general approach described before. In fact, we still have a "head" and a "tail" agent that would be otherwise removed if the loop were actually closed (i.e., with only "body" agents). The *Rolling Gait Tuple* is the tuple employed to let the robot roll. In general terms, it can have two states, T (turn) and F (flat). Consider, for example, a robot composed of 12 modules and assuming a turning angle of 45°. A tuple spread in the robot with a distributed shape like "FTTFTTFT-TFTT" closes in a loop. Then, if the tuple changes its content by "rolling" the above string (like the ROL assembler command), the robot performs the rolling gait. From the single tuple point of view, this consists in changing its content to assume values F - T - T iteratively. It is worth noting that such a kind of content change critically depends on the number of modules composing the robot and the number of turns we want to implement to let the robot close in a loop. For example, three turns of 60° each create a triangular track, four turns of 90° each create a rectangular track, etc. Moreover, it depends on the number of modules involved in each turn. Despite all these parameters, it is rather easy to build a general algorithm enabling a tuple to create dynamically, at runtime, the sequence of F and T states it has to cycle and the corresponding turning angle to enable the rolling gait. Some snapshots showing the rolling gait in action are in Fig. 3.

Rolling Gait Tuple
C = (state, angle)
P = (propagate hop-by-hop, cycling between the states F - T - T. Set the angle to 45deg if the state is T. Set the angle to 0 if the state is F)
M = (if the network topology changes, restart propagation according to new head, body and tail position)

4.3 Walking Gait

We performed this experiment on a "legged" robot that can move by coordinating legs movements. The idea of this experiment is to have the modules of the robot connected in a 6-legs configuration, and then coordinate the actions of these modules so as to let the legged robot walk. The robot

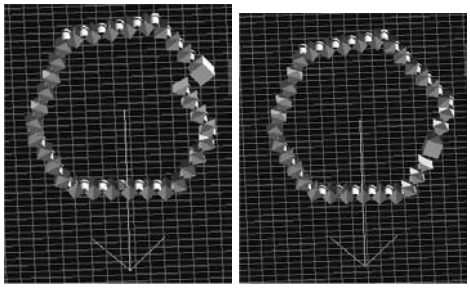

Figure 3: Some stages of a rolling gait in a chain-typed modular robot composed of 32 actuators.

can start moving the legs to proceed upward. This again is realized by letting the head of the robot inject another tuple that propagates across the modules. This *Walker Gait Tuple* tuple is very simple: it alternatively lets the left and right robot legs swing 45° forward. Some screen-shots of the actual robot movement are presented in Fig. 4.

Walker Gait Tuple
C = (state = LEFT—RIGHT, angle)
P = (propagate hop-by-hop. if current node is a spine node switch state. if state == LEFT turn left legs to 45deg and right legs to -45deg. if state == RIGHT turn right legs to 45deg and left legs to -45deg.
M = (if the network topology changes, restart propagation according to new head, body and tail position)

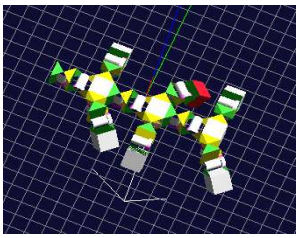

Figure 4: The legged robot walks by coordinating legs movements.

ABSTRACT

Hybrid architectures have been developed to preserve the responsiveness of reactive layers while also providing the benefits of higher level deliberative capabilities. The challenge of hybrid architecture design is to integrate layers of very different functional roles. We propose a component, called RADIC, that uses a generic technique for the construction of hybrid architectures from pre-existing reactive and deliberative layers that requires only minimal modifications to each layer. In particular, we give a high-level description of the operation and benefits of the component and its algorithms.

hybrid architectures, architecture integration, robotics

1. INTRODUCTION

Hybrid architectures for autonomous robots combine reactive and deliberative layers to preserve both responsiveness and the efficiency of symbolic representations. Yet, as pointed out in [11], "hybridism usually translates to *ad hoc* or unprincipled designs with all its attendant problems" and "hybrid architectures tend to be very application-specific."

To address these issues, we present a Reactive And Deliberative Layer Integration Component (RADIC) that provides a generalized "bridge" between layers. By maintaining layer separation, RADIC allows their principled design in isolation; by effecting a mapping of data between layers of disparate functionality, RADIC provides a general connection method to reduce application related specificity.

2. HYBRID ARCHITECTURES

For autonomous robotic agents, which require fast, highly responsive reactive layers (e.g., [7, 10]), the design of hybrid architectures is difficult, largely because the nature of the layers is so different. The challenge of hybrid architectures is to integrate the layers' disparate aspects of operation, at least achieving the following functional mappings:

F1: between "global" and "egocentric" relations
F2: from discrete actions to continuous motion
F3: between logical update time and real-time operation
F4: from stateful to stateless operation

We give a brief overview of a varied selection of hybrid architectures, describing how each satisfies items **F1-F4**:

***SSS* [4]:** Short for "*S*ervo, *S*ubsumption, *S*ymbolic" layers, the symbolic layer uses a coarse-grained world model that configures the reactive layer via parameterization of selected behaviors in the subsumption layer. SSS explicitly addresses the functional mappings by discretizing space between the servo and subsumption layers (**F1, F2**) and time between the subsumption and symbolic layers (**F3, F4**).

***AuRA* [2]:** AuRA's deliberative layer is composed of a planner, spatial reasoner, and sequencer, while the reactive layer consists of libraries of behavior schemas, activated by the sequencer and adaptable via a homeostatic component, producing actuation commands via vector summation of schema output. Functional mappings **F1**, **F3** and **F4** are made through the interaction of the schema controller with the plan sequencer, spatial reasoner, and planner, while **F2** is accomplished by the selection of behavior schemas.

***3T* [3]:** The 3T (short for "three tier") architecture, which extends work on both the RAPs [5] and ATLANTIS [6] architectures, uses a deliberative planner to synthesize goals in a partially ordered task list, executed by reactive skills (RAPs), bridged by a skill manager/sequencer (RAP interpreter). Tiers tend to operate at different time scales to fulfill mapping **F3**. Mappings **F1** and **F4** use all tiers; the planner operates at a high level of abstraction, the sequencer selects a set

of skills from the RAP library, while skills operate in a context dependent manner. Mapping **F2** is performed by the integration of skills and the sequencer; RAPs are symbolic, discrete steps for accomplishing a task composed of skills that implement continuous motion.

***Saphira* [8]:** Saphira uses a strong internal world model called the *local perceptual space* (LPS) that coordinates sensory data with representations. Planning is performed by the *PRS-Lite* component, which (de)activates sets of behaviors that are fused using fuzzy logic. Functional mappings **F1** and **F3** are accomplished via the LPS and PRS-Lite, while **F2** is accounted for by behavior selection and fuzzy logic fusion. Abstract representations are integrated in the LPS to fulfill mapping **F4**.

***4-D/RCS* [1]:** 4-D/RCS features a hierarchy of six levels (actuator, servo, primitive, subsystem, vehicle, and section) that operate on different scales. Each contains a supervisor and a set of subordinate agents that supervise units at the next lower level. Each node contains behavior generation, world modeling, sensory processing, value judgment processes and a knowledge database. Mappings **F1-F4** are explicitly made between each level.

While all of the above hybrid architectures successfully combines reactive and deliberative layers, each subscribes to a specific design philosophy, if not in integrating layers, then by specifying the design of the layers themselves. This restriction not only limits potential reuses of the developed layers and software, but more importantly the extent to which the designs themselves generalize. It would be desirable to achieve a more general connection or integration method that could be employed for many different reactive and deliberative layers without the need for much adaptation of either layer. Ideally, we would like a single, generic, "mediating component" to connect existing reactive and deliberative layers that successfully achieves the requisite functional mappings **F1-F4**. Several design desiderata suggest themselves for such a component; in particular, the method should:

I1: require minimal changes to existing layers

I2: provide integration of individual layers, while executing independently, autonomously, and in parallel

I3: use minimal processing time

I4: add functionality that improves the performance of systems that contain the layers in isolation

All the hybrid architectures above fail to satisfy some of **I1-I4**, in addition to the various criticisms (including those presented in [6, 3, 9]). Neither Saphira nor 4-D/RCS satisfies **I1**, albeit for different reasons. While the large amount of integration performed by the LPS in Saphira has the benefit of *coherency*, it also means that functional changes necessitate large modifications. On the other hand, the strict specification of interfaces between levels and substantial data flow within a single level in 4-D/RCS has the effect that slight modifications to functionality may entail large changes across components or levels. None of SSS, AuRA, and 3T meet **I2** because all switch completely back and forth between reactive and deliberative layers; the deliberative layer produces a fully formulated plan that is passed to the reactive layer, which then remains in control until a step either completes or fails. Both Saphira and 4-D/RCS suffer from difficulties with **I3**; the use of the LPS in Saphira requires a substantial amount of processing, while the full complement of components in 4-D/RCS introduces possibly redundant or unnecessary processing. Finally, **I4** presents difficulties for 3T, AuRA, and 4-D/RCS. In both 3T and AuRA, operation of the reactive layer is tightly knit and depends completely on the sequencer, making it difficult to add external functionality. A similar situation occurs with 4-D/RCS, where the functionality of a given level is specified completely by its internal operation. The proposed RADIC component, which we describe next, has been designed to satisfy all the functional mappings **F1-F4** and design desiderata **I1-I4**.

3. THE RADIC APPROACH

Functional mappings **F1-F4** are made in all hybrid architectures. The approach taken with RADIC can be described as effecting a *generic technique* for integrating (1) a *sequence of goals* originating from a deliberative layer, (2) a stream of *sensor data*, and (3) a *sequence of actions* (e.g., motor commands) from the reactive layer (see Figure 1), as performed by the `updateRADIC` algorithm given in Figure 2. The universality of a particular RADIC component is dependent on the representations used in mapping data between layers; at some application-dependent level, representations are either too abstract to be useful or too narrow to be applicable. For instance, a deliberative layer that produces a goal list composed of an ordered sequence of spatial locations to "visit" (such as in navigation or arm movement) requires translation of world-coordinates into egocentric-coordinates. While a RADIC component that integrates such layers may be applied to other tasks requiring spatial reasoning, it may not be adequate for, say, a higher level goal list that includes what to do at each location. RADIC provides a generic technique for integrating layers, but specificity is dependent on mapping implementation.

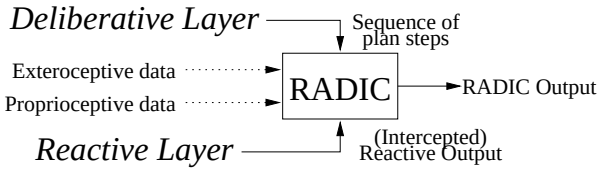

Figure 1: Functional diagram of the RADIC component showing (possible) inputs and output.

Functional mapping **F1** is satisfied by the `convertGoal` function, detailed below. The `updateRADIC` function is called at least as frequently as the reactive layer produces outputs (e.g., sends motor commands), and thus satisfies item **F3**. The functional mappings **F2** and **F4** are an inherent part of the RADIC component's operation: a goal is a discrete representation, while RADIC's output effects continuous motion (**F2**, either via discrete actions or via discrete motor commands), and the state of the deliberative layer is maintained in internal memory, while not requiring any state from the reactive layer other than its outputs (**F4**).

In more detail, the `updateRADIC` function takes as arguments the outputs from the reactive layer *R-out* (typically, intercepted motor commands), the changes as determined by sensors *S-change* (proprioceptive, exteroceptive, or missing), a sequence of goals from the delibera-

tive layer *D-goals* (which can be empty), and a strategy for goal attainment *G-strat*. The sequence of goals *D-goals* $= \langle G_1, G_2, ..., G_n \rangle$ is transformed, in accordance with item **F1**, from a "global" representation into an ego-centric representation $\langle \overline{G}_1, \overline{G}_2, ..., \overline{G}_n \rangle$ by the `convertGoal` function and stored in RADIC's internal memory M. `convertGoal` also associates a set of "blocking goals" B_G and a set of goal conditions C_G with each goal G that will depend on *G-strat* (in general, *G-strat* is a function that defines or influences the relation among G, B_G, and C_G). Blocking goals are used to impose a priority ordering on goals (goals that are blocked are not considered for action selection). Similarly, goal conditions are used to determine when goals have been achieved. A goal can then either be *active* or *inactive*, depending on whether or not its set of "blocking goals" is empty. A goal G is removed from M when at least one of its goal conditions $C \in C_G$ is met. The state of the robot is computed based on the old state using `updateState`, while the default action (i.e., output) is chosen in `defaultAction` based on *R-out*. All goals are then updated in `updateGoal` based on *R-out* and any possible changes detected via sensory inputs *S-change* and the active goals are used to determine the action of the robot via the `chooseAction` function based on the goal and the chosen action so far.

```
FUNCTION updateRADIC(R-out,S-change,D-goals,G-strat)
static M ← ∅
static currentState ← ∅
static oldState ← ∅
M ← M + convertGoal(D-goals, G-strat)
oldState ← currentState
currentState ← updateState(S-change)
action ← defaultAction(R-out)
for all G ∈ M do
  for all C ∈ C_G do
    if C_G then
      M ← M − {G}
    end if
  end for
  G ← updateGoal(R-out, S-change)
  if B_G = ∅ then
    action ← chooseAction(G, action)
  end if
end for
return action
```

Figure 2: The generic update algorithm for RADIC.

Note that the above algorithm is kept as generic as possible, allowing application to the broadest range of deliberative and reactive layers. To apply it to a particular architecture (e.g., to integrate two pre-existing layers), the five functions `convertGoal`, `updateState`, `defaultAction`, `updateGoal`, and `chooseAction` need to be implemented. RADIC can also be used in a standalone fashion with either type of layer, so long as the functionality of the other layer is implemented internally. Reactive layer functionality requires mapping goals to actions, while deliberative layer functionality requires appropriate internal representations (akin to the symbolic layer in SSS).

Unlike other hybrids, RADIC satisfies all of items **I1-4**. Minimal changes to each layer are required for integration (**I1**), as layer output is simply redirected as RADIC input; RADIC relies on internal data structures and functions for its operation. The RADIC component operates independently of either layer, performing its tasks in parallel with the layers' operation, responding to whatever input is received from either layer (**I2**). Computational cost is small (**I3**), as only state updates, goal list updates, and action choice are required. Updates of the goal list require both a measure of state change (via `updateState`) and a subsequent application of the calculated change for each point (via `updateGoal`). Only "active" goals are considered in modifications of the reactive layer's output at any given time. Finally, combining the layers improves overall performance (**I4**) by augmenting the reactive layer with planning capacities and providing the deliberative layer with the ability to act. Furthermore, custom improvements can easily be incorporated into the `updateState` (such as additional processing of *S-change*) and `updateGoal` (such as goal reordering or progress monitoring) functions.

4. CONCLUSION

RADIC has been experimentally validated and compared with other hybrid architectures in a trajectory following task. Beyond demonstrated performance improvements (and unlike other hybrid architectures), RADIC has the benefit of satisfying design desiderata **I1-4**, in the most extreme case actually substituting for a layer. The RADIC algorithm is not limited to navigation tasks, but can be used as a generic action sequencer in hybrid architectures for *any task*. RADIC can be attached to *any reactive layer* by virtue of its method of intercepting reactive output. Moreover, it can subsequently be used with *any deliberative layer* for which the `convertGoal` function is implemented.

ABSTRACT

In dangerous and uncertain environments initial plans must be revised. Communication failures hamper this replanning. We introduce *fractured subteams* as a novel formalism for modeling breakdowns in communication. We present a hybrid approach that employs distributed coordination mechanisms to provide robustness to these communication breakdowns and exploits opportunistic centralization. By modeling the problem as a mixed integer linear programming problem, we are able to apply constraint optimization techniques to efficiently find optimal or near optimal solutions to the difficult class of time critical tight coordination team planning problems. We then demonstrate that explicitly reasoning about communication failures through the incorporation of selective disruption minimization can improve team performance.

Keywords

Autonomous robots and robot teams, cooperation and coordination among agents, multi-agent planning

1. BACKGROUND

Teams of robots are necessary for a number of applications in which a single robot is unable or inefficient at accomplishing the goals. For example, time critical domains such as search and rescue, where lives are at stake, require careful consideration of plan efficiency. While some domains consist entirely of tasks that may be independently completed by individual robots permitting *loose coordination*, we are interested in the more challenging problem of *tight coordination* [2] where robots must work together to accomplish a *joint goal*. This requires robots to simultaneously solve the dual $\mathcal{NP}$-hard scheduling and task allocation problems with additional consideration for path planning [3].

The resulting domain of *time critical tight coordination team planning problems* are characterized by a set of robots, $\mathcal{R}$, with heterogeneous capabilities seeking to accomplish a set of joint goals, $\mathcal{G}$, with heterogeneous requirements. These goals are distributed throughout some physical environment, E. Additional system constraints, $\mathcal{C}$, may apply to robots, goals, or resources in the problem. The objective is to maximize team utility by accomplishing goals while goal rewards decrease over time to 0 at some time limit, T_{max}.

For teams of robots operating in physical environments, coordination inefficiencies may by magnified by the spatial constraints inherent to the problem. The time needed for robots to traverse the environment often dominates team performance. Consequently, it is beneficial to generate an optimal or near optimal plan at the start. In previous work [3], we describe COCoA, a Constraint Optimization Coordination Architecture, that maps this team planning problem to a mixed integer linear programming (MILP) problem and then combines domain specific heuristics and standard integer programming algorithms to efficiently generate optimal or near optimal plans. The resulting *team plan* generated by COCoA includes a schedule for each robot on the team broken down into the three components necessary to accomplish each of the robot's goals: time traveling to the goal, time waiting for teammates, and time working on the goal.

Unfortunately, few domains are so benign that this original plan can be successfully executed. Robots must interleave planning and execution as robots fail or are incapacitated, new robots join the team or receive new capabilities, goals are added and removed, goal requirements, rewards, or durations are changed, paths through the environment are found to be longer or shorter than believed, system constraints are added or removed, or the time limit is changed. Events that necessitate replanning are known as *replanning catalysts*. The discovery of replanning catalysts is beyond the scope of this paper but is discussed in other work [2].

Due to the physical nature of the environment, robots may not be in full communication at any given time. Although communication failure is a common phenomenon in multirobot coordination, models for these communication breakdowns are relatively primitive. Multirobot coordination architectures that address the problem assume any given message is lost with some uniform probability. However, since robots generally depend on peer to peer wireless

RF networks for communication, signal strength between two robots varies according to $\frac{1}{d^n}$ where d is the distance between the robots and n is the path loss exponent that is dependent on the environment [6]. Since robot communication is frequently based on TCP which is a reliable protocol, dropped packets are relatively unimportant. A more accurate model for robots which frequently have some limited range of communication is to model subsets of the team with good local communication but little or no communication between subsets. We introduce the terminology *fractured subteam* to refer to subsets of robots in the original team that are able to communicate with each other, directly or indirectly, but not with the rest of the team.

2. FRACTURED SUBTEAMS

A fractured subteam consists of a set of robots that jointly believe in a time critical tight coordination team planning problem, share a team plan, share a belief evolution model, are able to communicate with each other through transitive closure, and are unable to communicate with any robot not in the fractured subteam. A *belief evolution model* is a data structure that represents this fractured subteam's knowledge of beliefs of robots in other fractured subteams. Since all robots start with a common problem and team plan, all robots' belief evolution models contain a common element.

As robots seek to execute their team plan in dangerous and uncertain environments, they may discover that the problem and environment which they encounter does not match the problem for which they planned requiring them to refine their model of the problem and replan. This replanning must be performed quickly due to the time sensitive nature of the domain; COCoA has algorithms that can find good solutions in real time [3]. The second problem arises when failures in communication prevent the refined problem and solution from being disseminated to all team members resulting in inconsistencies. Fractured subteams force distributed replanning.

We extend COCoA from a purely centralized solver to a hybrid architecture. This hybrid architecture employs opportunistic centralization but is fundamentally distributed in that each fractured subteam is unable to communicate with other fractured subteams requiring distributed replanning. Each fractured subteam maintains its own knowledge from all previous subteams encountered which it uses for this replanning. Fractured subteams are themselves another variable in the system which must be considered while replanning.

Since COCoA was designed to be a centralized planner, only a single robot was required to possess the planning capabilities and complete problem and team plan. Other than this centralized planning robot, robots required only their individual tightly coupled schedule. In the distributed version of COCoA, each robot possesses full planning capabilities and a copy of the complete problem and team plan. The increase in communication cost is marginal. When a replanning catalyst is discovered, the architecture leverages the nature of a fractured subteam for opportunistic centralization. A robot from that fractured subteam is elected to replan and broadcast the results to the subteam.

Although the replanning is locally centralized, COCoA is distributed with respect to the individual fractured subteams. Each fractured subteam maintains its own problem and team plan. Each robot carries with it the complete knowledge of the fractured subteam to which it belongs. When two fractured subteams, F_1 and F_2, are merged into a single fractured subteam, their problems, team plans, and belief evolution models must likewise be merged. We have developed a simple algorithm for this merge, though we intend to investigate more sophisticated methods in the future since merging different beliefs is a deep research problem.

1. If the currently held problem and team plan of F_1 match the currently held problem and team plan of F_2, no changes need to be made.
2. If the currently held problem and team plan of F_1 match a state in the belief evolution model of F_2 and the team plan of F_2 is valid given the current status of the members of F_1 and F_2, all members of the merged fractured subteam adopt the problem, team plan, and belief evolution model of F_2.
3. By symmetry, the previous rule applies if the currently held problem and team plan of F_2 match a state in the belief evolution model of F_1.
4. If none of the above hold, create a new problem by combining the team planning problems of F_1 and F_2 and generate a new team plan to the resulting problem.

While full replanning works well in perfect communication, it tends to perform poorly with fractured subteams due to the inconsistencies in team plans. We can improve performance by explicitly reasoning about communication failure and fractured subteam composition during replanning and preferring solutions that only change the commitments of robots in the fractured subteam. The changes in coordination commitments are known as *disruption*.

One of the advantages of the MILP problem formulation in COCoA is the relative ease in combining multiple objective functions. We selectively minimize disruption by adding a cost function. There are several possible cost functions. We penalize near term changes more than long term changes since there is a higher probability that changes in the plan will be discovered in time for the robots to respond if the change is sufficiently far in the future. We then define our disruption objective function as follows. Minimize:

$$\sum_{m \text{ s.t. } G^m \in \mathcal{G}} [Cost(G^m) + \sum_{n \text{ s.t. } R^n \in \mathcal{R}} Cost(R^n, G^m)]$$

In general, every goal assigned to a robot represents a commitment to the team. However, not all changes to commitments are undesirable. If a robot is in the fractured subteam and aware of the replanning catalyst, some changes in the robot's schedule are advantageous as they increase system performance. Since the problem is tightly coupled, distinguishing between commitments that should be preserved and those that may be modified is challenging. We have developed *commitment graphs* to represent dependencies between robots in different fractured subteams. Commitment graphs can be easily generated from the team plan as described in Algorithm 1.

The cost function for each goal, $Cost(G^m)$, can be computed from the commitment graph and the current membership of the fractured subteam. The original time at which the goal was scheduled is denoted by $oldTime$. The new time at which the goal is to be scheduled (a variable in the MILP) is $newTime$, and the system time when replanning, is $replanTime$. If G^m has edges linking it to nodes of robots not in the fractured subteam and G^m was originally sched-

Algorithm 1 Build commitment graph

```
for all Goals G^m ∈ 𝒢 such that isScheduled(G^m) do
    Add goal node to graph
end for
for all Robots R^n ∈ ℛ do
    Add robot node to graph
    S_{R^n} = last known schedule for R^n in belief evolution model
    for all Goals in this robot's schedule do
        Add edge with robot coordination commitments from robot node to goal node
    end for
end for
for all Temporal goal constraints C_j ∈ 𝒞 do
    Add edge C_j between constrained goal nodes
end for
```

uled, canceling the goal results in a penalty of

$$\alpha_{cancel}(1 - \frac{oldTime - replanTime}{T_{max} - replanTime})$$

and changing the start time results in a penalty of

$$\alpha_{insert}(1 - \frac{newTime - replanTime}{T_{max} - replanTime})$$

The cost function for each robot not a member of the fractured subteam, $Cost(R^n, G^m)$, can also be calculated. If R^n is not currently allocated to G^m, the cost adding the goal into robot n's schedule is determined by equation (1).

$$\beta_{insert}(1 - \frac{newTime - replanTime}{T_{max} - replanTime}) \quad (1)$$

Similarly, the cost of removing a goal from robot n's schedule is determined by equation (2).

$$\beta_{cancel}(1 - \frac{oldTime - replanTime}{T_{max} - replanTime}) \quad (2)$$

We model the cost of changing the time of a goal in robot n's schedule as canceling and then adding a goal or the sum of equations (1) and (2).

The constants α and β may be tuned depending on the desired emphasis but should match the level of communication disruption in the environment. The new MILP combines the reward maximizing objective function [3] and the disruption minimization objective function.

3. EVALUATION

We conducted preliminary experiments to analyze the effect of fractured subteams on system performance. We used an abstract simulator with a randomly generated environment, 5 robots, and 10 goals. The environments are randomly partitioned into various blackout zones which impose the communication limitations, resulting in a set of fractured subteams. The number of fractured subteams is dependent on the topology of the environment and the composition of these subteams changes as robots traverse the environment. As an starting point for understanding the effect of communication breakdown on performance, we conducted a simple set of experiments in which one robot in the team was randomly disabled at some random time early in the plan.

We compared three different replanning strategies: *no replanning* where robots attempt to execute their original schedules, *full replanning* in which robots replan without consideration of communication failure, and *replanning with selective disruption minimization*. The results vary depending on the topology of the environment but we found that, in general, if the communication failures are minimal, full replanning outperforms the no replanning strategy, but as violations of the implicit assumption of full communication in the full replanning strategy increase, full replanning actually decreases team performance. By applying selective disruption minimization, as the number of partitions in the environment (communication failures) increases, the performance eventually converges to the *no replanning* strategy. Choosing α and β to match the amount of communication failure in the environment is an important challenge that we will address in future work.

4. RELATED WORK AND CONCLUSIONS

Market-based algorithms are a popular approach for multirobot coordination and have been successfully demonstrated in a variety of domains. A survey of the field [2] cites the lack of performance guarantees as one of the biggest drawbacks to current market-based approaches and suggests opportunistic centralization in future challenges. Our coordination approach addresses both of these issues.

In the MAS literature, token-based algorithms have been shown empirically to perform well in large scale teams [7]. However, token-based algorithms fail to provide the performance guarantees necessary for time critical domains. Existing work has assumed perfect communication. Pynadath and Tambe provide the COM-MTDP model for reasoning about the cost of communication [5] but do not explicitly model communication failure. The COM-MTDP model does not apply to time critical team planning problems since it uses a Markov assumption which does not immediately accommodate the time varying rewards or temporal constraints in our formulation of the problem. Distributed constraint optimization (DCOP) has been successfully applied to meeting scheduling [4] and to the multiagent plan coordination problem (MPCP) [1]. However, MPCPs require loose rather than tight coordination.

This preliminary work in developing an architecture interleaving planning and execution with communication failures for tightly coupled robot teams is promising and warrants additional investigation.

ABSTRACT

Encouraging voters to truthfully reveal their preferences in an election has long been an important issue. Previous studies have shown that some voting protocols are hard to manipulate, but predictably used $\mathcal{NP}$-hardness as the complexity measure. Such a *worst-case* analysis may be an insufficient guarantee of resistance to manipulation.

Indeed, we demonstrate that $\mathcal{NP}$-hard manipulations may be tractable in the *average-case*. For this purpose, we augment the existing theory of average-case complexity with new concepts; we consider elections distributed with respect to *junta distributions*, which concentrate on hard instances, and introduce a notion of *heuristic* polynomial time. We use our techniques to prove that a family of important voting protocols is susceptible to manipulation by coalitions, when the number of candidates is constant.

1. INTRODUCTION

In multiagent environments, it may be the case that different agents have diverse preferences, and it is therefore important to find a way to aggregate agent preferences. A general scheme for preference aggregation is *voting*: the agents reveal their preferences by ranking a set of candidates, and a winner is determined according to a voting protocol. The candidates can be various entities such as beliefs or plans, and indeed may be potential real-life parliament members.

Things are made complicated by the fact that in many settings (as in reality) the agents are self-interested. Such an agent may reveal its preferences untruthfully, if it believes this would make the final outcome of the elections more favorable for it. Consequently, the outcome may be one that does not maximize social welfare. This problem is provably acute: it is known [8, 10] that, for elections with three or more candidates, in any voting protocol that is non-dictatorial,[1] there are elections where an agent is better off by voting untruthfully.

Fortunately, it is reasonable to make the assumption that the agents are computationally bounded. Therefore, although in principle an agent may be able to manipulate an election, the computation required may be infeasible. This has motivated researchers to study the computational complexity of manipulating voting protocols. It has long been known [3] that there are voting protocols that are $\mathcal{NP}$-hard to manipulate by a single voter. Recent results by Conitzer and Sandholm [5, 4] show that some manipulations of common voting protocols are $\mathcal{NP}$-hard, even for a small number of candidates. Moreover, in [6], it is shown that adding a pre-round to some voting protocols can make manipulations hard (even $\mathcal{PSPACE}$-hard in some cases). Elkind and Lipmaa [7] show that the notion of pre-round, together with one-way functions, can be used to construct protocols that are hard to manipulate even by a large minority fraction of the voters.

In Computer Science, the notion of hardness is usually considered in the sense of worst-case complexity. Not surprisingly, most results on the complexity of manipulation use $\mathcal{NP}$-hardness as the complexity measure. However, it may still be the case that most instances of the problem are easy to manipulate.

A relatively little-known theory of average case complexity exists [11]; that theory introduces the concept of distributional problems, and defines what a reduction between distributional problems is. It is also known that average-case complete problems exist (albeit artificial ones, such as a distributional version of the halting problem).

Sadly, it is very difficult to show that a certain problem is average-case complete, and such results are known only for a handful of problems. Additionally, the goal of the

[1] In a dictatorial protocol, there is an agent that dictates the outcome regardless of the others' choices.

existing theory is to define when a problem is *hard* in the average-case; it does not provide criteria for deciding when a problem is *easy*. A step towards showing that a manipulation is easy on average was made in [7]. It involves an analysis of the plurality protocol with a pre-round, but focuses on a very specific distribution, which does not satisfy some basic desiderata as to what properties an "interesting" distribution should have.

In this paper, we engage in a novel average-case analysis, based on criteria we propose. Coming up with an "interesting" distribution of problem instances with respect to which the average-case complexity is computed is a difficult task, and the solution may be controversial. We analyze problems whose instances are distributed with respect to a *junta distribution*. Such a distribution must satisfy several conditions, which (arguably) guarantee that it focuses on instances that are harder to manipulate. We consider a protocol to be *susceptible* to manipulation when there is a polynomial time algorithm that can usually manipulate it: the probability of failure (when the instances are distributed according to a junta distribution) must be inverse-polynomial. Such an algorithm is known as a *heuristic* polynomial time algorithm.

We use these new methods to prove our main result: an important family of protocols, called *scoring* protocols, is susceptible to coalitional manipulation when the number of candidates is constant. Specifically, we contemplate *sensitive* scoring protocols, which include such well-known protocols as Borda and Veto. To accomplish this task, we define a natural distribution μ^* over the instances of a well-defined coalitional manipulation problem, and show that this is a junta distribution. Furthermore, we present the manipulation algorithm Greedy, and prove that it usually succeeds with respect to μ^*.

We also show that all protocols are susceptible to a certain setting of manipulation, where the manipulator is unsure about the others' votes. This result depends upon a basic conjecture regarding junta distributions, but also has implications that transcend our specific definition of these distributions.

In Section 2, we outline some important voting protocols, and properly define the manipulation problems we shall discuss. In Section 3, we formally introduce the tools for our average case analysis: junta distributions, heuristic polynomial time, and susceptibility to manipulations. In Section 4 we prove our main result: sensitive scoring protocols are susceptible to coalitional manipulation with few candidates. In Section 5, we discuss the case when a single manipulator is unsure about the other voters' votes. Finally, in Section 6, we present conclusions and directions for future research.

2. PRELIMINARIES

We first describe some common voting protocols and formally define the manipulation problems with which we shall deal. Next, we introduce a useful lemma from probability theory.

2.1 Elections and Manipulations

An election consists of a set C of m candidates, and a set V of n voters, who provide a total order on the candidates. An election also includes a winner determination function from the set of all possible combinations of votes to C. We note that throughout this paper, $m = O(1)$, so the complexity results are in terms of n.

Different voting protocols are distinguished by their winner determination functions. The protocols we shall discuss are:

- *Scoring protocols:* A scoring protocol is defined by vector $\vec{\alpha} = \langle \alpha_1, \alpha_2, \ldots, \alpha_m \rangle$, such that $\alpha_1 \geq \alpha_2 \geq \ldots \geq \alpha_m$ and $\alpha_i \in \mathbb{N} \cup \{0\}$. A candidate receives α_i points for each voter which ranks it in the i'th place. Examples of scoring protocols are:
  - *Plurality:* $\vec{\alpha} = \langle 1, 0, \ldots, 0, 0 \rangle$.
  - *Veto:* $\vec{\alpha} = \langle 1, 1, \ldots, 1, 0 \rangle$.
  - *Borda:* $\vec{\alpha} = \langle m-1, m-2, \ldots, 1, 0 \rangle$.
- *Copeland:* For each possible pair of candidates, simulate an election; a candidate wins such a pairwise election if more voters prefer it over the opponent. A candidate gets 1 point for each pairwise election it wins, and -1 for each pairwise election it loses.
- *Maximin:* A candidate's score in a pairwise election is the number of voters that prefer it over the opponent. The winner is the candidate whose minimum score over all pairwise elections is highest.
- *Single Transferable Vote (STV):* The election proceeds in rounds. In each round, the candidate's score is the number of voters that rank it highest among the remaining candidates; the candidate with the lowest score is eliminated.

Remark 1. We assume that tie-breaking is always adversarial to the manipulator.[2]

In the case of weighted votes, a voter with weight $k \in \mathbb{N}$ is naturally regarded as k voters who vote unanimously. In this paper, we consider weights in $[0, 1]$. This is equivalent, since any set of integer weights in the range $1, \ldots,$ poly$n$ can be scaled down to weights in the segment $[0, 1]$ with $O(\log n)$ bits of precision.

The main results of the paper focus on scoring protocols. We shall require the following definition:

Definition 1. Let P be a scoring protocol with parameters $\vec{\alpha} = \langle \alpha_1, \alpha_2, \ldots, \alpha_m \rangle$. We say that P is *sensitive* iff $\alpha_1 \geq \alpha_2 \geq \ldots \geq \alpha_{m-1} > \alpha_m = 0$ (notice the strict inequality on the right).

In particular, Borda and Veto are sensitive scoring protocols.

Remark 2. Generally, from any scoring protocol with $\alpha_{m-1} > \alpha_m$, an equivalent sensitive scoring protocol can be obtained by subtracting α_m on a coordinate-by-coordinate basis from the vector $\vec{\alpha}$. Moreover, observe that if a protocol is a scoring protocol but is not sensitive, and $\alpha_m = 0$, then $\alpha_{m-1} = 0$. In this case, for three candidates it is equivalent to the plurality protocol, for which most manipulations are tractable even in the worst-case. Therefore, it is sufficient to restrict our results to sensitive scoring protocols.

[2]This is a standard assumption, also made, for example, in [5, 4].

We next consider some types of manipulations, state the appropriate complexity results, and introduce some notations.

REMARK 3. We discuss the *constructive* cases, where the goal is trying to make a candidate win, as opposed to *destructive* manipulation, where the goal is to make a candidate lose. Constructive manipulations are always at least as hard (in the worst-case sense) as their destructive counterparts, and in some cases strictly harder (if one is able to determine whether p can be made to win, one can also ask whether any of the other $m-1$ candidates can be made to win, thus making p lose).

DEFINITION 2. In the INDIVIDUAL-MANIPULATION problem, we are given all the other votes, and a preferred candidate p. We are asked whether there is a way for the manipulator to cast its vote so that p wins.

Bartholdi and Orlin [3] show that IM is $\mathcal{NP}$-complete in Single Transferable Vote, provided the number of candidates is unbounded. However, the problem is in $\mathcal{P}$ for most voting schemes, and hence will not be studied here.

DEFINITION 3. In the COALITIONAL-WEIGHTED-MANIPULATION (CWM) problem, we are given a set of weighted votes S, the weights of a set of votes T which have not been cast, and a preferred candidate p. We are asked whether there is a way to cast the votes in T so that p wins the election.

We know [5, 4] that CWM is $\mathcal{NP}$-complete in Borda, Veto and Single Transferable Vote, even with 3 candidates, and in Maximin and Copeland with at least 4 candidates.

The CWM version that we shall analyze, which is specifically tailored for scoring protocols, is a slightly modified version whose analysis is more straightforward:

DEFINITION 4. In the SCORING-COALITIONAL-WEIGHTED-MANIPULATION (SCWM) problem, we are given an initial score $S[c]$ for each candidate c, the weights of a set of votes T which have not been cast, and a preferred candidate p. We are asked whether there is a way to cast the votes in T so that p wins the election.

$S[c]$ can be interpreted as c's total score from the votes in S. However, we do not require that there exist a combination of votes that actually induces $S[c]$ for all c.

DEFINITION 5. In the UNCERTAIN-VOTES-WEIGHTED-EVALUATION (UVWE) problem, we are given a weight for each voter, a distribution over all the votes, a candidate p, and a number $r \in [0,1]$. We are asked whether the probability of p winning is greater than r.

DEFINITION 6. In the UNCERTAIN-VOTES-WEIGHTED-MANIPULATION (UVWM) problem, we are given a single manipulative voter with a weight, weights for all other voters, a distribution over all the others' votes, a candidate p, and a number r, where $r \in [0,1]$. We are asked whether the manipulator can cast its vote so that p wins with probability greater than r.

If CWM is $\mathcal{NP}$-hard in a protocol, then UVWE and UVWM are also $\mathcal{NP}$-hard in it [5]. These problems will be studied in Section 5. We make the assumption that the given distributions over the others' votes can be sampled in polynomial time.

2.2 Chernoff's Bounds

The following lemma will be of much use later on. Informally, it states that the average of independent identically distributed (i.i.d.) random variables is almost always close to the expectation.

LEMMA 1 (CHERNOFF'S BOUNDS). *Let $X_1, \ldots, X_t$ be i.i.d. random variables such that $a \leq X_i \leq b$ and $\mathrm{E}[X_i] = \mu$. Then for any $\epsilon > 0$, it holds that:*

- $\Pr[\frac{1}{t}\sum_{i=1}^{t} X_i \geq \mu + \epsilon] \leq e^{-2t\frac{\epsilon^2}{(b-a)^2}}$
- $\Pr[\frac{1}{t}\sum_{i=1}^{t} X_i \leq \mu - \epsilon] \leq e^{-2t\frac{\epsilon^2}{(b-a)^2}}$

3. JUNTA DISTRIBUTIONS AND SUSCEPTIBLE MECHANISMS

In this section we lay the mathematical foundations required for an average-case analysis of the complexity of manipulations. All of the definitions are as general as possible; they can be applied to the manipulation of any mechanism, not merely to the manipulation of voting protocols.

We describe a distribution over the instances of a problem as a collection of distributions $\mu_1, \ldots, \mu_n, \ldots$, where μ_n is a distribution over the instances x such that $|x| = n$. We wish to analyze problems whose instances are distributed with respect to a distribution which focuses on hard-to-manipulate instances. Ideally, we would like to insure that if one manages to produce an algorithm which can usually manipulate instances according to this distinguished "difficult" distribution, the algorithm would also usually succeed when the instances are distributed with respect to most other reasonable distributions.

DEFINITION 7. Let $\mu = \{\mu_n\}_{n\in\mathbb{N}}$ be a distribution over the possible instances of an $\mathcal{NP}$-hard manipulation problem M. μ is a *junta* distribution if and only if μ has the following properties:

1. Hardness: The restriction of M to μ is the manipulation problem whose possible instances are only:
$$\bigcup_{n\in\mathbb{N}} \{x : |x| = n \wedge \mu_n(x) > 0\}.$$
Deciding this restricted problem is still $\mathcal{NP}$-hard.
2. Balance: There exist a constant $c > 1$ and $N \in \mathbb{N}$ such that for all $n \geq N$:
$$\frac{1}{c} \leq \Pr_{x\sim\mu_n}[M(x) = 1] \leq 1 - \frac{1}{c}.$$
3. Dichotomy: for all n and instances x such that $|x| = n$:
$$\mu_n(x) \geq 2^{-\mathrm{poly}n} \vee \mu_n(x) = 0.$$

If M is a voting manipulation problem, we also require the following property:

4. Symmetry: Let v be a voter whose vote is given, let $c_1, c_2 \neq p$ be two candidates, and let $i \in \{1, \ldots, m\}$. The probability that v ranks c_1 in the i'th place is the same as the probability that v ranks c_2 in the i'th place.

If M is a coalitional manipulation problem, we also require the following property:

5. Refinement: Let x be an instance such that $|x| = n$ and $\mu_n(x) > 0$; if all colluders voted identically, then p would not be elected.

The name "junta distribution" comes from the idea that in such a distribution, relatively few "powerful" and difficult instances represent all the other problem instances. Alternatively, our intent is to have a few problematic distributions (the family of junta distributions) convincingly represent all other distributions with respect to the average-case analysis.

The first three properties are basic, and are relevant to problems of manipulating any mechanism. The definition is modular, and additional properties may be added on top of the basic three, in case one wishes to analyze a mechanism which is not a voting protocol.

The exact choice of properties is of extreme importance (and, as we mentioned above, may be arguable). We shall briefly explain our choices. Hardness is meant to insure that the junta distribution contains hard instances. Balance guarantees that a trivial algorithm which always accepts (or always rejects) has a significant chance of failure. The dichotomy property helps in preventing situations where the distribution gives a (positive but) negligible probability to all the hard instances, and a high probability to several easy instances.

We now examine the properties that are specific to manipulation problems. The necessity of symmetry is best explained by an example. Consider CWM in STV with $m \geq 3$. One could design a distribution where p wins if and only if a distinguished candidate loses the first round. Such a distribution could be tailored to satisfy the other conditions, but misses many of the hard instances. In the context of SCWM, we interpret symmetry in the following way: for every two candidates $c_1, c_2 \neq p$ and $y \in \mathbb{R}$,

$$\Pr_{x \sim \mu_n}[S[c_1] = y] = \Pr_{x \sim \mu_n}[S[c_2] = y].$$

Refinement is less important than the other four properties, but seems to help in concentrating the probability on hard instances. Observe that refinement is only relevant to coalitional manipulation; we believe that in the analysis of individual voting manipulation problems, the first four properties are sufficient.

Definition 8. [11] A *distributional problem* is a pair $\langle L, \mu \rangle$ where L is a decision problem and μ is a distribution over the set $\{0,1\}^*$ of possible inputs.

Informally, an algorithm is a heuristic polynomial time algorithm for a distributional problem if it runs in polynomial time, and fails only on a small fraction of the inputs. We now give a formal definition; this definition is inspired by [11] (there the same name is used for a somewhat different definition).

Definition 9. Let M be a manipulation problem and let $\langle M, \mu \rangle$ be a distributional problem.

1. An algorithm A is a *deterministic heuristic polynomial time* algorithm for the distributional manipulation problem $\langle M, \mu \rangle$ if A always runs in polynomial time, and there exists a polynomial p and $N \in \mathbb{N}$ such that for all $n \geq N$:

$$\Pr_{x \sim \mu^n}[A(x) \neq M(x)] < \frac{1}{p(n)}. \quad (1)$$

2. Let A be a probabilistic algorithm, which uses a random string s. A is a *probabilistic heuristic polynomial time* algorithm for the distributional manipulation problem $\langle M, \mu \rangle$ if A always runs in polynomial time, and there exists a polynomial p and $N \in \mathbb{N}$ such that for all $n \geq N$:

$$\Pr_{x \sim \mu^n, s}[A(x) \neq M(x)] < \frac{1}{p(n)}. \quad (2)$$

Probabilistic algorithms have two potential sources of failure: an unfortunate choice of input, or an unfortunate choice of random string s. The success or failure of deterministic algorithms depends only on the choice of input.

We now combine all the definitions introduced in this section in an attempt to establish when a mechanism is susceptible to manipulation in the average case. The following definition abuses notation a bit: M is both used to refer to the manipulation itself, and the corresponding decision problem.

Definition 10. We say that a mechanism is *susceptible* to a manipulation M if there exists a junta distribution μ, such that there exists a deterministic/probabilistic heuristic polynomial time algorithm for $\langle M, \mu \rangle$.

4. SUSCEPTIBILITY TO SCWM

Recall [5, 4] that in Borda and Veto, CWM is $\mathcal{NP}$-hard, even with 3 candidates. Since Borda and Veto are examples of sensitive scoring protocols, we would like to know how resistant this family of protocols really is with respect to coalitional manipulation. In this section we use the methods from the previous section to prove our main result:

Theorem 1. *Let P be a sensitive scoring protocol. Then P, with candidates $C = \{p, c_1, \ldots, c_m\}$, $m = O(1)$, is susceptible to SCWM.*

Intuitively, the instances of CWM (or SCWM) which are hard are those that require a very specific partitioning of the voters in T to subsets, where each subset votes unanimously. These instances are rare in any reasonable distribution; this insight will ultimately yield the theorem.

The following proposition generalizes Theorem 1 of [5] and Theorem 2 of [4], and justifies our focus on the family of sensitive scoring protocols. A stronger version of Proposition 2 has been independently proven in [9]. Nevertheless, we include our proof, since it will be required in proving the hardness property of a junta distribution we shall design.

Proposition 2. *Let P be a sensitive scoring protocol. Then CWM in P is $\mathcal{NP}$-hard, even with 3 candidates.*

Definition 11. In the Partition problem, we are given a set of integers $\{k_i\}_{i \in [t]}$, summing to $2K$, and are asked whether a subset of these integers sum to K.

It is well-known that Partition is $\mathcal{NP}$-complete.

PROOF OF PROPOSITION 2. We reduce an arbitrary instance of PARTITION to the following CWM instance. There are 3 candidates, a, b, and p. In S, there are $K(4\alpha_1-2\alpha_2)-1$ voters voting $a \succ b \succ p$, and $K(4\alpha_1 - 2\alpha_2) - 1$ voters voting $b \succ a \succ p$. In T, for every k_i there is a vote of weight $2(\alpha_1+\alpha_2)k_i$. Observe that from S, both a and b get $(K(4\alpha_1 - 2\alpha_2) - 1)(\alpha_1 + \alpha_2)$ points.

Assume first that a partition exists. Let the voters in T in one half of the partition vote $p \succ a \succ b$, and let the other half vote $p \succ b \succ a$. By this vote, a and b each have

$$(K(4\alpha_1 - 2\alpha_2) - 1)(\alpha_1 + \alpha_2) + 2K(\alpha_1 + \alpha_2)\alpha_2$$
$$= (\alpha_1 + \alpha_2)(4K\alpha_1 - 1)$$

votes, while p has $(\alpha_1 + \alpha_2)4K\alpha_1$ points; thus there is a manipulation.

Conversely, assume that a manipulation exists. Clearly there must exist a manipulation where all the voters in T vote either $p \succ a \succ b$ or $p \succ b \succ a$, because the colluders do not gain anything by not placing p at the top in a scoring protocol. In this manipulation, p has $(\alpha_1+\alpha_2)4K\alpha_1$ points, while a and b already have $(K(4\alpha_1 - 2\alpha_2) - 1)(\alpha_1 + \alpha_2)$ points from S. Therefore, a and b must gain less than $(2\alpha_2K + 1)(\alpha_1 + \alpha_2)$ points from the voters in T. Each voter corresponding to k_i contributes $2(\alpha_1+\alpha_2)\alpha_2k_i$ points; it follows that the sum of the k_i corresponding to the voters voting $p \succ a \succ b$ is less than $K + \frac{1}{2\alpha_2}$, and likewise for the voters voting $p \succ b \succ a$. Equivalently, the sum can be at most K, since all k_i are integers and $\alpha_2 \geq 1$. In both cases the sum must be at most K; hence, this is a partition. □

Since an instance of CWM can be translated to an instance of SCWM in the obvious way, we have:

COROLLARY 3. *Let P be a sensitive scoring protocol. It holds that SCWM in P is $\mathcal{NP}$-hard, even with 3 candidates.*

4.1 A Junta Distribution

Let $w(v)$ denote the weight of voter v, and let W denote the total weight of the votes in T; P is a sensitive scoring protocol. We denote $|T| = n$: the size of T is the size of the instance.

Consider a distribution $\mu^* = \{\mu_n^*\}_{n\in\mathbb{N}}$ over the instances of CWM in P, with $m+1$ candidates $p, c_1, \ldots, c_m$, where each μ_n^* is induced by the following sampling algorithm:

1. $\forall v \in T$: Randomly and independently choose $w(v) \in [0,1]$ (up to $O(\log n)$ bits of precision).
2. $\forall i \in \{1,\ldots,m\}$: Randomly and independently choose $S[c_i] \in [(\alpha_1 - \alpha_2)W, \alpha_1 W]$ (up to $O(\log n)$ bits of precision).

We assume that $S[p] = 0$, i.e., all voters in S rank p last. This assumption is not a restriction. If it holds for a candidate c that $S[c] \leq S[p]$, then candidate c will surely lose, since the colluders all rank p first. Therefore, if $S[p] > 0$, we may simply normalize the scores by subtracting $S[p]$ from the scores of all candidates. This is equivalent to our assumption.

REMARK 4. We believe that μ^* is the most natural distribution with respect to which coalitional manipulation in scoring protocols should be studied. Even if one disagrees with the exact definition of junta distribution, μ^* should satisfy many reasonable conditions one could produce.

We shall, of course, (presently) prove that the distribution possesses the properties of a junta distribution.

PROPOSITION 4. *Let P be a sensitive scoring protocol. Then μ^* is a junta distribution for SCWM in P with $C = \{p, c_1, \ldots, c_m\}$, and $m = O(1)$.*

PROOF. We first observe that the dichotomy and symmetry conditions are obviously satisfied.

The proof of the hardness property relies on the reduction from PARTITION in Proposition 2. The reduction generates instances x of CWM in P with 3 candidates, where $W = 4(\alpha_1 + \alpha_2)K$, and

$$S[a] = S[b]$$
$$= (K(4\alpha_1 - 2\alpha_2) - 1)(\alpha_1 + \alpha_2)$$
$$= (\alpha_1 - \alpha_2/2)W - (\alpha_1 + \alpha_2),$$

for some K that originates in the PARTITION instance. These instances satisfy $(\alpha_1 - \alpha_2)W \leq S[a], S[b] \leq \alpha_1 W$. It follows that $\mu^*(x) > 0$ (after scaling down the weights).[3]

We now prove μ^* has the balance property. If for all i, $S[c_i] > (\alpha_1 - \alpha_2/m)W$, then clearly there is no manipulation, since at least $\alpha_2 W$ points are given by the voters in T to the undesirable candidates $c_1, \ldots, c_m$. This happens with probability at least $\frac{1}{m^m}$.

On the other hand, consider the situation where for all i,

$$S[c_i] < (\alpha_1 - \frac{m^2-1}{m^2}\alpha_2)W; \quad (3)$$

this occurs with probability at least $\frac{1}{(m^2)^m}$. Intuitively, if the colluders could distribute the votes in T in such a way that each undesirable candidate is ranked last in exactly $1/m$-fraction of the votes, this would be a successful manipulation: each undesirable candidate would gain at most an additional $\frac{m-1}{m}\alpha_2 W$ points. Unfortunately, this is usually not the case, but the following condition is sufficient for a successful manipulation (assuming condition (3) holds). Partition the voters in T to m disjoint subsets $p_1, \ldots, p_i$ (w.l.o.g. of size n/m), and denote by W_{p_i} the total weight of the votes in p_i. The condition is that for all $i \in \{1,\ldots,m\}$:

$$(1 - 1/m) \cdot 1/2 \cdot n/m \leq W_{p_i} \leq (1 + 1/m) \cdot 1/2 \cdot n/m. \quad (4)$$

This condition is sufficient, because if the voters in p_i all rank c_i last, the fraction of the votes in T which gives c_i points is at most:

$$\frac{(m-1)(1+1/m)}{(m-1)(1+1/m)+1-1/m} = \frac{m^2-1}{m^2+m-2}.$$

Hence the number of points c_i gains from the colluders is at most:

$$\frac{m^2-1}{m^2+m-2}\alpha_2 \leq \frac{m^2-1}{m^2}\alpha_2 < \alpha_1 W - S[c_i].$$

Furthermore, by Lemma 1 and the fact that the expected total weight of n/m votes is $1/2 \cdot n/m$, the probability that condition (4) holds is at least $1 - 2e^{-\frac{2n}{m^3}}$. Since m is a constant, this probability is larger than $1/2$ for a large enough n.

[3]It seems the reduction can be generalized for a larger number of candidates. The hard instances are the ones where all undesirable candidates but two have approximately $(\alpha_1 - \alpha_2)W$ initial points, and two problematic candidates have approximately $(\alpha_1 - \alpha_m/2)W$ points. These instances have a positive probability under μ^*.

Algorithm 1 Decides SCWM

```
1: procedure GREEDY(S, w⃗, p)
2:     for all c ∈ C do                          ▷ Initialization
3:         S_0[c] ← S[c]
4:     end for
5:     for i = 1 to n do                         ▷ All voters in T
6:         Let j_1, j_2, ..., j_m s.t. ∀l, S_{i-1}[c_{j_{l-1}}] ≤ S_{i-1}[c_{j_l}]
7:         Voter t_i votes p ≻ c_{j_1} ≻ c_{j_2} ≻ ... ≻ c_{j_m}
8:         for l = 1 to m do                     ▷ Update score
9:             S_i[c_{j_l}] ← S_{i-1}[c_{j_l}] + w(t_i)α_{l+1}
10:        end for
11:        S_i[p] ← S_{i-1}[p] + w(t_i)α_1
12:    end for
13:    if argmax_{c∈C} S_n[c] = {p} then          ▷ p wins
14:        return true
15:    else
16:        return false
17:    end if
18: end procedure
```

Finally, it can easily be seen that μ^* has the refinement property: if all colluders rank p first and candidate c second, then p gets $\alpha_1 W$ points, and c gets $\alpha_2 W + S[c]$ points. But $S[c] \geq (\alpha_1 - \alpha_2)W$, and thus p surely loses. □

4.2 A Heuristic Polynomial Time Algorithm

We now present our algorithm GREEDY for SCWM, given as Algorithm 1. $\vec{w}$ denotes the vector of the weights of voters in $T = \{t_1, \ldots, t_n\}$.

The voters in T, according to some order, each rank p first, and the rest of the candidates by their current score: the candidate with the lowest current score is ranked highest. GREEDY accepts if and only if p wins this election.

This algorithm, designed specifically for scoring protocols, is a realization of an abstract greedy algorithm: at each stage, voter t_i ranks the undesirable candidates in an order that minimizes the highest score that any undesirable candidate obtains after the current vote. If there is a tie between several permutations, the voter chooses the option such that the second highest score is as low as possible, etc. In any case, every colluder always ranks p first.

REMARK 5. This abstract scheme might also be appropriate for protocols such as Maximin and Copeland. Similarly to scoring protocols, in these two protocols the colluders are always better off by ranking p first. In addition, the abstract greedy algorithm can be applied to Maximin and Copeland since the result of an election is based on the score each candidate has (unlike STV, for example).

In the following lemmas, a *stage* in the execution of the algorithm is an iteration of the for loop.

LEMMA 2. *If there exists a stage i_0 during the execution of* GREEDY*, and two candidates $a, b \neq p$, such that*

$$|S_{i_0}[a] - S_{i_0}[b]| \leq \alpha_2, \tag{5}$$

then for all $i \geq i_0$ it holds that $|S_i[a] - S_i[b]| \leq \alpha_2$.

PROOF. The proof is by induction on i. The base of the induction is given by equation (5). Assume that $|S_i[a] - S_i[b]| \leq \alpha_2$, and without loss of generality: $S_i[a] \geq S_i[b]$. By the algorithm, voter t_{i+1} ranks b higher than a, and therefore:

$$S_{i+1}[b] - S_{i+1}[a] \geq -\alpha_2. \tag{6}$$

Since p is always ranked first, and the weight of each vote is at most 1, b gains at most α_2 points. Therefore:

$$S_{i+1}[b] - S_{i+1}[a] \leq \alpha_2. \tag{7}$$

Combining equations (6) and (7) completes the proof. □

LEMMA 3. *Let $p \neq a, b \in C$, and suppose that there exists a stage i_0 such that $S_{i_0}[a] \geq S_{i_0}[b]$, and a stage $i_1 \geq i_0$ such that $S_{i_1}[b] \geq S_{i_1}[a]$. Then for all $i \geq i_1$ it holds that $|S_i[a] - S_i[b]| \leq \alpha_2$.*

PROOF. Assume that there exists a stage i_0 such that $S_{i_0}[a] \geq S_{i_0}[b]$, and a stage $i_1 \geq i_0$ such that $S_{i_1}[b] \geq S_{i_1}[a]$; w.l.o.g. $i_1 > i_0$ (otherwise at stage i_0 it holds that $S_{i_0}[b] = S_{i_0}[a]$, and then we finish by Lemma 2). Then there must be a stage i_2 such that $i_0 \leq i_2 < i_1$ and $S_{i_2}[a] \geq S_{i_2}[b]$ but $S_{i_2+1}[b] \geq S_{i_2+1}[a]$. Since the weight of each vote is at most 1, b gains at most α_2 points by voter t_{i_2+1}. Hence the conditions of Lemma 2 hold for stage i_2, which implies that for all $i \geq i_2$: $|S_i[a] - S_i[b]| \leq \alpha_2$. In particular, $i_1 \geq i_2$. □

LEMMA 4. *Let P be a sensitive scoring protocol, and assume* GREEDY *errs on an instance of SCWM in P which has a successful manipulation. Then there is $d \in \{2, 3, \ldots, m\}$, and a subset of candidates $D = \{c_{j_1}, \ldots, c_{j_d}\}$, such that:*

$$\begin{aligned} &\sum_{i=1}^{d}(\alpha_1 W - S[c_{j_i}]) - \sum_{i=1}^{d-1}(i \cdot \alpha_2) \leq W \sum_{i=1}^{d} \alpha_{m+2-i} \\ &\leq \sum_{i=1}^{d}(\alpha_1 W - S[c_{j_i}]). \end{aligned} \tag{8}$$

PROOF. For the right inequality, for any d candidates, even if all voters in T rank them last in every vote, the total points distributed among them is $W \sum_{i=1}^{d} \alpha_{m+2-i}$. If this inequality does not hold, there must be some candidate c_i that gains at least $\alpha_1 W - S[c_i]$ points from the colluders, implying that this candidate has at least $\alpha_1 W$ points. However, p also has at most $\alpha_1 W$ points, and we assumed that there is a successful manipulation — a contradiction.

For the left inequality, assume the algorithm erred. Then at some stage i_0, there is a candidate c_{j_0} who has a total of at least $\alpha_1 W$ points (w.l.o.g. only one candidate passes this threshold simultaneously). Denote $T_0 = \{t_1, t_2, \ldots, t_{i_0}\}$, and let W_{T_0} be the total weight of the voters in T_0. Voter t_{i_0} did not rank c_{j_0} last, since $\alpha_{m+1} = 0$, and thus ranking a candidate last gives it no points. We have that there is another candidate c_{j_1}, such that: $S_{i_0-1}[c_{j_1}] \geq S_{i_0-1}[c_{j_0}]$. By Lemma 3, $S_{i_0}[c_{j_0}] - S_{i_0}[c_{j_1}] \leq \alpha_2$, and thus $S_{i_0}[c_{j_1}] \geq \alpha_1 W - \alpha_2$. If these candidates were not always ranked last by the voters of T_0, there must be another candidate c_{j_2} who was ranked strictly higher by some voter in T_0, w.l.o.g. higher than c_{j_1}. Therefore, we have from Lemma 3 that: $S_{i_0}[c_{j_1}] - S_{i_0}[c_{j_2}] \leq \alpha_2$, and so c_{j_2} has a total of at least $\alpha_1 W - 2\alpha_2$ points. By inductively continuing this reasoning, we obtain a subset D of d candidates (possibly $d = m$), who were always ranked in the d last places by the voters in T_0, and for the l'th candidate it holds that: $S_{i_0}[c_{j_l}] \geq \alpha_1 W - (l-1)\alpha_2$. The total points gained by this l'th candidate until stage i_0 must be at least $\alpha_1 W - (l-1)\alpha_2 - S[c_{j_l}]$.

Since the total points distributed by the voters in T_0 to the d last candidates is $W_{T_0}\sum_{i=1}^{d}\alpha_{m+2-i}$, we have:

$$\sum_{i=1}^{d}(\alpha_1 W - S[c_{j_i}]) - \sum_{i=1}^{d-1}(i\cdot\alpha_2) \le W_{T_0}\sum_{i=1}^{d}\alpha_{m+2-i} \le W\sum_{i=1}^{d}\alpha_{m+2-i}.$$

□

LEMMA 5. *Let M be SCWM in a sensitive scoring protocol P with $C=\{p,c_1,\ldots,c_m\}$, m=O(1). Then* GREEDY *is a deterministic heuristic polynomial time algorithm for $\langle M,\mu^*\rangle$.*

PROOF. It is obvious that if the given instance has no successful manipulation, then the greedy algorithm would indeed answer that there is no manipulation, since the algorithm is constructive (it actually selects specific votes for the colluders).

We wish to bound the probability that there is a manipulation and the algorithm erred. By Lemma 4, a necessary condition for this to occur is as specified in equation (8), or equivalently:

$$W\sum_{i=1}^{d}\alpha_1 - W\sum_{i=1}^{d}\alpha_{m+2-i} - \frac{d(d-1)}{2}\alpha_2 \le \sum_{i=1}^{d}S[c_{j_i}] \le W\sum_{i=1}^{d}\alpha_1 - W\sum_{i=1}^{d}\alpha_{m+2-i}. \quad (9)$$

In this case the algorithm may err; but what is the probability of equation (9) holding? Fix a subset D of size $d\in\{2,\ldots,m\}$. $\sum_{i=1}^{d}S[c_{j_i}]$ is a random variable that takes values in $[d(\alpha_1-\alpha_2)W, d\alpha_1 W]$. By fixing values for the $S[c_{j_i}]$, we have that the probability of $\sum_{i=1}^{d}S[c_{j_i}]$ taking values in some interval $[a,b]$ is at most the chance of $S[c_{j_d}]$ taking a value in an interval of size $b-a$, which is at most $\frac{b-a}{\alpha_1 W-(\alpha_1-\alpha_2)W}$, since $S[c_{j_d}]$ is uniformly distributed. By Lemma 1, $W<n/4$ with probability at most $\epsilon(n)=e^{-\frac{n}{8}}$. On the other hand, if $W\ge n/4$, then (9) holds for D with probability at most

$$\frac{\frac{d(d-1)}{2}\alpha_2}{\alpha_1 W-(\alpha_1-\alpha_2)W} = \frac{d(d-1)}{2W} \le \frac{2d(d-1)}{n} = \frac{1}{p^D(n)},$$

for some polynomial p^D. We complete the proof by showing that equation (1) holds:

$$\begin{aligned}&\Pr_{x\sim\mu_n^*}[\text{GREEDY}(x)\neq M(x)]\\ &\le \Pr[W\ge n/4\wedge(\exists D\subset C\ s.t.\ |D|\ge 2\wedge(9)\text{ holds})] + \Pr[W<n/4]\\ &\le \sum_{D\subset C:|D|\ge 2}\frac{1}{p^D(n)}+\epsilon(n)\\ &\le \frac{1}{\text{poly}\,n}\end{aligned}$$

The last inequality follows from the assumption that $m=O(1)$. □

Clearly, Theorem 1 directly follows.

Algorithm 2 Decides UVWM

```
1: procedure SAMPLE-AND-MANIPULATE(w⃗, ν, p, r)
2:     for all permutations of the m+1 candidates do
3:         π ← next permutation
4:         ν* ← the manipulator votes π
5:             ▷ others' votes are always distributed w.r.t. ν
6:         if SAMPLE(w⃗, ν*, p, r) then
7:             return true
8:         end if
9:     end for
10:    return false
11: end procedure
```

5. SUSCEPTIBILITY TO UVWM

In this section we shall prove:

THEOREM 5. *Let P be a voting protocol such that there exists a junta distribution μ^P over the instances of UVWM in P, with the following property: r is uniformly distributed in $[0,1]$. Then P, with candidates $C=\{p,c_1,\ldots,c_m\}$, $m=O(1)$, is susceptible to UVWM.*

The existence of a junta distribution with r uniformly distributed is a very weak requirement (it is even quite natural to have r uniformly distributed). In fact, the following claim is very likely to be true:

CONJECTURE 6. *Let P be a voting protocol. Then there exists a junta distribution μ^P over the instances of UVWM in P, with r uniformly distributed in $[0,1]$.*

If this conjecture is indeed true, we have that all voting protocols are susceptible to UVWM. If for some reason the conjecture is not true with respect to our definition of junta distributions, then perhaps the definition is too restrictive and should be modified accordingly.

To prove Theorem 5, we require a procedure named SAMPLE, which decides UVWE. SAMPLE samples the given distribution on the votes n^3 times, and calculates the winner of the election each time. If p won more than an r-fraction of the elections then the procedure accepts, otherwise it rejects. We omit the details of the procedure, as well as the proof of the following lemma, due to lack of space.

LEMMA 6. *Let P be a voting protocol, and E be UVWE in P with $C=\{p,c_1,\ldots,c_m\}$. Furthermore, let μ be a distribution over the instances of E, with r uniformly distributed in $[0,1]$. Then there exists N such that for all $n\ge N$:*

$$\Pr_{x\sim\mu_n}[\text{SAMPLE}(x)\neq E(x)] \le \frac{1}{\text{poly}n}.$$

We now present an algorithm, SAMPLE-AND-MANIPULATE that decides UVWM; it is given as Algorithm 2. Here, $\vec{w}$ denotes the weights of all voters including the manipulator, and ν is the given distribution over the others' votes.

Given an instance of UVWM, SAMPLE-AND-MANIPULATE generates $(m+1)!$ instances of the UVWE problem, one for each of the manipulator's possible votes, and executes SAMPLE on each instance. SAMPLE-AND-MANIPULATE accepts if and only if SAMPLE accepts one of the instances.

LEMMA 7. *Let P be a voting protocol, and M be UVWM in P with $C=\{p,c_1,\ldots,c_m\}$, $m=O(1)$. Furthermore,*

let μ be a distribution over the instances of UVWM, with r uniformly distributed in $[0,1]$. It holds that SAMPLE-AND-MANIPULATE *is a probabilistic heuristic polynomial time algorithm for $\langle M, \mu \rangle$.*

PROOF. For each independent call to SAMPLE, the chance of failure is inverse-polynomial. By applying the union bound we have that the probability of SAMPLE failing on any of the $(m+1)!$ invocations is at most $(m+1)!\frac{1}{\text{poly}n}$, which is still inverse-polynomial since m is constant. The lemma now follows from the fact that there is a manipulation if and only if there is a permutation of candidates, such that if the manipulator votes according to this permutation, the chance of p winning is greater than r.

Notice that SAMPLE-AND-MANIPULATE is indeed polynomial by the fact that $m = O(1)$, and we assumed that the given distribution over the votes can be sampled in polynomial time. □

6. FUTURE RESEARCH

The issue of resistance of mechanisms to manipulation is important, particularly in the context of voting protocols. Most results on this issue use $\mathcal{NP}$-hardness as the complexity measure. One of this paper's main contributions has been introducing tools that can be utilized in showing that manipulating mechanisms is *easy* in the average case. We were concerned with the likely case of coalitional manipulation, and showed that sensitive scoring protocols are susceptible to such manipulation when the number of candidates is constant.

These results suggest that scoring protocols cannot be safely employed. More importantly, this paper should be seen as a starting point for studying the average case complexity of other types of manipulations, in other protocols. In addition, the definitions in Section 3 are deliberately general, and can be applied to manipulations of mechanisms that are not voting mechanisms. One such mechanism of which we are aware, whose manipulation is $\mathcal{NP}$-hard, is presented in [1, 2].

There is still room for debate as to the exact definition of a junta distribution, especially if Conjecture 6 turns out to be false. It may also be the case that there are "unconvincing" distributions that satisfy all of the (current) conditions of a junta distribution. It might prove especially fruitful to show that a heuristic polynomial time algorithm with respect to a junta distribution also has the same property with respect to some easy distributions, such as the uniform distribution.

An issue of great importance is coming up with natural criteria to decide when a manipulation problem is *hard* in the average-case. The traditional definition of average-case completeness is very difficult to work with in general; is there a satisfying definition that applies specifically to the case of manipulations? Once the subject is more fully understood, this understanding can be used to design mechanisms that are hard to manipulate in the average-case.

The Communication Complexity of Coalition Formation among Autonomous Agents

ABSTRACT

It is self-evident that in numerous Multiagent settings, selfish agents stand to benefit from cooperating by forming coalitions. Nevertheless, negotiating a *stable* distribution of the payoff among agents may prove challenging. The issue of coalition formation has been investigated extensively in the field of cooperative n-person game theory, but until recently little attention has been given to the complications that arise when the players are software agents. The bounded rationality of such agents has motivated researchers to study the computational complexity of the aforementioned problems.

In this paper, we examine the *communication* complexity of coalition formation, in an environment where each of the n agents knows only its own initial resources and utility function. Specifically, we give a tight $\Theta(n)$ bound on the communication complexity of the following solution concepts in unrestricted games: Shapley value, the nucleolus and the modified nucleolus, equal excess theory, and the core. Moreover, we show that in some intuitively appealing restricted games the communication complexity is constant, suggesting that it is possible to achieve sublinear complexity by constraining the environment or choosing a suitable solution concept.

1. INTRODUCTION

In an environment teeming with autonomous agents, it is only natural for agents to cooperate in order to achieve goals, even under the assumption that the agents are selfish. Cooperation is realized through the formation of *coalitions*: the members of each coalition share their resources, and ultimately divide their payoff. In the second half of the 20th century, some of the most prominent researchers in game theory have studied cooperative games; the focus of most research was determining which coalitions would form in a given game, and how coalitions should divide their payoff among their members.

The trick is to divide the payoff in a way that keeps the coalition structure stable: the agents should be motivated to remain loyal to their respective coalitions, instead of deviating and forming new coalitions that might guarantee them a higher expected payoff. Different notions of stable solutions have been proposed. The strongest, named the *core* of the game, is sometimes empty. Other (weaker) solutions have different desirable properties.

In the past few years, a new layer has been added to the problem. The "players" in our cooperative game are software agents, which are limited in various (practical) ways. This complication has motivated researchers to study the computational complexity of different solution concepts for cooperative games [7, 1, 2, 4].

Another issue, that has so far received little attention in multiagent systems research, is the *communication complexity* of cooperative games in multiagent environments. In the multiparty communication complexity model, each of the players (agents[1]) holds some part of the input, and the players wish to jointly compute some function on the input. In this model, we assume the players have unlimited computational power; we are only interested in the worst-case number of bits of information they must pass among themselves. Although the study of communication complexity is not natural in the context of some problems, it seems especially appropriate in the context of multiagent systems in general[2] (see for example [3]), and cooperative games in particular.

Shehory and Kraus [8] analyzed the computational and communication complexity of two algorithms for payoff di-

[1]Throughout the paper, we use the terms "players" and "agents" interchangeably.

[2]As mentioned above, computational complexity issues are also important (perhaps even more so) in multiagent systems. These issues are not taken into account in the communication complexity model, but are studied separately.

vision in a multiagent environment. The environment introduced by Shehory and Kraus induces a partitioning of the information about the game among the agents — a fact that makes this environment an obvious candidate for a study of communication complexity.

In this paper, we analyze the communication complexity of computing the payoff, in different solution concepts, of an arbitrary player. This restricted problem (as opposed to computing the payoffs for all the players) is important in its own right: it is reasonable that an agent would like to know *a priori* its expected payoff from a game, in order to decide whether to participate in the game at all.[3] It seems possible that, for some solution concepts or specific types of games, it may be sufficient for an agent to elicit information only from a small subset of the other agents in order to compute its payoff.

We focus on two categories of solution concepts:

- Singleton Solutions: Shapley value, the nucleolus (and modified nucleolus), and equal excess theory.
- Solutions that are possibly empty: the core.

For such solution concepts, one can establish hardness of suitable decision questions, such as determining whether the payoff of a certain agent is greater than 0, or determining whether the solution set is empty. Deciding these problems is clearly easier than computing an agent's payoff in a solution (*the* solution in the case of singleton solutions). Studying division schemes that do not fall into one of the two categories is less straightforward, since there are no apparent decision problems that are easier than computing the payoff in a solution. For example, one could ask whether a given payoff configuration is a solution, but even if this problem is hard, it may still be easy to generate just one solution (out of a possibly large solution set). The insistence on having such decision problems will become apparent in Section 2.

We investigate an environment in which there are n agents, each holding a constant amount of information. We show a tight bound of $\Theta(n)$ on the communication complexity of computing the payoff for an arbitrary player under all solution concepts mentioned above. Furthermore, we show that in restricted (but common) types of cooperative games, the communication complexity of finding the payoff of a player in a solution is 1.

The rest of the paper is organized as follows. In Section 2 we explain the basics of cooperative games and communication complexity. In Section 3 we prove our results, and discuss the communication complexity of restricted games. In Section 4 we propose directions for future research.

2. PRELIMINARIES

2.1 Cooperative Games

We start by explaining the basic ideas of cooperative n-person games in characteristic form, and defining restricted types of games that will be needed later on. We next specify the different solution concepts. Last, we describe our environment and connect this representation with games in characteristic form.

[3]This becomes even more explicit when the agent has to pay so as to join the game.

In the next few paragraphs, we follow Chapter 2 of [5].

A *cooperative n-person game in characteristic form with side payments* is a pair $(N; v)$, where $N = \{1, 2, \ldots, n\}$ is a set of players, and v is the *characteristic function*, which assigns a real number $v(S)$ to each $S \subseteq N$. $v(S)$ is the *value* of S: the payoff the players in S can obtain by cooperating. It always holds that $v(\emptyset) = 0$. The collection of payoffs to the players is expressed as a payoff vector: $\vec{x} = \{x_1, x_2, \ldots, x_n\}$.

A *coalition structure* is a partition of N, of the form $\phi = \{S_1, S_2, \ldots, S_r\}$, which specifies how the players in N divide themselves into coalitions. A *Payoff Configuration* is a pair

$$(\vec{x}; \phi) = \{x_1, x_2, \ldots, x_n; S_1, S_2, \ldots, S_r\},$$

where $\vec{x}$ is a payoff vector and ϕ is a coalition structure, such that:

$$\forall j \in [r] : \; x(S_j) =_{\text{def}} \sum_{i \in S_j} x_i = v(S_j).$$

We shall refer to the coalition of all players as the *grand coalition*.

EXAMPLE 1. Consider the following 3-person game known as "Odd Man Out":

$$v(\{1\}) = v(\{2\}) = v(\{3\}) = v(N) = 0;$$
$$v(\{1,2\}) = 4;\; v(\{1,3\}) = 5;\; v(\{2,3\}) = 6.$$

The payoff configuration $(2, 2, 0; \{1, 2\}, \{3\})$ would be obtained if players 1 and 2 formed a coalition and split their payoff equally.

A game is *superadditive* if:

$$\forall S, T \subseteq N \; s.t. \; S \cap T = \emptyset : \; v(S \cup T) \geq v(S) + v(T).$$

Superadditivity is a reasonable assumption in many games, since the union $S \cup T$ of two coalitions may, in the worst case, act as two separate coalitions and receive the payoff $v(S) + v(T)$.

We next discuss special types of games. In *weighted majority* games, the players are assigned weights $w_1, w_2, \ldots, w_n$, and a criterion number q is specified, such that:

$$\forall S \subseteq N : \; v(S) = \begin{cases} 1 & \sum_{i \in S} w_i \geq q \\ 0 & \sum_{i \in S} w_i < q \end{cases}$$

Such a game is represented by the following shorthand notation:

$$[q; w_1, w_2, \ldots, w_n].$$

LEMMA 1. *Let $[q; w_1, w_2, \ldots, w_n]$ be a weighted majority game, where for all i, $w_i \in \{0, 1\}$. If $q \geq \lfloor n/2 \rfloor + 1$, then the game is superadditive.*

PROOF. Let $S, T \subseteq N$ such that $S \cap T = \emptyset$. If $|S| < q$ and $|T| < q$, then clearly $v(S \cup T) \geq v(S) + v(T)$. Otherwise, assume without loss of generality that $|S| \geq q$. Since $q \geq \lfloor n/2 \rfloor + 1$ and $S \cap T = \emptyset$, it holds that $|T| < q$; it follows that $v(T) = 0$. Therefore,

$$v(S \cup T) = 1 = 1 + 0 \geq v(S) + v(T).$$

□

A different type of restricted game is an *apex* game. In such games, the only coalitions that have nonzero value are those that contain a distinguished player called the *apex*

(and are of size at least 2), or the remaining $n-1$ players (called the *base*) are included. Constant-sum apex games have the weighted majority representation:

$$[n-1; 1, \ldots, 1, n-2, 1, \ldots, 1],$$

where $n-2$ is the weight of the apex player.

Similarly to apex games, in *veto* games a distinguished player is a necessary (but not sufficient) member of any coalition with nonzero value. The general homogeneous weighted majority representation of the veto game in which the veto player needs only one ally is:

$$[n; 1, \ldots, 1, n-1, 1, \ldots, 1],$$

where $n-1$ is the weight of the veto player.

2.1.1 Solution Concepts

In this part of the paper, we follow Chapters 3 and 6 of [5], as well as [9].

Over the years, many different solutions to characteristic function games with side payments have been proposed. These solutions differ in their notion of stability: given a coalition structure, the payoff division should be such that agents are not motivated to deviate, thus breaking down coalitions. For example, if $v(\{i\}) > 0$, any payoff configuration where $x_i = 0$ could not be stable, since player i would prefer to receive the payoff he could get by himself.

2.1.1.1 The Core.

The *core* C of a game $(N; v)$ is the following set of payoff configurations:

$$C = \{(\vec{x}, \phi) : \forall S \subseteq N, x(S) \geq v(S)\}.$$

Less formally, the core is the set of payoff configurations that leave no coalition in a position to improve the payoffs to all of its members.

The core is the strongest of all solution concepts; in fact, it is so strong that in some cases the core is empty. In such a case, at least one coalition will be dissatisfied with any payoff configuration.

2.1.1.2 Shapley Value.

The *Shapley value* is a payoff division scheme that is characterized axiomatically, and hence satisfies some important desiderata. Player i is called a *dummy* if $v(S \cup \{i\}) = v(S)$ for all coalitions S that do not include i; players i and j are *interchangeable* if $v((S - \{i\}) \cup \{j\}) = v(S)$ for every coalition S that includes i but not j. The axioms of the Shapley value are:

- *Symmetry:* If i and j are interchangeable, then $x_i = x_j$.
- *Dummies:* If i is a dummy, then $x_i = v(\{i\})$.
- *Additivity:* For any two games $(N; v)$ and $(N; w)$, x_i in $(N; v + w)$ equals x_i in $(N; v)$ plus x_i in $(N; w)$.

It is well known that the Shapley value, defined by:

$$x_i = \sum_{S \subseteq N} \frac{(|N| - |S|)!(|S| - 1)!}{|N|!}(v_S - v_{S-\{i\}}),$$

is the *unique* payoff division scheme that satisfies the axioms listed above.

2.1.1.3 The Nucleolus and the Modified Nucleolus.

The *excess* of a coalition S with respect to the payoff vector $\vec{x}$ is: $e(S, \vec{x}) = v(S) - x(S)$. Given a payoff configuration $(\vec{x}; \phi)$, an excess $e(S, \vec{x})$ can be constructed for any coalition S; there are 2^n such coalitions. Let $\theta(\vec{x})$ be a vector of length 2^n, whose components are all possible excesses, sorted in non-increasing order:

$$\begin{aligned}\theta(\vec{x}) &= \langle \theta_1(\vec{x}), \theta_2(\vec{x}), \ldots, \theta_{2^n}(\vec{x}) \rangle \\ &= \langle e(S_1, \vec{x}), e(S_2, \vec{x}), \ldots, e(S_{2^n}, \vec{x}) \rangle,\end{aligned}$$

where for all $i < j$: $e(S_i, \vec{x}) \geq e(S_j, \vec{x})$. $\theta(\vec{x})$ is said to be *lexicographically greater* than $\theta(\vec{y})$, denoted $\theta(\vec{x}) \succ \theta(\vec{y})$, if there exists an integer $q \in [2^n]$ such that $\theta_p(\vec{x}) = \theta_p(\vec{y})$ for all $p < q$, and $\theta_q(x) > \theta_q(y)$. If $\theta(\vec{x})$ is not lexicographically greater than $\theta(\vec{y})$, we write $\theta(\vec{x}) \not\succ \theta(\vec{y})$.

Example 2. Consider the following 3-person game:

$$v(\{1\}) = v(\{2\}) = v(\{3\}) = 0;\ v(N) = 105$$
$$v(\{1,2\}) = 90;\ v(\{1,3\}) = 80;\ v(\{2,3\}) = 70.$$

Define a payoff configuration $(\vec{x}, \phi) = (15, 55, 35; N)$. The 2^3 excesses with respect to $\vec{x}$ are

$$(0, 0, -15, -55, -35, 20, 30, -20)$$

for coalitions $(\emptyset, N, \{1\}, \{2\}, \{3\}, \{1,2\}, \{1,3\}, \{2,3\})$, respectively. Therefore,

$$\vec{\theta}(\vec{x}) = (30, 20, 0, 0, -15, -20, -35, -55).$$

Similarly, for $(\vec{y}; \phi) = (45, 15, 45; N)$ we have:

$$\vec{\theta}(\vec{y}) = (30, 10, 0, 0, -10, -15, -45, -45).$$

It follows that $\vec{\theta}(\vec{x}) \succ \vec{\theta}(\vec{y})$.

The *nucleolus* of a game is the set of all payoff configurations for which the sorted vector of excesses is lexicographically minimal:

$$\{(\vec{x}; \phi) : \theta(\vec{x}) \not\succ \theta(\vec{y}) \text{ for all } \vec{y}, \text{ given } \phi\}.$$

The *modified nucleolus* is defined identically, except that instead of a vector $\vec{\theta}$ with 2^n excesses, a sorted vector with $2^n - n - 2$ excesses is constructed, with components $e(S, \vec{x})$ for all coalitions S such that $1 < |S| < n$.

The nucleolus is unique for each coalition structure in any characteristic function game. It is also known that the modified nucleolus for the grand coalition consists of a unique payoff vector.

2.1.1.4 Equal Excess.

Equal excess theory yields a payoff vector that is the result of a bargaining process. At each stage, a player lodges a claim for a share of the value of each coalition of which he is a member. As a starting point, each player expects an equal share of the value of each such coalition.

More formally, the bargaining process consists of discrete *rounds*. In round r, player i has an *expectation* of the payoff he will obtain from coalition S of which he is a member; this expectation is denoted $E^r(i, S)$. Let $A^r(i, S) = \max_{T \neq S}[E^r(i, T)]$; this is player i's highest expectation from the alternative coalitions to S. Player i's expectation for round $r+1$ is created by:

$$E^{r+1}(i, S) = A^r(i, S) + \frac{v(S) - \sum_{j \in S} A^r(j, S)}{|S|}.$$

EXAMPLE 3. Consider the following 3-person game:

$$v(\{1\}) = v(\{2\}) = v(\{3\}) = v(N) = 0;$$
$$v(\{1,2\}) = 90;\ v(\{1,3\}) = 80;\ v(\{2,3\}) = 70.$$

In round 0, we have: $E^0(1,\{1,2\}) = E^0(2,\{1,2\}) = 45$, $E^0(1,\{1,3\}) = E^0(3,\{1,3\}) = 40$, and finally $E^0(2,\{2,3\}) = E^0(3,\{2,3\}) = 35$. If the game terminates at round 0 and the coalition structure is $\{\{1,2\},\{3\}\}$, for instance, then the payoffs would be $(45, 45, 0)$. If negotiation continues to round 1, then for example: $A^0(1,\{1,2\}) = 40$, $A^0(2,\{1,2\}) = 35$, and thus:

$$E^1(1,\{1,2\}) = 40 + \frac{90 - 40 - 35}{2} = 47.5.$$

For the same coalition structure as before, player 1's payoff after a round of negotiation would be 47.5.

If the bargaining process ends after m rounds, we say it is the solution generated by *m-round* equal excess. As far as we know, for all games examined, the sequence of expectations converges to an asymptotic value, but there is no proof of convergence. Assuming such a limit always exists, we say it is the solution generated by ∞-*round* equal excess.

2.1.2 Environment Description

We follow the presentation of the environment in [8] (with some simplifications). An exact description of the environment is important for our purposes, since it induces a distribution of the information about the game (or input) among the agents.

Our environment consists of autonomous agents $1, 2, \ldots, n$, with tasks to fulfill. Each agent has a given amount of the resources $l_1, \ldots, l_s$, which are required in order to deal with tasks (we denote by Q the set of all possible vectors of quantities of resources). An agent receives a payoff for fulfilling tasks. These concepts can be formalized as a *payoff function* $U^i : Q \to \mathbb{R}^+$, which gives the payoff of agent i for some arbitrary resources.

We assume that resources can be traded among agents. We also assume that payoff can be transferred from one agent to another (using money, or some other divisible desirable commodity).[4] The agents may try to tackle the tasks alone, but may also prefer to form coalitions, thus pooling (and redistributing) their resources. If S is a coalition, we say that its value is $v(S)$ if $v(S) = \sum_{i \in S} U^i(\overline{q}_i)$, where $\overline{q}$ is the vector of resources after optimal redistribution in the coalition.

It is important to recognize that such an environment can be represented using a characteristic function game, and sometimes vice versa; hence the concepts from the previous subsections can be used. However, the representation of the game proposed in this subsection is more realistic. In essence, the information about the game is distributed among the agents; each agent holds a *constant* amount of information, namely its resources and payoff function.

EXAMPLE 4. Consider the weighted majority game defined by $[q; w_1, w_2, \ldots, w_n]$. There is only one resource, of which each agent is given the initial quantity w_i; the utility function for all agents is:

$$U^i(z) = \begin{cases} 1 & z \geq q \\ 0 & z < q \end{cases}$$

In such games, the private information agent i has — its resources and production function — essentially defines its weight w_i (which can be deduced from its resources), and the value of q (which can be deduced from the common utility function, and is therefore common knowledge).

We do not assume that the environment is superadditive (although this is implied by the above definitions), and our results also apply to environments that do not have this property. However, note that in a superadditive game, we can assume that the grand coalition forms at some stage, and concern ourselves only with the payoff division (and not the coalition structure).

2.2 Communication Complexity

In this subsection, we present the multiparty communication complexity model with which we shall deal. A recommended, more detailed overview of communication complexity theory appears in [6].

There are several ways to generalize the two-party communication complexity model (introduced by Yao in [10]) to a multiparty setting. In our model,[5] player i ($i \in N$) holds an input $z_i \in \{0,1\}^k$. The players wish to compute together a function $f : (\{0,1\}^k)^n \to A$. They communicate via a "public blackboard" — all the players can see any bit a player sends. We are only interested in the amount of communication among the players, and therefore we allow the players to have unlimited computational power.

A *deterministic protocol* P is a binary tree where each internal node v is labeled by a function $g_{i,v}\{0,1\}^k \to \{0,1\}$, for a single $i \in N$, and each leaf is labeled with $a \in A$. The *value* of the protocol P on input $(z_1, z_2, \ldots, z_n)$ is the label of the leaf reached by starting from the root, and walking on the tree: at each internal node v labeled by $g_{i,v}$ walking left if $g_{i,v}(z_i) = 0$, and right if $g_{i,v}(z_i) = 1$. The *cost* of the Protocol P on input $(z_1, z_2, \ldots, z_n)$ is the length of the path taken on this input. The *cost* of the protocol P is the height of the tree. The *deterministic communication complexity* of a function f is the minimum cost of P, over all protocols P that compute f.

Intuitively, every internal node v labeled by $g_{i,v}$ is associated with a bit sent by player i: 0 if $g_{i,v}(z_i) = 0$, and 1 otherwise. At each point in the protocol, the current node in the tree is determined by the previous bits sent by the players. In this way, players take into account the bits communicated so far.

It is also possible to consider the *nondeterministic communication complexity* of f. An all-powerful prover is trying to convince the players that $f(z_1, z_2, \ldots, z_n) = a_0$. If it is indeed true that $f(z_1, z_2, \ldots, z_n) = a_0$, then the prover should be able to convince the players (by posting the answer and a proof to the blackboard). However, if this is not the case, the players should be able to detect the lie, regardless of what the prover says. It is obvious that a lower bound on the

[4]Such a transfer of payoff is called a *side payment*. Recall that we assumed side payments are possible when we described characteristic function games in Section 2.1.

[5]Another interesting model is the "number on the forehead" model, where each player holds a bit that all other players can see, but he cannot.

nondeterministic communication complexity of a problem is also a lower bound on the deterministic communication complexity of the problem. Furthermore, it is also a lower bound on the *randomized* communication complexity of the problem.

REMARK 1. Many problems in the multiparty model have a nondeterministic communication complexity of $o(n)$. For example, each player holds one bit, and

$$f = \max(z_1, z_2, \ldots, z_n).$$

If $f(z_1, z_2, \ldots, z_n) = 1$, the prover can post to the blackboard an index i of the player with $z_i = 1$ ($\log n$ bits); this player checks whether indeed $z_i = 1$.

There are several techniques for obtaining lower bounds on communication complexity. The most popular technique is the *fooling set*.

DEFINITION 1. Let $f : (\{0,1\}^k)^n \to \{0,1\}$. A subset H of $(\{0,1\}^k)^n$ is called a *fooling set* (for f) if there exists a value $f_0 \in \{0,1\}$ such that:

- For every $(z_1, z_2, \ldots, z_n) \in H$, $f(z_1, z_2, \ldots, z_n) = f_0$.
- For every two distinct vectors

$$(z_1^1, z_2^1, \ldots, z_n^1), (z_1^2, z_2^2, \ldots, z_n^2) \in H,$$

there exist $r_1, r_2, \ldots, r_n \in \{1,2\}$ such that

$$f(z_1^{r_1}, z_2^{r_2}, \ldots, z_n^{r_n}) = 1 - f_0.$$

Less formally, by "mixing" the coordinates of any two vectors in the fooling set, we can obtain an input vector whose value under f is $1 - f_0$.

It is known that the existence of a fooling set of size m for f entails a lower bound of $\log m$ on the nondeterministic communication complexity of f [6].

REMARK 2. In the context of cooperative games, f is the function which, given the resources and utility function for all the players and a distinguished player, outputs that player's payoff in some solution, according to a fixed solution concept. However, when proving our lower bounds, we will deal with boolean functions[6] (so that we can use the fooling set technique).

3. RESULTS

This section is devoted to proving a tight bound of $\Theta(n)$ on the communication complexity of computing a player's expected payoff in the following solution concepts (in this order): Shapley value, the nucleolus and modified nucleolus, m-round equal excess and ∞-round equal excess, and the core.

3.1 Upper Bound

Obtaining an upper bound on the communication complexity of any solution concept in our environment is immediate:

[6]Determining whether a given player's payoff is greater than 0, or determining whether the solution set is nonempty. This strengthens our results, since these decision problems are weaker than computing payoff.

PROPOSITION 1. *The deterministic communication complexity of any solution concept (even when computing the payoff of all players) is $O(n)$.*

PROOF. Recall that each agent holds a constant amount of information. Therefore, all n agents can communicate their entire part of the input (resources and utility function), and then compute a solution. □

3.2 Lower Bounds

The following lemma will soon be essential in the proof of Lemma 3.

LEMMA 2. $log\binom{n}{\lfloor \frac{n}{2} \rfloor + 1} = \Omega(n)$.

PROOF. Without loss of generality, assume n is even (for an odd n small changes are required, but the proof is similar). Observe that

$$\binom{n}{\frac{n}{2}+1} = \frac{n!}{(\frac{n}{2}+1)!(\frac{n}{2}-1)!} = \frac{n \cdot (n-1) \cdots (n/2+2)}{(n/2-1) \cdot (n/2-2) \cdots 1}.$$

We associate each factor in the denominator which is greater than or equal to $n/4+1$, with a factor in the numerator that is exactly twice as large. For example, $n/4+1$ is associated with $n/2+2$. We have $n/4-1$ such pairs, each with a ratio of 2. The other $n/4$ factors in the numerator are all greater than the other $n/4$ factors in the denominator. Therefore, we have: $\binom{n}{\frac{n}{2}+1} \geq 2^{n/4-1}$, and hence:

$$\log\binom{n}{\frac{n}{2}+1} \geq \log\left(2^{n/4-1}\right) = n/4 - 1 = \Omega(n).$$

□

The next definition and lemma are a part of the proof of Lemma 4. They yield a somewhat roundabout proof for Lemma 4, which is meant to provide intuition for the correctness of some of the main propositions.

DEFINITION 2. The *majority function*, denoted by *maj*, returns 1 if at least $\lfloor \frac{n}{2} \rfloor + 1$ players have the bit 1, and 0 otherwise.

Let E be the set of input vectors such that the number of ones is at most $\lfloor \frac{n}{2} \rfloor + 1$, and denote by $maj_{|E}$ the majority function restricted to the games in E.

LEMMA 3. *The nondeterministic communication complexity of $maj_{|E}$ is $\Omega(n)$.*

PROOF. We exhibit a fooling set of size $\binom{n}{n'}$, where $n' = \lfloor \frac{n}{2} \rfloor + 1$; the result follows from Lemma 2. The fooling set consists of all binary vectors of length n with exactly n' ones. Clearly, for any vector there is a majority of ones, and thus it remains to show that for any two vectors $\vec{w^1}$ and $\vec{w^2}$ in the fooling set, we can create a vector $\vec{w}$ where $w_i = w_i^1$ or $w_i = w_i^2$ for all $i \in N$, in such a way that $maj(\vec{w}) = 0$. Indeed, for any two such vectors, there must be $i_0 \in N$ such that $w_{i_0}^1 = 1$ but $w_{i_0}^2 = 0$. Let $w_i = w_i^1$ for all $i \neq i_0$, and $w_{i_0} = w_{i_0}^2 = 0$. $\vec{w}$ has exactly $n' - 1$ ones, as required. □

LEMMA 4. *Let G be the set of weighted-majority games $[q; w_1, w_2, \ldots, w_n]$ where $q = \lfloor \frac{n-1}{2} \rfloor + 2$, such that $w_i \in \{0,1\}$ for all i, $w_1 = 1$, and $\#\{i : i \geq 2 \wedge w_i = 1\} \leq \lfloor \frac{n-1}{2} \rfloor + 1$.*

Assume that some singleton solution concept satisfies the following property:

$$\forall g \in G,\ maj_{|_E}(w_2, w_3, \ldots, w_n) = 1 \implies x_1(g) > 0 \text{ for the grand coalition.} \quad (1)$$

Then the nondeterministic communication complexity of computing the payoff of an arbitrary agent in this solution concept is $\Omega(n)$ (even to decide whether the payoff of a given agent is greater than 0).

PROOF. Notice that all games in G are superadditive by Lemma 1, and thus we can assume the grand coalition forms. There is an obvious reduction from $maj_{|_E}$ with $n-1$ players to games in G: given an input $\langle w_2, w_3, \ldots, w_n\rangle$ for $maj_{|_E}$, complete the vector of weights with $w_1 = 1$, and set $q = n' + 1$, where $n' = \lfloor \frac{n-1}{2} \rfloor + 1$. Assuming property (1) holds, then $maj(w_2, w_3, \ldots, w_n) = 1$ if and only if $x_1(g) > 0$: "only if" follows from the fact that if $maj(w_2, w_3, \ldots, w_n) = 0$, then $\sum_{i\geq 2} w_i < n'$, and so the value of all coalitions is 0.

We have that if the nondeterministic communication complexity of deciding whether $x_1 > 0$ is $f(n)$ for some function f, then the nondeterministic communication complexity of $maj_{|_E}$ with $n-1$ players is at most $f(n)$. From Lemma 3, $f(n) = \Omega(n-1) = \Omega(n)$. □

We now prove our lower bounds. We start with the solution concepts that correspond to a singleton set of stable payoff configurations. These proofs rely on Lemma 4.

PROPOSITION 2. *The nondeterministic communication complexity of computing the payoff of an arbitrary agent according to the Shapley value is $\Omega(n)$ (even to decide whether the payoff of a given agent is greater than 0).*

PROOF. Let G be the set of weighted-majority games $[q; w_1, w_2, \ldots, w_n]$ where $q = \lfloor \frac{n-1}{2} \rfloor + 2$, such that $w_i \in \{0, 1\}$ for all i, $w_1 = 1$, and $\#\{i : i \geq 2 \wedge w_i = 1\} \leq \lfloor \frac{n-1}{2} \rfloor + 1$. We show that the Shapley value has property (1); this is sufficient to complete the proof by Lemma 4.

Fix a game from G, and let $S^* = \{i : w_i = 1\}$ (this coalition includes player 1). If we assume that

$$maj_{|_E}(w_2, w_3, \ldots, w_n) = 1,$$

then $|S^*| = q$; it follows that $x_1 > 0$, since:

$$\begin{aligned} x_1 &= \sum_{S \subseteq N} \frac{(|N| - |S|)!(|S| - 1)!}{|N|!}(v_S - v_{S-\{1\}}) \\ &\geq \frac{(|N| - |S^*|)!(|S^*| - 1)!}{|N|!}(v_{S^*} - v_{S^*-\{1\}}) \\ &= \frac{(n-q)!(q-1)!}{n!} \cdot (1 - 0) \\ &> 0. \end{aligned}$$

In fact, since all q players with $w_i = 1$ are interchangeable, and the rest are null players, we have from the axioms that characterize the Shapley value that $x_1 = \frac{1}{q}$. □

PROPOSITION 3. *The nondeterministic communication complexity of computing the payoff of an arbitrary agent according to the nucleolus[7] and the modified nucleolus is $\Omega(n)$ (even to decide whether the payoff of a given agent is greater than 0).*

[7]Recall that the nucleolus is a singleton for a given coalition structure. Here we investigate the nucleolus of the grand coalition.

PROOF. Let G be the set of weighted-majority games $[q; w_1, w_2, \ldots, w_n]$ where $q = \lfloor \frac{n-1}{2} \rfloor + 2$, such that $w_i \in \{0, 1\}$ for all i, $w_1 = 1$, and $\#\{i : i \geq 2 \wedge w_i = 1\} \leq \lfloor \frac{n-1}{2} \rfloor + 1$. We show that the nucleolus has property (1); this is sufficient to complete the proof by Lemma 4.

Fix a game from G, and let $\vec{x}$ be the nucleolus of the grand coalition. We assume that $maj(w_2, \ldots, w_n) = 1$; it follows that $\#\{i : w_i = 1\} = q$. We wish to show that $x_1 > 0$. Consider the payoff division $\vec{x^*}$, where $x^*_i = \frac{1}{q}$ for all i such that $w_i = 1$, and $x^*_i = 0$ otherwise. $\mathrm{e}(R, \vec{x^*}) = 0$ for coalitions R that contain all players with $w_i = 1$, and coalitions that do not contain any of these players. Moreover, for any other coalition, $\mathrm{e}(R, \vec{x^*}) < 0$: if the coalition contains $k < q$ players with $w_i = 1$, then $\mathrm{e}(R, \vec{x^*}) = -\frac{k}{q}$.

Now, assume $x_1 = 0$. If there exists i such that $w_i = 0$ but $x_i > 0$, then the coalition $S^* = \{i : w_i = 1\}$ must have $\mathrm{e}(S^*, \vec{x}) > 0$, since $v(S^*) = 1$ but $x(S^*) < 1$. But this means $\vec{\theta}(\vec{x}) \succ \vec{\theta}(\vec{x^*})$, and thus we can assume the payoff is distributed only among the players with $w_i = 1$. $\mathrm{e}(R, \vec{x}) = 0$ for coalitions R that contain all players with $w_i = 1$, and all coalitions that do not contain any of these players. Additionally, it holds that $\mathrm{e}(\{1\}, \vec{x}) = 0$. The number of zeros in $\vec{\theta}(\vec{x})$ is greater than the number of zeros in $\vec{\theta}(\vec{x^*})$, and thus $\vec{\theta}(\vec{x}) \succ \vec{\theta}(\vec{x^*})$; this is a contradiction to the assumption that $\vec{x}$ is the nucleolus.

For the modified nucleolus we have to slightly change the end of the proof, because the excess of coalitions of size 1 is no longer considered. However, observe that if $x_1 = 0$ (and we still have that $x_i = 0$ for all players with weight 0), there must be a player i_0 with $w_i = 1$ and $x_i \leq \frac{1}{q-1}$; hence, $\mathrm{e}(\{1, i_0\}, \vec{x}) \geq -\frac{1}{q-1}$. It holds that the number of 0's in $\vec{\theta}(\vec{x})$ and $\vec{\theta}(\vec{x^*})$ is equal, but the next smallest coordinate in $\vec{\theta}(\vec{x})$ is at least $-\frac{1}{q-1}$, while in $\vec{\theta}(\vec{x^*})$ it is $-\frac{2}{q}$. Hence, $\vec{\theta}(\vec{x}) \succ \vec{\theta}(\vec{x^*})$ — a contradiction to our assumption that $\vec{x}$ is the modified nucleolus of the grand coalition. □

PROPOSITION 4. *The nondeterministic communication complexity of computing the payoff of an arbitrary agent according to m-round and ∞-round equal excess is $\Omega(n)$ (even to decide whether the payoff of a given agent is greater than 0).*

PROOF. Let G be the set of weighted-majority games $[q; w_1, w_2, \ldots, w_n]$ where $q = \lfloor \frac{n-1}{2} \rfloor + 2$, such that $w_i \in \{0, 1\}$ for all i, $w_1 = 1$, and $\#\{i : i \geq 2 \wedge w_i = 1\} \leq \lfloor \frac{n-1}{2} \rfloor + 1$. We show that m-round equal excess has property (1); this is sufficient to complete the proof by Lemma 4.

Fix a game from G, and let $S^* = \{i : w_i = 1\}$; we assume that $|S^*| = q$. Observe that for all rounds r and players $i \in S^*$: $E^r(i, S^*) = 1/q$, by the symmetry of all players in S^*. Moreover, clearly it holds (again, by the symmetry of the players in S^*) that for all rounds r, $i \in S^*$ and $T \subseteq N$: $E^r(i, T) \leq 1/q$. Therefore,

$$\forall r, \forall i \in S^*, \forall T \subseteq N \text{ s.t. } S^* \subsetneq T :\ A^r(i, N) = 1/q. \quad (2)$$

For all players $i \notin S^*$ it holds that:

$$\forall T \subseteq N :\ E^0(i, T) \leq E^0(i, T^*) = \frac{1}{q+1}, \quad (3)$$

where $T^* = S^* \cup \{i\}$. In subsequent rounds r, we claim that:

$$\forall i \notin S^*, \forall T \subseteq N :\ E^r(i, T) \leq \frac{1}{q+1}. \quad (4)$$

This can be proven by induction: the base is given by equation (3). For the induction step, we have that $A^r(i,T) \leq \frac{1}{q+1}$ from the assumption. Any coalition T with non-zero value of which player i is a member also contains S^*. For such coalitions:

$$\begin{aligned} E^{r+1}(i,T) &= A^r(i,T) + \frac{v(s) - \sum_{j\in T} A^r(j,T)}{|T|} \\ &\leq \frac{1}{q+1} \\ &\quad + \frac{1 - \sum_{j\in S^*} A^r(j,T) - \sum_{j\in T-S^*} A^r(j,T)}{|T|} \\ &\overset{(2)}{=} \frac{1}{q+1} - \frac{\sum_{j\in T-S^*} A^r(j,T)}{|T|} \\ &\leq \frac{1}{q+1} \end{aligned}$$

Consequently, for all rounds r:

$$\begin{aligned} E^{r+1}(1,N) &= A^r(1,N) + \frac{v(N) - \sum_{j\in N} A^r(j,N)}{n} \\ &\overset{(2)}{=} \frac{1}{q} \\ &\quad + \frac{1 - \sum_{j\in S^*} A^r(j,N) - \sum_{j\in N-S^*} A^r(j,N)}{n} \\ &\overset{(2)}{=} \frac{1}{q} - \frac{\sum_{j\in N-S^*} A^r(j,N)}{n} \\ &\overset{(4)}{\geq} \frac{1}{q} - \frac{n-q}{n}\frac{1}{q+1} \\ &> 0. \end{aligned}$$

For m-round equal excess it holds that $x_1 = E^m(1,N)$; this completes the proof. Observe that we have from the proof that even for $m = \infty$, $E^\infty(1,N) > 0$. □

We now wish to analyze the communication complexity of payoff division according to the core. The core is not necessarily a singleton, but may be empty. Clearly, determining whether the core is empty is easier than computing the payoff of a player in some payoff configuration that is in the core.

PROPOSITION 5. *The nondeterministic communication complexity of computing the payoff of an arbitrary agent according to the core is $\Omega(n)$ (even to decide whether the core is empty).*

PROOF. We exhibit a fooling set of size $\binom{n}{n'}$, where $n' = \lfloor \frac{n}{2} \rfloor + 1$; the result follows from Lemma 2. All the inputs in the fooling set correspond to weighted majority games with $q = n' - 1 = \lfloor \frac{n}{2} \rfloor$; thus, an input in the fooling set can be fully represented by the vector of the agents' weights. The vectors $\langle w_1, w_2, \ldots, w_n \rangle$ in the fooling set have 1 in exactly n' coordinates, and 0 in the other $n - n'$ coordinates. There are $\binom{n}{n'}$ such vectors. Fix a game $\vec{w}$ in the set; we wish to show the core is empty. Since the game is superadditive,[8] it is sufficient to show that there is no stable payoff division for the grand coalition. Indeed, let $\vec{x}$ be a payoff vector, and let $i_0 = \text{argmax}_i\{x_i : w_i = 1\}$. The coalition S of q players i with $w_i = 1$ and $i \neq i_0$ benefits by deviating, since $v(S) = 1 = x(S) + x(N-S) > x(S)$. It follows that $\vec{x}$ cannot be in the core.

We still need to show that for any two vectors $\vec{w^1}$ and $\vec{w^2}$ in the fooling set, we can create a vector $\vec{w}$ where $w_i = w_i^1$ or $w_i = w_i^2$ for all $i \in N$, in such a way that the core is non-empty. For any two such vectors, there must be $i_0 \in N$ such that $w_{i_0}^1 = 1$ but $w_{i_0}^2 = 0$. Let $w_i = w_i^1$ for all $i \neq i_0$, and $w_{i_0} = w_{i_0}^2 = 0$. $\vec{w}$ has 1 in exactly q coordinates. It is clear that the following payoff distribution is in the core: $x_i = 1/q$ for all i such that $w_i = 1$, and $x_i = 0$ for all other players. □

[8]The proof of superadditivity is similar to Lemma 1, and relies on the fact that if $v(T) = 1$, T contains at least q players with $w_i = 1$, and so $N - T$ contains at most one such player.

3.3 Restricted Games

In Section 2, we defined some restricted types of games. In this subsection, we shall look more closely at apex and veto games. These two types of games have natural, real-world interpretations: in an apex game, the apex player may be described as a limited monopolist (who requires only one ally), while veto games are similar to such political bodies as the United Nations security council.

Apex and veto games are particularly interesting in the context of communication complexity, since a great deal of information about the game can be communicated by simply naming the apex or veto player.

PROPOSITION 6. *In constant-sum apex games, the* deterministic *communication complexity of computing the payoff of an arbitrary agent in any solution concept is 1.*

PROOF. Recall that constant-sum apex games have the weighted majority representation

$$[n-1; 1, \ldots, 1, n-2, 1, \ldots, 1],$$

where $n-2$ is the weight of the apex agent, and suppose w.l.o.g. that the goal is to compute the payoff of agent 1. It is sufficient that agent 1 simply announce (using one bit) whether it is the apex player; it can do this by determining whether its weight is $n-2$ (in other words, checking that it has $n-2$ resource units). By the symmetry between the non-apex agents, this knowledge is sufficient to compute the payoff of agent 1. □

Moreover, many important veto games have the weighted majority representation:

$$[n; 1, \ldots, 1, n-1, 1, \ldots, 1],$$

where $n-1$ is the weight of the veto player. Obviously, the deterministic communication complexity of payoff division in these games is also 1.

4. CONCLUSIONS AND FUTURE WORK

In an environment with n-agents, each holding a constant amount of information (the agent's utility function and initial resources), we have shown that the communication complexity of computing the payoff of an arbitrary player is $\Theta(n)$ in the following solution concepts: Shapley value, the nucleolus and modified nucleolus, equal excess theory, and the core. Additionally, we have shown that in constant-sum apex games and certain veto games, the deterministic communication complexity is 1.

As our upper bound is trivial, clearly the significance of the results lies in the lower bounds. Fortunately, a communication complexity lower bound of $\Omega(n)$ is usually not an obstacle. Nevertheless, when interpreted negatively, our results show that solving cooperative games may be infeasible in scenarios where the communication is severely restricted, or the number of agents is very large.

Our approach has some limitations. The results in this paper are relevant to coalition formation in our specific environment model; the bounds on communication complexity may be different in other models, although the model which was our focus is an intuitive and well-known one.

Another possible criticism of this work is that, even if a payoff division among the n players is known in advance, in general it takes $O(n)$ communication to broadcast this solution to the players. Nevertheless, recall that our goal here was to determine the value of a specific player in a given solution concept. As we noted in the introduction, this problem is also important in its own right. Our analysis of restricted games shows that $\Omega(n)$ communication is not a lower bound for this problem in certain games.

There are several appealing directions in which this research can be extended. An important task is to characterize the "interesting" games in which payoff division has a communication complexity of $o(n)$ (*small* O). A related issue is to determine whether there exist reasonable singleton solution concepts with communication complexity of $o(n)$ in general characteristic function games. It may also be the case that the communication complexity may be lowered for certain solutions, but only in specific games (where other solutions are still hard), or particular environments.

Our methods of obtaining lower bounds have prevented us from investigating such important solutions as the kernel and the bargaining set (see [5]). These solutions should also be examined in the future.

Another direction is to augment our model by adding another parameter m, which is the amount of information each agent holds (in our environment $m = O(1)$, since we assumed that each agent holds a constant amount of information). We expect that the bounds for many of the solution concepts can be generalized to $\Theta(n \cdot \log m)$, but the same issues we studied here may be even more explicit in this augmented model.

ABSTRACT

In this paper we follow the BOID (Belief, Obligation, Intention, Desire) architecture to describe agents and agent types in Defeasible Logic. We argue that the introduction of obligations can provide a new reading of the concepts of intention and intentionality. Then we examine the notion of social agent (i.e., an agent where obligations prevail over intentions) and discuss some computational and philosophical issues related to it. We show that the notion of social agent either requires more complex computations or has some philosophical drawbacks.

1. INTRODUCTION

Recent works on cognitive agents combine two apparently independent perspectives [6, 14, 8, 7, 9, 10]: (a) a classical cognitive account of agents that specifies their mental attitudes; (b) modelling agents' behaviour by means of normative concepts. For the first approach, the background is the belief-desire-intention (BDI) architecture, where mental attitudes are taken as primitives to give rise to a set of Intentional Agent Systems [20, 4]. This view is interesting especially when the behaviour of agents is the outcome of a rational balance among their (possibly conflicting) mental states. The normative aspect is rather based on the assumption that normative concepts play a role to characterise the idea of social co-ordination of autonomous agents [19]. The nice result of this combination of perspectives is that of leading to an account of agents' deliberation and behaviour in terms of the interplay between mental attitudes and normative (external) factors such as obligations.

Following [14, 8, 7] we discuss how this combination can be framed in Defeasible Logic (DL). As is well-known, DL is based on a logic programming-like language and it is a simple, efficient but flexible non-monotonic formalism able to deal with many different intuitions of non-monotonic reasoning and recently applied in many fields. In addition, several efficient implementations have been developed [17, 3]. Here we discuss and extend some aspects of a non-monotonic logic of agency, based on the framework of [1], developed in [8, 7]. Indeed, DL is one of the most expressive languages that allows for the definition of large sets of patterns called agent types. Here, the focus will be in particular on philosophical and computational aspects of the notion of social agent, by which we mean a norm-complying agent.

The layout of the paper is as follows. Section 2 provides the theoretical background of our system. In particular, since the concept of social agent focuses on the interplay between obligations and intentions, we will discuss which kind of intentions have to be considered in this regard. Section 3 will present our logical framework, based on DL, which will embed our intuitions and permit to deal with social agency. Some first conclusions will be provided with reference to the problematic nature of social agents. Section 4 deals with the computational complexity of social agency.

2. SOCIAL AGENTS: OBLIGATION AND INTENTION

This section provides some theoretical background for the rest of the paper. Our focus is on the so-called policy-based attitudes. The term was coined by Bratman [5] with specific reference to the idea of intention. The intuition behind policy-based intention is based on Bratman's view regarding *future directed intention* and *general intention*. Bratman terms general intentions as *general/personal policies*. Along with general policies go policy-based intentions. For example, I have a general policy to patch up and reboot the Unix server in the department once every month. This morning, on the basis of this policy, I form the intention to reboot the machine at 7.00 pm in the evening. My intention this morning to reboot the machine this evening is a *policy-based* intention. This specific intention will play a major part in my planning process for the day as it will pose problems about means and constrain my other options. Based on this distinction Bratman makes the following classification of intentions: *deliberative, non-deliberative* and *policy-based*.

The difference between the three is the following: When an agent i has an intention of the form $\mathrm{INT}_i^{t_1}\varphi, t_2$ (read as *agent i intends at*

t_1 *to* φ *at* t_2) as a process of *present* deliberation, then it is called *deliberative intention*. On the other hand, if the agent comes to have such an intention not on the basis of present deliberation, but at some earlier time t_0 and has retained it from t_0 to t_1 without reconsidering it, then this intention it is called *non-deliberative*. The third case arises when intentions are general and concern potentially recurring circumstances in an agent's life. Such general intentions constitute *policy-based intentions*. A policy-based intention is not a non-deliberative intention because it is not simply a case of retaining an intention previously formed. Neither is it a deliberative intention since it is not based on a full-blown deliberation where an attempt is made to weigh pros and cons for and against conflicting options. It also differs from an intention in favour of necessary means, i.e., intention in favour of a specific end, in the sense that the defeasibility of general policies makes it possible to *block* the application of the policy to the particular case without *abandoning* the policy. Otherwise one could abandon the intention in favour of the end. The difference here is that in each case the policy concerns not just a single future situation, but a kind of circumstance that is expected to recur in the agent loop and in each case the agent might well have a general intention to act in the particular circumstances. Whether the agent is able to perform that action or not depends on the circumstances.

As argued in detail elsewhere [13], it may happen that a policy-based intention needs to be *re-considered* if not *blocked* for the application to particular cases. But this does not mean that the agent should know all such conditions in a scenario, but only those she considers necessary for the intended outcome and that she is not confident of their being satisfied. To intend the necessary consequence the agent has to make sure that all the evidence to the contrary has been defeated, which is basically a defeasible conclusion.

The starting point of this paper is to extend the policy-based approach to other attitudes and motivational factors such as beliefs and obligations. In this way, all motivational factors are represented within a rule-based system: intentions and beliefs are viewed as constituting the internal constraints (based on policies) of an agent while obligations are her external constraints (based on rules). As constraints they are defeasible. Notice, in particular, that such an extension to obligations can capture the well-known defeasible character of deontic reasoning. In this last case, a policy-based obligation –conceived of as an external motivational attitude– turns out to be simply a conditional obligation, namely, a rule that allows for the inference of an obligation whenever the antecedent of this rule holds [18, 21].

2.1 Intentions and Normativity

According to Bratman, rational agents can be basically modelled as follows:

- agents are goal-directed without being necessarily aware of their activity;
- intentions are used to choose partial plans for the realisation of a goal;
- not all consequences are intended but only some initial intentions and the goal as a result of the plan; if some side-effects occur, they are never intended.

It is worthy discussing here the notion of side-effect. This well-known problem has to deal with several variants of logical omniscience: the problem arises when the agent is required to know all the truths defined by her logic, or when the logic that depicts the agent automatically includes all the logical truths of classical logic, or, finally, if the agent knows all the logical consequences of the known propositions [12]. Indeed, the problem is usually referred to as the *expected side-effects* problem [5], a problem which depends on the interactions between the reasoning mechanism for the propositional inferences and the mechanism ruling the introduction and the behaviour of the modal operators. A simple and rather unsatisfactory solution would be to consider two completely unrelated consequence relations, one for the propositional part and the second one for the modal operators. The consequence relation for a modal operator is meant to give the condition under which one can prove a modal formula. For example the pair $\Gamma \mid\sim_{\mathbf{X}} \alpha$, where $\mathbf{X}$ is a modal operator, means that if we can prove all the formulas in Γ then we can deduce $\mathbf{X}\alpha$. In what follows we will develop a system for mental states and motivational attitudes based on this idea. However, we will allow the consequence relation for intentions and obligations to interact with the propositional module and we will also consider possible interactions between the modal operators. To this end we have to show that the expected side-effects phenomenon is not a drawback for policy-based agents: such a kind of agents must accept the expected-side effects unless they have some reasons to reject the consequences corresponding to them.

In effect, though our proposed theory does not entertain many of the properties leading to logical omniscience, some aspects of the side-effects problem are accepted. Consider

$$\mathrm{INT}\mathit{Smoke},\ \mathit{Smoke} \rightarrow \mathit{Cancer} \mid\sim \mathrm{INT}\mathit{Cancer} \quad (1)$$

$$\mathrm{INT}\mathit{GoToRome},\ \mathit{GoToRome} \rightarrow \mathit{GoToItaly} \mid\sim \mathrm{INT}\mathit{GoToItaly} \quad (2)$$

Actually, whereas the first case is clearly unacceptable, the second should be accepted by a rational agent. In this perspective the side-effects problem is similar to the substitution of indiscernible in opaque contexts. An agent may have the intention to visit Rome and not to visit Italy. But if the agent knows that Rome is the capital of Italy then it would be irrational of the agent not to have the intention to go to Italy given the intention to visit Rome.

Accordingly, some cases of the side-effects problem are not necessarily a weakness of a theory. This holds in particular if we assume that our agents are *aware* of their activities. In our view, modelling rational agents corresponds to the following assumptions:

- agents are aware of their activities, of their policies;
- some cases of the side-effects problem can be accepted;
- if a case has to be rejected this means that its unpleasant consequences should not be intended;
- when unpleasant consequences are not intended, this only means that they are blocked by conflicting attitudes or facts.

The theory an agent is equipped with can be understood as the specification of the behaviour of the agent. If the agent is *aware* that B is an unavoidable/indisputable consequence of A and the agent intends A, then B is a consequence of the agent's intentions and the agent must accept it as part of her intentions. Suppose we have that "raising one's hand at an auction counts as making a bid". Thus if the agent (aware of this policy) intends to raise her hand, then she intends to bid in the auction, and her action will be understood as making a bid. In other words, in our system we will try to balance and moderate some unpleasant aspects of the side-effects problem with the equally important need for modelling rational agents. Of course, according to our view, we may have that something is intended even if it is causally distant with respect to the original derived intentions. But this is not necessarily a drawback if we conceive agents as rational and, as such, being aware of the policies which are related with the environment and with their interests: even a causally distant behaviour can be rationally

intended unless it is removed in the meantime from deliberation. But this case is indeed considered within our analysis because we may have concrete contexts in which some policy-based intentions, as soon as they are applicable, turn out to be overridden by other policies: we may have reasons to argue that, if an agent intends A and believes that B is a consequence of A, this is not a reason for necessarily intending B; in fact, the derivation of B as an intention may be blocked, in our view, by competing attitudes or made non-applicable by concrete facts.

According to the previous discussion it should be clear that, though inspired by Bratman's [5] analysis, the notion of intention we study in this paper is slightly different, as it focuses on the idea of *intentionality*. In Bratman's view intentions are used to choose partial plans for the realisation of a goal; in this way they have a close relation to means-ends. In our view intentions should be related not only to means-ends but also to the their consequences.

This concept of intention is particularly relevant in conjunction with deontic and normative notions, for example if we want to say that an agent is legally responsible for A if the agent did A with the intention to do A. In such cases the agent has to include in the set of her intentions not only her intentions in Bratman's sense but also some of their consequences. Our intuition is compatible with von Wright's [22] classical theory of normative actions. Von Wright's problem is to identify what should be the content of norms. He argues that norms should deal with actions. Roughly, actions can be described in terms of state transitions and as the sets of all changes of world that follow from them. It is not our purpose discussing here von Wright's theory of action. It should be noted, however, that he considers the related problem of intentions. On the one hand, von Wright is clear when he says that any action may have an arbitrary number of consequences and not all of them are intended. On the other hand, he provides a very broad concept of action, according to which all actions in norms, strictly speaking, are intentional. If so, what are the boundaries of intentions to be considered when they interplay with obligations?

Let us see how to recast Bratman's Strategic Bomber scenario [5] in this perspective. The basic scenario runs as follows: Strategic Bomber intends to bomb a munition plant of the enemy being aware that the resulting explosion will kill innocent children in a nearby school. Bratman argues that Strategic Bomber does not have the intention to kill the children. Let us expand the scenario by supposing that despite the bombing, Strategic Bomber loses the war, and that there is a process for war crimes against him. Civil casualties are a sad but almost unavoidable consequence of war, but usually the killing of civilians does not constitute a war crime if there was no intention to kill. According to Bratman, Strategic Bomber did not commit a war crime since he did not have such an intention. However, let us assume that Strategic Bomber did not do anything to prevent or minimise civil casualties (let us say by a movement of troops that might have resulted in an evacuation of the area surrounding the munition plant). In this extended scenario the killing of children is brought about by a (successful) intentional act of Strategic Bomber. Accordingly, he must be held responsible for the killing of innocent civilians.

Given this interpretation of intentions, we will see in the rest of this paper that some standard accounts of agent types, and of social agents in particular, are not satisfactory. We provide now some brief comments on the notion of agent type and social agent.

Classically, agent types are characterised by stating conflict resolution types in terms of orders of overruling between rules [6, 14, 7, 8]. In this perspective, agent types are meaningful within a nonmonotonic setting and are nothing but general strategies to detect and solve conflicts between the different components of the cognitive profiles of agent's deliberation. In [6] 24 possible types are identified while, in [8], based on a different framework, 20 combinations are proposed. Typically, rational agents are assumed to be at least *realistic*: a realistic agent, in fact, is such that rules for beliefs override all other components, as beliefs correspond to agent's account of how the environment is. If the realistic condition is abandoned, we may have situations where intentions and desires override beliefs, thus leading to various forms of wishful thinking.

Given the minimal assumption that a rational agent should be realistic, we may further constrain agent's deliberation in order not to violate obligations: a *social agent* type requires that obligations are stronger than the other motivational components with the exception of beliefs. Various forms of social agency correspond to assuming axiom schemata such as

$$\mathrm{OBL}\phi \rightarrow \neg\mathrm{INT}\neg\phi \tag{3}$$

$$\mathrm{OBL}\phi \rightarrow \neg\mathrm{DES}\neg\phi \tag{4}$$

$$(\mathrm{OBL}\phi \wedge \mathrm{DES}\neg\phi) \rightarrow \neg\mathrm{INT}\neg\phi \tag{5}$$

In this paper we will consider only the interaction between intentions and obligations. But, even confining the problem to these components, the question at stake is: How to deal with social agents? The simplest solution is the classical one, corresponding to adopting schema (3): when we have two rules, one leading to $\mathrm{INT}\phi$ and the other to $\mathrm{OBL}\neg\phi$, the former is blocked. Are we sure that this classical view is sufficient, given the account of policy-based attitudes we previously discussed?

3. BIO AGENTS IN DEFEASIBLE LOGIC

We focus on how beliefs, intentions and obligations jointly interplay in modelling agent's deliberation and behaviour. In particular, the system is meant to infer the goals the agent has to achieve.

The formal language contains modal literals and preferences, and is defined as follows:

DEFINITION 1. *Let $M = \{\mathrm{BEL}, \mathrm{INT}, \mathrm{OBL}\}$ be a set of modal operators, and P a set of propositional atoms. The set of literals is defined as $L = P \cup \{\neg p | p \in P\}$. If q is a literal, $\sim q$ denotes the complementary literal (if q is a positive literal p then $\sim q$ is $\neg p$; and if q is $\neg p$, then $\sim q$ is p).*

- *The language $\mathscr{L}$ is the smallest set including L and containing modal literals Xl and $\neg Xl$ when $l \in L$ is a literal and $X \in M$ is a modal operator.*

For $X \in \{\mathrm{BEL}, \mathrm{INT}, \mathrm{OBL}\}$, we have that $\phi_1, \ldots, \phi_n \rightarrow_X \psi$ is a *strict rule* such that whenever the premises $\phi_1, \ldots, \phi_n$ are indisputable so is the conclusion ψ. $\phi_1, \ldots, \phi_n \Rightarrow_X \psi$ is a *defeasible rule* that can be defeated by contrary evidence. A rule $\phi_1, \ldots, \phi_n \rightsquigarrow_X \psi$ is a *defeater* that is used to defeat some defeasible rules by supporting evidence to the contrary.

DEFINITION 2. *A* rule *r consists of its* antecedent *(or* body*) $A(r)$ ($A(r)$ may be omitted if it is the empty set), an arrow ($\rightarrow$ for a strict rule, $\Rightarrow$ for a defeasible rule, and $\rightsquigarrow$ for a defeater), and its* consequent *$C(r)$ (or* head*).*

- *The arrow is labelled with a modal operator $X \in \{\mathrm{BEL}, \mathrm{INT}, \mathrm{OBL}\}$. If the arrow is labelled with* BEL *the rule is for belief, and similarly for the other modal operators.*
- *Given a rule r, $A(r)$ is a set of literals or modal literals, and $C(r)$ is a literal.*
- *Given a set R of rules, we denote the set of all strict rules in R by R_s, the set of strict and defeasible rules in R by R_{sd}, the*

set of defeasible rules in R by R_d, and the set of defeaters in R by R_{dft}. $R[q]$ denotes the set of rules in R with consequent q. If any R is labelled with X, that is R^X, all expressions just defined will refer to rules for X.

The purpose of the system is to derive modalised literals (goals), with the exception of rules for beliefs. As we shall see, provability for beliefs will not generate goals, as in our view beliefs concern the knowledge an agent has about the world: they may contribute to derive goals (here, intentions and obligations), but they are not in themselves motivations for action. For example, the application of $p \Rightarrow_{\text{OBL}} q$ permits to infer OBLq. Accordingly, modalities will not occur in the consequents of rules to keep the system manageable.

DEFINITION 3. *A defeasible agent theory is a structure $D = (F, R^{\text{BEL}}, R^{\text{INT}}, R^{\text{OBL}}, >)$ where F is a finite set of facts, R^{BEL} is a finite set of rules for belief, R^{INT} is a finite set of rules for intention, R^{OBL} is a finite set of rules for obligation, and $>$, the superiority relation, is a binary relation over the set of rules.*

The *superiority relation* $>$ says when one rule may override the conclusion of another rule. *Facts* are indisputable statements.

The following example illustrates the agent theory.

EXAMPLE 1. (RUNNING EXAMPLE). Frodo, our Tolkienian agent, is entrusted by Elrond to be the bearer of the ring of power, a ring forged by the dark lord Sauron. Frodo has the task to bring the ring to Mordor, the realm of Sauron, and to destroy it by throwing it into the fires of Mount Doom. However, Frodo loves the place where he was born, the Shire, and intends to go there.

$$
\begin{aligned}
F &= \{\text{INT}\mathit{GoToShire},\ \mathit{EntrustedByElrond}\} \\
R &= \{r_1 : \mathit{EntrustedByElrond} \Rightarrow_{\text{BEL}} \mathit{RingBearer} \\
&\quad\ r_2 : \mathit{RingBearer} \Rightarrow_{\text{OBL}} \mathit{DestroyRing} \\
&\quad\ r_3 : \text{INT}\mathit{GoToShire} \Rightarrow_{\text{INT}} \neg\mathit{GoToMordor} \\
&\quad\ r_4 : \neg\mathit{GoToMordor} \Rightarrow_{\text{BEL}} \neg\mathit{DestroyRing}\} \\
> &= \{r_4 > r_2\}
\end{aligned}
$$

3.1 Inferences with Social Agents

DEFINITION 4. *Given an agent theory D, a proof in D is a linear derivation, i.e, a sequence of labelled formulas of the type $+\Delta_X q$, $-\Delta_X q$, $+\partial_X q$ and $-\partial_X q$, where the proof conditions defined in the rest of this section hold.*

The meaning of the proof tags $+\Delta_X$, $-\Delta_X$, $+\partial_X$ and $-\partial_X$ is as follows: $+\Delta_X q$ means that q is definitly provable using only facts and strict rules for X, $-\Delta_X q$ means that it has been proved that q is not definitely provable, $+\partial_X q$ that q is defeasibly provable in D and $-\partial_X q$ that q is not defeasibly provable.

We start with some terminology. As was explained, the following definition states the special status of belief rules, and that an introduction of a modal operator corresponds to being able to derive the associated literal using the rules for the modal operator.

DEFINITION 5. *Let $\# \in \{\Delta, \partial\}$, and $P = (P(1), \ldots, P(n))$ be a proof in D. A (modal) literal q is* #-provable *in P if there is a line $P(m)$ of P such that either*

1. *q is a literal and $P(m) = +\#_{\text{BEL}} q$ or*
2. *q is a modal literal Xp and $P(m) = +\#_X p$ or*
3. *q is a modal literal $\neg Xp$ and $P(m) = -\#_X p$.*

A literal q is #-rejected *in P if there is a line $P(m)$ of P such that*

1. *q is a literal and $P(m) = -\#_{\text{BEL}} q$ or*
2. *q is a modal literal Xp and $P(m) = -\#_X p$ or*
3. *q is a modal literal $\neg Xp$ and $P(m) = +\#_X p$.*

The definition of Δ_X describes just forward chaining of strict rules:

$+\Delta_X$: If $P(n+1) = +\Delta_X q$ then
(1) $q \in F$ if $X = \text{BEL}$ or $Xq \in F$ or
(2) $\exists r \in R_s^X[q]\ \forall a \in A(r)$ a is Δ-provable or
(3) $\exists r \in R_s^{\text{BEL}}[q]\ \forall a \in A(r)$ Xa is Δ-provable.

$-\Delta_X$: If $P(n+1) = -\Delta_X q$ then
(1) $q \notin F$ if $X = \text{BEL}$ and $Xq \notin F$ and
(2) $\forall r \in R_s^X[q]\ \exists a \in A(r) : a$ is Δ-rejected and
(3) $\forall r \in R_s^{\text{BEL}}[q]\ \exists a \in A(r)$ Xa is Δ-rejected.

For a literal q to be definitely provable we need to find a strict rule with head q, whose antecedents have all been definitely proved previously. And to establish that q cannot be definitely proven we must establish that for every strict rule with head q there is at least one antecedent which has been shown to be non-provable. Condition (3) says that a belief rule can be used as a rule for a different modal operator in case all literals in the body of the rule are modalised with the modal operator we want to prove. Thus given the rule $p, q \rightarrow_{\text{BEL}} s$, we can derive $+\Delta_Y s$ if we have $+\Delta_Y p$ and $+\Delta_Y q$.

Conditions for ∂_X are more complicated. We define when a rule is applicable or discarded. A rule for a belief is applicable if all the literals in the antecedent of the rule are provable with the appropriate modalities, while the rule is discarded if at least one of the literals in the antecedent is not provable. For the other types of rules we have to take complex derivations into account called conversions [14]. In this paper we say there is a conversion from X to Y if a rule fior X can also be used as a rule for Y. We have thus to determine conditions under which a rule for X can be used to directly derive a literal q modalised by Y. Roughly, the condition is that all the antecedents a of the rule are such that $+\partial_Y a$.

We represent all allowed conversions by a conversion relation c.

DEFINITION 6. *Let a conversion relation c be a binary relation over $\{\text{BEL}, \text{INT}, \text{OBL}\}$, such that (1) $c(X,Y)$ stands for the conversion of X rules into Y rules, (2) $Y \neq$ BEL. Given a derivation P, $P(1..n)$ denotes the initial part of the derivation of length n.*

- *A rule r in R^{BEL} is* applicable *iff $\forall a \in A(r)$, $+\partial_{\text{BEL}} a \in P(1..n)$ and $\forall Za \in A(r)$, where Z is a modal operator, $+\partial_Z a \in P(1..n)$.*
- *A rule r in R^{BEL} is* discarded *iff $\exists a \in A(r)$ such that $-\partial_{\text{BEL}} a \in P(1..n)$ or $\exists Za \in A(r)$ such that $-\partial_Z a \in P(1..n)$.*
- *A rule $r \in R_{sd}$ is* applicable *in the condition for $\pm\partial_Y$ iff*
  1. *$r \in R^Y$ and $\forall a \in A(r)$, $+\partial_{\text{BEL}} a \in P(1..n)$ and $\forall Za \in A(r)$ $+\partial_Z a \in P(1..n)$, or*
  2. *$r \in R^X$ and $\forall a \in A(r)$, $+\partial_Y a \in P(1..n)$.*
- *A rule r is* discarded *in the condition for $\pm\partial_Y$ iff we prove either $-\partial_{\text{BEL}} a$ or $-\partial_X a$ for some $a \in A(r)$.*
  1. *$r \in R^Y$ and $\exists a \in A(r)$ such that $-\partial_{\text{BEL}} a \in P(1..n)$ or $\exists Za \in A(r)$ such that $-\partial_Z a \in P(1..n)$; or*
  2. *$r \in R^X$ and $\exists a \in A(r)$ such that $-\partial_Y a \in P(1..n)$.*

EXAMPLE 2. The rule $a, \text{INT}b \Rightarrow_{\text{BEL}} c$ is applicable if we can prove both $+\partial_{\text{BEL}} a$ and $+\partial_{\text{INT}} b$.

EXAMPLE 3. If we have a type of agent that allows a deontic rule to be converted into a rule for intention, $c(\text{OBL},\text{INT})$, then the definition of applicable in the condition for $\pm\partial_{\text{INT}}$ is as follows: a rule $r \in R_{sd}[q]$ is applicable iff (1) $r \in R^{\text{INT}}$ and $\forall a \in A(r), +\partial_{\text{BEL}} a \in P(1..n)$ and $\forall Xa \in A(r), +\partial_X a \in P(1..n)$, (2) or $r \in R^{\text{OBL}}$ and $\forall a \in A(r), +\partial_{\text{INT}} a \in P(1..n)$. In this second case, for example, given the rule $p, q \Rightarrow_{\text{OBL}} s$, we can derive $+\partial_{\text{INT}} s$ if we have $+\partial_{\text{INT}} p$ and $+\partial_{\text{INT}} q$.

As a corollary of the definition of applicability, we can establish when a literal is supported (see Section 4 for the use of this notion):

DEFINITION 7. *Given a theory $D = (F, R^{\text{BEL}}, R^{\text{INT}}, R^{\text{OBL}}, >)$, a literal l is* supported *in D iff there exists a rule $r \in R[l]$ such that r is applicable, otherwise l is not supported. For $X \in \{\text{BEL}, \text{INT}, \text{OBL}\}$ we use $+\Sigma_X l$ and $-\Sigma_X l$ to indicate that l is supported / not supported by rules for X.*

We are now ready to provide proof conditions for $\pm\partial_X$:

$+\partial_X$:If $P(n+1) = +\partial_X q$ then
  (1)$+\Delta_X q \in P(1..n)$ or
    (2.1) $-\Delta_X \sim q \in P(1..n)$ and
    (2.2) $\exists r \in R_{sd}[q]$ such that r is applicable; and
    (2.3) $\forall s \in R[\sim q]$, either s is discarded, or
      (2.3.1) $\exists t \in R[q]$ such that r is applicable and $t > s$

$-\partial_X$: If $P(n+1) = -\partial_X q$ then
  (1) $-\Delta_X q \in P(1..n)$ and either
    (2.1) $+\Delta_X \sim q \in P(1..n)$ or
    (2.2) $\forall r \in R_{sd}[q]$, either r is discarded, or
    (2.3) $\exists s \in R[\sim q]$, such that s is applicable, and
      (2.3.1) $\forall t \in R[q]$ either t is discarded, or $t \not> s$

To show that q is defeasibly provable we have two choices: (1) We show that q is already definitely provable; or (2) we need to argue using the defeasible part of a theory D. For this second case, three (sub)conditions must be satisfied. First, we require that there must be a strict or defeasible rule for q which can be applied (2.1). Second, we need to consider possible reasoning chains in support of $\sim q$, and show that $\sim q$ is not definitely provable (2.2). Third, we must consider the set of all rules which are not known to be inapplicable and which permit to get $\sim q$ (2.3). Essentially, each such a rule s attacks the conclusion q. For q to be provable, s must be counterattacked by a rule t for q with the following properties: (i) t must be applicable, and (ii) t must be stronger than s. Thus each attack on the conclusion q must be counterattacked by a stronger rule. In other words, r and the rules t form a team (for q) that defeats the rules s. $-\partial_X q$ is defined in an analogous manner.

EXAMPLE 4. (RUNNING EXAMPLE; CONTINUED). Below is the set C of all conclusions we get using the rules in R:

$$C = \{\textit{RingBearer}, \text{INT}\neg\textit{GoToMordor}, \text{INT}\neg\textit{DestroyRing}\}$$

As facts, we know that Frodo has the primitive intention to go to the Shire and that he has been entrusted by Elrond. These facts make applicable rules r_3 and r_1, which permit to derive that Frodo is the ring bearer and that he has the intention not to go to Mordor. At this point we have a conflict if we assume $c(\text{BEL},\text{INT})$. In effect, given this conversion, r_4 permits to derive that Frodo has the intention not to destroy the ring while rule r_2 should lead to the obligation to destroy it. However, r_4 is stronger than r_2 and so we only get $+\partial_{\text{INT}}\neg\textit{DestroyRing}$.

3.2 The Problem of Social Agents

As suggested in [7, 8], agent types can be characterised in DL as follows:

DEFINITION 8. *An agent type is defined by a set of pairs (X,Y), $X,Y \in \{\text{BEL},\text{OBL},\text{INT}\}$, such that for every r and r' such that $r \in R^X[q]$ and $r' \in R^Y[\sim q]$, we have that $r > r'$.*

While realistic agents are such that $X = \text{BEL}$ and $Y \in \{\text{INT},\text{OBL}\}$, social agents are such that $X = \text{OBL}$ and $Y = \text{INT}$.

Unfortunately, this definition –adopted also in [6]– does not guarantee that agent's deliberation is oriented to fully complying with obligations. This drawback is mainly due to the introduction of conversions. Indeed, the notion of conversion should not sound strange. In many formalisms we can convert from one type of conclusion into a different one. Take for example the right weakening rule of non-monotonic consequence relations, where it is possible to combine non-monotonic with classical consequences: $B \vdash C$ and $A \mid\sim B$ imply $A \mid\sim C$ [15]. Here, conversions simply allow to obtain conclusions modalised by a certain X through the application of rules which are not modalised by X. In particular, they are fundamental in order to capture the fact that some side-effects should be accepted insofar as they are consequences of policies of which the agent is aware. Finally, some conversions seem useful to integrate the basic idea of social agency. For example, we may have agent types for which, given $p \Rightarrow_{\text{OBL}} q$ and $+\partial_{\text{INT}} p$, we can obtain $+\partial_{\text{INT}} q$. Of course, this is possible only if we assume a kind of norm regimentation, by which we impose that all agents intend what is prescribed by deontic rules.

It is clear that our system admits three different types of intentions and obligations. First, we have *primitive* intentions and obligations when these are facts of the theory. But we can also have what we may call *primary* and *secondary* intentions and obligations, depending on whether we accept at least basic conversions via belief rules.

Let us consider Example 1. INT*GoToShire* is a primitive intention. On the other hand, OBL*DestroyRing* –if it were derived from rule r_2– and INT$\neg$*GoToMordor* are primary obligations and intentions as they would be obtained without the use of conversions (see Example 4). Finally, INT$\neg$*DestroyRing* is a secondary intention because it is obtained from the rule $r_4 : \neg\textit{GoToMordor} \Rightarrow_{\text{BEL}} \neg\textit{DestroyRing}$ and from $+\partial_{\text{INT}}\neg\textit{GoToMordor}$ (again, see Example 4). It should be noted that OBL*DestroyRing* cannot be derived because $r_4 > r_2$, but this just amounts to assuming that the agent is realistic: r_4 is a belief rule whereas r_2 is a deontic rule. In other words, when we have in general that

$$\begin{array}{ll} a \Rightarrow_{\text{OBL}} q & b \Rightarrow_{\text{BEL}} \sim q \\ +\partial_{\text{BEL}} a & +\partial_{\text{INT}} b \end{array}$$

we are doomed to have social agents who cannot be truly social since some of their (primitive) intentions lead to behaviours against what would be otherwise obligatory for the agents. However, this issue is not a matter of a direct conflict between rules for intentions and obligations. Thus, to deal with norm-complying agents in these scenarios and to restore their sociality we are required to change the notion of agent type. We cannot anymore define it in terms of an order of overruling between rules, but we have to focus on how the conflicting literals are derived during the proof. Indeed, this is feasible, but has a high computational cost, and even then we cannot guarantee the sociality of an agent.

4. THE COST OF SOCIAL AGENTS

In this section we investigate the complexity of the defeasible logic for BIO agents where we assume the conversion $c(\text{BEL},\text{OBL})$ and $c(\text{BEL},\text{INT})$ and then we turn our attention to the complexity of social agents. We first introduce some notions to make precise the definition of the issues at hand.

DEFINITION 9. *Let # be one of the proof tags. Given a theory D, $D \vdash \pm\#p$ iff there is a derivation P in D such that for some n $P(n) = \pm\#p$.*

DEFINITION 10. *Given a theory D, the* universe *of D (U^D) is the set of all the atoms occurring in D; the* extension *of D (E^D), is defined as follows:*

$$E^D = (\Delta^+, \Delta^-, \partial^+, \partial^-)$$

where for $X \in \{\text{BEL}, \text{INT}, \text{OBL}\}$

$$\Delta^+ = \{Xl : D \vdash +\Delta_X l\};$$
$$\Delta^- = \{Xl : D \vdash -\Delta_X l\};$$
$$\partial^+ = \{Xl : D \vdash +\partial_X l\};$$
$$\partial^- = \{Xl : D \vdash -\partial_X l\}.$$

Two theories D and D' are *equivalent* if and only if they have the same extension, namely $D \equiv D'$ iff $E^D = E^{D'}$.

We now prove the main theorem about the complexity of our defeasible logic. We show that the logic has linear complexity if we compute the whole set of conclusions, i.e., the extension, of a given theory.

THEOREM 1. *For every theory D, E^D can be computed in time linear to the size of the theory, i.e., $O(|U^D| * |R|)$.*

PROOF. The proof is based on a modification of the algorithm given by Maher [16] to show that propositional defeasible logic has linear complexity.

The main idea of the proof is to build appropriate data structure to implement a series of transformations reducing the complexity of the rules, and where each literal and modal literal is examined only once. The focal point of the transformations is based on the following properties:

- Let $D \vdash +\partial p$ then
$$D \cup \{r : p_1, \ldots, p_n, p \Rightarrow q\} \equiv D \cup \{r : p_1, \ldots, p_n \Rightarrow q\}.$$
- Let $D \vdash -\partial p$ then $D \cup \{r : p_1, \ldots, p_n, p \Rightarrow q\} \equiv D$.

The properties allow us (1) to remove already proved literals from the body of rules and (2) to remove rules which have been discarded.

The algorithm has three phases. (1) A pre-processing phase where we use the transformations given in [2] to transform a theory into an equivalent theory without superiority relation and defeaters; the transformation is linear. (2) A *rule loader* that parses the theory obtained in the first phase and generates the data structure that encodes the theory. (3) The *inference engine* applies transformations to the data structure, where at every step it reduces the complexity of the data structure.

The rule loader builds a data structure as follows: for every atom $\alpha \in U^D$ we create three entries α, INTα and OBLα. Each entry has associated to it a list of hash tables:

For α we have

- $+h$ is a list of (pointers to) rules in R^{BEL} where α appears in the head;
- $-h$ is the list of rules in R^{BEL} where $\sim\alpha$ appears in the head;
- $+b$ is the list of rules in R where α occurs in the body;
- $-b$ is the list of rules in R where $\sim\alpha$ occurs in the body.

For $X\alpha$, $X \in \{\text{INT}, \text{OBL}\}$ we have

- $+h$ is a list of rules in R^X where α appears in the head;
- $-h$ is the list of rules in R^X where $\sim\alpha$ appears in the head;
- $+h^{\mathcal{B}}$ is a list of rules in R^{BEL} where α appears in the head;
- $-h^{\mathcal{B}}$ is a list of rules in R^{BEL} where $\sim\alpha$ appears in the head;
- $+b$ is the list of rules in R where $X\alpha$ occurs in the body;
- $-b$ is the list of rules in R where $X\sim\alpha$ occurs in the body.
- $+b_\sim$ is the list of rules in R where $\sim X\alpha$ occurs in the body;
- $-b_\sim$ is the list of rules in R where $\sim X\sim\alpha$ occurs in the body.

To each rule in R^X, $X \neq$ BEL, we associate a structure consisting of a (modal) literal (the head of the rule) and a set of pointers to the modal literals in the body of the rule, implemented as an hash table; while for belief rules we create the same structure as the other types of rules plus two other structures one for INT and one for OBL, the single pointer refers to the modal literal and the set of pointers corresponds to the literals in the body modalised, respectively, with INT and OBL.

The Inference Engine is based on an extension of the *Delores* algorithm/implementation proposed in [17] as a computational model of Basic Defeasible Logic. In turn

1. It asserts each fact (as an atom) as a conclusion and removes the atom from the rules where the atom occurs positively in the body, and it "deactivates" the rules where either the atom occurs negatively in the body, or incompatible modal literals occur in the body.
2. It scans the list of active rules for rules where the body is empty. It takes head and searches for rule (of the appropriate type) where the head is the negation of the atom or a modal literal incompatible with it. If there are no such rules then, the atom is appended to the list of facts, and removed from the rules
3. It repeats the first step.
4. The algorithm terminates when one of the two steps fails. On termination the algorithm outputs the set of conclusions.[1]

It is immediate to see that the algorithm runs in linear time. Each (modal) atom/literal in a theory is processed exactly once and every time we have to scan the set of rules, thus the complexity of the above algorithm is $O(|U^D| * |R|)$. □

Given the above result it might seem that social agents are computationally feasible. However, as we have seen in Section 3.1 there are situations (let us call them deviant situations) where social agents do not behave as expected. First of all, we have to identify when we have a deviant situation and what are the reasons why we have them, and what kind of control an agent has over them. Here we assume that a deviant situation depends on some primitive intentions of an agent (i.e., intentions given as facts). Since these intentions are independent of the policy the theory describe the only alternative a social agent has is to give up some of them. In the rest of the section we study whether this is possible and what price an agent has to pay to be social. The answer is negative; we will provide a theory that is essentially deviant, and we will show that social agents are (computationally) expensive.

First of all we have to give a precise definition of the problem.

[1] This algorithm outputs ∂^+; ∂^- can be computed by an algorithm similar to this with the "dual actions". For Δ^+ we have just to consider similar constructions where we examine only the first parts of step 1 and 2. Δ^- follows from Δ^+ by taking the dual actions.

Restoring Sociality Problem

INSTANCE:
Let I be a finite set of primitive intentions, OBLp a primary obligation, and D a theory such that $I \subseteq F$, $D \vdash -\partial_{\text{OBL}} p$, $D \vdash -\Sigma_{\text{OBL}} \sim p$, $D \vdash +\partial_{\text{INT}} \sim p$, $D \vdash +\Sigma_{\text{OBL}} p$ and $D \vdash -\Sigma_{\text{BEL}} \sim p$.

QUESTION:
Is there a theory D' equal to D apart from containing only a proper subset I' of I instead of I, such that $\forall q$ if $D \vdash +\partial_{\text{OBL}} q$ then $D' \vdash \partial_{\text{OBL}} q$ and $D' \vdash +\partial_{\text{OBL}} p$?

The specification of the problem is meant to formalise the situation we have described in the previous sections. The combination of the proof tags in the specification of the instance is only possible in case there is an applicable deontic rule for p ($+\Sigma_{\text{OBL}} p$) which would be otherwise unchallenged, i.e., there are no deontic rules to support $\sim p$ ($-\Sigma_{\text{OBL}} \sim p$) and there are no reasons to believe the opposite, is defeated, against the sociality of the agent, by the intentionality of $\sim p$ obtained as a consequence of an intention of the agent (this means it has been obtained by converting a belief rule into an intention rule). In other terms a potentially valid obligation is blocked by a consequence of an intentional behaviour.

EXAMPLE 5. Let us the consider the theory consisting of

$$F = \{\text{INT}p, \text{INT}s\}$$
$$R = \{r_1 : p, s \Rightarrow_{\text{BEL}} q \quad r_2 : \Rightarrow_{\text{OBL}} \sim q \quad r_3 : \Rightarrow_{\text{BEL}} s\}$$
$$> = \{r_1 > r_2\}$$

r_1 is a belief rule and so the rule is stronger than the deontic rule r_2. In addition we have that the belief rule is not applicable (i.e., $-\Sigma_{\text{BEL}} q$) since there is no way to prove $+\partial_{\text{BEL}} p$. There are no deontic rules for q, so $-\partial_{\text{OBL}} q$. However, rule r_1 behaves as an intention rule since all its antecedent can be proved as intentions, i.e., $+\partial_{\text{INT}} p$ and $+\partial_{\text{INT}} s$. Hence, since r_1 is stronger than r_2, the derivation of $+\partial_{\text{OBL}} \sim q$ is prevented against the sociality of the agent.

The related decision problem is whether it is possible to avoid the "deviant" behaviour by giving up some primitive intentions, retaining all the (primary) obligations, and maintaining a set of primitive intentions as close as possible to the original set of intentions.

EXAMPLE 5. (CONTINUED). When we examine the theory we notice that both primitive intentions concur to the prevention of the derivation of $+\partial_{\text{OBL}} \sim q$. These intentions are under the control of the agent. The agent has the opportunity to avoid the deviant behaviour if she gives up at least one of her primitive intentions. Accordingly, the agent has three alternatives: to give up INTp, to give up INTs, or to give up both. The first two options minimise the difference between the original theory and the resulting theory.

There could be cases where, no matter what intentions are removed, the theory will result in a deviant situation. The simplest case is where there are intentions that are at the same time primitive and primary.

EXAMPLE 6. Let the theory D be

$$F = \{\text{INT}p\}$$
$$R = \{r_1 : \Rightarrow_{\text{INT}} p \quad r_2 : p \Rightarrow_{\text{BEL}} q \quad r_3 : \Rightarrow_{\text{OBL}} \sim q\}$$
$$> = \{r_2 > r_3\}$$

In this theory we have only one primitive intention and therefore the only way to see whether it is possible to avoid the problem is to give up that intention. However, we have that r_1 is an intention rule for p, and thus we can use it to derive $+\partial_{\text{INT}} p$, which allows r_2 to be used to derive an intention instead of a belief, and consequently to prevent the derivation of an obligation against the sociality of the agent.

Notice that, given the non-monotonic nature of defeasible logic, it is possible that a solution to the problem is given by a superset of the original set of intentions instead of a subset.

EXAMPLE 7. Given a theory D as follows

$$F = \{\text{INT}a, \text{INT}b\}$$
$$R^{\text{BEL}} = \{r_1 : \text{INT}a \Rightarrow_{\text{BEL}} d, \quad r_2 : \text{INT}b \Rightarrow_{\text{BEL}} d,$$
$$r_3 : \text{INT}c \Rightarrow_{\text{BEL}} \sim d, \quad r_4 : d \Rightarrow_{\text{BEL}} e\}$$
$$R^{\text{INT}} = \{r_5 : \Rightarrow_{\text{INT}} a, \quad r_6 \Rightarrow_{\text{INT}} b\}$$
$$R^{\text{OBL}} = \{r_7 : \Rightarrow_{\text{OBL}} \sim e\}$$
$$> = \{r_3 > r_1, r_3 > r_2, r_4 > r_7\}$$

As we have seen in the previous example, throwing away the two primitive intentions is of no avail, they are reinstated by the intention rules r_5 and r_6. However, to block the side effect d of the two intentions we can introduce a further primitive intention, INTc.

If we replace the theory D by a theory D' obtained from D by emptying the set of intention rules, then we have two alternatives to avoid the deviance. The first is to drop both the primitive intentions INTa and INTb, or we can form a new primitive intention INTc. In this case the theory obtained from adding the new intention is, intuitively, more similar to the original theory than the theory obtained from dropping the two primitive intentions.

Variations of the problem can be obtained by changing other parameters of the specification. Some of these can define new types of agents. For example a *pro-active social agent* might try to recover from a deviant situation by changing the raw facts (facts that are neither primitive intentions nor primitive obligations). Thus a pro-active social agent tries to adapt the environment to her goals (intentions). A legalistic social agent, on other the hand, might change the set of primitive obligations, while a cheating social agent might change the rules. However, it is important to realise that all these variations have a structure isomorphic to the specification we discuss in this paper. In addition it is possible to generalise the problem to the case of multiple deviant behaviours.

THEOREM 2. *The Restoring Sociality Problem is NP-complete.*

PROOF. We have to show that the problem is both NP and NP-hard. For the NP part all we have to do is to notice that we can guess a theory, we compute the extension of the theory in linear time (Theorem 1) and then verify in linear time whether the restore conditions are satisfied.

For the NP-hard part we have to map a known NP-complete problem to the Restoring Sociality Problem. Here we use the *knapsack problem* [11, Problem MP9].

Knapsack Problem

INSTANCE:
Given a finite set U, for each $u \in U$ a size $s(u) \in \mathbb{Z}^+$ and a value $v(u) \in \mathbb{Z}^+$, and integer B and K.

QUESTION:
Is there a subset $U' \subseteq U$ such that $\sum_{u \in U'} s(u) \leq B$ and $\sum_{u \in U'} v(u) \geq K$?

The knapsack problem is encoded by a defeasible theory D where R is as follows:

- $\text{INT}load(u) \Rightarrow_{\text{BEL}} load(u)$ for each $u \in U$.
- $\sum_{s(u):D \vdash +\partial_{\text{BEL}} load(u)} s(u) > B \Rightarrow_{\text{INT}} overload$
- $\sum_{s(u):D \vdash +\partial_{\text{BEL}} load(u)} v(u) < K \Rightarrow_{\text{INT}} undervalue$
- $overload \Rightarrow_{\text{BEL}} \neg good$
- $undervalue \Rightarrow_{\text{BEL}} \neg good$
- $\Rightarrow_{\text{OBL}} good$

F is given by the relationship $\text{INT}load(u) \in F$ iff $u \in U'$.

The theory of the above construction has several interesting properties. First of all $D \vdash +\partial_{\text{BEL}} load(u)$ iff $\text{INT}load(u) \in F$, which means $u \in U'$; then $D \vdash +\partial_{\text{OBL}} good$ iff either of the two conditions of the knapsack problem are satisfied; notice that since there are no literals for $\neg load(u)$, the computation of the rule $\text{INT}load(u) \Rightarrow_{\text{BEL}} load(u)$ can be computed independently of the rest of the theory thanks to the modularity of DL [2], thus the sums in the antecedent of the second and third rule can be considered as "facts" in the theory. In case one of the condition of the knapsack problem is not satisfied we have exactly a deviant situation as in the restoring sociality problem. The encoding of the knapsack problem in DL is clearly linear, thus any algorithm that solves the restoring sociality problem in polynomial time will solve the knapsack problem in polynomial time. Therefore the restoring sociality problem is NP-complete. □

5. REVISING SOCIAL AGENTS

A first solution to the complexity of social agents is to avoid conversions. However, we believe, that this is a rather unsatisfactory approach for agents with both internal (intentions) and external (obligations) motivational attitudes. It is not possible to capture the notion of intentionality which is of paramount importance when we deal with agents situated in legal contexts.

A second solution would be to assume that belief rules behaving as intention rules (i.e., obtained from the conversion $c(\text{BEL}, \text{INT})$) are always weaker than deontic rules or belief rules behaving as deontic rules (i.e., where the conversion $c(\text{BEL}, \text{OBL})$ applies). In this case the problem is with theory like

$$\begin{array}{ll} r_1 : a \Rightarrow_{\text{BEL}} q & r_2 : b \Rightarrow_{\text{BEL}} \sim q \\ +\partial_{\text{INT}} a & +\partial_{\text{OBL}} b \\ r_1 > r_2 & \end{array}$$

where r_1 is at the same time stronger and weaker than r_2.

6. SUMMARY

The contribution of this paper is manifold. We extend the analysis of policy-based cognitive agents with the notion of obligation and we argue that in such case side-effects do not endanger the logical analysis but on the contrary are beneficial to explain notions, e.g., intentionality, of paramount importance for agents situated in legal contexts.

Policy based agents are represented in defeasible logic extended with the modalities of belief, intention and obligation. This choice was motivated by the computational feasibility of the logic. We have demonstrated that the logic has linear complexity. As far as we know this is the first result of this kind for cognitive agents.

Finally we have studied the notion of social agent and we have proved that a proper and philosophically sound treatment of this notion leads to an increase of the computational complexity of the problem. Again this is the first result of this kind we are aware of.

ABSTRACT

The *VCG mechanism* is the canonical method for motivating bidders in combinatorial auctions and exchanges to bid truthfully. We study two related problems concerning the VCG mechanism: the problem of revenue guarantees, and that of collusion. The existence of these problems even in one-item settings is well-known; in this paper, we lay out their full extent in multi-item settings. We study four settings: combinatorial forward auctions with free disposal, combinatorial reverse auctions with free disposal, combinatorial forward (or reverse) auctions without free disposal, and combinatorial exchanges. In each setting, we give an example of how additional bidders (colluders) can make the outcome much worse (less revenue or higher cost) under the VCG mechanism (but not under a first price mechanism); derive necessary and sufficient conditions for such an effective collusion to be possible under the VCG mechanism; and (when nontrivial) study the computational complexity of deciding whether these conditions hold.

Keywords

Combinatorial Auctions and Exchanges, VCG Mechanism

1. INTRODUCTION

Combinatorial markets are important mechanisms for allocating tasks and resources in multiagent systems. In a *combinatorial auction*, there are multiple items for sale, and bidders are allowed to place a bid on a *bundle* of these items rather than just on the individual items. A rapidly growing body of literature is devoted to the study of combinatorial auctions, and, to a lesser extent, variations of it, such as combinatorial reverse auctions (where the auctioneer seeks to procure certain items) and combinatorial exchanges (where bidders can offer goods for sale as well as express demand for goods—even within the same bid). One important problem is the *winner determination problem* [16, 6, 19], which is to label bids as accepted or rejected to maximize the total value of the bids accepted (or, in the case of a reverse auction, to minimize their total value), under the constraint that the corresponding allocation of items does not require more items than are available (or, in the case of a reverse auction, under the constraint that all the desired items are procured).

Another key problem in auctions and exchanges (combinatorial or not) is that in general, the bidders may not bid their true valuations for the goods. The problem with untruthful bidding is that the winner determination algorithm can only base the final allocation of the goods on the reported valuations, and thus the final allocation may not be optimal relative to the bidders' true valuations. Thus, economic efficiency may be lost. However, by changing the payment rule, it is possible to motivate bidders to bid their true valuations. The best-known such payment rule is the Vickrey-Clarke-Groves (VCG) mechanism [20, 5, 9]. If the setting is general enough, given certain requirements, the VCG mechanism (or its generalization to *Groves mechanisms*) is in fact the only mechanism promoting truthful bidding [8, 15, 10, 21].[1] Because of this, the VCG mechanism constitutes the standard approach to promoting truthful bidding, and variations such as anytime VCG mechanisms [13] as well as distributed computation of VCG mechanisms [14] have been proposed.

Unfortunately, there are also many problems with the

[1]It should be noted, however, that when the agents' valuations are more restricted, the characterization of truthful mechanisms becomes less stringent [1, 11, 12, 10, 17, 4].

VCG mechanism [18, 3]. We will focus on two related problems: the VCG mechanism is vulnerable to collusion, and may lead to low revenue/high payment for the auctioneer. It is well-known that these problems occur even in single-item auctions (where the VCG mechanism specializes to the *Vickrey* or second-price sealed-bid auction). However, in the single-item setting, these problems are not as severe. For example, in a Vickrey auction, it is not possible for colluders to obtain the item at a price less than the bid of any other bidder. Additionally, in a Vickrey auction, various types of revenue equivalence with (for example) first-price sealed-bid auctions hold. As we will show, in the multi-item setting these properties do not hold and can be violated to an arbitrary extent. Some isolated examples of such problems with the VCG mechanism in multi-item settings have already been noted in the literature [3, 22, 2] (these will be discussed later in the paper). In contrast, our goal in this paper is to give a *comprehensive* characterization of how severe these problems can be and when these severe problems can occur. For the various variants of combinatorial auctions and exchanges, we study the following single problem that relates both issues under consideration: *Given some of the bids, how bad can the remaining bidders make the outcome?* Informally, "bad" here means that the remaining bidders are paid an inordinately large amount, or pay an inordinately small amount, relative to the goods they receive and/or provide. This is closely related to the problem of making revenue guarantees to the auctioneer. But it is also the collusion problem, if we conceive of the remaining bidders as colluders. (The collusion problem can become more difficult if the collusion is required to be *self-enforcing*. A collusion is self-enforcing when none of the colluders have an incentive to unilaterally deviate from the collusion. We will also study how this extra requirement affects our results.)

As it turns out, our fundamental problem is often computationally hard. Computational hardness here is a double-edged sword. On the one hand, if the problem is hard, collusion may not occur (or to a lesser extent) because the colluders cannot find a beneficial collusion. On the other hand, if the problem is hard, it is difficult to make strong revenue guarantees to the auctioneer. Of course, in either case, the computational hardness may be overcome in practice if the stakes are high enough.

2. THE VCG MECHANISM—REVIEW

All the results in this paper hold even when all bidders are *single-minded*, that is, they bid only on a single bundle of items. (Hence, we do not need to discuss bidding languages.) The VCG mechanism proceeds as follows. First, solve the winner determination problem to maximize the sum of the agents' utilities before payments (the sum of the values of the accepted bids, or, in the case of a reverse auction, the negative thereof). Call this sum of utilities a. Then, to determine winning bidder i's payment, remove that bidder's bid, and see what the maximum sum of the utilities before payments would have been with only the remaining bids. Call this sum of utilities b_i. Winning bidder i must pay $b_i - a + v_i$ where v_i is the value of winning bidder i's bid. Effectively, it is the externality the bidder imposed on the other bidders (before payments). We observe that this payment is negative if the bidder's presence makes the other bidders better off (before payments)—for example, in reverse auctions.

3. COMBINATORIAL (FORWARD) AUCTIONS

In a *combinatorial auction*, there is a set of items $I = \{s_1, s_2, \ldots, s_m\}$ for sale. A bid takes the form $b = (B, v)$, where $B \subseteq I$ and $v \in \mathbb{R}$. The winner determination problem is to label bids as accepted or rejected, to maximize the sum of the values of the accepted bids, under the constraint that no item occurs in more than one accepted bid. (This is assuming *free disposal*: items do not have to be allocated to anyone.)

3.1 Motivating example

(A similar example to the one described in this subsection has been given before [3], and examples of vulnerability to false-name bidding in combinatorial auctions [22] can in fact also be used to demonstrate the basic point. We include this subsection for completeness.) Consider an auction with two items, s_1 and s_2. Suppose we have collected two bids (from different bidders), both $(\{s_1, s_2\}, N)$. If these are the only two bids, one of the bidders will be awarded both the items and, under the VCG mechanism, will have to pay N. However, suppose two more bids (by different bidders) come in: $(\{s_1\}, N+1)$ and $(\{s_2\}, N+1)$. Then these bids will win. Moreover, neither winning bidder will have to pay anything! (This is because a winning bidder's item would simply be thrown away if that winning bidder were removed.)

This example demonstrates a number of issues. First, the addition of more bidders can actually decrease the auctioneer's revenue from an arbitrary amount to 0. Second, the VCG mechanism is not revenue-equivalent to the sealed-bid first-price mechanism in combinatorial auctions, even when all bidders' true valuations are common knowledge[2]—unlike in the single-item case. Third, even when the other bidders by themselves would generate nonnegative revenue for the auctioneer under the VCG mechanism, it is possible that two colluders can bid so as to receive all the items without paying anything.

The following sums up the properties of this example.

PROPOSITION 1. *In a forward auction (even with only 2 items), the following can hold simultaneously: 1. The winning bidders pay nothing under the VCG mechanism; 2. If the winning bids are removed, the remaining bids generate revenue N under the VCG mechanism; 3. If these bids were*

[2]Consider the above example with $N \geq 9$ and suppose that the four bids reflect the bidders' true valuations—since bidding truthfully is a weakly dominant strategy in the VCG mechanism. Running a first-price sealed bid auction in this setting, when all bidders' valuations are common knowledge, will not generate expected revenue less than $\frac{N}{8}$. For suppose the expected revenue is less than this. Then the probability that the revenue is at least $\frac{N}{4}$ must be less than $\frac{1}{2}$ by Markov's inequality. So, bidding $(\{A, B\}, \frac{N}{4})$ will win any bidder both items with probability at least $\frac{1}{2}$, leading to an expected utility of at least $\frac{1}{2}(N - \frac{N}{4}) = \frac{3N}{8}$. Because at most one of the three bidders with valuations $(\{A\}, N+1)$ or $(\{A, B\}, N)$ can win its desired bundle, it follows that at least one of these bidders has a probability of at most $\frac{1}{3}$ of winning its desired bundle, and thus has an expected utility of at most $\frac{N+1}{3}$. Because $N \geq 9$, $\frac{3N}{8} > \frac{N+1}{3}$, so this bidder would be better off bidding $(\{A, B\}, \frac{N}{4})$—contradicting the assumption that we are in equilibrium.

truthful (as we would expect under VCG), then if we had run a first-price sealed-bid auction instead (and the bidders' valuations were common knowledge), any equilibrium would have generated revenue $\Theta(N)$.

3.2 Characterization

We now characterize the settings where, given the noncolluders' bids, the colluders can receive all the items for free.

LEMMA 1. *If the colluders receive all the items at cost 0, then for any positive bid on a bundle B of items by a noncolluder, at least two of the colluders receive an item from B.*

PROOF. Suppose that for some positive bid b on a bundle B by a noncolluder i, one of the colluders c receives all the items in B (and possibly others). Then, in the auction where we remove that colluder's bids, one possible allocation gives every remaining bidder all the goods that bidder received in the original auction; additionally, it gives i all the items in bundle B; and it disposes of all the other items c received in the original auction. With this allocation, the total value of the accepted bids by bidders other than c is at least $v(b)$ more than in the original auction. Because the total value obtained in the new auction is at least the value of this particular allocation, it follows that c imposes a negative externality of at least $v(b)$ on the other bidders, and will pay at least $v(b)$. □

LEMMA 2. *Suppose all the items in the auction can be divided among the colluders in such a way that, for any positive bid on a bundle of items B by a noncolluder, at least two of the colluders receive an item from B. Then the colluders can receive all the items at cost 0.*

PROOF. For the given partition of items among the noncolluders, let each colluder place a bid with an extremely large value on the bundle consisting of the items assigned to him in the partition. (For instance, twice the sum of the values of all noncolluders' bids.) Then, the auction will clear awarding each colluder the items assigned to him by the partition. Moreover, if we remove the bids of one of the colluders, all the remaining colluders' bids will still win—and thus none of the noncolluders' bids will win, because each such bid requires items assigned to at least two colluders by the partition (and at least one of them is still in the auction and wins these items). Thus, each colluder (individually) imposes no externality on the other bidders. □

Combining these two lemmas, we get:

THEOREM 1. *The colluders can receive all the items at cost 0 if and only if it is possible to divide the items among the colluders in such a way that, for any positive bid B by a noncolluder, at least two colluders receive an item from B.*

3.3 Self-enforcing collusion

It turns out that requiring that the collusion is self-enforcing (i.e., no colluder has an incentive to unilaterally deviate) is no harder for the colluders:

THEOREM 2. *Whenever the colluders can receive all the items for free, they can also receive them all for free in a self-enforcing way.*

PROOF. Let each colluder bid on the same bundle as before; but, increase the bid value of each colluder by an amount that exceeds the utility that any colluder can get from any bundle of items. The colluders will continue to receive all the items at a cost of 0. Now, the only reason that a colluder may wish to deviate from this is that the colluder wishes to obtain items outside of the colluder's assigned bundle. However, doing so would prevent one of the other bundles from being awarded to its designated colluder. This would cause a decrease in the total value of bids awarded to bidders other than the deviating colluder that exceeds the utility of the deviating colluder for any bundle, and the deviating colluder would have to pay for this decrease under the VCG mechanism. Therefore, there is no incentive for the colluder to deviate. □

3.4 Complexity

In order to collude in the manner described above, the n colluders must solve the following computational problem.

DEFINITION 1 (DIVIDE-SUBSETS). *Suppose we are given a set I, as well as a collection $R = \{S_1, \ldots, S_q\}$ of subsets of it. We are asked whether I can be partitioned into n parts $T_1, T_2, \ldots, T_n$ so that no subset $S_i \in R$ is contained in one of these parts.*

THEOREM 3. *DIVIDE-SUBSETS is NP-complete, even when $n = 2$.*

PROOF. The problem is technically identical to HYPERGRAPH-2-COLORABILITY, which is known to be NP-complete [7]. □

This hardness result only states that it is hard to identify the *most* beneficial collusion, and one may wonder whether it is perhaps easier to find *some* beneficial collusion. It turns out that the hardness of the former problem implies the hardness of the latter problem: the utility functions of the colluders can always be such that only the most beneficial collusion actually benefits them, in which case the two problems are the same. This observation can also be applied to hardness results presented later in the paper.

4. COMBINATORIAL REVERSE AUCTIONS

In a *combinatorial reverse auction*, there is a set of items $I = \{s_1, s_2, \ldots, s_m\}$ to be procured. A bid takes the form $b = (B, v)$, where $B \subseteq I$ and $v \in \mathbb{R}$. (Here, v represents the value that the bidder must be compensated by in order to provide the goods B.) The winner determination problem is to label bids as accepted or rejected, to minimize the sum of the values of the accepted bids, under the constraint that each item occurs in at least one accepted bid. (This is assuming free disposal.)

4.1 Motivating example

Consider a reverse auction with m items, $s_1, s_2, \ldots, s_m$. Suppose we have collected two bids (from different bidders), both $(\{s_1, s_2, \ldots, s_m\}, N)$. If these are the only two bids, one of the bidders will be chosen to provide all the goods, and, under the VCG mechanism, will be paid N. However, suppose m more bids (by different bidders) come in: $(\{s_1\}, 0), (\{s_2\}, 0), \ldots, (\{s_m\}, 0)$. Then, these m bids will

win. Moreover, each bidder will be paid N under the VCG mechanism. (This is because without this bidder, we would have had to accept one of the original bids.) Thus, the total payment that needs to be made is mN.[3]

Again, this example demonstrates a number of issues. First, the addition of more bidders may actually increase the total amount that the auctioneer needs to pay. Second, the VCG mechanism requires much larger payments than a first-price auction in the case where all bidders' valuations are common knowledge. (The first-price mechanism will not require a total payment of more than N for these valuations in any pure-strategy equilibrium.[4][5]) Third, even when the other bidders by themselves would allow the auctioneer to procure the items at a low cost under the VCG mechanism, it is possible for m colluders to get paid m times as much for all the items.

The following sums up the properties of this example.

PROPOSITION 2. *In a reverse auction, the following can hold simultaneously: 1. The winning bidders are paid mN under the VCG mechanism; 2. If the winning bids are removed, the remaining bids allow the auctioneer to procure everything at a cost of only N under the VCG mechanism; 3. If these bids were truthful (as we would expect under VCG), then if we had run a first-price sealed-bid reverse auction instead (and the bidders' valuations were common knowledge), any equilibrium in pure strategies would have required total payment of at most N. (However, there are also mixed-strategy equilibria with arbitrarily large expected total payment.)*

4.2 Characterization

Letting N be the sum of the values of the accepted bids when all the colluders' bids are taken out, it is clear that no colluder can be paid more than N. (With the colluder's bid, the sum of the values of others' accepted bids is still at least 0; without it, it can be at most N, because in the worst case the auctioneer can accept the bids that would be accepted if none of the colluders are present.) In this subsection, we will identify a necessary and sufficient condition for the colluders to be able to each receive N.

LEMMA 3. *If a colluder receives N, then the items that it has to provide cannot be covered by a subset of the noncolluders' bids with cost less than N.*

PROOF. If they could be covered by such a set, we could simply accept this set of bids (including those that were accepted already) rather than the colluder's bid, and increase the total cost by less than N. Thus, the colluder's VCG payment is less than N. □

Thus, in order for each of the n colluders to be able to receive N, it is necessary that there exist n disjoint subsets of the items, each of which cannot be covered with a subset of the noncolluders' bids with total value less than N. The next lemma shows that this condition is also sufficient.

LEMMA 4. *If there are n disjoint sets of items $R_1, \ldots, R_n$, each of which cannot be covered by a subset of the noncolluders' bids with cost less than N, then n colluders can be paid N each.*

PROOF. Let colluder i (for $i < n$) bid $(R_i, 0)$, and let colluder n bid $(R_n \cup (S - \bigcup_i R_i), 0)$. Then the total cost of all accepted bids with all the colluders is 0; but when one colluder is omitted, the items it won cannot be covered at a cost less than N (because its bid contained one of the R_i). Thus, each colluder's VCG payment is N. □

The next lemma shows that the necessary and sufficient condition above is equivalent to being able to *partition* all the items into n sets, so that no element of the partition can be covered by a subset of the noncolluders' bids with total value less than N. That is, we can restrict our attention to the case where the subsets exhaust all the items.

LEMMA 5. *The condition of Lemma 4 is satisfied if and only if it is possible to partition the items into $T_1, \ldots, T_n$ such that no T_i can be covered by a subset of the noncolluders' bids with cost less than N.*

PROOF. The "if" part is trivial: given T_i that satisfy the condition of this lemma, simply let $R_i = T_i$. For the "only if" part, given R_i that satisfy the condition of Lemma 4, let $T_i = R_i$ for $i < n$, and $T_n = R_n \cup (S - \bigcup_i R_i)$. We observe that this last set can also not be covered at a cost of less than N because it contains R_n. □

Combining all the lemmas, we get:

THEOREM 4. *The n colluders can receive a payment of N each (simultaneously), where N is the sum of the values of the accepted bids when all the colluders' bids are removed, if and only if it is possible to partition the items into $T_1, \ldots, T_n$ such that no T_i can be covered by a subset of the noncolluders' bids with cost less than N.*

4.3 Self-enforcing collusion

Unlike the case of combinatorial forward auctions, in reverse auctions, a stronger condition is required if the collusion is also required to be self-enforcing.

[3]Similar examples have been discovered in the context of purchasing paths in a graph [2]. However, in that setting, the buyer does not seek to procure all of the items, and hence the examples cannot be applied directly to combinatorial reverse auctions.

[4]Consider the above example and suppose that the $n+2$ bids reflect the bidders' true valuations—since bidding truthfully is a weakly dominant strategy in the VCG mechanism. Supposing that a pure-strategy equilibrium is being played, let the total payment to be made in this equilibrium be π. (We observe that the final allocation can still be uncertain, e.g. if there is a random tie-breaking rule.) Suppose $\pi > N$. Then, the expected utility for either one of the bidders interested in providing the whole bundle can never exceed $\pi - N$ (because the bidder will be paid 0 whenever none of its bids are accepted, and providing any items at all will cost it N). Moreover, it is not possible for both of these bidders to simultaneously have an expected utility of $\pi - N$ (as this would mean that both are paid π with certainty, contrary to the fact that the total payment is π). It follows at least one has an expected utility of $\pi - N - \epsilon$ for some $\epsilon > 0$. But then this bidder would be better off bidding $\pi - \frac{\epsilon}{2}$ for the whole bundle, which would be accepted with certainty and give an expected utility of $\pi - N - \frac{\epsilon}{2}$. It follows that the total payment in a pure-strategy equilibrium cannot exceed N.

[5]Perhaps surprisingly, the first-price combinatorial reverse auction for this example (with commonly known true valuations corresponding to the given bids) actually has mixed-strategy equilibria with arbitrarily high expected payments. We omit the proof because of space constraint.

THEOREM 5. *The n colluders can receive a payment of N each (simultaneously), where N is the sum of the values of the accepted bids when all the colluders' bids are removed, if and only if it is possible to partition the items into $T_1, \ldots, T_n$ such that 1) no T_i can be covered by a subset of the noncolluders' bids with cost less than N, 2) for no colluder i, the following holds: there exists a subset $T_i' \subseteq T_i$ such that T_i' can be covered by a set of noncolluders' bids with total cost less than $v_i(T_i) - v_i(T_i - T_i')$ (the marginal savings to agent i of not having to provide T_i').*

PROOF. Omitted due to space constraint. □

4.4 Complexity

In order to collude in the manner described above, the n colluders must solve the following computational problem.

DEFINITION 2 (CRITICAL-PARTITION). *We are given a set of items I, a collection of bids (S_i, v_i) where $S_i \subseteq I$ and $v_i \in \mathbb{R}$, and a number n. Say that the* cost *of a subset of these bids is the sum of their v_i; and that the cost $c(T)$ of a subset $T \subseteq I$ is the lowest cost of any subset of the bids whose S_i cover T. We are asked whether there exists a partition of I into n disjoint subsets $T_1, T_2, \ldots, T_n$, such that for any $1 \leq i \leq n$, $c(T_i) = c(I)$.*

THEOREM 6. *Even when the bids are so that a partition $T_1, \ldots, T_n$ is a solution if and only if no set $I - T_i$ covers all items in a bid, CRITICAL-PARTITION is NP-complete (even with $n = 2$).*

PROOF. The problem is in NP in this case because given a partition $T_1, \ldots, T_n$, it is easy to check if any set $I - T_i$ covers all items in a bid.

To show NP-hardness, we reduce an arbitrary NAESAT[6] instance (given by a set of clauses C over a set of variables V, with each variable occurring at most once in any clause) to the following CRITICAL-PARTITION instance with $n = 2$ (where we are trying to partition into T_1 and T_2). Let I be as follows. For every variable $v \in V$, there are two items labeled s_{+v} and s_{-v}. Let the bids be as follows. For every variable $v \in V$, there is a bid $(\{s_{+v}, s_{-v}\}, 2)$. For every clause $c \in C$, there are two bids $(\{s_l : l \in c\}, 2m_c - 1)$ and $(\{s_l : -l \in c\}, 2m_c - 1)$ where m_c is the number of literals occurring in c.

First we show that this instance satisfies the condition that a partition $T_1, \ldots, T_n$ is a solution if and only if no set $I - T_i$ covers all items in a bid. First, we observe that $c(I) = |I|$ (we can use all the bids of the form $(\{s_{+v}, s_{-v}\}, 2)$, getting a per-item cost of 1; no other bid gives a lower per-item cost).

Now, if some set $I - T_i$ covers all the items in a bid of the form $(\{s_{+v}, s_{-v}\}, 2)$, then $c(T_i) \leq 2|I| - 2$ (because we can simply omit this bid from the solution for all the items). If some set $I - T_i$ covers all the items in a bid of the form $(\{s_l : l \in c\}, 2m_c - 1)$, then $c(T_i) = |I| - 1$. (This is because we can now accept the "complement" bid $(\{s_l : -l \in c\}, 2m_c - 1)$, and we will have covered all the items s_{+v} and s_{-v} in T_i such that v occurs in c (precisely $2m_c$ items, because variables do not reoccur within a clause); for any other item s_{+v} or s_{-v}, we can accept the bid $(\{s_{+v}, s_{-v}\}, 2)$, and we need to accept at most $|V| - m_c$ such bids, leading to a total cost of $2m_c - 1 + 2(|V| - m_c) = |I| - 1$.)

On the other hand, suppose there is no set $I - T_i$ that covers all the items in a bid. Then, either T_i must include at precisely one of s_v and s_{-v}. (Otherwise one T_i would include neither and $I - T_i$ would cover all items in the bid $(\{s_{+v}, s_{-v}\}, 2)$.) Thus, when we are trying to cover T_i, covering items in it with bids of the form $(\{s_{+v}, s_{-v}\}, 2)$ would result in a per-item cost of 2. On the other hand, covering items in it with bids of the form $(\{s_l : l \in c\}, 2m_c - 1)$ or $(\{s_l : -l \in c\}, 2m_c - 1)$ would result in a per-item cost of at least $\frac{2m_c - 1}{m_c - 1} > 2$ (because at most $m_c - 1$ of the m_c items in the bid can be in T_i, otherwise T_i would cover all the items in the bid; but $T_i = I - T_{3-i}$ which by assumption does not cover all the items in any bid). It follows that $C(T_i) = 2|V| = |I| = c(I)$.

Now we show that the two instances are equivalent. First suppose there exists a solution to the NAESAT instance. Then partition the elements as $T_1 = \{s_l : l = \textit{true}\}$ and $T_2 = \{s_l : l = \textit{false}\}$, according to this solution. Clearly neither of $I - T_i = T_{3-i}$ covers a bid of the form $(\{s_{+v}, s_{-v}\}, 2)$. Also, because no clause has all its literals set to the same value (we have a NAESAT solution), the items in a corresponding bid $(\{s_l : l \in c\}, 2m_c - 1)$ or $(\{s_l : -l \in c\}, 2m_c - 1)$ are not all in the same set. By the previously proved property, it follows that this partition is a solution to the CRITICAL-PARTITION instance.

On the other hand, suppose that there exists a solution to the CRITICAL-PARTITION instance. Then label a literal *true* if $s_l \in T_1$, and *false* otherwise. By the previously proved property, because $(\{s_{+v}, s_{-v}\}, 2)$ is a bid, only one of s_{+v} and s_{-v} can be in $T_1 = I - T_2$, so this provides a consistent setting of the literals. Additionally, because $(\{s_l : l \in c\}, 2m_c - 1)$ is a bid, not all the s_l in that bid can be in $T_1 = I - T_2$. It follows that some of the literals $l \in c$ are set to *false*. Similarly, not all the s_l in that bid can be in $T_2 = I - T_1$, so some of the literals $l \in c$ are set to *true*. It follows that this assignment of truth values to variables is a solution to the NAESAT instance. □

5. COMBINATORIAL FORWARD (OR REVERSE) AUCTIONS WITHOUT FREE DISPOSAL

A combinatorial forward auction *without free disposal* is exactly the same as one with free disposal, with the exception that every item must be allocated to some bidder. Here, bids with a *negative* value may still be useful, as they allow us to remove some of the items—which may allow us to accept better bids for the remaining items.

Similarly, a combinatorial reverse auction without free disposal is exactly the same as one with free disposal, with the exception that no additional items can be procured. Here, bids with a *negative* value may occur—the (nondisposable) item may be a liability to the bidder.

In both cases, we seek to identify a subset of the bids that constitutes an exact cover of the items (no item covered more than once), and to maximize the bidders' total utility under this constraint. Therefore, the settings are technically identical, and in the rest of this section, we can restrict our attention to forward auctions without free disposal.

[6]The goal in NAESAT is to assign truth values to all variables in such a way that there is no clause with all its literals set to *true*, and no clause with all its literals set to *false*.

5.1 Motivating example

Consider a forward auction with two nondisposable items, s_1 and s_2. Suppose we have collected two bids (from different bidders), both $(\{s_1, s_2\}, N)$. If these are the only two bids, one of the bidders will be awarded both the items and, under the VCG mechanism, will have to pay N. However, suppose two more bids (by different bidders) come in: $(\{s_1\}, N+M)$ and $(\{s_2\}, N+M)$, with $M > 0$. Then these bids will win. Moreover, because without free disposal, we cannot accept either of these bids without the other, each of these bidders will be *paid* M under the VCG mechanism!

Again, this example demonstrates a number of issues. First, additional bidders may change the auctioneer's revenue from an arbitrarily large positive amount to an arbitrarily large negative amount (an arbitrarily large cost). Second, the VCG mechanism may require arbitrarily large payments from the auctioneer even in cases where a first-price auction would actually generate revenue for the auctioneer, in the case where all bidders' valuations are common knowledge. (The first-price mechanism will generate a revenue of at least N for these valuations in any pure-strategy equilibrium.[7][8]) Third, even when the other bidders by themselves would generate positive revenue for the auctioneer under the VCG mechanism, it is possible that two colluders can make the auctioneer pay each of them an arbitrarily large amount.

The following sums up the properties of this example.

PROPOSITION 3. *In a forward auction without free disposal (even with only two items), the following can hold simultaneously: 1. Each winning bidder is paid an arbitrary amount M under the VCG mechanism (where M depends only on the winners' bids); 2. If the winning bids are removed, the remaining bids actually generate revenue N to the auctioneer under the VCG mechanism; 3. If these bids were truthful (as we would expect under VCG), then if we had run a first-price sealed-bid auction instead (and the bidders' valuations were common knowledge), any equilibrium in pure strategies would have generated revenue N. (However, there are mixed-strategy equilibria with arbitrarily large cost to the auctioneer.)*

[7]Consider the above example and suppose that the four bids reflect the bidders' true valuations—since bidding truthfully is a weakly dominant strategy in the VCG mechanism. Supposing that a pure-strategy equilibrium is being played, let the total revenue to the auctioneer be ρ, where ρ is possibly negative. (We observe that the final allocation can still be uncertain, e.g. if there is a random tie-breaking rule.) Suppose $\rho < N$. Then the expected utility for either of the bidders interested in providing the whole bundle is at most $N - \rho$. (If the bidder receives a singleton item, its utility is $-\infty$; if it receives nothing, its utility is 0; if it receives both items, its utility is $N - \rho$.) Moreover, it is not possible for both of these bidders to both have an expected utility of $N - \rho$, as this would mean they both receive both items with probability 1. It follows that at least one of them has an expected utility of $N - \rho - \epsilon$ where $\epsilon > 0$. But then this bidder would be better off bidding $\rho + \frac{\epsilon}{2}$, as this bid would be accepted with certainty and give an expected utility of $N - \rho - \frac{\epsilon}{2}$. It follows that the expected revenue in a pure-strategy equilibrium cannot be less than N.

[8]Similarly to the case of the combinatorial reverse auction with free disposal, there are mixed-strategy equilibria in the first-price auction where the auctioneer is forced to make arbitrarily large payments—we omit the proof because of space constraint.

5.2 Characterization

In this subsection, we will identify a necessary and sufficient condition for the colluders to be able to each receive an arbitrary amount. Let $v(b)$ denote the value of bid b.

LEMMA 6. *If each colluder receives a payment of more than $2\sum_d |v(b_d)|$ (where d ranges over the noncolluders), then for each colluder c, the set of all items awarded to either that colluder or a noncolluder (that is, $s_c \cup \bigcup_d s_d$, where s_b is the set of items awarded to bidder b and d ranges over the noncolluders) cannot be covered exactly with bids from the noncolluders.*

PROOF. Say that the sum of the values of accepted noncolluder bids is D (which may be negative). Suppose that for one colluder c, the set of all items awarded to either her or a noncolluder (that is, $s_c \cup \bigcup_d s_d$) can be covered by a set of noncolluder bids of combined value C (which may be negative). Then removing colluder c can make the allocation at most $D - C$ worse to the other bidders (relative to their reported valuations), because we could simply accept the bids of combined value C and no longer accept the bids of combined value D, and keep the rest of the allocation the same. Thus, under VCG, that colluder should be rewarded at most $D - C \leq 2\sum_d |v(b_d)|$. □

Thus, in order for each colluder to be able to receive an arbitrarily large payment, it is necessary that there are n disjoint subsets of the items such that no such subset taken together with the remaining items can be covered exactly by the noncolluders' bids. Also, the set of remaining items must be exactly coverable by the noncolluders' bids (otherwise we cannot accept all the colluders' bids). The next lemma shows that this condition is also sufficient.

LEMMA 7. *If it is possible to partition the items into $R_1, \ldots, R_n, R_{n+1}$ such that for no $1 \leq i \leq n$, $R_i \cup R_{n+1}$ can be covered exactly with bids from the noncolluders; and such that R_{n+1} can be covered exactly with bids from the noncolluders; then for any $M > 0$, n colluders can place additional bids such that each of them receives at least M.*

PROOF. Let colluder i place a bid $(R_i, M + 3\sum_d |v(b_d)|)$ (where d ranges over the noncolluders). All these bids will be accepted, because it is possible to do so by also accepting the noncolluder bids that cover R_{n+1} exactly; and these noncolluder bids will have a combined value of at least $-\sum_d |v(b_d)|$, so that the sum of the values of all accepted bids is at least $(3n-1)\sum_d |v(b_d)| + nM$. (We observe that if we do not accept all of the colluder bids, the sum of the values of all accepted bids is at most $(3(n-1)+1)\sum_d |v(b_d)| + (n-1)M = (3n-2)\sum_d |v(b_d)| + (n-1)M$, which is less.) Now, if the bid of colluder i is removed, it is no longer possible to accept all the remaining $n-1$ colluder bids, because $R_i \cup R_{n+1}$ cannot be covered exactly with noncolluder bids. It follows that the total value of all accepted bids when i's bid is removed can be at most $(3(n-2)+1)\sum_d |v(b_d)| + (n-2)M$. When i's bid is not omitted, the sum of the values of all accepted bids other than i's is at least $(3(n-1)-1)\sum_d |v(b_d)| + (n-1)M$. Subtracting the former quantity from this, we get that the VCG payment to i is at least $\sum_d |v(b_d)| + M$. □

The next lemma shows that the necessary and sufficient condition above is equivalent to being able to partition all the items into n sets, so that no element of the partition can be covered exactly by a subset of the noncolluders' bids. That is, we can restrict our attention to the case where $R_{n+1} = \emptyset$.

LEMMA 8. *The condition of Lemma 7 is satisfied if and only if the items can be partitioned into $T_1, \ldots, T_n$ such that no T_i can be covered exactly with bids from the noncolluders.*

PROOF. For the "if" part: given T_i that satisfy the condition of this lemma, let $R_i = T_i$ for $i \leq n$, and $R_{n+1} = \emptyset$. Then no $R_i \cup R_{n+1} = T_i$ can be covered exactly with bids from the noncolluders, and $R_{n+1} = \emptyset$ can trivially be covered exactly with noncolluder bids. For the "only if" part: given R_i that satisfy the condition of Lemma 7, let $T_i = R_i$ for $i < n$, and let $T_n = R_n \cup R_{n+1}$. That T_n cannot be covered exactly by noncolluder bids now follows directly from the conditions of Lemma 7. But also, no T_i with $i < n$ can be covered exactly: because if it could, then we could cover $R_i \cup R_{n+1} = T_i \cup R_{n+1}$ using the bids that cover T_i exactly together with the bids that cover R_{n+1} exactly (which exist by the conditions of Lemma 7). □

Combining all the lemmas, we get:

THEOREM 7. *The n colluders can receive a payment of at least M each (simultaneously), where M is an arbitrarily large number, if and only if it is possible to partition the items into $T_1, \ldots, T_n$ such that no T_i can be covered exactly with bids from the noncolluders.*

5.3 Self-enforcing collusion

Again, a stronger condition is required if the collusion is also required to be self-enforcing.

THEOREM 8. *The n colluders can receive a payment of at least M each (simultaneously), where M is an arbitrarily large number, if and only if it is possible to partition the items into $T_1, \ldots, T_n$ such that 1) no T_i can be covered exactly with noncolluder bids, 2) for no colluder i, the following holds: there exists a subset $T_i' \subseteq T_i$ such that T_i' can be covered by a set of noncolluders' bids with total value greater than $v_i(T_i) - v_i(T_i - T_i')$ (the marginal value to agent i of receiving T_i').*

PROOF. Omitted due to space constraint. □

5.4 Complexity

In order to collude in the manner described above, the n colluders must solve the following computational problem.

DEFINITION 3 (COVERLESS-PARTITION). *We are given a set I and a collection of subsets $S_1, S_2, \ldots, S_q \subseteq I$. We are asked whether there is a partition of I into subsets $T_1, T_2, \ldots T_n \subseteq I$ such that no T_i can be covered exactly by some of the S_i.*

THEOREM 9. *Even if there is a singleton S_i for all but two elements a and b, and $n = 2$, COVERLESS-PARTITION is NP-complete.*

PROOF. Omitted due to space constraint. □

5.5 An easier collusion problem

So far in this section, we have formulated the collusion problem so that *each* colluder should receive M, where M is an arbitrary amount. An easier problem for the colluders is to make sure that *together*, they receive M, where M is an arbitrary amount. Such a collusion may be less stable (because some of the colluders may be receiving very little). Nevertheless, as we will show, this type of collusion is possible whenever a weak (and easily verified, given the noncolluders' bids) condition holds: at least one item has no singleton bid on it. (A singleton bid is a bid on only one item.) We first show that this condition is necessary.

LEMMA 9. *If at least one colluder receives a payment of more than $\sum_d |v(b_d)|$ (where d ranges over the noncolluders), then there is at least one item s on which no noncolluder places a singleton bid.*

PROOF. If each item has a singleton noncolluder bid placed on it, then when we remove a colluder's bid, we can simply cover all the items in it with singleton bids (with a combined value of at least $-\sum_d |v(b_d)|$), and leave the rest of the allocation unchanged. It follows that the VCG payment to the colluder can be at most $\sum_d |v(b_d)|$). □

We now show that the condition is sufficient.

LEMMA 10. *If there is at least one item s on which no noncolluder places a singleton bid, then if one colluder bids $(\{s\}, 0)$, and the other colluder bids $(I - \{s\}, M + 2\sum_d |v(b_d)|)$ (for $M > 0$), then the total payment to the colluders is at least M.*

PROOF. The colluders' bids will be the only accepted ones (because colluder 2's bid has a greater value than all other bids combined). If we removed colluder 2's bid, the total value of the accepted bids would be at most $\sum_d |v(b_d)|$, so colluder 2 will pay at most this much under the VCG mechanism. If we removed colluder 1's bid, colluder 2's bid could no longer be accepted (because $\{s\}$ cannot be covered by itself), and thus the total value of the accepted bids could be at most $\sum_d |v(b_d)|$). It follows that colluder 1 is paid at least $M + \sum_d |v(b_d)|$). So the total payment to the colluders is at least M □

Combining the two lemmas, we get the desired result:

THEOREM 10. *Two (or more) colluders can receive a total payment of M, where M is an arbitrarily large number, if and only if there is at least one item that has no singleton bid placed on it by a noncolluder.*

6. COMBINATORIAL EXCHANGES

In a *combinatorial exchange*, there is a set of items $I = \{s_1, s_2, \ldots, s_m\}$ that can be traded. A bid takes the form $b = (\lambda_1, \ldots, \lambda_m, v)$, where $\lambda_1, \ldots, \lambda_m, v \in \mathbb{R}$ (possibly negative). (Each λ_i is the number of units of the ith item that the bidder seeks to procure, and v is how much the bidder is willing to pay.) The winner determination problem is to label bids as accepted or rejected, under the constraint that the sum of the accepted vectors has its first m entries ≤ 0, to

maximize the last entry of the sum of the accepted vectors. (This is assuming free disposal.) We will also use the notation $(\{(s_{i_1}, \lambda_{i_1}), (s_{i_2}, \lambda_{i_2}), \ldots, (s_{i_k}, \lambda_{i_k})\}, v)$ for representing a bid in which λ_{i_j} units of item s_{i_j} are demanded (and 0 units of each item that is not mentioned).

6.1 Characterization

In a combinatorial exchange with at least two items s_1 and s_2, let q_1 (respectively, q_2) be the total number of units of s_1 (respectively, s_2) offered for sale in bids so far (by noncolluders). Now consider the following two bids (by colluders): $(\{(s_1, q_1 + 1), (s_2, -q_2 - 1)\}, M + \sum_d |v(b_d)|)$ and $(\{(s_1, -q_1 - 1), (s_2, q_2 + 1)\}, M + \sum_d |v(b_d)|)$, where $M > 0$ and d ranges over the original (noncolluding) bids. Both these bids will be accepted (for otherwise, the total value of the accepted bids could be at most $M + 2\sum_d |v(b_d)| < 2(M + \sum_d |v(b_d)|)$). Moreover, if we remove one of these two bids, the other cannot be accepted (because its demand cannot be met), so the total value of the accepted bids can be at most $\sum_d |v(b_d)|$). It follows that the VCG payment to each of these two bidders is at least M. This proves the following:

THEOREM 11. *In a combinatorial exchange with at least two items, for any set of bids by noncolluders, two colluders can place bids so that each of them will receive at least M, where M is an arbitrary amount. Moreover, each one receives exactly the items that the other provides, so that their net contribution in terms of items is nothing.*

7. CONCLUSIONS

The VCG mechanism is the canonical mechanism for motivating the bidders to bid truthfully in combinatorial auctions and exchanges; if the setting is general enough, under some requirements, it is the only one. Unfortunately, it also introduces many problems. In this paper, we focused on the related problems of revenue guarantees and bidder collusion. We showed that these problems can be much worse in combinatorial auctions and exchanges than in single-item settings. We gave necessary and sufficient conditions for when these highly undesirable scenarios can occur, and showed how computationally hard it is to verify these conditions. One direction for future research is to characterize when similar but less severe failures of the VCG mechanism can occur. A more interesting (and difficult) direction is to find (possibly untruthful) mechanisms (perhaps for restricted settings) that do not suffer from these problems.

ABSTRACT

The ability to coordinate effectively is critical for agents to accomplish their goals in a multi-agent system. A number of researchers have modeled the coordination problem for multi-agent systems using decision theory. The most general models have proven to be extremely complex to solve optimally (NEXP-complete). Some of the more restricted models have been much more tractable, though still difficult (NP-complete). What is missing is an understanding about why some models are much easier than others. This work fills this gap by providing a condition that distinguishes between problems in NP and those strictly harder than NP. This condition relates to the quantity of information each agent has about the others, and whether this information can be represented in a succinct way. We show that the class of problems that satisfy this condition is NP-complete. We illustrate this idea with two interaction protocols that satisfy the condition. For those problems that do not satisfy this condition we demonstrate how our theoretical results can be used to generate an NP approximation of the original problem.

1. INTRODUCTION

In a multi-agent system, the agents do not act alone and must take into account the behaviors of the other agents in order to coordinate effectively and achieve their goals. Recently, multi-agent coordination problems have received attention from the decision theory community, and several distributed POMDP frameworks have been built to model these problems. These models assume that the agents have partial or noisy observations about the current world state, and that communication between the agents may have a cost. This partial observability of the world state leads to an increased complexity of NEXP-complete [4, 12]. However, two subclasses of distributed POMDPs have been identified whose complexity is much more tractable than the general case. One of them is the class of distributed POMDPs where the agents interact with each other only through a global reward function while their local transitions and observations remain independent [3]. In the other class of problems agents are allowed to communicate with each other, however, when they do they are required to transmit sufficient information such that all agents know the global state [6, 1]. Both subclasses have been proven to be NP-complete [7, 3].

The focus of this paper is to quantify the characteristics of a class of multi-agent coordination problems that determines its complexity. Our key result is that the complexity of the problem depends on the amount of important information each agent has about the other agents, and whether this information can be represented in a succinct way. Information is important if knowing it could allow the agents to achieve a higher expected reward, and by succinct we mean that the set of all possible important information the agents could acquire is polynomial in the number of states. We prove that this criteria is both sufficient and necessary for the class of problems to be NP-complete. We illustrate this idea with two examples from the literature and prove that both have this property.

Our goal in this paper is not to introduce new models or algorithms, but to change the way people view interactions between agents in the context of distributed POMDPs. Multi-agent researchers have long intuitively understood that the interaction between the agents is the cause of their high complexity. The theoretical results of this paper are significant in that they both formally justify this intuition as well as explain how the interaction affects the complexity. This new understanding of interaction and its relationship to complexity will help us to identify new classes of multi-agent systems with a lower complexity.

The significance of this theoretical result also has a more practical side. Most multi-agent systems are provably harder than NP and solving them optimally is very difficult. Much work has been put into developing good algorithms for approximating these problems. This work provides theoretical guidance in understanding how the approximations in a model limit the search space and reduce the complexity.

We demonstrate this on two problems that does not meet our condition by providing two approximations that impose additional restrictions on the interactions among the agents and reduce the complexity to no harder than NP.

There is existing work that looks at different types of interactions in distributed POMDPs. Synchronizing communication in an otherwise transition and observation independent DEC-MDP has been studied most extensively [6, 1]. Very little research has been done studying the transfer of only partial observation history between agents. Shen et al. [13] studies the problem of what to communicate in a Distributed Sensor Interpretation setting, where at every step only part of the local state is transferred between the agents. Some researchers [8, 5] have studied the case where the agents send their policies or actions to each other. In a sense, exchanging actions or policies between the agents accomplishes the same goal as transferring partial observation history. Both of them change each agent's belief of the global state and/or the other agent's local view of the global state without completely synchronizing the global views. The interaction history in these problems contains information that is not polynomial in the number of states and therefore they are harder than NP.

This work builds on previous work in the distributed POMDP field. Xuan and Lesser [14] proposed one of the first decentralized extensions to the single agent MDP, in which an agent has its local state in addition to the global state. Several more general distributed POMDP models have been independently developed and can be grouped into two categories. Partially Observable Identical Payoff Stochastic Games (POIPSG) [11], Decentralized Partially Observable Markov Decision Processes (DEC-POMDP) and Decentralized Markov Decision Processes (DEC-MDP) [4] do not explicitly model the communication actions but instead view them as a part of the normal action space. In contrast, Communicative Multi-agent Team Decision Problems (COM-MTDP) [12] and DEC-MDPs with Communication (DEC-MDP-Com) [6] make a clear distinction between a domain level action and an explicit communication action. In this paper, we prove that these two classes of models are equivalent. While making a clear distinction between explicit communication and domain level actions allows us to study the effects of communication more easily, this distinction does not increase the expressiveness of the model. Becker et al [2] made an early attempt to identify and exploit structure in the interactions between agents to reduce the complexity. This work explains the complexity results they found.

This paper is organized as follows. Section 2 presents two formal models that we use throughout the paper. Section 3 discusses different types of interactions between agents and presents the condition that determines the complexity of a distributed MDP. Two examples of NP-complete interaction protocols are found in Section 4, and Section 5 contains two examples of how harder problems can be approximated. Section 6 discusses future work and conclusions.

2. FORMAL MODELS

There have been a number of distributed decision-theoretic models for multi-agent systems published in the last few years. Many of these models describe the same class of problems. We will discuss two models, the DEC-MDP-Com and the DEC-MDP. While these two models are equivalent, they do represent interactions between the agents differently and it is therefore useful to examine both.

The models are based on the single agent Partially Observable Markov Decision Process (POMDP) extended to apply to systems with multiple agents. In this paper, we will define them for two agents i and j, but the definitions easily extend to any number of agents. The basic idea is that the state, now known as the global state, encompasses all of the necessary information about the state of each agent (local state) and the environment. Each agent has its own set of actions it takes and observations it makes. The transition function is from world states to world states given the actions taken by each agent, the joint action. The complexity of these models is NEXP-complete [4]. The reason that it is harder than the POMDP is that the agents are all receiving different observations, and only together could they identify the current global state. To predict what action agent i will take requires agent j to maintain not only a belief about the global state (similar to a POMDP) but also a belief about the belief agent i has. Interactions between the agents are built into the transition and observation functions. The likelihood that agent i will see a particular observation depends directly on the actions of both agents as well as the new global state, which in turn depends on the actions of both agents. The DEC-MDP stops there in its definition (see [4] for a formal definition), but the DEC-MDP-Com explicitly represents another form of interaction, communication.

DEFINITION 1 (ADAPTED FROM [7]). *A DEC-MDP-Com is a tuple: $\langle S, A, \Sigma, C_\Sigma, P, R, \Omega, O \rangle$, where:*

- *S is a finite set of global states, with a distinguished initial state s_0.*
- *$A = A_i \times A_j$ is a finite set of joint actions. A_i are the local actions for agent i.*
- *$\Sigma = \Sigma_i \times \Sigma_j$ is the alphabet of messages. $\sigma_i \in \Sigma_i$ denotes an atomic message sent by agent i. $\overline{\sigma}_i$ is a sequence of atomic messages sent by agent i. $\epsilon_\sigma \in \Sigma_i$ denotes not sending a message to the other agent.*
- *$C_\Sigma \rightarrow \Re$ is the cost of transmitting an atomic message.*
- *$P : S \times A \times S \rightarrow \Re$ is the transition function. $P(s'|s, a_i, a_j)$ is the probability of the outcome state s' when the joint action (a_i, a_j) is taken in state s.*
- *$R : S \times A \times S \rightarrow \Re$ is the reward function. $R(s, a_i, a_j, s')$ is the reward obtained from taking joint action (a_i, a_j) in state s and transitioning to state s'.*
- *$\Omega = \Omega_i \times \Omega_j$ is a finite set of joint observations. Ω_i is the set of observations for agent i.*
- *$O : S \times A \times S \times \Omega \rightarrow \Re$ is the observation function. $O(s, a_i, a_j, s', o_i, o_j)$ is the probability of agents i and j seeing observations o_i and o_j after the sequence s, (a_i, a_j), s' occurs.*
- *Joint full observability: the pair of observations made by the agents together fully determine the current state. If $O(s, a_i, a_j, s', o_i, o_j) > 0$ then $P(s'|o_i, o_j) = 1$.*

The policy for an agent is a mapping from all of the available information to a domain action and a communication action. Even though the global state is Markov, the agents base their decisions on the history of observations just like in a POMDP. However, if the agents ever communicate such that they both know the global state, i.e., they exchange their most recent observation, then they do not need to remember the prior history due to the Markov property. In

effect, this synchronization resets the problem but with a new starting state.

DEFINITION 2. *The local policy for agent i, π_i, is a mapping from the history of observations $\overline{\Omega}_i$, the history of messages sent $\overline{\Sigma}_i$, and the history of messages received $\overline{\Sigma}_j$ since the last synchronized world state S to a domain action and a communication action.*

$$\pi_i : S \times \overline{\Omega}_i \times \overline{\Sigma}_i \times \overline{\Sigma}_j \rightarrow A_i \times \Sigma_i.$$

The goal for a DEC-MDP-Com is to find a joint policy $\pi = \langle \pi_i, \pi_j \rangle$ that maximizes the expected value.

An important question is whether or not the communication explicitly represented in the DEC-MDP-Com increases the expressiveness of the model. It turns out that it does not – the communication actions are just special types of domain actions and the message received are just special types of observations.

THEOREM 1. *DEC-MDP-Com is equivalent to DEC-MDP.*

PROOF.

• **DEC-MDP $\leq_p$ DEC-MDP-Com.**

This reduction is trivial. To any DEC-MDP, we add $\Sigma = C_\Sigma = \emptyset$ and we get an equivalent DEC-MDP-Com.

• **DEC-MDP-Com $\leq_p$ DEC-MDP.**

We reduce a DEC-MDP-Com $\langle S, A, \Sigma, C_\Sigma, P, R, \Omega, O \rangle$ to an equivalent DEC-MDP $\langle \hat{S}, \hat{A}, \hat{P}, \hat{R}, \hat{\Omega}, \hat{O} \rangle$.

The basic idea is to introduce the two step process of the DEC-MDP-Com into the DEC-MDP by doubling the state space: $\hat{S} = S \times \{0, 1\}$. The states $\hat{s} = [s, 0]$ are for taking domain actions A_i and receiving observations Ω_i. The states $\hat{s} = [s, 1]$ are for taking communication actions Σ_i and receiving communications Σ_j. The total space of actions is therefore $\hat{A}_i = A_i \cup \Sigma_i$. The observations that agent i receives include both the messages sent by agent i and the messages received from agent j, i.e., $\hat{\Omega}_i = \Omega_i \times \Sigma_i \times \Sigma_j$. When taking domain actions nothing changes in the functions $\hat{P}$, $\hat{R}$ and $\hat{O}$:

$$\hat{P}([s, 0], a_1, a_2, [s', 1]) = P(s, a_1, a_2, s').$$
$$\hat{R}([s, 0], a_1, a_2, [s', 1]) = R(s, a_1, a_2, s').$$
$$\hat{O}([s, 0], a_1, a_2, [s', 1], o_1, o_2) = O(s, a_1, a_2, s', o_1, o_2).$$

When taking the communication actions, they do change:

$$\hat{P}([s, 1], \sigma_1, \sigma_2, [s, 0]) = 1.$$
$$\hat{R}([s, 1], \sigma_1, \sigma_2, [s, 0]) = C_\Sigma(\sigma_1) + C_\Sigma(\sigma_2).$$
$$\hat{O}([s, 1], \sigma_1, \sigma_2, [s, 0], \sigma_1\sigma_2, \sigma_2\sigma_1) = 1.$$

Therefore, the DEC-MDP-Com is equivalent to the DEC-MDP. □

Theorem 1 states that DEC-MDP-Com and DEC-MDP have the same expressiveness. However, the distinction between the communication actions and the domain actions can be very useful, as we will show in the next section.

3. POLYNOMIALLY ENCODABLE INTERACTIONS

The DEC-MDP-Com and related models allow for a very general form of interaction between the agents. The complexity for those problems has been proven to be NEXP-complete [4, 7]. At the other end of the spectrum would be to disallow all interactions between the agents. In effect, each agent would be independently solving a local MDP that represents its part of the system. MDPs are P-complete, so there is something about the interactions between the agents which is the cause of the complexity. As additional evidence, Becker et al [3] defined a class of multi-agent problems in which the agents were almost completely independent. Each agent had a local MDP that described its part of the system. The agents could not communicate in any way nor could they take an action that would influence another agent. However, the system received a reward that depended on the local states and actions of all of the agents, and the goal was to find a joint policy that maximized the sum of the expected local and global rewards. This class of problems in which the agents can only interact through the reward function proved to be NP-complete. Goldman and Zilberstein [7] also showed that by following certain communication protocols the agents from the previous example could communicate with each other and the problem remained at NP-complete.

This section will examine different types of interactions between agents and provide theoretical results to explain how and why the interactions affect the complexity of finding optimal solutions. The next section will elaborate on the two NP-complete examples introduced above and prove that they meet this condition.

We classify the actions agents can take into two groups: non-interacting (or independent) actions and interacting (or dependent) actions. Independent actions are those that do not affect the other agent and neither agent receives any information about the other. Dependent actions are those that affect the other agent in some way. For example, robot i could pick up robot j and move it, which would affect the local state of robot j. Communication is another example: agent i could send a message to agent j, which would change the knowledge agent j has. We can further subdivide dependent actions into explicit and implicit communication. Normally when one thinks about communication, i.e., sending a message, one is talking about explicit communication. This is the communication part of the DEC-MDP-Com. Implicit communication is the information an agent receives by a domain action, like the example of a robot picking up and moving another robot. The robot being picked up gains information about the local state and belief of the other robot, namely the location of the other robot and the fact that the other robot felt this was a useful action to take.

We will illustrate these interactions with a token collecting example. There is a $n \times n$ grid world, which is populated by two agents and a number of tokens. The agents can observe their own locations and the locations of the tokens. When an agent picks up a token, the system gets a positive reward. The goal of the system is to maximize the total reward within time T. This problem can be modeled in a DEC-MDP. The world state includes the locations of both agents, the locations of the tokens and the time left. The agents' observations at each time step include the agents' own location, the location of the tokens, and the time left. At every time step, each agent can either move to an adjacent square or pick up a token at its current location. If an agent moves, its action does not affect the other agent's observations, and therefore the movement actions are independent actions. However, if agent i picks up a token, agent j can observe the fact that one of the tokens just dis-

appeared. By comparing its current observation and the observation at the last time step, agent j can infer the exact location of agent i and therefore has the complete knowledge of the current world state. As a result, the token collecting action is a dependent action even though there is no explicit communication in the system.

We defined a dependent action as an action that affects the observations of the other agent and therefore changes its belief about the global state. If a dependent action is explicitly modeled in a DEC-MDP-Com, its effect is recorded by the communication action σ_i itself. On the other hand, if it is not explicitly modeled in a DEC-MDP-Com, its effect is recorded by the observations of the agents. The observation history $\overline{\Omega}_i$ records the interaction history of agent i in the DEC-MDP. Consequently, in a DEC-MDP-Com where there are communication actions explicitly modeled, the interaction history of agent i is $\overline{\Omega}_i \times \overline{\Sigma}_i \times \overline{\Sigma}_j$.

DEFINITION 3. *We call E_i an* **encoding** *of the interaction history of agent i, if a joint policy $\tilde{\pi} = \langle \tilde{\pi}_1, \tilde{\pi}_2 \rangle$ is sufficient to maximize the global value, where $\tilde{\pi}_i$ is of the form $S \times E_i \rightarrow A_i \times \Sigma_i$ for a DEC-MDP-Com, or of the form $E_i \rightarrow A_i$ for a DEC-MDP.*

The encoding represents removing all elements from the interaction history that are unnecessary to generate an optimal policy. The important characteristic is the size of the smallest encoding. The interaction history is normally considered to be exponential in $|S|$ because the length of the observation sequence is $O(|S|)$. In some problems, however, the smallest encoding is only polynomial in $|S|$.

DEFINITION 4. *The interaction history of a DEC-MDP/DEC-MDP-Com is* **polynomially encodable** *if there exists an encoding E_i for each interaction history $\overline{\Omega}_i$ and a constant c_i, such that $|E_i| = O(|S|^{c_i})$.*

The criteria that determines the complexity of a multi-agent system is whether the interaction history can be polynomially encoded. If it can, then the problem is in NP. If it cannot be polynomially encoded, then it is provably harder than NP. The following two theorems prove this relationship between the encoding and the complexity.

THEOREM 2. *Deciding a polynomially encodable DEC-MDP/DEC-MDP-Com is NP-complete.*

PROOF. Here we prove the DEC-MDP case, the DEC-MDP-Com is essentially the same.

To prove NP-completeness, we (1) provide a polynomial time verifier and (2) show a reduction from an NP-Complete problem to this one.

(1) A joint policy in a DEC-MDP can be evaluated by representing it as a belief state graph. Each node in the graph is composed of the state, the sequence of observations for agent i and for agent j. Each node has a single joint action, which is defined by the joint policy. The transitions between the nodes depends only on the transition and observation functions, and each transition has a reward defined by the reward function. The belief state graph can be evaluated using the standard MDP recursive value function and policy evaluation, which runs in time polynomial in the size of the graph. For a DEC-MDP, this size is $|S| \times |\Omega_i|^T \times |\Omega_j|^T$, where $T = O(|S|)$. However, since there exists a polynomial encoding E_i for each observation sequence $\overline{\Omega}_i$, the size of the graph is only $|S| \times |E_i| \times |E_j|$ and the policy evaluation takes $O((|S|^{c_i+c_j+1})^c)$, which is polynomial in the size of the state space for constants c_i, c_j and c.

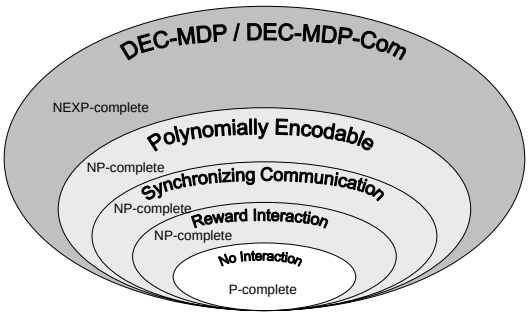

Figure 1: The relationships and complexity between various distributed MDP models.

(2) To prove the lower bound we will reduce the NP-complete problem DTEAM [9, 10] to this problem. DTEAM is a single-step discrete team decision problem with two agents. Agent i observes a random integer k_i, $1 \leq k_i \leq N$, and takes an action $\gamma_i(k_i) \in \{1, \ldots, M\}$. Their actions incur cost $c(k_i, k_j, \gamma_i(k_i), \gamma_j(k_j))$. The problem is to find policies γ_i and γ_j that minimize the expected cost:

$$\sum_{k_i=1}^{N} \sum_{k_j=1}^{N} c(k_i, k_j, \gamma_i(k_i), \gamma_j(k_j)).$$

The reduction is quite straightforward. In the initial state, the agents take a null action and transition to one of N^2 intermediate states that correspond to the random integers k_i and k_j. Agent i observes k_i and takes its action to reach the final state. The reward is negative the cost, $R(\cdot) = -c(\cdot)$. The size of the observation sequence $|\overline{\Omega}_i| = N = O(|S|)$ is polynomial in the size of the state space.

Given the polynomial time verifier and the reduction, a DEC-MDP with a polynomially encodable interaction history is NP-complete. □

THEOREM 3. *Deciding a non-polynomially encodable DEC-MDP/DEC-MDP-Com is harder than NP.*

PROOF. We prove this by contradiction. Assume that an arbitrary DEC-MDP without a polynomial encoding is in NP. This means that there exists a polynomial time verifier for any policy in the DEC-MDP. If a policy can be verified in polynomial time then it must have a polynomial sized representation. Since a policy is a mapping from $E_i \rightarrow A_i$, this polynomial sized representation is the encoding of the interaction history. Contradiction. Therefore, the DEC-MDP without a polynomial encoding is not in NP.

The proof for DEC-MDP-Com is similar. □

Figure 1 illustrates the relationship and complexity between the models discussed in this paper. Polynomially Encodable interaction histories are an NP-complete subset of DEC-MDPs. Other models, like the synchronizing communication are NP-complete subsets of polynomially encodable problems. No interaction between the agents is a P-complete class of problems.

4. EXAMPLES OF PROTOCOLS

In this section, we present two interaction protocols known to be NP-complete, and demonstrate how to prove the existence of a polynomial encodings.

4.1 Reward Dependence

The first example is a DEC-MDP in which the agents are mostly independent of each other. All of their actions are independent actions. The dependence between the agents comes from the reward function which depends on the world state and joint action. Becker et al. [3] formally defined this class of problems as a Transition Independent DEC-MDP (TI-DEC-MDP). It is a DEC-MDP with a factored state space, which means that there is a local state for each agent and the global state is the product of all of the local states, $S = S_i \times S_j$. The transition from one local state to the next depends only on the actions of that agent. Similarly, the observations of agent i depends only on i's local states and actions. We call these properties transition and observation independent.

DEFINITION 5 ([3]). *A factored DEC-MDP is said to be* **transition independent** *if the new local state of each agent depends only on its previous local state and the action taken by that agent:*

$$P(s_i'|(s_i, s_j), (a_i, a_j), s_j') = P_i(s_i'|s_i, a_i).$$

DEFINITION 6 ([3]). *A factored DEC-MDP is said to be* **observation independent** *if the observation an agent sees depends only on that agent's current and next local state and current action:* $\forall o_i \in \Omega_i$

$$P(o_i|(s_i, s_j), (a_i, a_j), (s_i', s_j'), o_j) = P(o_i|s_i, a_i, s_i').$$

At each step each agent fully observes its local state, and observes no information about the local state of the other agent.

DEFINITION 7 ([3]). *A factored DEC-MDP is said to be* **locally fully observable** *if each agent fully observes its own local state at each step., i.e.,* $\forall o_i \ \exists s_i \ : P(s_i|o_i) = 1$.

The interaction history of the DEC-MDP is the sequence of local observations, which in this problem translates into the sequence of local states. However, due to the limited interaction, the most recent local state and the time step is sufficient to maximize the global value. Proving that this encoding is sufficient is the primary component in proving that this class of problems is polynomially encodable.

THEOREM 4. *The interaction history of a DEC-MDP with independent transitions and independent observations is polynomially encodable.*

PROOF. The interaction history of a transition independent and observation independent DEC-MDP is a sequence of local states $\overline{s}_i$ with an upper bound on the length being $T = O(|S|)$. We will prove that there exists an encoding of the interaction history composed of the last state in the sequence and the length of the sequence. This encoding $E_i = S_i \times T$ is polynomial: $|S_i \times T| = O(|S|^2)$.

The Q value of the belief state graph (see Theorem 2) is the Q value of taking the given action in the current state sequence and then following the given optimal policy $\overline{\pi}^* = \langle \overline{\pi}_1^*, \overline{\pi}_2^* \rangle$, where $\overline{\pi}_i^* : \overline{S}_i \rightarrow A_i$.

$$Q_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) = \sum_{s_1' s_2'} P(s_1' s_2' | \overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) \times$$
$$[R(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2, s_1' s_2') + \gamma V_{\overline{\pi}^*}(\overline{s}_1 s_1 s_1', \overline{s}_2 s_2 s_2')].$$

If for all possible histories $\overline{s}_1', \overline{s}_2'$ of length T that led to the current state, the Q value is the same, then the history of states is irrelevant and can be replaced in the policy by just the length of the sequence T.

To prove $Q_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) = Q_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2)$, we have to show three things:

1. $P(s_1' s_2' | \overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) = P(s_1' s_2' | \overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2)$.

From the definition of Markov,

$$P(s_1' s_2' | \overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) = P(s_1' s_2' | s_1 s_2, a_1 a_2). \quad (1)$$

2. $R(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2, s_1' s_2') = R(\overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2, s_1' s_2')$.

From the definition of reward,

$$R(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2, s_1' s_2') = R(s_1 s_2, a_1 a_2, s_1' s_2'). \quad (2)$$

3. $V_{\overline{\pi}^*}(\overline{s}_1 s_1 s_1', \overline{s}_2 s_2 s_2') = V_{\overline{\pi}^*}(\overline{s}_1' s_1 s_1', \overline{s}_2' s_2 s_2')$

We show $V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) = V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2)$ by induction.

Base case: s_1 and s_2 are final states and their values are always zero. $V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) = 0$, $V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2) = 0$.

Inductive case: We assume it is true for

$$V_{\overline{\pi}^*}(\overline{s}_1 s_1 s_1', \overline{s}_2 s_2 s_2') = V_{\overline{\pi}^*}(\overline{s}_1' s_1 s_1', \overline{s}_2' s_2 s_2'), \quad (3)$$

we need to show that it is true for

$$V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) = V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2).$$

The value function is very similar to the Q function, except the current action is chosen from the policy.

$$\begin{aligned}
& V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) \\
= & \sum_{s_1' s_2'} P(s_1' s_2' | \overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2) \times \\
& [R(\overline{s}_1 s_1, \overline{s}_2 s_2, a_1 a_2, s_1' s_2') + \gamma V_{\overline{\pi}^*}(\overline{s}_1 s_1 s_1', \overline{s}_2 s_2 s_2')] \\
\overset{(1),(2)}{=} & \sum_{s_1' s_2'} P(s_1' s_2' | s_1 s_2, a_1 a_2) \times \\
& [R(s_1 s_2, a_1 a_2, s_1' s_2') + \gamma V_{\overline{\pi}^*}(\overline{s}_1 s_1 s_1', \overline{s}_2 s_2 s_2')] \\
\overset{(1),(2),(3)}{=} & \sum_{s_1' s_2'} P(s_1' s_2' | \overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2) \times \\
& [R(\overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2, s_1' s_2') + \gamma V_{\overline{\pi}^*}(\overline{s}_1' s_1 s_1', \overline{s}_2' s_2 s_2')]
\end{aligned}$$

Since a_1' and a_2' are optimal actions, we have:

$$\begin{aligned}
& \sum_{s_1' s_2'} P(s_1' s_2' | \overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2) [R(\overline{s}_1' s_1, \overline{s}_2' s_2, a_1 a_2, s_1' s_2') \\
& + \gamma V_{\overline{\pi}^*}(\overline{s}_1' s_1 s_1', \overline{s}_2' s_2 s_2')] \\
\leq & \sum_{s_1' s_2'} P(s_1' s_2' | \overline{s}_1' s_1, \overline{s}_2' s_2, a_1' a_2') [R(\overline{s}_1' s_1, \overline{s}_2' s_2, a_1' a_2', s_1' s_2') \\
& + \gamma V_{\overline{\pi}^*}(\overline{s}_1' s_1 s_1', \overline{s}_2' s_2 s_2')] \\
= & V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2)
\end{aligned}$$

As a result, we have $V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) \leq V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2)$. Due to symmetry, we can also show that $V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2) \leq V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2)$. Therefore $V_{\overline{\pi}^*}(\overline{s}_1 s_1, \overline{s}_2 s_2) = V_{\overline{\pi}^*}(\overline{s}_1' s_1, \overline{s}_2' s_2)$.

Since the value of taking a joint action while following the optimal policy does not depend on the history, the same joint action is optimal for all histories and the policy need not include it. The interaction history can be summarized by the current state and time. □

Theorem 4 implies that a DEC-MDP with independent transitions and observations can be decomposed into two independent MDPs, with local states only affected by the local actions. The policies are standard policies for MDPs with the addition of time, and the goal is to maximize the expected reward received from a global value function.

4.2 Synchronizing Communication

In the DEC-MDP with independent transitions and observations presented above, the agents interact only through reward function. This highly restricted form of interaction does not reveal any information about other agent's local state or observations. In this section, we look at a less restricted form of interaction, which we call **synchronizing communication**. We define it in the context of DEC-MDP-Com, since the explicit modeling of communication allows it to remain distinct from the domain actions.

Definition 8. *A communication protocol is said to be a* **synchronizing communication protocol** *if whenever any agent communicates, all agents send sufficient information to all other agents to unify their world views. Such an exchange is viewed as a single communication action with a single cost, even though there are potentially many messages sent.*

In a DEC-MDP-Com with a synchronizing communication protocol, whenever there is communication, each agent has the same view of the world. Since the world state is jointly fully observable, each agent has a complete view of the world state, and knows that the other agent has a complete view as well. The DEC-MDP-Com is essentially reset to an identical problem with a different start state, and the agents are safe to forget their past observation histories and communication histories. The communication actions essentially divide the DEC-MDP-Com into individual episodes, each of which is a DEC-MDP with no communication actions. The length of each episode varies depending on when it is optimal to communicate.

There are many applications in which synchronizing communication is an appropriate protocol. In certain problems, the communication setup cost is so high that it does not matter how much actual information is transferred. In other systems, the minimum packet size sent over the network may be larger than the messages the agents send, giving them a constant cost per message. For applications such as these, the amount of information contained in each message does not change its cost. A communication protocol is said to have **constant cost** if all the communication actions have the same cost. Specifically, a synchronizing communication action has the same cost as any other communication actions, no matter how many messages are actually exchanged to synchronize their partial views of the world state. Goldman and Zilberstein [7] proved that given a DEC-MDP-Com with constant communication cost, there is an optimal communication policy such that whenever there is communication, the agents exchange their last observations. Since a DEC-MDP-Com is jointly fully observable, when the agents exchange their last observations, they synchronize their views of the global state. As a result, if a DEC-MDP-Com has constant communication cost, there is an optimal communication policy such that whenever there is communication between the agents, it is synchronizing communication.

The second example of a polynomially encodable interaction protocol is the synchronizing communication in a DEC-MDP-Com with independent transitions and observations and a constant communication cost. This protocol has been studied in other work [7, 1].

Theorem 5. *The interaction history of a DEC-MDP-Com with independent transitions and observations and constant communication cost is polynomially encodable.*

Proof. From Definition 2, a local policy for a DEC-MDP-Com is of the form $\pi_i : S \times \overline{\Omega}_i \times \overline{\Sigma}_i \times \overline{\Sigma}_j \rightarrow A_i \times \Sigma_i$, where S is the last synchronized state, and $\overline{\Omega}_i$, $\overline{\Sigma}_i$ and $\overline{\Sigma}_j$ are the observation history and communication history since S. Since the DEC-MDP-Com has a constant communication cost, a synchronizing communication protocol is optimal. As a result, whenever there is communication the last synchronized global state S is updated to the newly synchronized state, and $\overline{\Omega}_i$ is set to $\emptyset$. When there is no communication, the observation is appended to $\overline{\Omega}_i$. Neither $\overline{\Sigma}_i$ nor $\overline{\Sigma}_j$ are used. Therefore, between communications the DEC-MDP-Com is equivalent to a DEC-MDP with independent transitions and observations, which is polynomially encodable (from Theorem 4). Since the interaction history between communications is polynomially encodable and communication resets the interaction history to $\emptyset$, the problem is polynomially encodable. □

Even though a DEC-MDP-Com with independent transitions and observations and constant communication cost has considerably more communication than a DEC-MDP with only reward dependence, Theorem 5 shows that its interaction protocol is still polynomially encodable, and therefore it remains in NP.

5. EXAMPLES OF APPROXIMATIONS

For applications where communication cost is constant, one can find an optimal policy that periodically synchronizes the world views of the agents. However, there are many other applications where the cost of message depends on its contents, and it may be beneficial to send less information than would synchronize the agents' world views. Unfortunately, most such interactions do not seem to be polynomially encodable because each piece of information changes an agent's belief about the local state of the other agent. A good guideline is that an agent needs to keep track of both the other agent's local state as well as the other agent's knowledge. However, we may still be able to design approximate encodings that are polynomial for such problems. The purpose of these encodings is to put extra restrictions on the interactions so that the complexity of approximating the optimal policy is reduced to at most NP. In this section, we show two examples of such approximations.

5.1 Constant Horizon

Consider the token collecting example. While there is no explicit communication between the agents, both of the agents observe the location of all available tokens. When agent i picks up a token at time t, agent j observes the fact that a token disappeared and can infer the location of agent

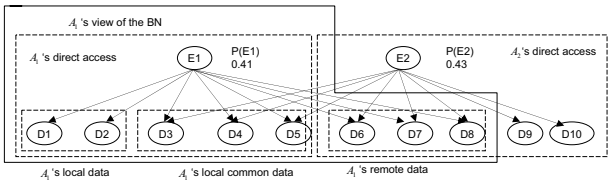

Figure 2: There are two events E_1 and E_2. Data $D_1, D_2, ...D_{10}$ are distributed between two agents. A_1 has access to $D_1, ...D_5$ and is responsible for solving E_1, while A_2 can see only $D_6, ...D_{10}$ and is responsible for solving E_2. The objective is for A_1 and A_2 to figure out what E_1 and E_2 are with required confidence and with minimum expected communication cost

i. With this observation, agent j knows the global state but agent i does not, so the interaction is not synchronizing but what we call asymmetric synchronizing. Asymmetric synchronization is where an agent either gains no information about the other agent's local state or complete information, giving it a belief of 1.0 about the current global state. The difference between synchronization and asymmetric synchronization is in the asymmetric case the agents do not necessarily both synchronize at the same time.

This difference precludes a polynomial encoding. In the token collecting example when agent i picks up a token both agents i and j know that i picked it up as well as both know the other knows, and so on. Agent i, then, must keep track of the information j has collected about i to best predict what j will do at least until j picks up a token itself and i learns where j is located. Remembering this sequence of information is exponential in the size of the state space in the worst case.

While the problem itself is harder than NP, it can be approximated by making assumptions that allow the interaction history to be polynomially encoded. For example, instead of keeping track of the entire history of interaction, one could assume that the last c interactions, for some constant c, was sufficient. The interaction history is now of size $|S|^c$, which is polynomial in the size of the state space. In the token collecting example this could correspond to agent i remembering the last 5 tokens it collected.

5.2 Flat Representation

Now let us look at a communication optimization problem in a Distributed Sensor Interpretation (DSI) system [13]. There are two agents in the system. Each agent directly observes data from a group of sensors and is responsible for solving a subset of the interpretation problem to best explain the sensor data collectively observed by the agents. Since each subproblem may relate to not only the sensor data collected by the agent itself, but also those collected by the other agent, the agents may need to communicate with each other in order to solve its local problem with required confidence. Figure 2 illustrates such a DSI system that is represented in a Bayesian Network. The top level nodes are the events that are the possible causes of the observed data, while the leaves are the raw data gathered by various agents. There are two classes of actions for each agent: SEND and REQUEST. An agent can only send one piece of data that the other agent has no knowledge of, and can only request one piece of the remote data that it has

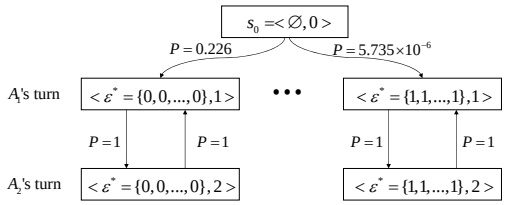

Figure 3: The decentralized MDP generated for the problem in Figure 2.

not yet acquired. The two agents alternate actions until the confidence threshold is reached by both. The communication optimization problem is, for the specified BN structure, to find the communication strategy whose expected cost is minimized in order to reach the required confidence for both agents.

Shen et al. [13] models this problem with a DEC-MDP as shown in Figure 3. Every global state is in the form of $s = \langle e^*, i \rangle$, where e^* is all of the sensor data values observed by the system, and i is an external feature that indicates it is agent i's turn to communicate. s_0 is a dummy start state $\langle \emptyset, 0 \rangle$. When all the sensors collect their data, the start state transitions to one of the possible real global states $\langle e^*, 1 \rangle$ before any communication takes place. A_1 and A_2 are action sets of the two agents, $A_i = \{$SEND x, REQUEST $y\}$ for local data x and remote data y. An observation o_i is the data value just sent or received by agent i. As a special case, after s_0 each agent observes the values of its local data.

In this DEC-MDP every action is explicit communication. Instead of explicitly modeling it as Σ in a DEC-MDP-Com, these actions are implicitly modeled in the DEC-MDP framework itself. The observation history $\overline{\Omega}$ records the interaction history of the system. Since every observation at every time step is needed to calculate the confidence level achieved, it is necessary for the agents to remember all the data values transferred between the agents in the past. Furthermore, remembering the order in which the data are exchanged is valuable because it carries useful information. An agent can infer why the other agent chose to transfer this piece of data before the other piece. Therefore, remembering the entire $\overline{\Omega}$ is essential to generating the optimal policy. We write the number of local sensor data as n, and assume that each sensor data has at most m possible values. As a result, $|S| = m^n$, and $|\overline{\Omega}| = O(n! \cdot m^n) = O(n^n) = O(|S|^{\log_2 n})$. Since n is not independent of $|S|$, $\overline{\Omega}$ is not polynomially encodable and therefore the DEC-MDP is harder than NP.

One way to approximate the optimal solution to this problem is that, instead of remembering the entire $\overline{\Omega}$, each agent only remembers the values of the data exchanged so far without remembering the order in which they were transferred. This is a reasonable approximation since to calculate the confidence level of the local interpretations, only the sensor data values are needed. In this approximation, the approximate encoding E_i of $\overline{\Omega}$ is of the size $O((m+1)^n) = O(|S|^{\log_m (m+1)})$. Since m is independent of $|S|$, E_i is a polynomial encoding, and therefore this approximation is no harder than NP.

6. CONCLUSIONS

Distributed POMDPs have been developed and employed to model various multi-agent coordination problems. Un-

derstanding the source of their high complexity is crucial to identifying new and more tractable models as well as developing appropriate approximations to otherwise intractable problems. This paper establishes that the interactions present among the agents is the cause of the high complexity of distributed POMDPs. We proved that deciding a distributed POMDP whose interaction history contains information of a size polynomial in the number of states is NP-complete, and that deciding a non-polynomially encodable distributed POMDP is harder than NP. We demonstrated how two subclasses of distributed POMDPs known to be NP-complete can be polynomially encoded. This is the first time that a well-defined condition has been identified that can distinguish between multi-agent problems in NP and those that are strictly harder than NP. It is an important step in mapping out the complexity hierarchy of multi-agent systems.

Our goal in this paper was not to introduce new models or algorithms, but to change the way people view interactions between agents in the context of distributed POMDPs. Multi-agent researchers have long intuitively understood that the interaction between the agents is the cause of their high complexity. The theoretical results of this paper are significant in that they both formally justify this intuition as well as explain how the interaction affects the complexity. This new understanding of interaction and its relationship to complexity will help us to identify new classes of multi-agent systems with a lower complexity.

The significance of this theoretical result also has a more practical side. Most multi-agent systems are provably harder than NP and solving them optimally is not possible. Much work has been put into developing good algorithms for approximating these problems. This work provides theoretical guidance in understanding how the approximations in a model limit the search space and reduce the complexity. We demonstrate this on two non-polynomially encodable problems by providing two assumptions that reduce the complexity to no harder than NP.

We are currently pushing this work in two directions. First, we are searching for new examples of polynomially encodable interaction protocols, as well as common protocols that we can prove are not polynomially encodable. Second, we are evaluating the performance of the approximations we presented here in addition to finding new approximations appropriate to the protocols that we can prove to be harder than NP.

ABSTRACT

We present a technique for reducing a normal-form (aka. (bi)matrix) game, O, to a smaller normal-form game, R, for the purpose of computing a Nash equilibrium. This is done by computing a Nash equilibrium for a subcomponent, G, of O for which a certain condition holds. We also show that such a subcomponent G on which to apply the technique can be found in polynomial time (if it exists), by showing that the condition that G needs to satisfy can be modeled as a Horn satisfiability problem. We show that the technique does not extend to computing Pareto-optimal or welfare-maximizing equilibria. We present a class of games, which we call ALAGIU (Any Lower Action Gives Identical Utility) games, for which recursive application of (special cases of) the technique is sufficient for finding a Nash equilibrium in linear time. Finally, we discuss using the technique to compute *approximate* Nash equilibria.

1. INTRODUCTION

Nash equilibrium is the most important solution concept for games. A vector of mixed strategies for the players (that is, for each player, a probability distribution over that player's actions in the game) is a Nash equilibrium if no individual player can benefit from changing her strategy. Every finite game has at least one Nash equilibrium [20]. However, for the concept to be operational, the mere existence result is not sufficient: it needs to be accompanied by an *algorithm* for finding an equilibrium. Unfortunately, even in 2-player normal-form games, it is still unknown whether a polynomial-time algorithm exists for computing a Nash equilibrium. The *Lemke-Howson* algorithm [15] is the best-known algorithm for computing a Nash equilibrium in a 2-player normal-form game, but it can require exponential time [25]. Some special cases can be solved in polynomial time (for example, zero-sum games [18]); other related questions, such as finding a welfare-maximizing equilibrium, are NP-hard [11, 5].

Recently, there has been a renewed surge of interest in the computation of Nash equilibria. Christos Papadmitriou has called the basic problem "a most fundamental computational problem whose complexity is wide open" and "together with factoring, [...] the most important concrete open question on the boundary of P today" [22],[1] and new (exponential-time) algorithms have been suggested that search over the supports of the mixed strategies [23, 24]. Also, there has been growing interest in computing equilibria of games with special structure that allows them to be represented concisely [13, 16, 2, 12, 1].

The idea we pursue in this paper is the following. For the basic problem of computing a Nash equilibrium of a normal-form game, it would be helpful to have a recursive technique that decomposes a Nash equilibrium computation problem into one or more smaller such problems, in such a way that a solution to the original problem can easily be computed from the solutions to the smaller problems. If there were such a technique that could be applied to *any* game, and that de-

[1] A recent sequence of papers [8, 3, 9, 4] shows that the problem of finding a Nash equilibrium (even in the two-player case) is complete for a class of problems called PPAD. This makes it seem less likely that a polynomial-time algorithm for finding a Nash equilibrium exists; on the other hand, unlike (say) NP, PPAD is not known to contain many problems of interest, so that it would be less of a shock if PPAD turned out to be contained in P.

composed it into small enough subproblems, then repeatedly applying this technique would constitute a polynomial-time algorithm for computing a Nash equilibrium. However, even if the technique could not be applied to all games, it would still be of interest. It could be used as a preprocessing step in computing a Nash equilibrium, thereby reducing the load on the algorithm that is eventually called to solve the irreducible subproblems. The technique could also be applied at intermediate stages of any other algorithm that works by reducing the size of the game. Moreover, there may be special subclasses of games such that the technique can be applied on any of those games, as well as on any subproblem resulting from applying the technique on those games. In that case, the technique would constitute a polynomial-time Nash equilibrium finding algorithm for the particular subclass of games.

In this paper, we introduce such a technique for 2-player normal-form games. When possible, this technique finds a subcomponent, G, of the original game, O, for which a certain condition holds. G is then solved recursively. Based on the recursively computed equilibrium of G, the original game O is then reduced to a smaller game, R, which is also solved recursively. From the computed equilibria of G and R, an equilibrium of the original game O can then easily be constructed. To our knowledge, this is the first recursive technique for computing a Nash equilibrium (other than the iterated elimination of dominated strategies[2]).

2. MAIN TECHNIQUE

In this section, we introduce our main technique. We are given a 2-player normal-form game O, in which the row player chooses a pure strategy from Σ_1 and the column player chooses a pure strategy from Σ_2. Suppose that the strategies in Σ_1 can be labeled as u_i, s_i, and those in Σ_2 as v_j, t_j, so that the game can be written as follows:

	v_1	v_2	$\cdots$	v_l	t_1	t_2	$\cdots$	t_n
u_1					c_{11}, b_1	c_{12}, b_1	$\cdots$	c_{1n}, b_1
u_2					c_{21}, b_2	c_{22}, b_2	$\cdots$	c_{2n}, b_2
$\vdots$		H			$\vdots$	$\vdots$		$\vdots$
u_k					c_{k1}, b_k	c_{k2}, b_k	$\cdots$	c_{kn}, b_k
s_1	a_1, d_{11}	a_2, d_{12}	$\cdots$	a_l, d_{1l}				
s_2	a_1, d_{21}	a_2, d_{22}	$\cdots$	a_l, d_{2l}				
$\vdots$	$\vdots$	$\vdots$		$\vdots$		G		
s_m	a_1, d_{m1}	a_2, d_{m2}	$\cdots$	a_l, d_{ml}				

The condition that allows for writing the game like this is the following:

CONDITION 1. *Against any fixed v_j, all the s_i give the row player the same utility (a_j); and against any fixed u_i, all the t_j give the column player the same utility (b_i).*

The intuition for why this condition is useful is the following. Suppose that the row player has decided to play one of the s_i, but has not yet decided which s_i. If the column player plays one of the v_j, then it does not matter which of the s_i the row player plays. Thus, in deciding which s_i to play, the row player only needs to consider the probabilities that the column player places on the t_j. Symmetrically, if the column player has decided to play one of the t_j (but has not yet decided which t_j), then the column player only needs to consider the probabilities that the row player places on the s_i. Hence, intuitively, the parts of the players' mixed strategies that concern the s_i and t_j should themselves be in equilibrium.

So, let us compute a Nash equilibrium of the game G (using any technique):

	t_1	t_2	t_3	$\cdots$	t_n
s_1					
s_2					
s_3		G			
$\vdots$					
s_m					

Let $p^G_{s_i}$ be the row player's probabilities in that Nash equilibrium, and let $p^G_{t_j}$ be the column player's probabilities. Also, let π^G_s be the expected utility for the row player, and let π^G_t be the expected utility for the column player. We can use these to reduce the original game O, as follows. We replace the lower left quadrant of O with a single row. The row player's payoff in the jth entry is a_j (which is the row player's payoff in the jth entry for any of the original rows). The column player's payoff in the jth entry is $\sum_{i=1}^{m} p^G_{s_i} d_{ij}$—that is, the average of the column player's payoffs in the jth entry, taken across the replaced rows, weighted by the probability with which the corresponding s_i is played in the computed equilibrium of G. We replace the upper right quadrant of O with a single column in a similar fashion. Finally, we replace the lower right quadrant (G) with a single entry π^G_s, π^G_t (the expected utilities of the players in the computed equilibrium of G). Thus, the reduced game R is the following:

	v_1	v_2	$\cdots$	v_l	t
u_1					$\sum_{j=1}^{n} p^G_{t_j} c_{1j}, b_1$
u_2					$\sum_{j=1}^{n} p^G_{t_j} c_{2j}, b_2$
$\vdots$		H			$\vdots$
u_k					$\sum_{j=1}^{n} p^G_{t_j} c_{kj}, b_k$
s	$a_1, \sum_{i=1}^{m} p^G_{s_i} d_{i1}$	$a_2, \sum_{i=1}^{m} p^G_{s_i} d_{i2}$	$\cdots$	$a_l, \sum_{i=1}^{m} p^G_{s_i} d_{il}$	π^G_s, π^G_t

We then compute a Nash equilibrium for R (using any technique), obtaining equilibrium probabilities $p^R_{u_i}, p^R_s$ for the row player and equilibrium probabilities $p^R_{v_j}, p^R_t$ for the column player. Then (as we will show later in the section), setting $p^O_{u_i} = p^R_{u_i}, p^O_{s_i} = p^R_s p^G_{s_i}, p^O_{v_j} = p^R_{v_j}$, and $p^O_{t_j} = p^R_t p^G_{t_j}$ constitutes a Nash equilibrium of O.

Before proving formally that the technique is correct, we first illustrate it with a small example. Consider the following game O:

[2]Most variants of iterated dominance can be executed in polynomial time [14, 19, 10, 6]. We have recently proposed a more general strategy eliminability criterion that can help in computing a Nash equilibrium [7], but it is not a recursive technique.

	v_1	t_1	t_2
u_1	$2,2$	$0,3$	$2,3$
s_1	$1,2$	$4,0$	$0,4$
s_2	$1,4$	$0,4$	$4,0$

Condition 1 holds for this game. Thus, we first solve the subcomponent G:

	t_1	t_2
s_1	$4,0$	$0,4$
s_2	$0,4$	$4,0$

This is a matching-pennies game where in equilibrium, each player places probability $1/2$ on each pure strategy and receives expected utility 2.[3] Thus, the reduced game R becomes:

	v_1	t
u_1	$2,2$	$1,3$
s	$1,3$	$2,2$

Again, this is a matching-pennies game where in equilibrium, each player places probability $1/2$ on each action. Thus, we have discovered an equilibrium for the original game O where u_1 and v_1 are played with probability $1/2$ each, and s_1, s_2, t_1, t_2 are played with probability $(1/2) \cdot (1/2) = 1/4$ each. We now prove the technique is correct in general.

THEOREM 1. *Suppose O is reduced to R using the equilibrium $p^G_{s_i}, p^G_{t_j}$ of G. If $p^R_{u_i}, p^R_s, p^R_{v_j}, p^R_t$ constitute a Nash equilibrium of R, then setting $p^O_{u_i} = p^R_{u_i}, p^O_{s_i} = p^R_s p^G_{s_i}, p^O_{v_j} = p^R_{v_j}$, and $p^O_{t_j} = p^R_t p^G_{t_j}$ constitutes a Nash equilibrium of O.*

Proof. To show that these mixed strategies constitute a Nash equilibrium for O, we first observe that the row player has no incentive to redistribute the probability placed on strategies s_i to another strategy $s_{i'}$. That is, *given* that the row player plays one of the strategies s_i (note that given this, the probability that the row player plays a given strategy s_i is $p^R_s p^G_{s_i} / p^R_s = p^G_{s_i}$), there is no incentive to switch to another strategy $s_{i'}$. The reason is as follows. Given that the column player plays a given strategy v_j, both $p^G_{s_i}$ and $s_{i'}$ will give the same utility. Given that the column player plays one of the strategies t_j (note that given this, the probability that the column player plays a given strategy t_j is $p^R_t p^G_{t_j} / p^R_t = p^G_{t_j}$), $p^G_{s_i}$ is a best response because $p^G_{s_i}, p^G_{t_j}$ constitute a Nash equilibrium for G. As a result, to show that we have an equilibrium for O, we do not need to consider deviations to an arbitrary s_i; instead, we only need to consider deviations to the mixed strategy $p^G_{s_i}$.

Next, we observe that the expected utility for the row player of playing a given u_i is the same as in the equilibrium computed for R. The reason is as follows. The probability that the column player plays a given v_j is the same in both R and O, and so is the row player's utility for the outcome (u_i, v_j). Moreover, the probability that the column player plays one of the strategies t_j in O is p^R_t, and the expected utility for the row player of playing u_i in that case is $\sum_{j=1}^{n} p^G_{t_j} c_{ij}$, which is the same as in R.

We also observe that the expected utility for the row player of playing $p^G_{s_i}$ (that is, the row player's mixed strategy given that the row player plays one of the strategies s_i) is the same as the expected utility of playing s in the equilibrium computed for R. The reason is as follows. The probability that the column player plays a given v_j is the same in both R and O, and the row player's utility in either case is a_j. Moreover, the probability that the column player plays one of the strategies t_j in O is p^R_t, and the expected utility for the row player of playing $p^G_{s_i}$ in that case is the expected utility the row player gets in the equilibrium of G, namely, π^G_s, which is the same as the row player's utility for the outcome (s, t) in R.

But from these last two observations, and the fact that we used an equilibrium for R, it follows that the row player has no incentive to deviate to any u_i or to $p^G_{s_i}$; and from the first observation, the fact that the row player has no incentive to deviate to $p^G_{s_i}$ implies that the row player has no incentive to deviate to any s_i. Hence, the row player has no incentive to deviate; by symmetry, neither does the column player. ■

3. DETECTING WHETHER THE TECHNIQUE CAN BE APPLIED

It is easy to verify whether Condition 1 holds when the pure strategies of the game are labeled u_i, s_i, v_j, t_j. However, in general, this labeling will not be given to us. As an example, suppose we are given the following game:

	β_1	β_2	β_3
α_1	$4,0$	$1,2$	$0,4$
α_2	$0,3$	$2,2$	$2,3$
α_3	$0,4$	$1,4$	$4,0$

This game is, in fact, the same game that was used as an example in Section 2, with the rows and columns permuted $(\alpha_1 = s_1, \alpha_2 = u_1, \alpha_3 = s_2, \beta_1 = t_1, \beta_2 = v_1, \beta_3 = t_2)$. But we cannot apply the technique without knowing the labeling of the strategies as u_i, s_i, v_j, and t_j.

Hence, we need an algorithm that finds a labeling of the strategies as u_i, s_i, v_j, and t_j such that Condition 1 holds. Note that it does not matter whether we label a given strategy (*e.g.*) s_1 or s_2. That is, all we need to do is partition the row player's strategies Σ_1 into two subsets, the ones labeled u_i and the ones labeled s_i; and partition the column player's strategies Σ_2 into two subsets, the ones labeled v_j and the ones labeled t_j.

There are two trivial ways of labeling the strategies so that the condition holds: 1. Label all strategies s_i or t_j. 2. Label at most one strategy s_i, and at most one strategy t_j. These trivial labelings are not useful: the first would give us $G = O$ to recurse on, and the second would not reduce the game at all $(R = O)$. Any other labeling for which Condition 1 is satisfied, though, would give us a game G that is smaller than O to recurse on, and reduce the game to a game R that is smaller than O. Moreover, the number of rows (columns) by which R is smaller than O is equal to

[3]We emphasize that there is no restriction that the game G or R should be a zero-sum game (or any other special type of game).

the number of rows (resp. columns) in G, minus 1. Hence, our objective is to find a labeling for which the condition is satisfied, other than the two trivial ones described above.

We now show how to reformulate this problem as a Horn satisfiability problem. (Recall that a satisfiability clause is a Horn clause if it can be written as $(\neg x_1 \vee \neg x_2 \vee \ldots \vee \neg x_n \vee y)$, or equivalently, $x_1 \wedge x_2 \wedge \ldots \wedge x_n \Rightarrow y$.) Let the variable $v(\sigma)$ be *true* if σ is labeled as one of the s_i or t_j, and *false* if σ is labeled as one of the u_i or v_j. The key observation is that to satisfy Condition 1, if row player strategies α_1 and α_2 obtain different payoffs for the row player against column player strategy β, then it cannot be the case that α_1 and α_2 are both labeled as one of the s_i and β is labeled as one of the v_j—in other words, $v(\alpha_1) \wedge v(\alpha_2) \Rightarrow v(\beta)$. Similarly, if column player strategies β_1 and β_2 obtain different payoffs for the column player against row player strategy α, then $v(\beta_1) \wedge v(\beta_2) \Rightarrow v(\alpha)$.

Using this, the game described at the beginning of this section has the following Horn clauses:[4]

1. $v(\alpha_1) \wedge v(\alpha_2) \Rightarrow v(\beta_1) \wedge v(\beta_2) \wedge v(\beta_3)$,
2. $v(\alpha_1) \wedge v(\alpha_3) \Rightarrow v(\beta_1) \wedge v(\beta_3)$,
3. $v(\alpha_2) \wedge v(\alpha_3) \Rightarrow v(\beta_2) \wedge v(\beta_3)$,
4. $v(\beta_1) \wedge v(\beta_2) \Rightarrow v(\alpha_1) \wedge v(\alpha_2)$,
5. $v(\beta_1) \wedge v(\beta_3) \Rightarrow v(\alpha_1) \wedge v(\alpha_3)$,
6. $v(\beta_2) \wedge v(\beta_3) \Rightarrow v(\alpha_1) \wedge v(\alpha_2) \wedge v(\alpha_3)$.

It is straightforward to check that the only nontrivial satisfying assignment, that is, the only assignment that

- satisfies all these clauses,
- does not set all variables to *true*, and
- sets either at least two $v(\alpha_i)$ to *true* or at least two $v(\beta_j)$ to *true*;

sets $v(\alpha_1), v(\alpha_3), v(\beta_1)$, and $v(\beta_3)$ to *true* and everything else to *false*. We note that this corresponds to the labeling that we presented. The Horn clauses can be computed efficiently:

LEMMA 1. *The set of Horn clauses for a normal-form game can be computed in time* $O(|\Sigma_1|^2 \cdot |\Sigma_2| + |\Sigma_1| \cdot |\Sigma_2|^2)$.

We now show that the Horn clauses fully capture the problem, that is, the Horn clauses being satisfied is a necessary and sufficient condition for Condition 1 to be satisfied.

THEOREM 2. *A labeling of the strategies as* u_i, s_i, v_j, *and* t_j *satisfies Condition 1 if and only if it satisfies all the Horn clauses.*

Proof. First, suppose that not all of the Horn clauses are satisfied. Then (without loss of generality) there exist $\alpha_{i_1}, \alpha_{i_2}$, and β_j such that $v(\alpha_{i_1}) \wedge v(\alpha_{i_2}) \Rightarrow v(\beta_j)$, $v(\alpha_{i_1})$ and $v(\alpha_{i_2})$ are set to *true*, and $v(\beta_j)$ is set to *false*. (Alternatively the roles of the α_i and β_j could be reversed, but by symmetry we can without loss of generality restrict our attention to the first case.) That is, α_{i_1} and α_{i_2} are among the strategies s_i, β_j is among the strategies v_j, and α_{i_1} and α_{i_2} give the row player different payoffs against β_j. But then Condition 1 is not satisfied.

Now, suppose that all of the Horn clauses are satisfied. We must show, for any v_j, that any s_{i_1} and s_{i_2} give the row player the same payoff against v_j. (We must show the same for the u_i and the t_j, but this will follow by symmetry.) Suppose they do not; then one of the Horn clauses must be $v(s_{i_1}) \wedge v(s_{i_2}) \Rightarrow v(v_j)$. But this clause would then be *false*, which is contrary to our assumption. ■

A general systematic approach to finding a nontrivial satisfying assignment is to start by setting two $v(\alpha_i)$ (or two $v(\beta_j)$) to *true*, and subsequently iteratively apply the implication clauses; if this process ends without all the variables being set to *true*, we have found an assignment with the desired properties. If we do this once for every initial pair of $v(\alpha_i)$ and every initial pair of $v(\beta_j)$, then we will find an assignment with the desired properties if it exists.

For instance, in the above example, we start by setting $v(\alpha_1)$ and $v(\alpha_2)$ to *true*; then, applying the first implication, we find that all the $v(\beta_j)$ must be set to *true* as well, and hence by the last implication so must $v(\alpha_3)$, so that all variables are set to *true*. Then, we try again, starting by setting $v(\alpha_1)$ and $v(\alpha_3)$ to *true*; by the second implication, we find that $v(\beta_1)$ and $v(\beta_3)$ must also be set to *true*. Then we apply the fifth implication, but this does not set any new variables to *true*, so the process ends here, and we have found an assignment with the desired properties.

THEOREM 3. *The algorithm described above requires* $O((|\Sigma_1| + |\Sigma_2|)^4)$ *applications of a Horn clause.*

Proof. There are $O((|\Sigma_1| + |\Sigma_2|)^2)$ iterations of the outer loop (choosing which pair of variables to start with). Moreover, within each iteration, we never need to apply the same clause twice, and there are only $O((|\Sigma_1| + |\Sigma_2|)^2)$ clauses. ■

4. LIMITATIONS OF THE TECHNIQUE

One may wonder whether the technique can be extended to find Nash equilibria with special properties. For example, if we compute a Pareto optimal or social-welfare maximizing Nash equilibrium in each recursive call, will this give us a Pareto optimal or social-welfare maximizing Nash equilibrium for the original game? The following game O shows that this is not the case.

	v_1	t_1	t_2
u_1	$1,1$	$4,0$	$0,0$
s_1	$0,4$	$3,3$	$0,0$
s_2	$0,0$	$0,0$	$2,2$

The subcomponent G is as follows:

	t_1	t_2
s_1	$3,3$	$0,0$
s_2	$0,0$	$2,2$

It has multiple equilibria, but the only Pareto optimal Nash equilibrium is (s_1, t_1). Thus the reduced game R becomes:

[4]When we have Horn clauses $v(\alpha_1) \wedge v(\alpha_2) \Rightarrow v(\beta_1)$ and $v(\alpha_1) \wedge v(\alpha_2) \Rightarrow v(\beta_2)$, we aggregate them into $v(\alpha_1) \wedge v(\alpha_2) \Rightarrow v(\beta_1) \wedge v(\beta_2)$ to improve readability.

	v_1	t
u_1	$1,1$	$4,0$
s	$0,4$	$3,3$

This is a Prisoner's Dilemma game where the only equilibrium is (u_1, v_1), and thus we will compute the equilibrium (u_1, v_1) for the original game O. Unfortunately, this is not a Pareto optimal equilibrium for O, because (s_2, t_2) is also a Nash equilibrium for O. Of course, in practice, choosing a Nash equilibrium with high social welfare in each recursive call may still be a useful heuristic for finding good equilibria.

5. ALAGIU GAMES: A CLASS OF GAMES THAT CAN BE SOLVED BY APPLYING THE TECHNIQUE RECURSIVELY

In general, we may only be able to apply the technique a limited number of times, after which we need to resort to other algorithms to obtain Nash equilibria for games in the recursive calls on which the technique cannot be applied. However, in this section, we present a subclass of normal-form games such that the technique works on any of these games, and any game resulting from a recursive call is itself in the subclass as well. Thus, the technique is sufficient for finding a Nash equilibrium.

DEFINITION 1. *We say that a 2-player normal-form game is an* ALAGIU (Any Lower Action Gives Identical Utility) *game if each player's strategy set Σ_i is a subset of $\mathbb{R}$, and the game has the property that for any pure opponent strategy $\sigma_{-i} \in \Sigma_{-i}$, for any $\sigma_i^1, \sigma_i^2 \in \{\sigma_i \in \Sigma_i : \sigma_i < \sigma_{-i}\}$, we have $\pi_i(\sigma_i^1, \sigma_{-i}) = \pi_i(\sigma_i^2, \sigma_{-i})$. That is, given that a player chooses a lower strategy than the opponent, it does not matter to that player which of the lower strategies she chooses.*

Before showing how the technique can be applied to (finite) ALAGIU games, we first give some examples. The first one is very simple:

EXAMPLE 1 (MATCHING n-SIDED PENNIES). *In matching n-sided pennies, both players choose an integer in $\{1, 2, \ldots, n\}$; player 1 wins if the players' integers are the same, and player 2 wins if they are different.*

Incidentally, this example shows that ALAGIU games can have nontrivial equilibria:

PROPOSITION 1. *There exist ALAGIU games (of arbitrary size) that have only one equilibrium in which each player randomizes uniformly over all strategies.*

PROOF. We claim that matching n-sided pennies has the property. This is a zero-sum game, and thus any equilibrium strategy is a minimax strategy. For player 1, the only minimax strategy is to place probability $1/n$ on each integer, because if player 1 plays some integer with lower probability, the other player will be better off playing that integer. Similarly, for player 2, the only minimax strategy is to place probability $1/n$ on each integer, because if player 2 plays some integer with higher probability, the other player will be better off playing that integer. ■

We note that state-of-the-art equilibrium finding algorithms tend to have difficulty computing equilibria with large supports (*i.e.* in which the players randomize over many strategies). For example, the PNS algorithm [23] for finding a Nash equilibrium explicitly searches over all (exponentially many) possible supports, searching the smaller supports first. Other algorithms similarly tend to require more time on games that only have equilibria with large supports.

Matching n-sided pennies does not illustrate the full generality of ALAGIU games. The next (somewhat playful) example allows for richer structure:

EXAMPLE 2 (VENDORS ON A ONE-WAY STREET). *Say we have a hot dog vendor and an ice cream vendor that must each choose a location on a one-way street. Assume that, given that a vendor chooses a location earlier on the street than the other vendor, it does not matter to the earlier vendor where exactly she locates herself (all traffic must pass her anyway). However, it may matter to the later vendor where he locates himself. (For example, it may be bad for the ice cream vendor to immediately follow the hot dog vendor, because potential customers will have their hands full with the hot dog. In contrast, it may be good for the ice cream vendor to locate himself significantly later on the street than the hot dog vendor, to provide some dessert.) Then, this is an ALAGIU game.*

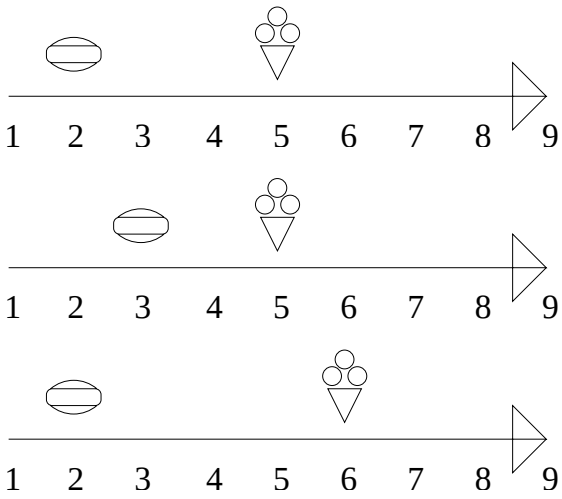

Figure 1: Three outcomes for the vendor game. Under the ALAGIU restriction, the hot dog vendor's utility must be the same for the top two outcomes. However, the ice cream vendor's utility need not be the same in any of the three outcomes.

More practically, our final example shows that ALAGIU games also encompass typical auctions.

EXAMPLE 3 (HIGHER-BIDDER-WINS AUCTIONS). *Any two-player single-item auction in which a lower bidder never wins and never pays anything is an ALAGIU game. Note that arbitrary allocation rules are allowed in case of ties. Also, arbitrary payment rules for the winning bidder are allowed, including first price and second price (but also bizarre,* e.g. *nonmonotonic, payment rules).*

Perhaps surprisingly, in contrast to auctions, *bargaining* games typically do not have the structure of ALAGIU games.[5]

[5]We thank Piotr Gmytrasiewicz for asking the question whether bargaining games are ALAGIU games.

We discuss this in more detail in the appendix, but we now move on to showing how ALAGIU games can be solved using the technique described in this paper. It turns out that any finite ALAGIU game takes one of three special forms described below, each of which satisfies Condition 1. Consider the highest strategy in the game, that is, $\sigma_M = \max\{\sigma : \sigma \in \Sigma_1 \cup \Sigma_2\}$. If only the row player has σ_M in her strategy set ($\sigma_M \in \Sigma_1 - \Sigma_2$), then the game must have the following form:

	t_1	t_2	t_3	$\cdots$	t_n
$u_1 = \sigma_M$	c_{11}, b_1	c_{12}, b_1	c_{13}, b_1	$\cdots$	c_{1n}, b_1
s_1					
s_2					
s_3			G		
$\vdots$					
s_m					

On the other hand, if only the column player has σ_M in his strategy set ($\sigma_M \in \Sigma_2 - \Sigma_1$), then the game must have the following form:

	$v_1 = \sigma_M$	t_1	t_2	t_3	$\cdots$	t_n
s_1	a_1, d_{11}					
s_2	a_1, d_{21}					
s_3	a_1, d_{31}			G		
$\vdots$	$\vdots$					
s_m	a_1, d_{m1}					

Finally, if both the row and the column player have σ_M in their strategy sets ($\sigma_M \in \Sigma_1 \cap \Sigma_2$), then the game must have the following form:

	$v_1 = \sigma_M$	t_1	t_2	t_3	$\cdots$	t_n
$u_1 = \sigma_M$	h_1, h_2	c_{11}, b_1	c_{12}, b_1	c_{13}, b_1	$\cdots$	c_{1n}, b_1
s_1	a_1, d_{11}					
s_2	a_1, d_{21}					
s_3	a_1, d_{31}			G		
$\vdots$	$\vdots$					
s_m	a_1, d_{m1}					

Our technique can be applied to every one of these three forms. Moreover, in each case the subcomponent G is still an ALAGIU game, and thus we can apply the technique recursively. The reduced game R is a 2×1, 1×2, or 2×2 game (for the three cases, respectively), so it can easily be solved.

THEOREM 4. *Using the technique described in this paper, a Nash equilibrium of a finite ALAGIU game can be computed in time $O(|\Sigma_1| \cdot |\Sigma_2|)$ (that is, in time linear in the size of the game).*

Proof. The subcomponent G that the algorithm recurses on is one row and/or column smaller than the current game. Whenever G is one row smaller (which happens $O(|\Sigma_1|)$ times), after the recursion we need to compute a weighted average of the c_{ij}, which requires $O(|\Sigma_2|)$ time. Similarly, whenever G is one column smaller (which happens $O(|\Sigma_2|)$ times), after the recursion we need to compute a weighted average of the d_{ij}, which requires $O(|\Sigma_1|)$ time. ■

6. USING THE TECHNIQUE TO COMPUTE APPROXIMATE EQUILIBRIA

It is known that *approximate* Nash equilibria can be computed faster than (we know how to compute) exact Nash equilibria [17]. In this section, we study how the technique can be used to compute approximate equilibria. Specifically, if we have found that there is no subcomponent G that satisfies the condition, we can *modify* the game so that in the modified game O', there does exist a subcomponent G' that satisfies the condition. Of course, the equilibria of O and O' are, in general, not the same, so that the equilibrium that we compute for O' using the technique is not actually an equilibrium for O. However, as we will show, if O' is close to O, then the equilibrium that we compute for O' is an approximate equilibrium for O. As our notion of distance between two games (of equal dimensions), we will use the maximum difference between two payoffs that occur in the same position in the matrices: $d(O, O') = \max_{i \in \{r,c\}} \max_{\alpha,\beta} |\pi_i^O(\alpha, \beta) - \pi_i^{O'}(\alpha, \beta)|$ (where π_r is the row player's utility function and π_c is the column player's utility function). We will use *ϵ-equilibrium* as our notion of approximate equilibrium. An ϵ-equilibrium is a pair of strategies for the agents such that neither can improve its expected payoff by more than ϵ by deviating.

LEMMA 2. *If O and O' have equal dimensions, and $d(O, O') \leq \epsilon/2$, then any equilibrium for O' is an ϵ-equilibrium for O.*

PROOF. Let p_r be the row player's mixed strategy in the computed equilibrium for O', and let p_c be the column player's mixed strategy in the computed equilibrium for O'. Let p'_r be a best response to p_c *in the original game* O. Because we computed an equilibrium, we have $\pi_r^{O'}(p_r, p_c) \geq \pi_r^{O'}(p'_r, p_c)$. Moreover, because $d(O, O') \leq \epsilon/2$, we have $\pi_r^O(p_r, p_c) \geq \pi_r^{O'}(p_r, p_c) - \epsilon/2$ and $\pi_r^{O'}(p'_r, p_c) \geq \pi_r^O(p'_r, p_c) - \epsilon/2$. Hence, $\pi_r^O(p_r, p_c) \geq \pi_r^{O'}(p_r, p_c) - \epsilon/2 \geq \pi_r^{O'}(p'_r, p_c) - \epsilon/2 \geq \pi_r^O(p'_r, p_c) - \epsilon$, as desired. By symmetry, the same holds for the column player. ■

For sufficiently large ϵ, we can always find a game O' with $d(O, O') \leq \epsilon$ for which there is a subcomponent G satisfying the condition. For example, if ϵ is larger than all of the payoffs in the game, then O' can simply be the game in which all payoffs are 0. Of course, this weakens the guarantee on how much the agents can gain by deviating. Thus, the challenge is to find a game O' that is as close as possible to O while still having a subcomponent G satisfying the condition. One greedy way of finding such a game is the following: for a given column (row), take two utilities that the row (column) player can obtain in this column (row) that are very close, and change both of them (wherever they occur in the column (row)) to the average of the two. Then, check if the modified game has a subcomponent G satisfying the condition using the technique in Section 3; if not, repeat with the modified game.

7. CONCLUSIONS

In this paper, we presented a technique for reducing a game, O, to a smaller game, R, for the purpose of computing a Nash equilibrium. This is done by computing a Nash equilibrium for a subcomponent, G, of O for which a certain

condition holds. We also showed that such a subcomponent G on which to apply the technique can be found in polynomial time (if it exists), by showing that the condition that G needs to satisfy can be modeled as a Horn satisfiability problem. We showed that the technique does not extend to computing Pareto-optimal or welfare-maximizing equilibria. We presented a class of games, which we call ALAGIU (Any Lower Action Gives Identical Utility) games, for which recursive application of (special cases of) the technique is sufficient for finding a Nash equilibrium in linear time. Finally, we discussed using the technique to compute *approximate* Nash equilibria.

Future research includes extending the techniques presented here to games with more than two players (we note, however, that from the viewpoint of complexity theory, the two-player case is as hard as the n-player case [4]). It also includes testing experimentally whether the technique is helpful in finding equilibria in games for which we do not have a theoretical result (as we do for ALAGIU games), for instance on test suites of game generators (such as GAMUT [21]). Of course, the games generated will need to have some structure in order for the technique to have a chance—for example, if the payoffs are drawn independently from an interval of real numbers, then the probability that the technique can be applied is 0, because the probability of any two payoffs being the same is 0. (However, this does not prevent us from searching for approximate equilibria using the technique, as described in Section 6.) Yet another avenue is to find other, complementary game reduction techniques that can be applied when the techniques presented here cannot. Ideally, this would lead to a portfolio of efficient techniques of which at least one can always be applied, giving us a polynomial-time algorithm for computing a Nash equilibrium.

APPENDIX

In this appendix, we show that, in contrast to auctions, bargaining games typically do not have the structure of ALAGIU games, or even the structure required for the technique to be useful. Consider a dollar-splitting game in which each of two agents must simultaneously ask for a fraction of the dollar. If the fractions that the agents ask for sum to at most a dollar, they each receive their fraction; otherwise, neither agent receives anything. We note that this game *appears* to have somewhat similar structure to ALAGIU games, in the sense that if an agent asks for an amount that is too high, then it does not matter to the agent by how much the amount is too high. However, there is a subtle difference: informally, in (for example) auctions, bids are too low when the other bidder's bid is high, whereas in bargaining games such as this one, demands are too high if the other bargainer's demand is *also* high. We now show formally that the technique is in general not useful on bargaining games.

For simplicity, suppose that the agents can only ask for \$0.25, \$0.50, or \$0.75. Then the game is the following.

	\$0.25	\$0.50	\$0.75
\$0.25	$0.25, 0.25$	$0.25, 0.50$	$0.25, 0.75$
\$0.50	$0.50, 0.25$	$0.50, 0.50$	$0, 0$
\$0.75	$0.75, 0.25$	$0, 0$	$0, 0$

We will use the technique from Section 3 to show that there is no subcomponent G on which to apply the technique. Denoting by α_x agent 1's strategy of demanding x, and by β_x agent 2's strategy of demanding x, we obtain the following clauses:

1. $v(\alpha_{\$0.25}) \wedge v(\alpha_{\$0.50}) \Rightarrow v(\beta_{\$0.25}) \wedge v(\beta_{\$0.50}) \wedge v(\beta_{\$0.75})$,
2. $v(\alpha_{\$0.25}) \wedge v(\alpha_{\$0.75}) \Rightarrow v(\beta_{\$0.25}) \wedge v(\beta_{\$0.50}) \wedge v(\beta_{\$0.75})$,
3. $v(\alpha_{\$0.50}) \wedge v(\alpha_{\$0.75}) \Rightarrow v(\beta_{\$0.25}) \wedge v(\beta_{\$0.50})$,
4. $v(\beta_{\$0.25}) \wedge v(\beta_{\$0.50}) \Rightarrow v(\alpha_{\$0.25}) \wedge v(\alpha_{\$0.50}) \wedge v(\alpha_{\$0.75})$,
5. $v(\beta_{\$0.25}) \wedge v(\beta_{\$0.75}) \Rightarrow v(\alpha_{\$0.25}) \wedge v(\alpha_{\$0.50}) \wedge v(\alpha_{\$0.75})$,
6. $v(\beta_{\$0.50}) \wedge v(\beta_{\$0.75}) \Rightarrow v(\alpha_{\$0.25}) \wedge v(\alpha_{\$0.50})$.

It is straightforward to see that this set of clauses only has trivial solutions (all variables set to *true*, or at most one per player set to *true*). Hence the technique cannot be applied on this game (which also implies that the game is not an ALAGIU game).

Information-theoretic approaches to branching in search*

ABSTRACT

Deciding what to branch on at each node is a key element of search algorithms. We present four families of methods for selecting what question to branch on. They are all information-theoretically motivated to *reduce uncertainty in remaining subproblems*. In the first family, a good variable to branch on is selected based on lookahead. In real-world procurement optimization, this entropic branching method outperforms default CPLEX and strong branching. The second family combines this idea with strong branching. The third family does not use lookahead, but instead exploits features of the underlying structure of the problem. Experiments show that this family significantly outperforms the state-of-the-art branching strategy when the problem includes indicator variables as the key driver of complexity. The fourth family is about branching using carefully constructed linear inequality constraints over *sets* of variables.

search, branching heuristics, entropic branching, mixed-integer programming

1. INTRODUCTION

Search is a fundamental technique for problem solving in AI and operations research (OR). At a node of the search tree, the search algorithm poses a question, and then tries out the different answers (which correspond to the branches emanating from that node). Many different ways of deciding which question to pose (branching strategies) have been studied. In this paper we introduce a new paradigm for developing branching strategies, employing information theory as the principle that guides the development. In the context of solving integer programs, we develop four high-level families of strategies, and show that some of those families significantly improve performance over existing strategies. All four strategies aim to reduce the uncertainty in the current subtree.

The rest of this section introduces the necessary background material. Each of the following four sections introduces one high-level family of new strategies.

1.1 Integer programming

One of the most important computational problems in CS and OR is integer programming. Applications of integer programming include scheduling, routing, VLSI circuit design, and facility location [4]. Integer programming is the problem of optimizing a linear function subject to linear constraints and integrality constraints on some of the variables. While (the decision version of) MIP is $\mathcal{NP}$-complete, there are many sophisticated techniques that can solve very large instances in practice.

1.2 Strong branching

At every node of a tree search, the search algorithm has to decide what question to branch on (and thus what the children of the node will be). One commonly used method is to branch on the variable whose value is furthest from being integral [6]. In other words, the question is: "What should the value of this variable be?", and the children correspond to different answers to this question. For many problem instances, this approach is effective.

A more sophisticated approach, which is better suited for certain hard problem instances, is *strong branching* [1]. The algorithm performs a one-step lookahead for each variable that is non-integral in the LP at the node. The one-step lookahead computations solve the LP relaxation for each of the children.

2. ENTROPIC LOOKAHEAD FOR VARIABLE SELECTION

The main idea behind our approaches is to treat the fractional portion of integer-constrained variables as probabilities, indicating the probability with which we expect the variable to be greater than its current value in the optimal solution. Using this reasoning, our branching heuristic is designed to guide the search so as to remove uncertainty from the partial solution in the current search node. For any search algorithm, the beginning of the search is where there is the most uncertainty about the optimal solution to

the problem. When the search is complete, there is zero uncertainty as the optimal solution has been found. Our branching heuristic is designed to direct the search from the root node (with high uncertainty) to the optimal node (with zero uncertainty) in as direct a way as possible. We determine the variable to branch on using one-step lookahead as in strong branching. The difference is that instead of examining the objective values of potential child nodes, we examine the remaining *uncertainty* in potential child nodes, choosing a variable to branch on that yields children with the least uncertainty.

While there has been much work on developing branching heuristics, to our knowledge this is the first work that takes an information-theoretic approach to guiding the search process.

Before we describe our approach to branching in search, it will be useful to define how we can quantify the "uncertainty" of a partial solution. For this, we borrow some definitions from information theory, from which the primary contribution is the notion of *entropy*, which measures the amount of uncertainty in a random event. Given an event with two outcomes (say 0 or 1) where outcome 0 occurs with probability x, we can compute the entropy of the event from the probability of each outcome occurring:

$$e(x) = \begin{cases} -x\log_2 x - (1-x)\log_2(1-x) : 0 < x < 1 \\ 0 : x \in \{0,1\}. \end{cases}$$

Now we are ready to present our variable selection method:

ALGORITHM 1. Entropic Branching (EB)

1. *candidates* $\leftarrow \{i \mid x_i$ fractional$\}$
2. *For each* $i \in$ *candidates:*
   (a) $x_f \leftarrow x_i - \lfloor x_i \rfloor$
   (b) *Let* $\hat{x}^l$ *be solution vector of LP with* $\hat{x}^l_i \leq \lfloor x_i \rfloor$.
   (c) *Let* $\hat{x}^u$ *be solution vector of LP with* $\hat{x}^u_i \geq \lceil x_i \rceil$.
   (d) $entropy(x_i) \leftarrow \sum_{j=1}^{n}(1-x_f)e\left(\hat{x}^l_j\right) + x_f e\left(\hat{x}^u_j\right)$
3. $i^* \leftarrow \text{argmin}_{i \in candidates}\ entropy(x_i)$
4. *Return* i^*

EB is a *general* method, usable on any MIP as it does not make any assumptions about the underlying model for the problem on which it is used. EB (and SB) could be modified to perform more than one-step lookahead in a straightforward way. However, we suspect that this increased computational effort would not reduce tree size enough to be beneficial.

For illustrative purposes, there is an interesting (though not exact) analogy between our entropic lookahead method for question selection at search nodes and algorithms for decision tree induction. In most recursive decision tree induction algorithms, a question is inserted at a leaf that results in the greatest information gain. Similarly, in search, by choosing questions whose children have the least entropy, we are creating children that in a sense also result in the greatest information gain.

3. COMBINING SB AND EB

From the descriptions, it is clear that SB and EB are computed quite similarly. A natural question arises: can we develop a hybrid approach combining the strengths of both without using significantly more computational resources? In this section we answer this question in the affirmative by introducing a second family of variable selection strategies. In this family, SB and EB are hybridized in different ways. Each of these methods requires only a small amount of additional computation compared to performing *only* SB or EB (because the same lookahead with the same child LP solves is used). We classify our hybrid approaches into two categories: tie-breaking and combinational.

3.1 Tie-breaking methods

In this approach, we first perform the SB computations, but instead of simply branching on the variable with best score, we break ties using an entropy computation. Since we have already computed the LP relaxations for each branch, computing the entropy is a negligible computational cost (relative to computing the LP relaxations). In addition to breaking exact ties, we can also consider two variables having SB scores within x% of each other as tied. For a given percentage x, we refer to this method as TB(x%).

3.2 Combinational methods

We present two methods of combining information from SB and EB in order to compute a single score for a variable. The variable with the best score will then be branched on.

The first method, RANK, performs the computation for SB and EB first. (Again, these computations are performed simultaneously at little additional cost beyond doing either SB or EB alone.) Define $rank_{SB}(x_i)$ to be the rank of variable x_i in terms of its SB score (*i.e.*, the variable with the largest score would have rank 1, the variable with the second-largest score would have rank 2, and so on). Similarly, define $rank_{EB}(x_i)$ to be the rank of variable x_i in terms of its EB entropy. Then, for each variable, we let $rank(x_i) = rank_{SB}(x_i) + rank_{EB}(x_i)$ and choose the variable x_i with the smallest rank.

The second method, COMB(α,$1-\alpha$), computes a convex combination of the SB score (with weight α) and the current entropy minus the EB score (with weight $1-\alpha$). It then selects the variable with the highest final score.

3.3 Experiments on these lookahead-based branching strategies

We conducted a host of experiments with the search methods described above, both on MIPLIB and real-world procurement optimization instances. To briefly summarize, EB and SB performed comparably on the MIPLIB data, while EB was 29.5% faster on the real-world procurement optimization instances. All of our experimental results are available in a separate technical report [3].

4. ENTROPIC LOOKAHEAD-FREE VARIABLE SELECTION

In this section we introduce a third family of branching strategies, again within the entropy-based branching paradigm. This method is computationally less expensive than the methods we have presented thus far because it does not use lookahead. However, it does require an advanced knowledge of the structure of the problem.

The problem with which we experiment is motivated by a real-world electronic commerce application: a combinatorial procurement auction (aka. reverse auction) where the buyer specifies the maximum number of winning suppliers [2, 5].

DEFINITION 1. *(Combinatorial procurement auction with*

maximum winners constraint)
Let $\mathcal{M} = \{1, \ldots, m\}$ be the m goods that the buyer wishes to procure (the buyer wants at least one unit of each good). Let $\mathcal{S} = \{1, \ldots, s\}$ be the s suppliers participating in the procurement and let $\mathcal{B} = \{B_1, \ldots, B_n\}$ be the bids, where $B_i = \langle G_i, s_i, p_i \rangle$ indicates that supplier s_i can supply the bundle of goods $G_i \subseteq \mathcal{M}$ at price p_i. Finally, the buyer indicates the maximum number of winners, k. The winner determination problem is to identify the winning bids so as to minimize the buyer's cost subject to the constraints that the buyer's demand is satisfied and that the maximum number of winners constraint is satisfied.

We can very naturally formulate the above generalized winner determination problem as a MIP:

$$\begin{array}{lll} \text{minimize} & \sum_{i=1}^{n} p_i x_i & \\ \text{such that} & \sum_{i \mid j \in G_i} x_i \geq 1 & j \in \{1, \ldots m\} \\ & \sum_{i \mid s_i = j} x_i - m y_j \leq 0 & j \in \{1, \ldots, s\} \\ & \sum_{j=1}^{s} y_j - k \leq 0 & \\ & x_i \in \{0, 1\} & i \in \{1, \ldots, n\} \\ & y_j \in \{0, 1\} & j \in \{1, \ldots, s\} \end{array}$$

This problem is $\mathcal{NP}$-complete, even if the bids are on single items only [5]. The formulation is typical of a common class of problems in which binary "indicator" variables—the y_j variables in the formulation above—are used to model logical connectives [4] (for example an implication that if an indicator is zero, then each of a set of other variables has to be zero). Constraints that state that at most (or exactly) k variables from a set of variables can be nonzero are an important special case. Typically, the LP relaxation gives poor approximate values for the indicator variables, and as we show, the branching method that we propose helps significantly to address this problem.

4.1 Branching strategy

The hardness in this problem comes primarily from determining the winning set of suppliers. In terms of the above MIP, we need to determine the y_j values. The main idea in our branching strategy for this problem is to branch on y_j values that correspond to suppliers about which we are most uncertain. But rather than deriving this uncertainty from the variable y_j (for which the LP gives very inaccurate values), we derive it from the variables corresponding to supplier $j's$ bids. The branching strategy works as follows. For each supplier j where $y_j \notin \{0, 1\}$, compute

$$entropy(j) = \sum_{i \mid s_i = j} e(x_i)$$

and branch on the variable $y_{j'}$ where

$$j' = \text{argmin}_j \; entropy(j).$$

This strategy does not use lookahead: it only uses the LP values of the current search node. We call this branching strategy *Indicator Entropic Branching (IEB)*. Our experimental results (available in a longer version of this paper [3]) for this problem indicate that IEB significantly outperforms the state-of-the-art branching strategy.

5. ENTROPIC LOOKAHEAD FOR MULTI-VARIABLE BRANCHES

In this section we introduce a fourth family of methods for determining good questions to branch on. In EB, we performed a one-step lookahead for each non-integral variable. Here, we generalize entropic lookahead beyond branching on variables. It is known that in integer programming one can branch on the sum of the values of a *set* of variables. For example, if the LP relaxation at the current search node has $x_i = 0.2$ and $x_j = 0.6$, we could set one branch to be $x_i + x_j \leq 0$ and the other branch to be $x_i + x_j \geq 1$. In general, given a set $\mathcal{X}$ of variables and the current LP relaxation solution $\hat{x}$, we can let $k = \lfloor \sum_{i \in \mathcal{X}} \hat{x}_i \rfloor$ and we can generate the following two branches:

$$\sum_{i \in \mathcal{X}} x_i \leq k \quad \text{and} \quad \sum_{i \in \mathcal{X}} x_i \geq k + 1.$$

No other value of k is worth considering; any other integer value would cause one child to be exactly the same as the node. Then, instead of branching on the variable with the smallest amount of entropy in its child nodes, we select the *set* of variables for branching that results in the smallest amount of entropy in the two child nodes. In step 2.d of EB, we weighted the entropy of each child by the probability that we expect the optimal solution to occur in each child. In the multi-variable case, we still perform this weighting, but it is more complicated since the probability of each branch depends on several variables.

Preliminary experimental results indicate that this branching scheme is successful at reducing the size of the search tree, but the extra time at each node makes it not worth it.

6. CONCLUSIONS

We introduced a new paradigm for branch selection in search based on an information-theoretic approach. In the beginning of a search, there is the most uncertainty about the optimal solution. When the search is complete, there is zero uncertainty. Using this observation, we developed four families of methods for selecting what question to branch on at a search node so as to reduce the amount of uncertainty in the search process. All four of our families of methods are information-theoretically motivated to reduce remaining entropy.

ABSTRACT

This paper presents complexity results for model checking concurrent programs against temporal-epistemic formulae. We apply these results to evaluate the complexity of verifying programs by means of two model checkers for multi-agent systems: MCMAS and Verics.

General Terms

Algorithms; Theory; Verification

Keywords

Model checking multi-agent systems; Complexity

1. PRELIMINARIES

1.1 Temporal logics and model checking

The language of Computational Tree Logic (CTL, [7, 4]) is defined over a set of atomic formulae $AP = \{p, q, \dots\}$ as follows:

$$\varphi ::= p | \neg\varphi | \varphi \vee \varphi | EX\varphi | E[\varphi U \psi] | EG\varphi.$$

Other temporal operators to express eventuality and universality can be derived in standard way. We refer to [4] for more details.

CTL formulae are interpreted in *Kripke models*. A Kripke model M for CTL is a tuple $M = (S, R, V, I)$ where S is a set of states, $R \subseteq S \times S$ is a serial transition relation (the *temporal* relation), $V : S \rightarrow 2^{AP}$ is an evaluation function, and $I \subseteq S$ is a set of initial states. *Satisfiability* of a CTL formula φ at a state $s \in S$ in a given CTL model M is defined in a standard way, see [4] for more details.

Model checking is the problem of establishing whether or not a formula φ is satisfied on a given model M. While this check may be defined for a model M of any logic, traditionally the problem of model checking has been investigated mainly for temporal logics. In practical instances, when using model checkers, states and relations in temporal models are not listed *explicitly*. Instead, a *compact description* is usually given for a model M. Various techniques are available to give these specifications, a popular being *concurrent programs* [6]. Concurrent programs offer a suitable framework to investigate the computational complexity of model checking when compact representations are used because, as exemplified in Section 3, various techniques can be reduced as accepting concurrent programs as input.

Formally, a program in this setting is a tuple $D =< AP, AC, S, \ , s^0, L >$, where AP is a set of atomic propositions, AC is a set of actions, S is a set of states, $\ : S \times AC \rightarrow S$ is a transition function, s^0 is an initial state, and $L : S \rightarrow 2^{AP}$ is a valuation function. Given n programs $D_i =< AP_i, AC_i, S_i, \ _i, s_i^0, L_i >$ ($i \in \{1, \dots, n\}$), a concurrent program $D_C = < AP_C, AC_C, S_C, \ _C, s_C^0, L_C >$ is defined as the parallel composition of the n programs D_i, as follows: $AP_C = \cup_{1 \leq i \leq n} AP_i$; $AC_C = \cup_{1 \leq i \leq n} AC_i$; $S_C = \prod_{1 \leq i \leq n} S_i$; $(s, a, s') \in \ _C$ iff (i) $\forall 1 \leq i \leq n$, if $a \in AC_i$, then $(s[i], a, s'[i]) \in \ _i$, where $s[i]$ is the i-th component of a state $s \in S$; (ii) if $a \notin AC_i$, then $s[i] = s'[i]$; $L_C(s) = \cup_i L_i(s[i])$ (in the remainder, we will drop the subscript C when this is clear from the context). CTL formulae can be interpreted on a (concurrent) program D by using the standard Kripke semantics for CTL formulae. By slight abuse of notation, we will sometimes refer to the programs D_i and to D with the term "Kripke models".

Traditionally, the complexity of temporal logics model checking has been investigated assuming that models are given explicitly. Following this approach, the complexity is given as a function of the size of the model and of the formula being checked. In the case of CTL, the problem of model checking is P-complete [3]. Instead, the complexity of model checking concurrent programs against CTL specifications is investigated in [6] where it is shown that model checking is a PSPACE-complete problem.

1.2 CTLK

CTLK is an extension of CTL with epistemic operators $K_i, i \in \{i, \dots, n\}$ [5]. The formula $K_i\varphi$ expresses the fact that agent i *knows* φ. **CTLK** formulae may be interpreted in a Kripke model $M = (W, R_t, \sim_1, \dots, \sim_n, V)$ where W is a set of states, $R_t \subseteq S \times S$ is a serial transition relation (the *temporal* relation), $\sim_i \subseteq S \times S$ are equivalence relations (the *epistemic* relations), and $V : S \rightarrow 2^{AP}$ is an evaluation function for a given set AP of atomic propositions. Formulae are interpreted in a standard way, by extending the interpretation of CTL formulae with the following:

$$M, w \models K_i\varphi \quad \text{iff} \quad \text{for all } w' \in W, w \sim_i w' \text{ implies } M, w' \models \varphi,$$

CTLK formulae can be interpreted in concurrent programs as well: the temporal operators of **CTLK** are interpreted as in [6], while epistemic operators are evaluated by defining epistemic accessibility relations based on the equality of the components of the

states of a concurrent program (a similar approach can be found in [5]).

2. COMPLEXITY OF MODEL CHECKING CONCURRENT PROGRAMS

In this section we present a proof for the PSPACE-completeness of the problem of model checking concurrent programs against **CTLK** specifications. The following two lemmas will be used:

LEMMA 1. *Given a Kripke model $M = (S, R, V, I)$ for CTL, a state $s \in S$, and a formula φ, $M, s \models EG\varphi$ iff there exists a sequence of states π starting from s of length $|\pi| \geq |M|$ s.t. $M, \pi_i \models \varphi$ for all $0 \leq i \leq |M|$.*

LEMMA 2. *Given a Kripke model $M = (S, R, V, I)$ for CTL, a state $s \in S$, and two formulae φ and ψ, $M, s \models E[\varphi U \psi]$ iff there exists a sequence of states π starting from s s.t. $M, \pi_i \models \psi$ for some $i \leq |M|$, and $M, \pi_j \models \varphi$ for all $0 \leq j < i$.*

THEOREM 1. *Model checking concurrent programs against* **CTLK** *specifications is a PSPACE-complete problem.*

PROOF. Given a **CTLK** formula and n programs D_i defining a concurrent program D , we define a deterministic, polynomially-space bounded Turing machine T that halts in an accepting state iff $\neg\varphi$ is satisfiable in D (i.e., iff there exists a state $s \in S$ such that $D, s \models \neg\varphi$). Based on this, we conclude that the problem of model checking is in co-PSPACE. As deterministic complexity classes are closed under complement, we conclude that the problem is PSPACE-complete (the lower bound being given by the complexity of model checking CTL in concurrent programs). T is a multi-string Turing machine whose inputs are the n programs D_i and the formula φ. T operates "inductively" on the structure of the formula φ (see also [2] for similar approaches), by calling other machines ("sub-machines") dealing with a particular logical operator only. The input of T includes the states of the program S_i ($1 \leq i \leq n$), the transition relations, the evaluation functions and all the other input parameters of each $_i$. This information can be stored on a single input tape, separated by appropriate delimiters, together with the formula φ. T returns "yes" iff there exists a state $s \in S$ such that $D, s \models \neg\varphi$. The machine T iterates over the set of states $s = (s_1, \ldots, s_n)$ and checks whether or not $\neg\varphi$ holds in one of these. If a state is found such that $D, s \models \neg\varphi$, then the machine halts in a "yes" state; if the machine loops over all the states without finding a state satisfying $\neg\varphi$, then T halts in a "no" state.

The REACHABILITY algorithm [9] can be used here to check reachability from initial states; notice that only a polynomial amount of space is needed to store states, as they are the product of states of D_i.

A "main" procedure SATISFIABLE can be defined, which operates recursively on the structure of the formula by calling one of the machines described below. Each machine accepts a state s and a formula, and returns either "NO" (the formula is false at s) or "YES" (the formula is true at s). Notice that each machine can call any of the other machines. The following is a description of the formula-specific machines that may be called by SATISFIABLE:

- The machine T_p for atomic formulae simply checks whether or not a `state` is in L(`state`), where the evaluation L is obtained from the evaluations for each program in the input string; if the proposition is true at `state`, then T_p returns YES, otherwise it returns NO.
- The machine $T_\neg$ for formulae of the form $\psi = \neg\varphi$ calls the appropriate machine for φ and returns the opposite value.
- The machine $T_\vee$ for the disjunction $\psi = \psi' \vee \psi''$ first calls the machine for ψ'. If the result is yes, it outputs yes, otherwise it outputs the result of the machine for ψ''.
- The machine T_{EX} accepts a formula φ and a state as input; the machine iterates over the set of states and for each state it checks whether the state is reachable from the input state; if this is the case, then T_{EX} checks whether or not φ is satisfied. If T_{EX} finds such a state, then it halts in a YES state; otherwise, if no reachable state satisfying φ can be found T_{EX} terminates in a NO state. Notice that this machine uses a polynomial amount of space: the space required to store the value of the state.
- The machine T_{EU} for formulae of the form $\psi = E[\varphi' U \psi'']$ is as follows:

```
T_EU(φ,  ,state) {
 state2 = (1, 1, ..., 1);
 repeat
  if SATISFIABLE(  ,state2) then
   if ( state == state2) return YES;
   else
    if ( PATH(state,state2,φ,N) ) then
     return YES;
    else
     move to next state2;
    end if;
   end if;
  else
   move to next state2;
  end if
 until last state2;
 return NO;
}
```

  The machine T_{EU} accepts two formulae and a state. The machine checks whether ψ holds in `state2` and whether `state` and `state2` are the same state. If this is the case, then the machine halts in a YES state. Otherwise, the machine checks whether or not there is a sequence of states from `state` to `state2` such that φ holds along the sequence. This check is performed by the procedure PATH(`state`,`state2`,φ,N), which returns YES if there is such a path, of length at most 2^N. By Lemma 2, we take N to be the logarithm of the size of the model. A recursive algorithm to solve PATH is presented in [9]; this algorithm employs at most space proportional to N, and it can be extended by adding a simple check for the satisfiability of φ. As there can be at most $|\varphi|$ checks, PATH uses at most $O(n \cdot |\{D_i\}_{i\in\{1,\ldots,n\}}| \cdot |\varphi|)$ space (i.e. it operates in PSPACE).
- Based on Lemma 1, a non-deterministic machine NT_{EG} can be defined to guess a sequence of states of length greater than $|\{D_i\}_{i\in\{1,\ldots,n\}}|$ in which φ holds. When (and if) such a sequence is found, the machine returns yes (notice that this machine uses a polynomial amount of space and always halts). As NPSPACE=PSPACE [9], it is possible to build a deterministic machine T_{EG} in PSPACE that returns yes iff there exists a sequence of states of length greater than $|\{D_i\}_{i\in\{1,\ldots,n\}}|$ in which φ holds.
- The machine T_K accepts a formula φ, an index i, and and a state as input; this machine operates similarly to T_{EX}, but uses epistemic relations instead of temporal relations.

Each of the machines above uses at most a polynomial amount of space, and there are at most $|\varphi|$ calls to these machines in each run of T. Thus, T uses a polynomial amount of space. □

This proof differs from the proof of PSPACE-completeness for model checking concurrent programs against CTL specifications presented in [6]. The authors of [6] investigate the complexity of various automata and apply their results to the verification of branching time logics. This technique cannot be easily extended to the verification of temporal *and* epistemic modalities. Thus, the proof above provides an alternative proof of the upper bounds for model checking CTL in concurrent programs, which can be easily extended to CTLK.

3. APPLICATIONS

3.1 The complexity of model checking MCMAS programs

MCMAS [11] is a symbolic model checker for interpreted systems. Interpreted systems [5] provide a semantics for temporal and epistemic operators, based on a system of *agents*. Each agent is characterised by a set of local states, by a set of actions, by a protocol specifying the actions allowed in each local state, and by an evolution function for the local states. MCMAS accepts as input a description of an interpreted system and builds a *symbolic* representation of the model by using Ordered Binary Decision Diagrams. We refer to [5, 10, 11] for more details. An interpreted systems described in MCMAS can be reduced to a concurrent program: each agent can be associated with a program $D_i =< AP_i, AC_i, S_i, \ _i, s_i^0, L_i >$, where AC_i is the set of actions for agent i, S_i is the set of local states for agent i, and the evolution function $\ _i$ is the one provided for the agent.

Conversely, the problem of model checking a formula φ in the parallel composition of n programs $D_i =< AP_i, AC_i, S_i, \ _i, s_i^0, L_i >$ can be reduced to an MCMAS program. Indeed, it suffices to introduce an agent for each program, whose local states are S_i and whose actions are AC_i. The transition conditions for the agent can be taken to be $\ _i$, augmented with the condition that a transition between two local states is enabled if all the agents including the same action in AC_i perform the transition labelled with the particular action.

Therefore, we conclude that the problem of model checking MCMAS programs is a P-complete problem.

It is worth noticing that the actual implementation of MCMAS requires, in the worst case, an exponential space to perform verification. Indeed, MCMAS uses OBDDs, and it is known [1] that for certain problems OBDDs may have a size which is exponential in the number of variables used, irrespective of the ordering of variables chosen.

3.2 The complexity of model checking Verics programs

Verics [8] is a tool for the verification of various types of timed automata and for the verification of **CTLK** properties in multi-agent systems. In this section we consider only the complexity of verification of **CTLK** properties in Verics using un-timed automata.

A multi-agent system is described in Verics by means of a network of (un-timed) automata: each agent is represented as an automaton, whose states correspond to local states of the agent. In this formalism a single set of action is present, and automata synchronise over common actions.

The reduction from Verics code to concurrent programs is straightforward: each automaton is a program D_i and no changes are required for the parallel composition, and similarly a concurrent program can be seen as a network of automata. Thus, we conclude that the problem of model checking un-timed Verics programs is PSPACE-complete.

Notice that the actual implementation of Verics performs verification by reducing the problem to a satisfiability problem for propositional formulae. Similarly to MCMAS, this reduction may lead to exponential time and space requirements in the worst case.

ABSTRACT

We address the problem of navigating from an initial node to a goal node by a group of agents in an unknown physical environment. In such environments mobile agents must physically move around to discover the existence of nodes and edges. We assume that agents communicate by exchanging messages about their discoveries, their current locations and their intended plans. We also assume that an agent can only communicate with a predefined set of *neighboring* agents. A distributed algorithm, which is run independently by each agent, is presented. Given the current knowledge of the agent about the environment and the positions and intentions of other agents, the algorithm instructs the agent where to go next. An experimental evaluation of the algorithm is presented, with constrained and liberal neighborhood schemes. Results show that it is more beneficial to have a constrained neighborhood scheme because with this scheme the distributed intelligent behavior of agents generates a spread of knowledge throughout the environment more efficiently. Agents reach the goal node fast and the length of the path that they find is very close to that of the optimal path.

1. INTRODUCTION

We address the problem of navigation from an initial node to a goal node in an unknown physical environment, by a group of agents. To abstract away from problems of real robots and obstacle avoidance [2, 3] and to concentrate on navigation, we use the notion of a partially known physical graph [4]. The environment is represented by a planer graph where nodes are physical points and a weight of an edge is the Euclidean distance between the two nodes it connects. In such environments, only when an agent physically visits a node, the weights of outgoing edges and the adjacent nodes are revealed. Therefore, agents must move around the graph in order to find information about other nodes and about weights of edges.

1.1 Navigation versus optimal path finding

Let us start by making a distinction between navigating to a node and finding the optimal path from an initial node to a goal node. When navigating, the task is to reach the goal node as soon as possible. At every step the task of the navigator is to find a path from its current node to the goal node. Once the navigator reaches the goal, the task is accomplished. Many times, the navigator did not travel via the shortest path between the initial and goal node and does not even know this shortest path upon arriving to the goal node. Much of the literature on navigation deals with physical mobile robots that move in a real environment. The published research usually focuses on the issue of assisting the robot to recognize physical objects in its environment. We refer the reader to [2, 3] which contain extensive surveys of various approaches and state of the art techniques of robot navigation . The present work is different, as it represents the physical world by a discrete abstract graph which is initially unknown.

Finding an optimal (shortest) path is different than navigation. Here, even if we have some path from the initial node to the goal node, we must perform a systematic search on the graph in order to guarantee the optimality of the path. A common method for finding the shortest path in graphs is to use the A* algorithm [5]. A* keeps an *Open-list* of generated nodes and expands them in a best-first order according to a cost function defined by $f(n) = g(n) + h(n)$. In standard A*, $g(n)$ is the distance from the initial node to node n, and $h(n)$ is an *admissible* heuristic estimate of the cost of the path from node n to the goal node. $h(n)$ is *admissible* if it is always a lower bound on actual cost from node n to the goal (e.g. Euclidean distance between the two nodes in a physical environment).

Usually, A* (or its variants, e.g., IDA*) are applied to exponential combinatoric problems. In such domains, an A* expansion cycle is carried out in constant time as it takes a constant amount of time to retrieve a node from the open-list and to generate all its neighbors by applying domain-specific operators to the expanded node. Therefore, the time complexity of A* is usually measured in terms of the number of generated nodes. This is not the case in physical graphs where an agent needs to physically travel to a node in order to explore it. The Physical A* algorithm (PHA*) and its multi-agent version MAPHA* [4] find the optimal path between two points in a partially known real physical environment with either one or many mobile agents. These algorithms modify the A* algorithm to work on graphs with physical characteristics where agents need to physically travel to a node in order to learn about its neighbors. The focus of these algorithms is to minimize the travel effort of the agents. In MAPHA*, a complete sharing of knowledge between agents is assumed. This could be achieved by a supervisor agent coordinating all agents or by a global database which holds the entire knowledge. A reminiscent approach is the D* algorithm family (e.g., D*-lite) [6] where a mobile robot needs to find the shortest path in an environment that was completely known but changes dynamically over time.

The present paper addresses the navigation problem in the partially known physical environments by a distributed group of agents. Agents are autonomous entities, processing information received from other agents and making their own navigational decisions. The task is to reach the goal node as soon as possible. When the first agent reaches the goal the task is achieved and the agents terminate. Agents explore the graph by moving on it, sharing their discovered nodes and edges as well as their current position and running a distributed navigation algorithm (presented below) to arrive at the goal node. Each agent runs the same algorithm but uses its own partial knowledge of the environment. A distributed algorithm is in general more fault tolerant and is expected to reduce communication, compared to a centralized algorithm [8]. A distributed navigation algorithm is naturally scalable to a large number of navigators.

1.2 Communication models

There are many models of communication in multi-agent systems that allow agents to cooperate and coordinate their decision making. The most trivial model is a complete knowledge sharing where any new discovery of an agent is immediately shared with all the other agents. Other models restrict the level of communication.

The present study focuses on a natural and realistic model for the communication among agents where each agent can only communicate with a subset of the agents - its *neighboring agents* (or *neighbors* in short). The *neighbor* relation is symmetric. We assume that agents can communicate with one another only if the distance between them is below a given radius R. We call this the*radius constraint*. To satisfy these two constraints, we enforce neighboring agents to stay close to one another at all times in order to be able to communicate. Neighboring agents exchange relevant information, such as their current location and the length of the outgoing edges. In each step, agents receive messages from other agents, decide whether and where to move, and send updates to their neighboring agents.

We use two performance measures - the path traveled by the first agent arriving at the goal node and the quality of the best path found compared to the optimal path. Our agents are designed to reach the goal as fast as possible and to minimize their travel effort. This corresponds to the first measure. On the other hand, during navigation they also explore many nodes and the shortest path that will be known to them at the end might improve. This corresponds to the second measure. These two measures might be in conflict with each other. This is known as the exploration versus exploitation conflict. In this paper we show that even though we are mostly concerned with the travel effort measure, a good balance between the two measures can be achieved. Indeed, experimental results show that when the algorithm terminates the quality of the best known path is very close to the optimal path.

The DisNAV algorithm was implemented on a distributed asynchronous simulator. Experiments were run on different graphs and different number of agents and neighborhood schemes. Results show that the proposed distributed navigation algorithm generates an efficient spread of knowledge throughout the environment. Agents reach the goal node very fast and the length of the path that they find is close to that of the optimal path. We have considered three different communication schemes and show that using a constrained scheme on the defined neighborhood produces better results than using a more liberal scheme.

2. NEIGHBORHOOD SCHEMES

The main motivation of the present study is to look at multi-agent navigation as a distributed problem, where agents communicate only with their neighboring agents. Given an agent A, its *neighborhood* N is a subset of the agents. A must coordinate its moves with all the agents in N. We have defined three different neighborhood schemes: *static neighborhood*, *unconstrained dynamic neighborhood*, and *constrained dynamic neighborhood*. In all these schemes, we have defined a radius parameter R such that agents can only receive messages sent by an agent distanced away no more than R units. We call this the *radius constraint*. However, the schemes differ in the definition of neighborhood. Extreme values for the radius R significantly influence the entire behavior of the multi agent system. With large R, the radius constraint becomes meaningless and the communication scheme is similar to the full knowledge sharing. With small R, moves are limited and we get close to the behavior of a single agent. Thus, the value for R should be carefully chosen.

2.1 Static neighborhood

In order to simplify the definition of the distributed navigation problem, we have defined the notion of static neighborhood which enable an easy definition of a static connected communication network of agents. In a static neighborhood each agent is assigned a set of neighbors and this set is fixed throughout the entire navigation. An agent has to coordinate its moves with all its neighbors therefore must keep the radius constraint with all them. The rationale behind this restriction is that new discoveries of an agent will always be propagated to its neighbors. Static neighborhoods can cause some restriction on agent moves since the *radius constraint* may prevent agents from making some of their possible moves, if they move too far from their neighbors. Note that in the static neighborhood scheme an agent does

not communicate with an agent which is not its neighbor even if it is located nearby.

2.2 Constrained dynamic neighborhood

In this scheme, an agent needs to coordinate its moves with K agents within the radius R. However, unlike the *static neighborhood* version where the set of neighboring agents is predefined, here, any K agents suffice. The only requirement is to keep the *radius constraint* with any K agents whose identities can change over time. Agents broadcast their move proposal and wait for any K approvals from agents within the radius R.

2.3 Unconstrained dynamic neighborhood

This is the most liberal scheme. Here, when an agent chooses a move, it broadcasts its decision and performs that move without the need to coordinate it with anyone. Of course, only agents within the radius R actually receive its move decision and other messages. The pitfall of this scheme is that an agent can travel by itself to a distant location where it cannot communicate with any other agent. This will weaken the knowledge sharing of the entire multi-agent system as this agent becomes isolated.

3. DISTRIBUTED NAVIGATION

We now turn to describe the DisNAV algorithm, focusing first on the main case of *static neighborhood*. We then present the modifications that are needed for the *constrained dynamic neighborhood* and the *unconstrained dynamic neighborhood* cases.

3.1 DisNAV for static neighborhood

The DisNAV algorithm is run by each agent independently. Agents communicate with their neighbors, exchanging messages which contain information such as their current position, node discoveries and move proposals. Agent navigation is based on its known information which is gathered by its own discoveries as well by information received in messages from other agents. Agents keep their local information in three main data structures: *KnownGraph*, *AgentView* and *Open-list*, all are described below.

KnownGraph - The *KnownGraph* is the part of the world currently known to the agent. *KnownGraph* is a subgraph of the entire environment modeled as a weighted graph. We assume that all agents start from the same initial node. Since agents send each node discovery to their neighbors (as will be described below) the *KnownGraph* will always be a connected graph. Each agent uses its own *KnownGraph* to calculate distances between nodes during the execution of the algorithm. In addition, when the algorithm terminates, *KnownGraph* is used for calculating the best path between the initial node and the goal node.

AgentView - The *AgentView* data structure, contains important information about each of the neighbors of the agent.
AgentView is updated by messages received from the neighbors. In particular, *AgentView* of an agent contains the current position and the current target or the move proposals of each of its neighbors.

Open-list - Each agent maintains a local *Open-list* of nodes which are in the frontier of its *KnownGraph*. Nodes are inserted to the *Open-list* when they are first known to the agent either by its own discovery or by a message from one of its neighbors. Similarly, a node is being deleted from the *Open-list* when the agent (or one of its neighboring agents that has just sent him a message) physically visits it and discovers all its neighbors (which are themselves inserted to the *Open-list*). The *Open-list* is maintained as a priority queue according to an intelligent cost function described below. Agents choose the best node on the *Open-list* and propose to physically travel to it.

We now turn to present the details of the DisNAV algorithm. The pseudo-code for the algorithm is given in Figure 1. The navigation is done as follows. First, an agent picks a *target* node from its *Open-list* and proposes a *move* to that target. Each proposed move should be approved by all neighbors before its actual performance. When the move is approved by the neighbors, the agent physically navigates from its current node to the target node.

The main procedure run by each agent is ***DisNAV*** which is a message driven distributed algorithm. In each *cycle* of DisNAV an agent reads all the received messages (lines 5-6) and decides about a proper resulting operation. The resulting operation can be a message sending (e.g. NODE, APPROVAL etc.) and can also include a performance of an approved move. An agent running the algorithm can be in one of several possible logical states. Different events can change the state of an agent. The initial state of an agent is READY. Each agent runs a loop, which ends when the agent enters the TERMINATED state.

The basic state is the READY state. In this state the agent selects a *target* node from the *Open-list*. The *target* is chosen to be the best node on it its *Open-list* according to the cost function described below. Then, the agent sends an *OK?* message to its neighbors in which it proposes to move to this target and asks for their approval (***proposeMove***, lines 51-54). The state of the agent is now changed to WAIT_FOR_APPROVAL.

Note that we ensure that targets that break the *radius constraint* between an agent and the current location of its neighbors will not be selected by giving them a cost of infinity. Therefore, sometimes agents choose targets not in the front of the *Open-list* and might even decide to remain idle.

Receiving an OK? message (lines 19-23), an agent has two choices. It can either approve the proposal, replying with an APPROVAL message or reject the move using a NOGOOD message. We say that move proposals of two neighboring agents are in *conflict* if performing them both at the same time will break the *radius constraint* between them. Such a conflict is resolved in favor of the move with the lower cost. In such a case, a NOGOOD message is sent only by the agent with the better move. When that proposing agent receives a NOGOOD (lines 29-31), the state returns to READY and the move proposal is canceled.

When the proposing agent receives APPROVALs from all its neighbors (lines 25-28), its state changes to IN_TRANSIT. In this case the target node is removed from the *Open-list*, and the agent starts performing the *move* to the target. A *move* includes a sequence of navigation *steps*. At each *step* the agent chooses the neighbor w that minimizes the sum of the distances from the current node v to w and from w to the target node t. This cost function is called A*DFS in [4] since it uses a cost function which is similar to that of A*, i.e., $f(n) = g(n) + h(n)$. Note, that this cost function is used here locally to find a path from the current node to the target node.

Upon agent arrival to a node (line 37), the procedure ***uponArrivalToNode*** (lines 40-50) is called. If it is the goal node, the agent changes its state to TERMINATED and sends a TERMINATE message. Each agent receiving such a message (lines 32-34), sends it to its neighbors and changes the state to TERMINATED. Otherwise, if the node is not the goal, the agent learns about this node's neighbors and sends a NODE message, to inform its neighboring agents about its current position and about the node's neighbors. If the current node is in the *Open-list* this node is *expanded*, i.e., it is removed from the *Open-list*, and the node's neighbors which where not visited yet, are inserted to the *Open-list*. If the current node is the target node (lines 48-50) the state returns to READY and the agent considers another move proposal.

Agent receiving a NODE message (lines 8-18) updates its *AgentView* with the sender location and updates its *KnownGraph* with the new nodes and edges discovered. Of course, in case the node is in the *Open-list*, it is immediately expanded by the agent without the need for the agent to physically visit that node. This is the main contribution of data sharing among neighboring agents.

3.2 Unconstrained dynamic neighborhood

The unconstrained dynamic neighborhood scheme is a simplified variation of the static neighborhood algorithm. When an agent decides on its target (the best node in its *Open-list*), it broadcasts a MOVE message declaring it. The agent changes its state to IN_TRANSIT and removes the target from the *Open-list*. This step replaces the sending of an OK? move proposal and waiting for APPROVAL and NOGOOD messages as done in the static neighborhood (or the constrained dynamic neighborhood). The OK?, APPROVAL and NOGOOD messages, as well as the state WAIT_FOR_APPROVAL, become irrelevant in this scheme.

3.3 Constrained dynamic neighborhood

In this scheme, each agent has a dynamic set of *current neighbors* all of them are within the radius R. When all agents start at the same point, the set initially includes all the other agents. Otherwise, the set is modified according to agent positions as they are received in NODE messages. During navigation, agents are added and removed from the set according to the moves performed. A *neighbor* in this context is therefore a member of the *current neighbors* set. The changes that the constrained dynamic neighborhood algorithm imposes on the static neighborhood version are the following:

1. Agents propose only moves which are consistent with all their *current neighbors* locations.

2. Agents wait for k APPROVALs. When they are received, the agent broadcasts a MOVE message declaring its target, changes its state to IN_TRANSIT and removes the target from the *Open-list*.

3. If an OK? is received from an agent which is not a *neighbor* but within the radius R, send an APPROVAL and add the agent to the set of *current neighbors*.

4. If an APPROVAL is received from an agent which is not a *neighbor* and if the move proposal is preformed then add the agent to the *current neighbors*.

```
DisNAV:
1.  state ← READY; node ← initial; proposal ← null
2.  expand node
3.  update KnownGraph and Open-list
4.  while(state ≠ TERMINATED)
5.    while(not msgQueue.isEmpty)
6.      msg ← msgQueue.getFirst
7.      switch msg.type
8.        NODE:
9.          update KnownGraph, AgentView
9a.           and Open-list
10.         if(state=READY)
11.           proposeMove
12.         else if(state=WAIT_FOR_APPROVAL)
13.           if(move proposal is redundant)
14.             state ← READY
15.             ignore proposal
16.           else if(move proposal should be updated)
17.             update proposal
18.             send(OK?,neighbors)
19.       OK?:
20.         if(self already sent a better conflicting
20a.            move proposal)
21.           send(NOGOOD,sender)
22.         else
23.           send(APPROVAL,sender)
24.       APPROVAL:
25.         if(state=WAIT_FOR_APPROVAL
25a.           and all approved)
26.           state ← IN_TRANSIT
27.           target ← proposal
28.           remove target from Open-list
29.       NOGOOD:
30.         if(state=WAIT_FOR_APPROVAL)
31.           state ← READY
32.       TERMINATE:
33.         state ← TERMINATED
34.         send(TERMINATE,neighbors)
35.   if(state=IN_TRANSIT)
36.     move to a neighboring node, navigating to target
37.     uponArrivalToNode
38.   else if(state=READY and proposal=null)
39.     proposeMove

uponArrivalToNode:
40. if(node=goal)
41.   state ← TERMINATED
42.   send(TERMINATE,neighbors)
43. else
44.   discover node neighbors
45.   send(NODE,neighbors)
46.   if(node in Open-list or node=target)
47.     update KnownGraph and Open-list
48.     if(node=target)
49.       state ← READY
50.       proposeMove

proposeMove:
51. proposal ← get best node from Open-list
52. if(proposal is worthwhile)
53.   send(OK?,neighbors)
54.   state ← WAIT_FOR_APPROVAL
```

5. If a conflicting MOVE is received from a *neighbor*, remove the agent from the *current neighbors*.

4. COST FUNCTION HEURISTICS

We now turn to describe the cost function for choosing a target node. Each agent running the DisNAV algorithm, owns a local *Open-list* which includes nodes discovered during navigation, as well as nodes discovered by neighboring agents. The nodes are chosen as targets in a best-first order according to a cost function[1].

The ordinary cost function used by A* and other search algorithms for finding optimal paths is $f(n) = g(n) + h(n)$, where $g(n)$ is the distance traveled from the initial node to the node n, and $h(n)$ is a heuristic estimate of the cost of traveling from node n to the goal node. A reminiscent algorithm is Real-Time-A* (RTA*) [7]. RTA* selects the node with the best cost in the *Open-list*. The problem solver then moves one step along the path to that node, and the search continues from the new state of the problem solver. The cost function for an arbitrary node n in RTA* is also $f(n) = g(n) + h(n)$ but in this case $g(n)$ is an estimation of the distance of node n from the current node and not from the initial node.

DisNAV deals with physical graphs where nodes can be expanded only after an agent physically visits them and learns about their locations and outgoing edges. This is completely different from RTA* which assumes that a node can be expanded in the computer's memory without an agent having to physically visit that node. However, the cost function used in DisNAV treats $g(n)$ similarly to RTA* and is measured according to the current location of the agent. Thus, at every step the cost values of the entire set of nodes in the *Open-list* are changed so that g will reflect the current location. The best node in the open list according to the cost function is selected and becomes the target node of that agent.

A good cost function for our purpose needs to combine both navigation and exploration. In other words, we want to get to the goal node as fast as possible but also to learn about new regions of the graph in order to provide useful information to other agents. For this purpose, one can use combinations of the following two functions:

- $f(n) = g(n) + h(n)$ where g is measured from the current node and h is the Euclidean distance from n to the goal. This is the navigation part which leads the agent to the goal as fast as possible.
- $vc(n)$ - a counter that keeps track of the number of visits to the node n done by other agents. $vc(n)$ is initially set to 0 and is incremented every time the agent is informed of a visit in n.

When combining both cost functions then nodes with small f-value are preferred, but on the other hand, so are nodes with small vc-value. Such nodes are on a promising path to the goal and are distanced away from paths chosen by other agents. A number of combinations between f and vc were tried. The best results were obtained by using

$$c(n) = f(n) \cdot [1 + p \cdot vc(n)]$$

[1]When an agent knows that one of its neighbors is navigating to a target node, this node can be removed from the *Open-list*, so the agent will not choose the same target for choosing a target node from the open list. The constant p defines the weight of the exploration in the cost function. Our extensive empirical studies have shown that $p \approx 0.3$ produces the best performance.

5. CORRECTNESS

DisNAV terminates when the first agent reaches the goal node. An important role of the algorithm is to delete nodes from the open list and to add new nodes to it. Also, it is easy to see that a node cannot be inserted to the *Open-list* more than once. In other words, the frontier of the *KnownGraph* is always expanding. Therefore, as long as we keep doing this, more and more new nodes will be discovered and since the graph is finite we will eventually reach the goal node. There are, however, some "pathological" cases where the entire multi-agent system enters a *deadlock* and cannot continue because there is not even one agent with a legal target node in its *Open-list*. This happens when for each agent all the nodes in the *Open-lists* break the radius constraint with at least one of its neighboring agents. Of course, deadlocks are not possible in the unconstrained neighborhood scheme since the radius constraint is not kept.

5.1 Deadlock elimination

We want to eliminate such deadlocks and ensure the termination of the algorithm even when keeping the *radius constraint*. We provide a solution to the static neighborhood scheme. A solution to the dynamic constrained neighborhood scheme can be easily modified since the basic principle is similar. The basic idea for deadlock elimination is to choose a *leader* agent. When a deadlock occurs, the leader chooses a move from its open-list and perform it. The other agents are forced to move in such a way that the radius constraint is kept given that leader performs its chosen move. We choose the leader that will benefit the most by its chosen move. The deadlock elimination steps are the following:

1. **Initialization -** An agent with no legal move initializes the deadlock elimination process by sending an *INVITE* message to all its neighbors declaring its wish to start a deadlock elimination process.
2. **Joining -** Agents receiving the *INVITE* can *join* this process and invite their neighbors as well or continue their navigation as usual, as long as they have legal moves in their *Open-list*.
3. **Leader Election -** All the agents which joined the deadlock elimination process pick a leader. The agent with the move of the best cost (of all the *Open-lists*) is elected and allowed to perform its move. This is done using a leader election algorithm [1].
4. **Distributed Search -** The agents solve the distributed constraint satisfaction problem (DisCSP) [10, 12] of finding a legal move for each of them. They run a DisCSP search algorithm (e.g. ABT [11, 12]) where moves of an agent are sorted according to their cost.
5. **Moves are performed -** The agents perform their moves found by the distributed search.

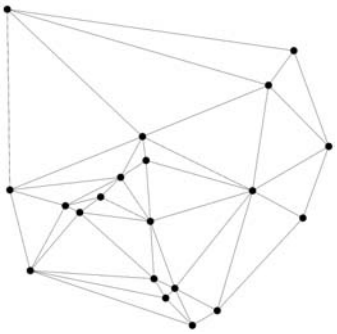

Figure 2: Delaunay graph of 20 nodes.

6. EXPERIMENTAL EVALUATION

DisNAV was evaluated experimentally on random Delaunay graphs [9] which are common testbeds (e.g., [4]) for simulating physical graphs. They are derived from Delaunay triangulations computed over a set of planar point, generated by a *Poisson point process* [9]. Points are distributed at random over a square, using a uniform probability density function. In regular Delaunay graphs, each node is connected by edges to its nearest neighbors as illustrated in figure 2. This property may not always apply to a real road map. For example, nearby geographic locations may not always be connected by a road segment, due to the existence of obstacles like a mountain or a river. To capture this additional characteristic, sparse Delaunay graphs [4] were considered. Instances of these variants can be easily obtained from regular Delaunay graphs by random deletion of edges. We define the *density* as the fraction of Delaunay edges left in the graph. The graphs were generated to be connected, by first adding a spanning tree edges and then adding random Delaunay edges up to the desired *density*.

In all our experiments we used Delaunay graphs which were randomly generated on a square with 100x100 units. For each experiment we generated 100 different graphs and selected a pair of nodes with maximal distance as the initial and goal nodes. Every data point in the figures below is the average over these 100 cases.

6.1 Comparing the different neighborhoods

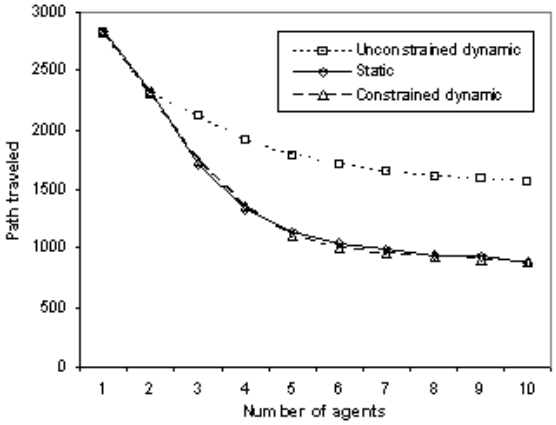

Figure 3: Different neighborhood schemes

Figure 3 presents the length of the path traveled by the first agent reaching the goal node, as a function of the number of participating agents on a Delaunay graph with 500 nodes. The radius R was set to 25 units, which is much smaller than the diameter of the problem and information is only shared locally. There are three curves in the figure, one for each neighborhood schemes. The neighborhood topology for the static neighborhood scheme was a chain where each agent was defined to be a neighbor of its predecessor and successor in the chain. Thus, each agent (except for the agents at the two ends of the chain) has two neighbors, but no 3-agent cliques exist. Similarly, the size of the dynamic constrained neighborhood was set to 2.

For all neighborhood schemes, as more agents are added the first agent reaches the goal node after traveling a shorter path. However, the figure clearly shows that the two constrained neighborhood schemes significantly outperform the unconstrained neighborhood scheme and that the path to the goal is found much faster with the constrained schemes. The two constrained schemes produced results which are not significantly different. We have performed an extensive number of experiments with all three neighborhood schemes and obtained results with the same tendency.

The unconstrained scheme performs rather poorly. If an agent is not constrained to actually stay close to other agents it might work on its own task and run away from the others. With this behavior, a valuable knowledge sharing is not guaranteed and the performance of the multi-agent system derogates. This teaches us the following valuable lesson in multi-agent communication - in order to have an efficient multi-agent system we should build a strong and constrained communication scheme to guarantee the knowledge sharing and data spread.

The two constrained schemes (static and dynamic) behave similarly. However, there are a number of advantages in the static neighborhood scheme. First, this scheme is simpler as an agent always has the same set of neighbors and thus we have a fixed and connected communication graph. This allows a simpler and faster termination of the entire task. Furthermore, the number of messages sent in this scheme is much smaller than the dynamic scheme. In the static scheme an agent only sends messages to the specific set of neighbors while in the dynamic neighborhood scheme the agents actually broadcast their discoveries and proposals to the entire set of agents. Therefore, for the remaining part of the experiments we focus on the static neighborhood results.

6.2 Static neighborhood

The next set of experiments compares different densities on sparse Delaunay graphs with 1000 nodes. The radius R was set to 75 units. Note that since agents communicate only with a predefined (static) set of agents, the relatively large radius (75) does not cause global information sharing. The number of agents in the experiments was varied from one to ten and the neighborhood topology was again a chain where each agent has two neighbors.

Figure 4 shows the length of the path traveled by the first agent reaching the goal node, as a function of the number of participating agents. The three curves correspond to graph densities of 0.3, 0.35 and 0.4. Again, adding more agents improves the results. It is also clear that as the density of the graph grows, the path traveled by the first agent is shorter. In graphs with high densities, agents have more alternative

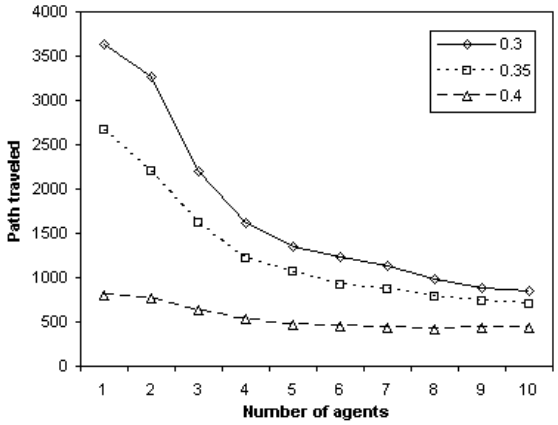

Figure 4: Path traveled (1000 nodes)

paths to the goal and there are only a few dead-ends. Such graphs are easy for navigating and agents can find their way by simple directional navigation. They do not need a lot of information from their neighbors. Thus, the improvement for adding more agents is small and a single agent is almost as good as many agents. When the graph is sparse and there are many dead-ends, the distributed algorithm outperforms a single agent. In other words, the first agent from the group reaches the goal much earlier than a single agent.

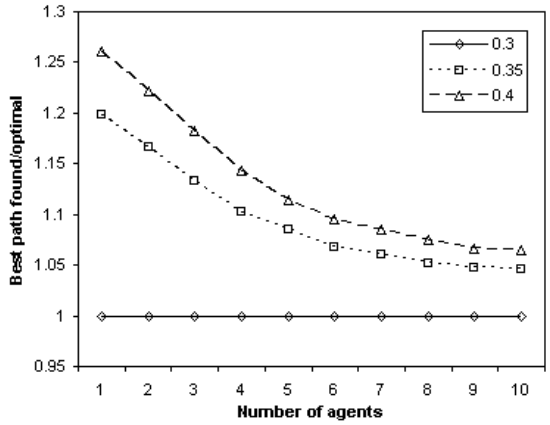

Figure 5: Best path found (1000 nodes)

Figure 5 presents the ratio between the length of the best path known when the first agent reaching the goal node and the optimal path. It is clear from figure 5 that as the number of participating agents grows, the first agent to reach the goal node knows a better path, compared to the optimal. In graphs with low densities (0.3 and below) the best known path is actually the optimal path. This is an interesting result. In such graphs agents cover a much larger portion of the graph due to dead-ends, so on arriving to the goal node, their *KnownGraph* covers a larger portion of the complete graph. In other words, the higher cost needed to reach the goal node (figure 4) reveals a path that is closer to the optimal. The combined result of figures 4 and 5 can be stated as follows. Using a minimal number of neighbors and using a large number of agents, the harder problems (low density graphs) are solved close to optimality.

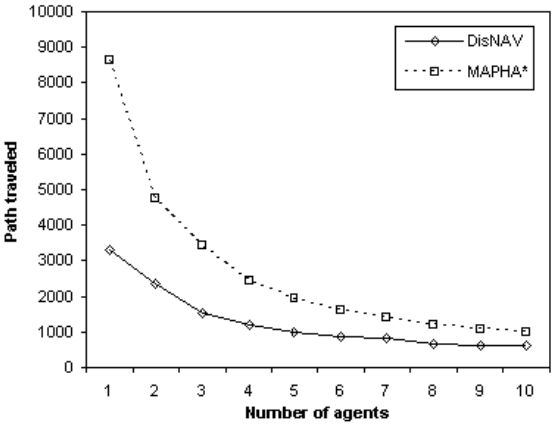

Figure 6: DisNAV vs. MAPHA* (500 nodes)

Figure 6 presents a comparison between DisNAV and MAPHA*, the multi-agent physical A* algorithm of [4], on a graph with 500 nodes and a density of 0.3. Note again, that MAPHA* actually activates a systematic global search and is guaranteed to return an optimal solution. The two curves correspond to the length of the path traveled by the first agent running DisNAV that reached the goal node, and the path traveled by the agents performing MAPHA*. As shown in figure 6, the first DisNAV agent that reaches the goal node, travels a shorter path than the MAPHA* agent. Recall from figure 5 that for a density of 0.3 the best path found by DisNAV is in practice the optimal path. This means that in graphs with low densities it is more beneficial to use DisNAV agents than MAPHA* agents as they both find the optimal path in practice.

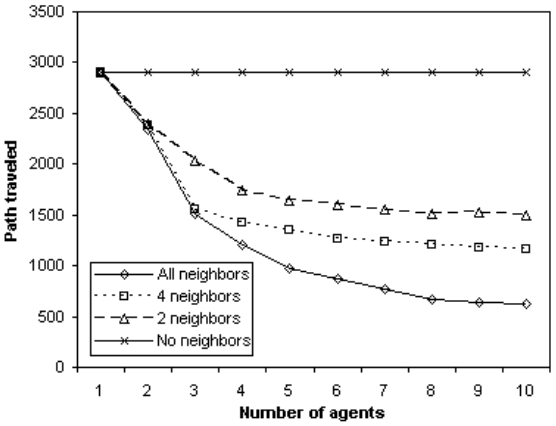

Figure 7: Different number of neighbors (500 nodes)

In another experiment the number of neighbors connected to each agent was varied. Figure 7 shows the length of the path traveled by the first agent reaching the goal node, as a function of the number of agents. The four curves correspond to cases where there are no neighbors, when the number of neighboring agents is 2 and 4 and when all agents

are connected to each other. The results show that adding neighbors improves the total knowledge sharing and reduce the travel effort. We see a diminishing return when adding more neighbors to each agent and the biggest jump is between the case of no neighbors and the case where each agent has two neighboring agents.

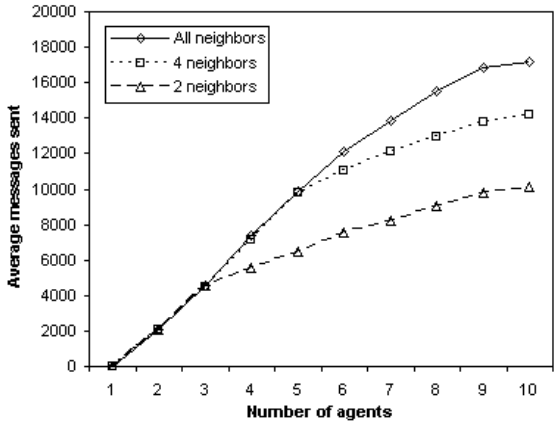

Figure 8: Communication load (500 nodes)

Figure 8 presents the average overall number of messages sent by the agents. The three curves correspond to different number of neighboring agents. It is clear from the results that as the number of neighbors increases, the average number of messages sent by an agent increases as well.

7. DISCUSSION

A multi-agent distributed algorithm for navigation in an unknown physical environment was presented. Our approach assumes that agents have limited communication abilities, and each of them is able to communicate only with a predefined set of agents. In our algorithm each agent is only navigating to the goal and we do not activate a systematic global search to find the optimal path. Former studies (MAPHA* [4]) activate a systematic global search and use complete knowledge sharing between the agents. Therefore, the travel effort and communication overhead of our agents are much smaller than MAPHA*. Even with the above limits, the experiments have demonstrated that our agents, using a simple distributed knowledge sharing, work together very efficiently. The path found by them in practice, is very close (and in many cases equal) to the optimal path. Thus, in practice, unless the optimal path is a hard requirement, our distributed algorithm is preferable. Furthermore, in many cases an agent that arrives at the goal node can prove that the best path known to it is actually the optimal path. This can be done by activating A* from the initial node to the goal. If all nodes generated by A* are included in the *KnownGraph* then the agent can prove that it has the optimal path. Our experimental results show that in small, sparse graphs (e.g., 200 nodes and a density of 0.3) the agents always found the optimal path and in 40% of the cases they could even prove that it is optimal.

Our experiments show that as the number of participating agents grows, the path traveled by the first agent arriving at the goal node is shorter and the best known path is also shorter. This benefit is more pronounced as the graph density decreases. In dense graphs even single agent would travel a relatively short path and will find a path which is a good approximation of the optimal path and adding more agents does not improve the results. However, in sparse graphs, the best path known to a single agent is far from the optimal path and adding more agents improves the results dramatically.

In addition, our experiments with the different neighborhood schemes teach us an important lesson about the influence of the communication constraints on the behavior of the entire multi-agent systems. Indeed, such constraints add strength to the knowledge sharing of the system and the entire multi-agent system performs much better.

Future work will examine how do the communication network topology, the neighborhood radius and the connectivity affect the overall performance. Another interesting question is to examine the cases where agents are starting from different initial nodes and when all agents are required to arrive at the goal node in order to complete the task.

ABSTRACT

This paper focuses on the Noisy Iterated Prisoner's Dilemma, a version of the Iterated Prisoner's Dilemma (IPD) in which there is a nonzero probability that a "cooperate" action will accidentally be changed into a "defect" action and vice versa. Tit-For-Tat and other strategies that do quite well in the ordinary (non-noisy) IPD can do quite badly in the Noisy IPD.

This paper presents a technique called *symbolic noise detection*, for detecting whether anomalies in player's behavior are deliberate or accidental. The key idea is to construct a model of the other agent's behavior, and watch for any deviation from this model. If the other agent's next action is inconsistent with this model, the inconsistency can be due either to noise or to a genuine change in their behavior; and we can often distinguish between two cases by waiting to see whether this inconsistency persists in next few moves.

We entered several different versions of our strategy in the 2005 Iterated Prisoner's Dilemma competition, in Category 2 (noisy environments). Out of the 165 contestants in this category, our programs consistently ranked among top ten. The best of our programs ranked third, and it was beaten only by two "master-slave strategy" programs that each had a large number of "slave" programs feeding points to them.

1. INTRODUCTION

The Iterated Prisoner's Dilemma (IPD) has become well known as an abstract model of a class of multi-agent environments in which agents accumulate payoffs that depend on how successful they are in their repeated interactions with other agents. An important variant of the IPD is the *Noisy* IPD, in which there is a small probability, called the *noise level*, that accidents will occur. In other words, the noise level is the probability of executing "cooperate" when "defect" was the intended move, or vice versa.

Accidents can cause difficulty in cooperations with others in real-life situations, and the same is true in the Noisy IPD. Strategies that do quite well in the ordinary (non-noisy) IPD may do quite badly in the Noisy IPD [4, 6, 7, 18, 19, 20]. For example, if two players both use the well-known Tit-For-Tat (TFT) strategy, then an accidental defection may cause a long series of defections by both players as each of them punishes the other for defecting.

In this paper, we describe a technique called *symbolic noise detection* for dealing with noise. The key idea is to build a symbolic model of how the other agent behaves, and watch for any deviation from this model. If the other agent's next move is inconsistent with their past behavior, this inconsistency can be due either to noise or to a genuine change in their behavior; and we can often distinguish between these two cases by waiting to see if this inconsistency persists or not in the next few iterations of the game.

To test our technique, we wrote several programs that used it, and entered them as contestants in Category 2 (the Noisy IPD) of the 2005 Iterated Prisoner's Dilemma competition [14]. In the competition, the noise level was 10%. The result of the competition showed an impressive performance for symbolic noise detection (Table 1). Seven of our nine symbolic noise detection programs placed among top ten according to their overall average score. Our best program, DBSz, placed third, and it was the best-performing non-master-slave program in Category 2.[1]

[1]Each participant in the competition was allowed to submit up to 20 programs as contestants. Some participants took advantage of this to submit collections of programs that worked together in a conspiracy in which 19 of their 20 programs (the "slaves") worked to give as many points as possible to the 20th program (the "master"). In contrast, DBS is not a master-slave program. Instead, DBS builds behavioral models of the other contestants in order to coop-

This paper describes the design of DBS, particularly the implementation of the symbolic noise detection in DBS. Section 2 presents the motivation for the approach, Section 3 gives the basic definitions, and Section 4 gives an overview of how DBS works. Section 5 how the opponent modeling is done and in particular the symbolic noise detection works. Section 6 discusses DBS's performance in the 2005 Iterated Prisoner's Dilemma competition, and contrasts DBS to the notorious master-and-slaves strategy. Section 7 discusses related work, and Section 8 is the conclusion.

2. MOTIVATION AND APPROACH

The techniques used in DBS are motivated by a British army officer's story that was quoted in [3, page 40]:

> I was having tea with A Company when we heard a lot of shouting and went out to investigate. We found our men and the Germans standing on their respective parapets. Suddenly a salvo arrived but did no damage. Naturally both sides got down and our men started swearing at the Germans, when all at once a brave German got onto his parapet and shouted out: "We are very sorry about that; we hope no one was hurt. It is not our fault. It is that damned Prussian artillery." (Rutter 1934, 29)

Such an apology was an effective way of resolving the conflict and preventing a retaliation because it told the British that the salvo was not the intention of the German infantry, but instead was an unfortunate accident that the German infantry did not expect nor desire. The reason why the apology was convincing was because it was consistent with the German infantry's past behavior. The British had was ample evidence to believe that the German infantry wanted to keep the peace just as much as the British infantry did.

More generally, an important question for conflict prevention in noisy environments is *whether a misconduct is intentional or accidental.* A deviation from the usual course of action in a noisy environment can be explained in either way. If we form the wrong belief about which explanation is correct, our response may potentially destroy our long-term relationship with the other player. If we ground our belief on evidence accumulated before and after the incident, we should be in a better position to identify the true cause and prescribe an appropriate solution. To accomplish this, DBS uses the following key techniques:

1. **Learning about the other player's strategy.** DBS uses an induction technique to identify a set of rules that model the other player's recent behavior. The rules give the probability that the player will cooperate under different situations. As DBS learns these probabilities during the game, it identifies a set of *deterministic* rules that have either 0 or 1 as the probability of cooperation.

2. **Detecting noise**. DBS uses the above rules to detect anomalies that may be due either to noise or a genuine change in the other player's behavior. If a move is different from what the deterministic rules predict, this inconsistency triggers an *evidence collection process* that will monitor the persistence of the inconsistency in the next few iterations of the game. The purpose of the evidence-collection process is to determine whether the violation is likely to be due to noise or to a change in the other player's policy.

3. **Temporarily tolerating possible misbehaviors by the other player.** Until the evidence-collection process finishes, DBS assumes that the other player's behavior is still as described by the deterministic rules. Once the evidence collection process has finished, DBS decides whether to believe the other player's behavior has changed, and updates the deterministic rules accordingly.

Since DBS emphasizes the use of deterministic behaviors to distinguish noise from the change of the other player's behavior, it works well when the other player uses a pure (i.e., deterministic) strategy or a strategy that makes decisions deterministically most of the time. Fortunately, deterministic behaviors are abundant in the Iterated Prisoner's Dilemma. Many well-known strategies, such as TFT and GRIM, are pure strategies. Some strategies such as Pavlov or Win-Stay, Lose-Shift strategy (WSLS) [15, 16, 17, 21] are not pure strategies, but a large part of their behavior is still deterministic. The reason for the prevalence of determinism is discussed by Axelrod in [2]: clarity of behavior is an important ingredient of long-term cooperation. A strategy such as TFT benefits from its clarity of behavior, because it allows other players to make credible predictions of TFT's responses to their actions. We believe the success of our strategy in the competition is because this clarity of behavior also helps us to fend off noise.

The results of the competition show that the techniques used in DBS are indeed an effective way to fend off noise and maintain cooperation in noisy environments. When DBS defers judgment about whether the other player's behavior has changed, the potential cost is that DBS may not be able to respond to a genuine change of the other player's behavior as quickly as possible, thus losing a few points by not retaliating immediately. But this delay is only temporary, and after it DBS will adapt to the new behavior. What is more important is that the techniques used in DBS greatly reduce the probability that noise will cause it to end a cooperation and fall into a mutual-defect situation. Our experience has been that it is hard to re-establish cooperation from a mutual-defection situation, so it is better avoid getting into mutual defection situations in the first place. When compared with the potential cost of ending an cooperation, the cost of temporarily tolerating some defections is worthwhile.

Temporary tolerance also benefits us in another way. In the noisy Iterated Prisoner's Dilemma, there are two types of noise: one that affects the other player's move, and the other affects our move. While our method effectively handles the first type of noise, it is the other player's job to deal with the second type of noise. Some players such as TFT are easily provoked by the second type of noise and retaliate immediately. Fortunately, if the retaliation is not a permanent one, our method will treat the retaliation in the same way as the first type of noise, thus minimizing its effect.

3. DEFINITIONS

3.1 Iterated Prisoner's Dilemma with Noise

In the Iterated Prisoner's Dilemma, two players play a finite sequence of classical prisoner's dilemma games, whose

erate with them as effectively as possible.

payoff matrix is:

		Player 2	
		Cooperate	Defect
Player 1	Cooperate	(u_{CC}, u_{CC})	(u_{CD}, u_{DC})
	Defect	(u_{DC}, u_{CD})	(u_{DD}, u_{DD})

where $u_{DC} > u_{CC} > u_{DD} > u_{CD}$ and $2u_{CC} > u_{DC} + u_{CD}$. In the competition, u_{DC}, u_{CC}, u_{DD} and u_{CD} are 5, 3, 1 and 0, respectively.

At the beginning of the game, each player knows nothing about the other player and does not know how many iterations it will play. In each iteration, each player chooses either to cooperate (C) or defect (D), and their payoffs in that iteration are as shown in the payoff matrix. We call this decision a *move*, hence $\{C, D\}$ is the set of possible moves. After both players choose a move, they will each be informed of the other player's move before the next iteration begins.

If $a_k, b_k \in \{C, D\}$ are the moves of Player 1 and Player 2 in iteration k, then we say that (a_k, b_k) the *outcome* of iteration k. If there are N iterations in a game, then the total scores for Player 1 and Player 2 are $\sum_{1 \le k \le N} u_{a_k b_k}$ and $\sum_{1 \le k \le N} u_{b_k a_k}$, respectively.

The *Noisy Iterated Prisoner's Dilemma* is a variant of the Iterated Prisoner's Dilemma in which there is a small probability called the *noise level*[2] that a player's moves will be mis-implemented. The noise level is the probability of executing C when D was the intended move, or vice versa. The incorrect move is recorded as the player's move, and determines the outcome of the iteration.[3] Furthermore, neither player has any way of knowing whether the other player's move was executed correctly or incorrectly.[4]

3.2 Strategies and Policies

A *history* H of length k is the sequence of outcomes of all iterations up to and including iteration k. We write $H = \langle (a_1, b_1), (a_2, b_2), \ldots, (a_k, b_k) \rangle$. We let $\mathcal{H} = \{(C, C), (C, D), (D, C), (D, D)\}^*$ be the set of all possible histories. A *strategy* $M : \mathcal{H} \to [0, 1]$ associates with each history H a number $M(H) \in [0, 1]$ called the *degree of cooperation*. $M(H)$ is the probability that M chooses to cooperate at iteration $k + 1$, where k is H's length.

As an example, suppose the Player 2 is TFT. We can model this as a function M_{TFT} such that $M_{TFT}(H) = 1$ if H's length is zero or $a_k = C$, and $M_{TFT}(H) = 0$ otherwise.

A *condition* $Cond : \mathcal{H} \to \{\mathsf{True}, \mathsf{False}\}$ is a mapping from histories to boolean values. A history H *satisfies* a condition $Cond$ if $Cond(H) = \mathsf{True}$. A *policy schema* is a set of conditions such that each history in $\mathcal{H}$ satisfies exactly one of the conditions. A *rule* is a pair $(Cond, p)$ which we will write as $Cond \to p$, where $Cond$ is a condition and p is a degree of cooperation. A *policy* is a set of rules whose conditions constitute a policy schema. We will use a policy to approximate the behavior exhibited by a strategy.

[2]The noise level in the competition was 0.1.

[3]Hence, a mis-implementation is different from a misperception, which would not change the outcome of the iteration. The competition included mis-implementations but no misperceptions.

[4]As far as we know, the definitions of "mis-implementation" used in the existing literature are ambiguous about whether either of the players should know that an action has been mis-executed.

```
Procedure DerivedBeliefStrategy()
1.  R_d ← R_TFT      // the default rule set
2.  R_c ← ∅          // the current rule set
3.  a_0 ← C ; b_0 ← C ; H ← ⟨(a_0, b_0)⟩; π = R_d
4.  a_1 ← MoveGen(π, H) ; k ← 1 ; v ← 0
5.  Loop until the end of the game
6.     Output a_k and obtain the other player's move b_k
7.     r+ ← ((a_{k-1}, b_{k-1}) → b_k)
8.     r− ← ((a_{k-1}, b_{k-1}) → ({C, D} \ {b_k}))
9.     If r+, r− ∉ R_c
10.       If ShouldPromote(r+) = true, insert r+ into R_c.
11.    If r+ ∈ R_c, set the violation count of r+ to zero
12.    If r− ∈ R_c and ShouldDemote(r−) = true
13.       R_d ← R_c ∪ R_d; R_c ← ∅; v ← 0
14.    If r− ∈ R_d, then v ← v + 1
15.    If v > RejectThreshold, or (r+ ∈ R_c and r− ∈ R_d)
16.       R_d ← ∅; v ← 0
17.    R_p ← {(C → p') ∈ ψ_{k+1} : C not appear in R_c or R_d}
18.    π ← R_c ∪ R_d ∪ R_p   // R_p is the probabilistic rule set
19.    H ← ⟨H, (a_k, b_k)⟩; a_{k+1} ← MoveGen(π, H) ; k ← k + 1
```

Figure 1: An outline of the DBS strategy. ShouldPromote first increases r^+'s promotion count, and then if r^+'s promotion count exceeds the promotion threshold, ShouldPromote returns true and resets r^+'s promotion count. Likewise, ShouldDemote first increases r^-'s violation count, and then if r^-'s violation count exceeds the violation threshold, ShouldPromote returns true and resets r^-'s violation count. ψ_{k+1} in Line 17 is calculated from Equation 1.

We can model M_{TFT} as a policy as follows: we write $Cond = (a, b)$ as a condition about the outcomes of the last iteration of a history, such that $Cond(H) = \mathsf{True}$ if and only if $a_k = a$ and $b_k = b$. For simplicity, if the length of H is zero, then $Cond(H) = \mathsf{True}$ if and only if $a = C$ and $b = C$. The policy for M_{TFT} is $R_{TFT} = \{(C, C) \to 1.0, (C, D) \to 1.0, (D, C) \to 0.0, (D, D) \to 0.0\}$.

4. DERIVED BELIEF STRATEGY

Figure 1 outlines the DBS strategy. DBS maintains a *hypothesized policy* to model the other player's strategy. DBS initially assumes that the other player's policy is TFT, but at each iteration of the game, DBS updates the hypothesized policy according to how the player has actually played. Section 5 describes how the updating works.

DBS uses the current hypothesized policy to decide what move to make. For this, it uses the MoveGen procedure on line 4 of the figure. MoveGen is bascially a game-tree search procedure for maximizing DBS's utility, assuming that the hypothesized policy π does not change. We omit the details due to lack of space; for details see [1].

An important question is how large a policy schema to use for the hypothesized policy. If the other player's strategy is complicated and the policy schema is too small, the policy schema won't provide enough detail to give useful predictions of the other player's behavior. But if the policy schema is too large, DBS will be unable to compute an accurate approximation of each rule's degree of cooperation, because the number of iterations in the game will be too small. In the competition, we used a policy schema of size 4: $\{(C, C), (C, D), (D, C), (D, D)\}$. We have found this to be good enough for modeling a large number of strategies.

5. LEARNING HYPOTHESIZED POLICIES IN NOISY ENVIRONMENTS

We now describe how DBS learns another player's strategy. Section 5.1 describes how DBS maintains a *discounted frequency* for each behavior: instead of keeping an ordinary frequency count, DBS applies discount factors based on how recent each occurrence of the behavior was. Sections 5.2–5.5 describe why discounted frequencies alone are not sufficient to deal with noise, and how DBS uses symbolic noise detection and temporary tolerance to help overcome the difficulty.

5.1 Learning by Discounted Frequencies

Given a history $H = \{(a_1, b_1), (a_2, b_2), \ldots, (a_k, b_k)\}$, a real number α between 0 and 1 (called the *discount factor*), and an initial hypothesized policy $\pi_0 = \{Cond_1 \rightarrow p_1^0, Cond_2 \rightarrow p_2^0, \ldots, Cond_n \rightarrow p_n^0\}$ whose policy schema is $\mathcal{C} = \{Cond_1, Cond_2, \ldots, Cond_n\}$, the *probabilistic policy* at iteration $k+1$ is $\psi_{k+1} = \{Cond_1 \rightarrow p_1^{k+1}, Cond_2 \rightarrow p_2^{k+1}, Cond_n \rightarrow p_n^{k+1}\}$, where p_i^{k+1} is computed by the following equation:

$$p_i^{k+1} = \frac{\sum_{0 \le j \le k} (\alpha^{k-j} g_j)}{\sum_{0 \le j \le k} (\alpha^{k-j} f_j)} \quad (1)$$

and where

$$g_j = \begin{cases} p_i^0 & \text{if } j = 0, \\ 1 & \text{if } 1 \le j \le k,\ Cond_i(H_{j-1}) = \mathsf{True} \text{ and } b_j = C, \\ 0 & \text{otherwise;} \end{cases}$$

$$f_j = \begin{cases} p_i^0 & \text{if } j = 0, \\ 1 & \text{if } 1 \le j \le k,\ Cond_i(H_{j-1}) = \mathsf{True}, \\ 0 & \text{otherwise;} \end{cases}$$

$$H_{j-1} = \begin{cases} \emptyset & \text{if } j = 1, \\ \{(a_1, b_1), (a_2, b_2), \ldots, (a_{j-1}, b_{j-1})\} & \text{otherwise.} \end{cases}$$

In short, the current history H has $k+1$ possible prefixes, and f_j is bascially a boolean function indicating whether the prefix of H up to the $j-1$'th iteration satisfies $Cond_i$. g_j is a restricted version of f_j.

When $\alpha = 1$, p_i is approximately equal to the frequency of the occurrence of $Cond_i \rightarrow p_i$. When α is less than 1, p_i becomes a weighted sum of the frequencies that gives more weight to recent events than earlier ones. For our purposes, it is important to use $\alpha < 1$, because it may happen that the other player changes its behavior suddenly, and therefore we should forget about its past behavior and adapt to its new behavior (for instance, when GRIM is triggered). In the competition, we used $\alpha = 0.75$.

It is important to have a good initial hypothesized strategy because at the beginning of the game the history is not long enough for us to derive any meaningful information about the other player's strategy. In the competition, the initial hypothesized policy is TFT: $\{(C, C) \rightarrow 1.0, (C, D) \rightarrow 1.0, (D, C) \rightarrow 0.0, (D, D) \rightarrow 0.0\}$.

5.2 The Deficiency of using Discounted Frequency to Deal with Noise

It may appear that the probabilistic policy learnt by the discounted-frequency learning technique should be inherently capable of tolerating noise, because it takes many, if not all, moves in the history into account: if the number of terms in the calculation of the average or weighted average is large enough, the effect of noise should be small. However, there is a problem with this reasoning: it neglects the effect of multiple occurences of noise within a small time interval.

A mis-implementation that alters the move of one player would distort an established pattern of behavior observed by the other player. The general effect of such distortion to the Equation 1 is hard to tell—it varies with the value of the paramters and the history. But if several distortions occur within a small time interval, the distortion may be big enough to alter the probabilistic policy and hence change our decision about what move to make. This change of decision may potentially destroy an established pattern of mutual cooperation between the players.

At first glance, it might seem rare for several noise events to occur at nearly the same time. But if the game is long enough, the probability of it happening can be quite high. The probability of getting two noise events in two consecutive iterations out of a sequence of i iterations can be computed recursively as $X_i = p(p + qX_{i-2}) + qX_{i-1}$, providing that $X_0 = X_1 = 0$, where p is the probability of a noise event and $q = 1 - p$. In the competition, the noise level was $p = 0.1$ and $i = 200$, which gives $X_{200} = 0.84$. Similarly, the probabilities of getting three and four noises in consecutive iterations are 0.16 and 0.018, respectively.

In the 2005 competition, there were 165 players, and each player played each of the other players five times. This means every player played 825 games. On average, there were 693 games having two noises in two consecutive iterations, 132 games having three noises in three consecutive iterations, and 15 games having four noises in four consecutive iterations. Clearly, we did not want to ignore situations in which several noises occur nearly at the same time.

The *symbolic noise detection* and temporary tolerance outlined in Section 2 provide a way to reduce the amount of susceptibility to multiple occurrences of noise in a small time interval. The basic idea is to partition the set of rules in the current hypothesized policy into two sets: the set of *deterministic rules* (whose degrees of cooperation are either zero or one) and the set of *probabilistic rules* (whose degrees of cooperation are between zero and one). The deterministic rules are then used to detect noise in the way that we mentioned in Section 2.

In the following subsections, we first present the induction technique we used to identify the deterministic rules in the other player's behavior. Then we describe the evidence-collection process in the symbolic noise detection. After that, we discuss how to cope with the ignorance of the other player's new behavior when the evidence-collection process decides that there is a change in the other player's behavior.

5.3 Identifying Deterministic Rules Using Induction

As we discussed in Section 2, deterministic behaviors are abundant in the Iterated Prisoner's Dilemma. Deterministic behaviors can be modeled by deterministic rules, whereas random behavior would require probabilistic rules.

Deterministic rules have only two possible degrees of cooperation: zero or one. Therefore, there should be ways to learn deterministic rules that are much faster than the discounted frequency method described earlier. For example, if we knew at the outset which rules were deterministic, it would take only one occurrence to learn each of them: each time the condition of a deterministic rule was satisfied, we could assign a degree of cooperation of 1 or 0 depending on

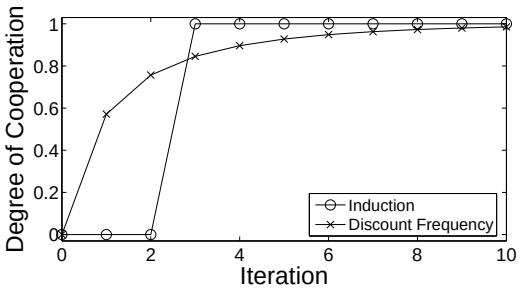

Figure 2: Learning speeds of the induction method and the discounted frequency method when the other player always cooperates. The initial degree of cooperation is zero, the discounted rate is 0.75, and the promotion threshold is 3.

whether the player's move was C or D.

The trick, of course, is to determine which rules are deterministic. We have developed an inductive-reasoning method to distinguish deterministic rules from probabilistic rules during learning and to learn the correct degree of cooperation for the deterministic rules.

In general, induction is the process of deriving general principles from particular facts or instances. To learn deterministic rules, the idea of induction can be used as follows. If a certain kind of behavior occurs repeatedly several times, and during this period of time there is no other behavior that contradicts to this kind of behavior, then we will hypothesize that the chance of the same kind of behavior occurring in the next few iterations is pretty high, regardless of how the other player behaved in the remote past.

More precisely, let $K \geq 1$ be a number which we will call the *promotion threshold*. Let $H = \langle (a_1, b_1), (a_2, b_2), \ldots, (a_k, b_k) \rangle$ be the current history. For each condition $Cond_j \in \mathcal{C}$, let I_j be the set of indexes such that for all $i \in I_j$, $i < k$ and $Cond_j(\langle (a_1, b_1), (a_2, b_2), \ldots, (a_i, b_i) \rangle) = \mathsf{True}$. Let $\hat{I}_j$ be the set of the largest K indexes in I_j. If $|I_j| \geq K$ and for all $i \in \hat{I}_j$, $b_{i+1} = C$ (i.e., the other player chose C when the previous history up to the i'th iteration satisties $Cond_j$), then we will hypothesize that the other player will choose C whenever $Cond_j$ is satisfied; hence we will use $Cond_j \rightarrow 1$ as a deterministic rule. Likewise, if $|I_j| \geq K$ and for all $i \in \hat{I}_j$, $b_{i+1} = D$, we will use $Cond_j \rightarrow 0$ as a deterministic rule. See Line 7 to Line 10 in Figure 1 for an outline of the induction method we use in DBS.

The induction method can be faster at learning deterministic rules than the discounted frequency technique (see Figure 2). A faster learning speed allows us to infer the deterministic rules with a shorter history. The promotion threshold K controls the speed of the identification of deterministic rules. The larger the value of K, the slower the speed of identification, but the less likely we will mistakenly hypothesize that the other player's behavior is deterministic.

5.4 Symbolic Noise Detection and Temporary Tolerance in DBS

Once DBS has identified the set of deterministic rules, it can readily use them to detect noise. As we said earlier, if the other player's move violate a deterministic rule, it can be caused either by noise or by a change in the other player's behavior, and DBS uses an evidence collection process to figure out which is the case. More precisely, once a deterministic rule $Cond_i \rightarrow o_i$ is violated (i.e., the history up to the previous iteration satisfies $Cond_i$ but the other player's move in the current iteration is different from o_i), DBS keeps the violated rule but marks it as violated. Then DBS starts an *evidence collection process* that in the implementation of our competition entries is a violation counting: for each violated probabilistic rule DBS maintains a counter called the *violation count* to record how many violations of the rule have occurred (Line 12). In the subsequent iterations, DBS increases the violation count by one every time a violation of the rule occurs. However, if DBS encounters a positive example of the rule, DBS resets the violation count to zero and unmark the rule (Line 11). If any violation count excesses a threshold called the *violation threshold*, DBS concludes that the violation is not due to noise; it is due to a change of the other player's behavior. In this case, DBS invokes a special procedure (described in Section 5.5) to handle this situation (Line 13).

The drawback of the discount frequency method is that it fails to deal with several misinterpretations caused by noise within a small time interval. The way to avoid this drawback is to set a larger violation threshold. But if the threshold is too large, it will slow down the speed of adaptation to changes in the other player's behavior. In the competition, we entered DBS several times with several different violation thresholds; and in the one that performed the best, the violation threshold was 4.

5.5 Coping with Ignorance of the Other Player's New Behavior

When the evidence collection process detects a change in the other player's behavior, DBS knows little about the other player's new behavior. How DBS copes with this ignorance is critical to its success.

DBS maintains two sets of deterministic rules: the *current rule set* R_c and the *default rule set* R_d. Symbolic noise detection and temporary tolerance makes use of the rules in R_c but not the rules in R_d. However, DBS makes use of the rules in both R_c and R_d when DBS decides the next move (Line 18). More precisely, when DBS constructs a hypothesized policy π for move generation, it uses every rule in R_c and R_d. In addition, for any missing rule (i.e., the rule those condition are different from any rule's condition in R_c or R_d), we regard it as a probabilistic rule and approximate its degree of cooperation by Equation 1 (Line 17). These probabilistic rules form the probabilistic rule set $R_p \subseteq \psi_{k+1}$.

The default rule set is designed to be *rejected*: we maintain a violation count to record the number of violations to any rule in R_d. Every time any rule in R_d is violated, the violation count increased by 1 (Line 14). Once the violation count exceeds a *rejection threshold*, we drop the default rule set entirely (set it to an empty set) and reset the violation count (Line 15 and Line 16). We also reject R_d whenever any rule in R_c contradicts any rule in R_d (Line 15).

At the beginning of a game, R_d is R_{TFT} and R_c is empty (Line 1 and Line 2). While DBS can insert any newly found deterministic rule in R_c, it insert rules into R_d *only when* the evidence collection process detects a change of the other player's behavior. When it happens, DBS copies all the rules in R_c to R_d, and then set R_c to an empty set (Line 13).

Table 1: Scores of the top 20 programs, averaged over the five runs in Competition 2.

Rank	Program	Avg. score
1	BWIN	433.8
2	IMM01	414.1
3	DBSz	408.0
4	DBSy	408.0
5	DBSpl	407.5
6	DBSx	406.6
7	DBSf	402.0
8	DBStft	401.8
9	DBSd	400.9
10	lowESTFT_classic	397.2
11	TFTIm	397.0
12	Mod	396.9
13	TFTIz	395.5
14	TFTIc	393.7
15	DBSe	393.7
16	TTFT	393.4
17	TFTIa	393.3
18	TFTIb	393.1
19	TFTIx	393.0
20	mediumESTFT_classic	392.9

We preserve the rules in R_c mainly for sake of providing a smooth transition: we don't want to convert all deterministic rules to probabilistic rules at once, as it might suddenly alter the course of our moves and lead to uncertain outcomes. Furthermore, some of these rules may still hold, and we don't want to learn them from scratch.

6. COMPETITION RESULTS

The 2005 IPD Competition was actually a set of four competitions, each for a different version of the IPD. The one for the Noisy IPD was Competition 2, which used a noise level of 0.1.

Within Competition 2 there were five runs of 200 iterations each. Table 1 shows the average scores of the top twenty programs, averaged over the five runs. The competition website at http://www.prisoners-dilemma.com gives a more extensive set of tables showing each program's ranking for each of the five runs.

We entered nine different versions of DBS into the competition, each with a different set of parameters or different implementation. The one that performed best was DBSz, which makes use of the set of features we mentioned in this paper. Versions of DBS that had fewer features or additional features than DBSz did not do as well, but all nine of versions of DBS were in the top 25, and they dominated the top ten places. This implies that DBS's performance is insensitive to the parameters in the programs and the implementation details of an individual program.

DBSz is ranked third in the table; it lost only to BWIN and IMM01. BWIN and IMM01 both used the *master-and-slaves* strategy, in which a collection of *slave* programs sacrifice their own performance in order to give as many points as possible to another program called the *master* program.

Each participant was allowed to submit 20 programs. Each of the three master-and-slaves strategies (the third one, CNGF, was not good enough to make it into our table) has one master and 19 slaves. At the start of a run, the master and slaves would each make a series of moves using a predefined protocol, in order to identify themselves to each other. From then on, the master program would always play "defect" when playing with the slaves and the slave programs would always play "cooperate" when playing with the master, so that the master would gain the highest possible payoff at each iteration. Furthermore, a slave would alway plays "defect" when playing with a program other than the master, in order to try to minimize that player's score.

DBS does not use a master-slave strategy, nor does it conspire with other programs in any other way. Nonetheless, DBS remained competitive with the master-slave strategies in the competition, and performed much better than the master-slave strategies if the score of each master is averaged with the scores of its slaves. In particular, the average score for BWIN and its slaves was 379.9, and the average score for IMM01 and its slaves was 351.7. Furthermore, a more extensive analysis [1] shows that if the size of each master-and-slaves team had been limited to less than 10, DBSz would have outperformed the best master-slave strategy in the competition, even without averaging the score of each master with its slaves.

To show the destructive effect of the master-and-slaves strategies, Table 2 gives the percentages of each of the four possible outcomes when any program from one group plays with any program from another group. Note that:

- When BWIN and IMM01 play with their slaves, about 64% and 47% of the outcomes are (D, C), but when non-master-and-slave strategies play with each other, only 19% of the outcomes are (D, C).
- When the slave programs play with non-master-and-slaves programs, over 60% of outcomes are (D, D), but when non-master-and-slaves programs play with other non-master-and-slaves programs, only 31% of the outcomes are (D, D).
- The master-and-slaves strategies decrease the overall percentage of (C, C) from 31% to 13%, and increase the overall percentage of (D, D) from 31% to 55%.

Next, we consider how DBSz performs against TFT and TFTT, (the latter, Tit-For-Two-Tats, is like TFT except that it retaliates only when the other player defected in both of the last two iterations).

- Table 2 shows that when playing with another cooperative

Table 2: Percentages of different outcomes. *"All but M&S"* means all 105 programs that did not use master-and-slaves strategies, and *"all"* means all 165 programs in the competition.

Player 1	Player 2	(C, C)	(C, D)	(D, C)	(D, D)
BWIN	BWIN's slaves	12%	5%	64%	20%
IMM01	IMM01's slaves	10%	6%	47%	38%
CNGF	CNGF's slaves	2%	10%	10%	77%
BWIN's slaves	*all but M&S*	5%	9%	24%	62%
IMM01's slaves	*all but M&S*	7%	9%	23%	61%
CNGF's slaves	*all but M&S*	4%	8%	24%	64%
TFT	*all but M&S*	33%	20%	20%	27%
DBSz	*all but M&S*	54%	15%	13%	19%

TFT	*all*	23%	19%	16%	42%
DBSz	*all*	36%	14%	11%	39%
TFTT	*all*	38%	21%	10%	31%
all but M&S	*all but M&S*	31%	19%	19%	31%
all	*all*	13%	16%	16%	55%

player, TFT cooperates ((C, C) in the table) 33% of the time, DBSz does so 54% of the time, and TFTT does so 55% of the time. Furthermore, when playing with a player who defects, TFT defects ((D, D) in the table) 27% of the time, DBSz does so 19% of the time, and TFTT does so 14% of the time. From this, one might think that DBSz's behavior is somewhere between TFT's and TFTT's.

- But on the other hand, when playing with a player who defects, DBSz cooperates ((C, D) in the table) only 15% of the time, which is a lower percentage than for TFT and TFTT (both 20%). Since cooperating with a defector generates no payoff, this makes TFT and TFTT perform worse than DBSz overall. DBSz's average score was 408 and it ranked 3rd, but TFTT's and TFT's average scores were 388.4 and 388.2 and they ranked 30th and 33rd.

7. RELATED WORK

Early studies of the effect of noise in the Iterated Prisoner's Dilemma focused on how TFT, a highly successful strategy in noise-free environments, would do in the presence of noise. TFT is known to be vulnerable to noise; for instance, if two players use TFT at the same time, noise would trigger long sequences of mutual defections [18]. A number of people confirmed the negative effects of noise to TFT [4, 6, 7, 18, 19, 20]. Axelrod found that TFT was still the best decision rule in the rerun of his first tournament with a one percent chance of misperception [2, page 183], but TFT finished sixth out of 21 in the rerun of Axelrod's second tournament with a 10 percent chance of misperception [10]. In Competition 2 of the 2005 IPD competition, the noise level was 0.1, and TFT's overall average score placed it 33rd out of 165.

The oldest approach to remedy TFT's deficiency in dealing with noise is to be more forgiving in the face of defections. A number of studies found that more forgiveness promotes cooperation in noisy environments [7, 19]. For instance, Tit-For-Two-Tats (TFTT) retaliates only when it receives two defections in two previous iterations. TFTT can tolerate isolated instances of defections caused by noise and is more readily to avoid long sequences of mutual defections. However, TFTT is susceptible to exploitation of its generosity and was beaten in Axelrod's second tournament by TESTER, a strategy that may defect every other move. In Competition 2 of the 2005 IPD Competition, TFTT ranked 30—a slightly better ranking than TFT's. In contrast to TFTT, DBS can tolerate not only an isolated defection but also a sequence of defections caused by noise, and at the same time DBS monitors the other player's behavior and retaliates when exploitation behavior is detected (i.e., when the exploitation causes a change of the hypothesized policy, which initially is TFT).

[18] proposed to mix TFT with ALLC to form a new strategy which is now called Generous Tit-For-Tat (GTFT) [22]. Like TFTT, GTFT avoids an infinite echo of defections by cooperating when it receives a defection in certain iterations. The difference is that GTFT forgives randomly: for each defection GTFT receives it randomly choose to cooperate with a small probability (say 10%) and defect otherwise. DBS, however, does not make use of forgiveness explicitly as in GTFT; its decisions are based entirely on the hypothesized policy that it learned. But temporary tolerance can be deemed as a form of forgiveness, since DBS does not retaliate immediately when a defection occurs in a mutual cooperation situation. This form of forgiveness is carefully planned and there is no randomness in it.

Another way to improve TFT in noisy environments is to use contrition: unilaterally cooperate after making mistakes. However, this is less useful in the Noisy IPD since a program does not know whether its action is affected by noise or not.

A family of strategies called "Pavlovian" strategies, or simply called Pavlov, was found to be more successful than TFT in noisy environments [15, 16, 17, 21]. When an accidental defection occurs, Pavlov can resume mutual cooperation in a smaller number of iterations than TFT [15, 16]. Pavlov learns by conditioned response through rewards and punishments; it adjusts its probability of cooperation according to the previous outcome. Like Pavlov, DBS learns from its past experience. DBS, however, has an intermediate step between learning from experience and decision making: it maintains a model of the other player's behavior, and uses this model to reason about nosie.

The use of opponent modeling is common in games of imperfect information such as Poker [5, 8, 9] and RoShamBo [12]. There have been many works on learning the opponent's strategy in the non-noisy IPD [11, 13, 23]. By assuming the opponent's next move depends only on the outcomes of the last few iterations, these works model the opponent's strategy as probabilistic finite automata, and then use various learning methods to learn the probabilities in the automata. In contrast, DBS does not aim at learning the other player's strategy completely; instead, it learns the other player's recent behavior, which is subject to change. We believe that the other player may alter its strategy at the middle of a game, and therefore it is difficult for any learning method to converge. It is essentially true in noisy IPD, since noise can provoke the other player. Moreover, the length of a game is usually too short for us to learn any non-trivial strategy completely.

To the best of our knowledge, ours is the first work on using opponent models in the IPD to detect errors in the execution of another agent's actions.

8. SUMMARY AND FUTURE WORK

For conflict prevention in noisy environments, a critical problem is to distinguish between situations where another player has misbehaved intentionally and situations where the misbehavior was accidental. That is the problem that DBS was formulated to deal with.

DBS's impressive performance in the 2005 Iterated Prisoner's Dilemma competition occurred because DBS was better able to maintain cooperation in spite of noise than any other program in the competition.

To distinguish between intentional and unintentional misbehaviors, DBS uses a combination of symbolic noise detection plus temporary tolerance: if an action of the other player is inconsistent with the player's past behavior, we continue as if the player's behavior has not changed, until we gather sufficient evidence to see whether the inconsistency was caused by noise or by a genuine change in the other player's behavior.

Since clarity of behavior is an important ingredient of long-term cooperation in the IPD, most IPD programs have behavior that follows clear deterministic patterns. The clarity of these patterns made it possible for DBS to construct policies that were good approximations of the other players'

strategies, and to use these policies to fend off noise.

We believe that clarity of behavior is also likely to be important in other multi-agent environments in which agents have to cooperate with each other. Thus it seems plausible that techniques similar to those used in DBS may be useful in those domains.

In the future, we are interested in studying the following issues:

- The evidence collection process takes time, and the delay may invite exploitation. For example, the policy of temporary tolerance in DBS may be exploited by a "hypocrite" strategy that behaves like TFT most of the time but occasionally defects even though DBS did not defect in the previous iteration. DBS cannot distinguish this kind of intentional defection from noise, even though DBS has built-in mechanism to monitor exploitation. We are interested to seeing how to avoid this kind of exploitation.

- In multi-agent environments where agents can communicate with each other, there is a probability for the agents to detect noise by a predefined communication protocol. However, we believe there is no protocol that can guarantee to tell which action has been affected by noise, as long as the agents cannot completely trust each other. It would be interested to compare these alternative approaches with symbolic noise detection and see how symbolic noise detection could enhance these methods or vice versa.

- The type of noise in the competition assumes that no agent know whether an execution of an action has been affected by noise or not. Perhaps there are situations in which some agents may be able to obtain partial information about the occurrence of noise. For example, some agents may obtain a plan of the malicious third party by counter-espionage. We are interested to see how to utilitize these information into symbolic noise detection.

On using Multi-agent Systems in Playing Board Games

ABSTRACT

Computer programs able to play different kinds of games (aka bots) is a growing area of interest for the computer game industry as the demand for better skilled computerized opponents increase. We propose a general architecture of a Multi-agent System (MAS) based bot able to play complex board games and show that this solution is able to outperform other bots in two quite different games, namely no-press Diplomacy and Risk. Based on these results, we formulate a hypothesis of the applicability of MAS based bots in the domain of board games and identify the need for future investigations in the area.

Multiagent system architecture, Board games, RISK, Diplomacy

1. INTRODUCTION

Creating programs able to play classical strategic games such as Othello, Chess, Risk, Diplomacy and Go has since the early days of AI been a challenge [6]. Some of these, Chess, and especially Othello, Checkers, Backgammon are now considered *solved* in the sense that the programs are able to beat the top human players [1, 10, 14, 19], while games such as Go, Risk and Diplomacy still remain among the ones that we have a hard time to find an optimal computerized player for. The main problem of the latter games is the branching of possible moves. To take one example, the branching factor of chess is 20 for the first move ($20^2 = 400$ for the first round of moves), whereas in Diplomacy, there are 4430690040914420 unique openings [11]. This makes it intractable to use traditional minimax-based algorithms to search for good moves in the games.

Previous attempts to make agent based solutions to games include:

- Chess - Drogoul [3] and Fransson [4] have tried to create MASs playing Chess based on various kinds of negotiations between the Chess pieces, rather than traditional minimax search algorithms, but the performance of these systems is not overwhelming.
- Stratego - Treijtel made a MAS based Stratego player where the system implemented a distributed rule based decision system [22].
- Diplomacy - Kraus and Lehmann [9] and lately also Shaheed [15] have made heterogeneous MASs of agents able to negotiate with other players.
- No-press Diplomacy - Johansson and Håård show promising results in this version of Diplomacy with a bot based on a homogeneous MAS [7].
- Risk - Johansson and Olsson made a MAS playing Risk which showed to be successful [8].

The latter two will be described more in detail in Section 5. In the next section we will describe a general model of games, followed by a general MAS architecture in Section 3. We will then in Section 6 discuss how to evaluate MAS based bots before we finish with a discussion and draw some conclusions.

2. GENERAL MODEL OF THE GAME

We have chosen to limit this investigation to games which have the following properties:

1. It has a set of starting players S, where $|S|$ is either fixed, or within a certain interval.
2. The game has a set of territories T with an adjacency set $A \subseteq T \times T$.
3. The game has a set P of different types of pieces.
4. Each type of piece $p \in P$, may move according to $A_p \subseteq A$
5. The game is divided into a number of synchronized turns $T = \{t_0, t_1, ...\}$.

6. Each turn may be carried out in the sequence of the players, or in parallel.

7. The turns are divided into (at least) three phases: initial phase, action phase(s), and finish phase.

8. In the initial phase, I, new resources (if available) are entered into the system and preparations are made for the actions of the coming phases.

9. In an action phase, A, the player decides what actions to take and these are then performed according to the rules of the game.

10. In the finish phase, F, the player make preparations for the next phase.

In addition to this, each game may have a number of other properties, e.g.

- Typically, the state of the game restricts A_p even more.
- The state of the game may be partially unknown to the players.
- The territories may be occupied by none, one or several pieces at the same time.
- The adjacency matrix may be symmetric, or arbitrary.
- The game may have non-deterministic outcomes of the actions of the players.
- Each turn may consist of a single move, or a (dynamically set) sequence of moves.
- The game can be exogenous, zero-sum, or endogenous (in the sense that resources are enriched by the game, staying equal throughout the game, or being consumed in the game).

2.1 An example of a game

As an exemplification of our general model, let us take a closer look at the well-known game of chess. It is a game with six types of pieces (King, Queen, Bishop, Knight, Tower and Pawn). Each type has its own adjecency matrix[1], but the moves that are possible to make are further restricted by the state of the game (e.g. a pawn may only move straight forward unless the space in front of it is not occupied). Each turn, which are carried out in sequence, consists of an empty initial phase, a one-move action phase, and an empty finish phase (unless the players are using a clock). The outcome of an action is deterministic and the state of the game is known to its two players. The game is of the endogenous type and the territories may at most hold at most one piece at a time.

3. GENERAL MODEL OF THE BOT

The general idea is to have a multi-agent system where each important unit of the player on the board corresponds to an agent in the system. These agents may either correspond to the pieces or the territories of the player(s). The agents will then negotiate about what actions to take in the system, possibly helped by a mediator agent taking care of the actual negotiation (e.g. carry out an auction) through a negotiator mechanism. The architecture is depicted in Figure 1.

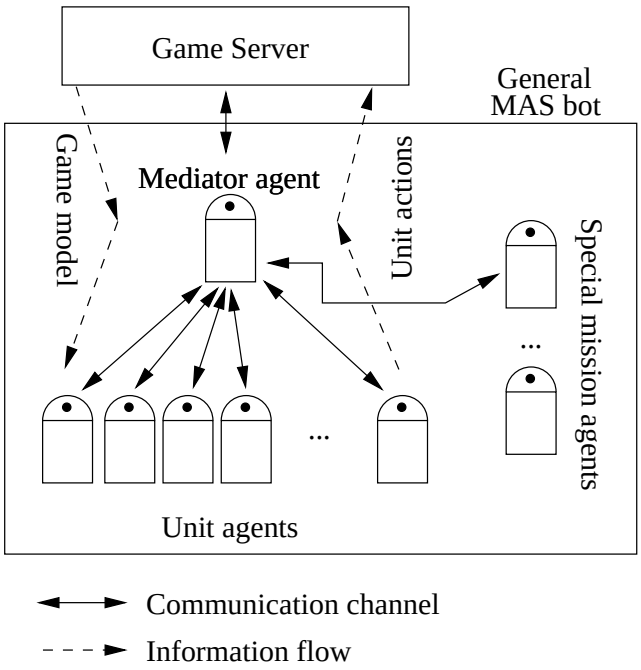

Figure 1: The agent system of the general model.

Typically, the mediator agent is also propagating the information from the agent system (i.e. what actions to perform) to the game server, as well as spreading the information from the server (e.g. the moves of the opponents) to the agent system (see the information router in Figure 2). This includes translating the information from its internal representation, to the external format used by the present game server and vice versa. This task is dedicated to the game server interface.

There may also be other agents in the system with dedicated missions, such as keeping track of the time (if it is a time critical game) or holding properties of the player that is not associated with a certain unit agent, e.g. opponent modeling.

In addition, there may be environment variables or parameters common to the whole MAS. These may be static throughout the game, or dynamically changed by the game server, or the agents of the system. Examples of such variables may be attack and defence weights, territory valuations, or algorithmic parameters (such as search depths).

Note that the proposed architecture is not restricted to the general model of the game outlined in Section 2. It would be possible to have play games that involve skipping turns or change the order of the play.

4. TWO INSTANCES OF GAMES

We will now (briefly) describe two games, no-press Diplomacy and Risk[2], which on the surface seems to be similar, but that are quite different in the way they are played. Among the similarities, the goal of the players in both games

[1]In fact, the bishop has two: one for the white squares, and one for the black squares

[2]Both games are ©Hasbro inc.

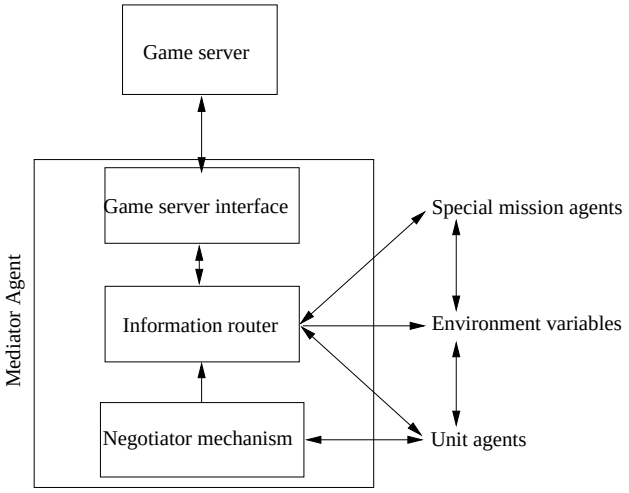

Figure 2: The mediator agent of the general bot

Property	Diplomacy	Risk	Chess
# players	7	2–6	2

Pieces/prov.	0–1	1–∞	0–1

Table 1: Differences between the games Diplomacy, Risk and Chess. The phases are *Initial, Action* and *Finish* (IAF).

is to conquer the map by defeating their opponents, but that is where the differences begin. As a reference we have included Chess as well in the comparison (see Table 1).

We will now describe some central details of the games.

4.1 The Characteristics of no-press Diplomacy

In no-press Diplomacy, seven players each control one of the great powers in the 1901 Europe (see Figure 3). The players control armies and fleets and the goal is to take control over the majority of some special territories (the production centers). All pieces of all players act in parallell in the action phases, either by moving, supporting, cutting opponent support (all of these to neighbouring territories only), or standing still. For a move to be successful, the moving piece must be superior in uncut support if the opponent also tries to move to that position (or already resides there). After each phase where the pieces try to act, a finish phase decides what moves that were successful, and what moves that were not. After two rounds of movements, the production center ownerships decide what powers that will get new pieces to place at their territories (this finish one year in the game). To avoid stale mates in the games (especially when bots are playing), a common solution is to finish the game in 1950 or when no production centers have changed owners for the last five years.

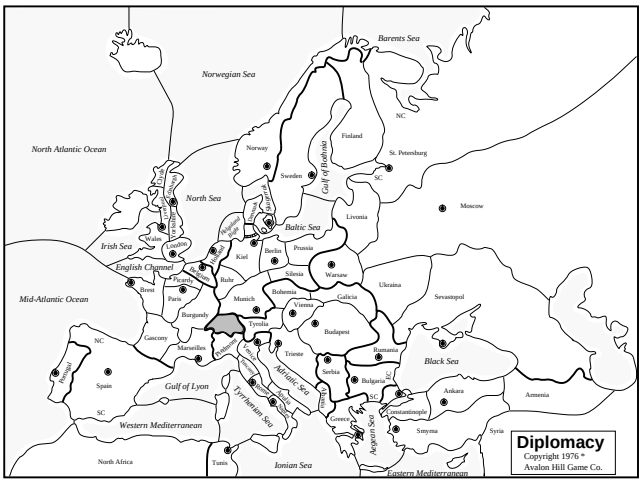

Figure 3: The map of the game of Diplomacy

Figure 4: The map of the game of RISK

4.2 The Characteristics of Risk

Risk is a game of two to six players, where the objective is to take control over the world (see Figure 4). This is achieved through invading opponent territories, and taking control over continents.[3] The players act in turns of three phases. In the initial phase, the player will get extra armies to place in its territories based upon the number of territories and the continents that they own. During the action phases, the player battles against opponents and tries to invade neighbour territories. This may be repeated for as long as the player has any armies left to attack with. In the finish phase, the player may move its armies. However, each army may only move one step and there must be at least one army left in each territory. If at least one battle has been successful, the player gets a bonus card that may be used in combination with other cards in the coming initial phases to get extra armies.

5. TWO INSTANCES OF BOTS

Following the general architecture of Section 3, we will now describe two bots able to play no-press Diplomacy and

[3]Many modern rule variations use special mission cards (where different players get different missions) to shorten the time it takes to play the game. However, we will not use missions cards in this work, but regard the total world domination as the common goal of all players.

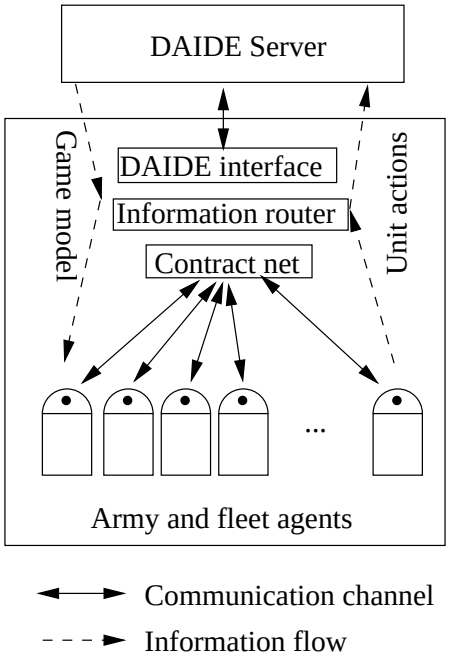

Figure 5: The no-press Diplomacy bot HaAI

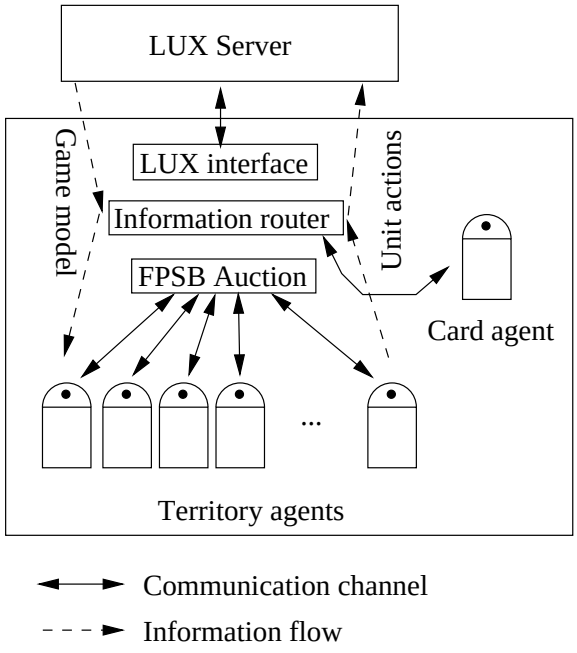

Figure 6: The RISK bot MARS

Risk respectively. For further details on the implementation we refer to previous work by Johansson and Håård [7] and Johansson and Olsson [8].

5.1 HaAI — A no-press Diplomacy Bot

The HaAI bot consists of a mediator agent and a set of unit agents. The mediator agent has an interface to the game server (in our case the DAIDE server [2]) and an information router that distributes the information going in and out of the system. To coordinate the actions of the units, a contract net-mechanism is used [17]. Here the units suggest prioritized tasks and adapt to support such tasks until all agents are doing the best they can to expand their territories and defend themselves from the opponent forces, see Figure 5.

The unit agents correspond to the armies and fleets of the player, so that each unit has the possibility to decide by itself what action to take (to move, to support the movement of another unit, or to cut the support of an opponent unit). A number of parameters are used in the evaluation of the different candidate actions [7].

5.2 MARS — A Risk Bot

The MARS bot consists of a mediator agent with a LUX interface, an information router, and a first price sealed bid (FPSB) auction mechanism that handles the coordination between the unit agents. In MARS, each territory has an agent (as opposed to each piece owned by the player, as was the case in the HaAI bot). A dedicated card agent keeps track of the cards of the player and exchange them for new armies in an optimal way (see Figure 6).

The initial phase starts by letting all territories (the own as well as the ones held by the opponents) calculate the value of holding that particular territory [8]. Such an approach, using the territories rather than the pieces, is as far as we know novel in the field of bots for board games. In the case of the own territory, this is a defensive bid, in the case of an opponent territory, the information of how many armies that defends it and the value of owning it is propagated to all neighbours. Their values and armies are added, the path is added (possible cycles are removed), and the information is propagated further in a recursive way (up to a predefined depth). When the paths with the values and number of defending armies reach an own territory, it is considered by the territory as an offensive bid. The agents of the own territories then calculate the accumulated probabilities of reaching the goals given the different numbers of armies that they may use in the attacks. The bids with the highest ratio of value/(expected number of armies needed to succeed) will get their share of the new armies. The card agent will also possibly cash in some extra armies for the system to use at this stage.

An action phase consists of a battle, where the plans of the winning bids of the initial phase are realised. Such plans may be single step plans, but often they consist of several battles carried out in sequence.

In the finish phase, the own territory agents use a distributed max flow algorithm to find the optimal movements of the armies. If MARS has won any battle during the action phase(s), the card agent will get a new card.

6. ON THE EVALUATION OF BOTS

We have used open bot tournaments as a way to measure the performance of our solutions. In both the Diplomacy and the Risk communities, there are bot developers that are willing to try their solutions in competition with others. Although previous work has presented successful attempts to use humans in training and/or evaluating bots (see e.g. [20]), there are a few reasons why we have chosen not to compare the solution with human players in these tournaments:

1. Bot tournaments can be batched, humans not. It is easy to set up a round robin tournament with say 1000 matches using a simple script, but to get a human player to participate to the same extent is impossible.

2. Bots are in general faster than human players, thus decreasing the time to get to the result.

3. Bots are blind and objective, while humans may decide to eliminate the bots first (just because they are bots). This *bots first strategy* is highly developed in the Risk (LUX) community. Unfortunately, such a strategy makes it hard to do a fair evaluation of the strengths of the different players.

In both cases we called for the participation of an open tournament through the fora and mailing lists of the communities. We invited the designers of bots for the largest game server platforms of the games (DAIDE and LUX respectively). The tournament was then run in a Round Robin fashion (i.e. everyone met every other set of opponents) and the scores of all matches were noted. We also measured the time it took for the bots to play the games in order to be able to compare the efficiency of the different solutions.

6.1 The Results of the no-press Diplomacy Tournament

A total of 592 matches were run on DAIDE out of which 487 ended with a single winner and 105 matches were draws. In case of a draw (no one has won after 50 simulated years), the score of seven points is divided between the remaining players. We see (in Table 2) that the two versions of HaAI manage quite well, ending up at the first and third place in the tournament.

What the efficiency is concerned, according to Table 3, HaAI does not have the best figures (not the worst either). It is clearly the fastest Java-based bot among the participators, but not as fast as the C++-implemented *DumbBot 2*.

6.2 The Results of the RISK Tournament

The RISK tournament was run on the LUX platform which is the platform for which there are the greatest number of bots available [16]. Twelve bots participated in addition to our MARS bot and played 792 matches each. MARS was a clear winner of this tournament with more than 50 per cent more wins than the second and third placed *Bort* and *EvilPixie*.

When it comes to efficiency, MARS still comes out at the top of the others. If we compare the amount of calculations needed (at an average) to win a game, we see that the ratio Wins/(average time per turn) is higher for MARS (even though it is among the slowest bots, see Table 5). This shows that MARS uses an efficient way of calculating good RISK moves.

Bot	Matches won	Solo score	Total score
HaAI 0.63 Berserk	109	763	866.05
DiploBot 1.2	95	665	763.10
HaAI 0.63 Vanilla	81	567	724.64
Man'Chi AttackBot	75	525	658.32
DumbBot 2	87	609	651.34
Man'Chi DefenceBot	40	280	444.27
RandBot	0	0	0.06

Table 2: Scores of the Diplomacy tournament. The total score include the scores of the draw matches.

Bot type	Orders/s	Impl. Language

7. DISCUSSION

We will now comment the results, and discuss the possible general conclusions that may be drawn from the experiments.

7.1 Comments on the results

The results of the tournaments raise a lot of questions. Were they mostly due to an intelligent setting of the parameters of the environment? Did we use the best opponents? How did our choice of game platform effect the behavior of our solution? What are the drawbacks of the approach?

Let us start with the parameters. Both MARS and HaAI use a wide range of parameters.[4] In the case of HaAI, a first *ad hoc* setting of the parameters was made and minor adjustments led to the two versions that entered the tournament[5]. MARS used a slightly more structured approach where we iteratively narrowed the search space of the two major parameters — the bonus for being offensive and the threshold probability for attacking [13]. Of course the values of the parameters play an important role when it comes to the performance of the bot. However, we have no reason to believe that we are superior in this respect (compared to our competitors). On the contrary, we believe that great improvements can be achieved by using machine learning

[4]HaAI has about 11 main parameters, and MARS has about 14.

approaches to find the right set of parameters, but that has not been the focus of this project.

The platforms were chosen based on the number (and quality) of opponents, and the documentation of the system. In both cases, the chosen game platforms were the ones which had the largest number of competitive opponent bots (among the ones we chose from).

The set of opponents is of course questionable. We encouraged the communities to send in their bots to us for participation in the tournaments; thus we did what we could to get the best possible opponents. However, this does not mean that there are not any bots out there that for one reason or another did not wish to participate e.g. due to bugs, or the unwillingness to share their programming secrets with us (see e.g. Håård [5]).

In all we believe that the successful results in the tournaments are to a great extent the results of a well implemented distributed problem solving mechanism based on the MAS architecture outlined in Section 3. Possibly the choice of parameters and the set of opponents may have had an additional positive effect on the results.

Among the drawbacks of our solution are that it may be hard (in its pure form) to implement strategic sacrifices, since all unit agents are trying to maximize their own utilities and they do only use a single step look-ahead. The way to address this problem may be to use special mission agents that focus on strategic issues through dynamic updates of the utility functions.

So, what are the key factors that makes our approach work better than the opponent bots in the investigated domains?

Our hypothesis is that game domains holding the following properties are especially well suited for MAS-based bots (compared to traditional search tree-based bots):

- *Large number of units in the game.* When there are a lot of units (i.e. armies or territories), each of which behavior may be modelled separately by an agent, the MAS bot seems to be a dynamic, but yet easily understood solution.
- *Large action space.* In both Risk and Diplomacy, the number of actions a player may take in each turn is considerably larger than e.g. in chess. It does of course not *help* us to have many options, but since our solutions do not rely on opponent modeling and thereby a search in the tree of possible outcomes (c.f. minimax), they do not get caught in the exponential explosion of possible states that such a search leads to.
- *Large number of players.* A large number of players furthermore increases the difficulty to predict the future state of the game since it increase the branching factor.
- *Unreliable outcome of the performed actions.* The more precisely the effect of the actions a player take can be predicted, the easier it is to predict the future state of the game.

Support for this hypothesis is to be found both in previous work on bots for variants of Diplomacy [7, 9, 15] and Risk [8], but also in the less successful attempts to make bots based on MAS principles for playing e.g. Chess [3, 4]. However, it is still too early to draw any conclusions based upon these initial studies. More work is needed in the area before we may consider MAS based bots in general to be strong solutions in complex board game playing while being less appropriate to use in games requiring long look-ahead.

8. CONCLUSIONS

Our conclusion is that the MAS architecture described here may be a suitable candidate for creating competitive bots able to play games with high branching factors that are distributed in nature. We support this claim by reporting positive results from testing our solution in two different domains, namely the game of Diplomacy and the game of Risk. Despite the success in these isolated domains, we identify the need for more research within the area in order to draw any wider conclusions.

9. FUTURE WORK

There is support for the claim that complex domains such as the ones outlined in Section 7.1 above are favoured by multi-agent solutions [12, 18]. MAS based bots have shown to work well in Diplomacy and Risk, but what about the games which do not hold all the properties of these two

games? Go is one such game. It has got a large number of possible moves and a large number of stones[5]. However, the game has only two players and the moves are fully deterministic. It is therefore an open problem whether Go can be successfully played by a MAS based bot.

Settlers of Catan[6] is another game that has reached a large audience during the last years, especially through its online versions, e.g. *Java Settlers* by Robert Shaun Thomas [21]. Thomas used single agent bots and although he does not rule out the possibility to build bots with distributed architectures, he claims the single agent solution to be simpler (and thus better referring to the *less is more* principle) [20].

We will in our future work examine what game properties that are the most significant when it comes to the results of MAS based solutions. This will be done by trying a number of different suitable board games, e.g. Go and Settlers of Catan.

There are also a number of possible improvements regarding the roles of the special mission agents, e.g.:

- *Opponent short term modeling*, i.e. dynamic real time updates of the environment variables in order to adjust to the current opponent strategies.

- *Opponent classification* By learning the characteristics of different players and store the classification between the games, we may at an earlier stage identify what player that is playing what power and update the dynamic variables faster than what would have been the case if we used short term modeling only.

- *Parameter optimization*; the parameters of the environment may be updated based on the results of the games. This may effect the willingness to attack, or the utility of holding certain territories in the longer perspective.

- *Added functionality* In Diplomacy (without the prefix no-press), the players are allowed (and encouraged) to cooperate in order to achieve their goals. The system of e.g. Kraus and Lehmann [9] uses additional agents such as *minister of defence*, and *secretary of the prime minister* to deal with the negotiations with the opponent players. Such functionality may be added to the proposed architecture as special mission agents.

Last, but not least, we would like to carry out experiments with human players in order to measure the strength of our solution compared to the one of human players.

10. ACKNOWLEDGEMENTS

The author would like to thank Fredrik Håård and Fredrik Olsson for their hard work on the implementation of the bots and the creative discussions and co-authoring that led to our previous publications [7, 8]. We would also like to thank the game communities of DAIDE and LUX for the resistance in the tournaments, the reviewers of AAMAS'06 for the valuable comments and Blekinge Institute of Technology for funding this project.

ABSTRACT

A distributed constraint optimization problem (DCOP) is a formalism that captures the rewards and costs of local interactions within a team of agents, each of whom is choosing an individual action. When rapidly selecting a single joint action for a team, we typically solve DCOPs (often using locally optimal algorithms) to generate a single solution. However, in scenarios where a set of joint actions (i.e. a set of assignments to a DCOP) is to be generated, metrics are needed to help appropriately select this set and efficiently allocate resources for the joint actions in the set. To address this need, we introduce *k*-optimality, a metric that captures the desirable properties of diversity and relative quality of a set of locally-optimal solutions using a parameter that can be tuned based on the level of these properties required. To achieve effective resource allocation for this set, we introduce several upper bounds on the cardinalities of *k*-optimal joint action sets. These bounds are computable in constant time if we ignore the graph structure, but tighter, graph-based bounds are feasible with higher computation cost. Bounds help choose the appropriate level of *k*-optimality for settings with fixed resources and help determine appropriate resource allocation for settings where a fixed level of *k*-optimality is desired. In addition, our bounds for a 1-optimal joint action set for a DCOP also apply to the number of pure-strategy Nash equilibria in a graphical game of noncooperative agents.

1. INTRODUCTION

In a large class of multi-agent scenarios, a set of agents chooses a joint action (JA) as a combination of individual actions. Often, the locality of agents' interactions means that the utility generated by each agent's action depends only on the actions of a subset of the other agents. In this case, the outcomes of possible JAs can be compactly represented in cooperative domains by a distributed constraint optimization problem (DCOP)[12, 20] or, in noncooperative domains, by a graphical game [6]. Each of these models can take the form of a graph (or hypergraph) in which each node is an agent and each edge (or hyperedge) denotes a subset of agents whose actions, when taken together, incur costs or rewards, either to the agent team (in DCOPs) or to individual agents (in graphical games). In the case of DCOP, if each agent controls a single variable, then a single JA is a complete assignment of values to variables (i.e. every agent chooses an individual action for itself). We focus primarily on the team setting, using DCOP, whose applications include multi-agent plan coordination [4], sensor networks [12], and RoboCup soccer [17].

Traditionally, researchers have focused on obtaining a single JA, expressed as a single assignment of actions to agents in a DCOP. However, in this paper, we consider a multi-agent system that generates a *set* of JAs, i.e. multiple assignments to the same DCOP. Generating sets of JAs is useful in domains such as disaster rescue (to provide multiple rescue options to a human commander) [15], patrolling (to execute multiple patrols in the same area) [14], training simulations (to provide several options to a student) and others [16]. We provide three key contributions to address such domains. The first contribution is to determine the appropriate metric for evaluating a set of JAs. While high absolute reward is an appropriate metric in single-solution domains, reward alone is a poor metric for these multiple-JA domains, as it often yields clusters of very similar JAs, as shown in Section 2 of this paper. Clustering is undesirable, as diversity, the difference among JAs, is a key property for a JA set in many domains [16]. Diversity alone is undesirable, because it leads to low-quality solutions. Hence, this paper introduces a new metric, *k*-optimality, that naturally captures the diversity and relative quality of a JA set. A *k*-optimal JA has the highest reward within a neighborhood of other JAs that differ from it by at most *k* individual actions; i.e. no *k*-optimal JA can be improved if *k* or fewer agents change actions. Therefore, *k*-optimality quantifies the neighborhood in which a JA is optimal. In a *k*-optimal JA set, defined as a set of JAs, each of which is itself *k*-optimal, all JAs in the set are guaranteed a particular level of relative quality (best in their neighborhoods), as well as diversity (every two JAs must be separated by at least $k + 1$ individual actions).

Domains requiring repeated patrols in an area by a team of UAVs (unmanned air vehicles), UGVs (unmanned ground vehicles), or robots, for peacekeeping or law enforcement after a disaster, provide one key illustration of the utility of *k*-optimality. For example, given a team of patrol robots in charge of executing multiple joint

patrols in an area as in [14], each robot may be assigned a region within the area. Each robot is controlled by a single agent, and hence, for one joint patrol, each agent must choose one of several possible routes to patrol within its region. A joint patrol is a JA, where each agent's action is the route it has chosen to patrol, and rewards and costs arise from the combination of routes patrolled by agents in adjacent or overlapping regions. For example, if two nearby agents choose routes that largely overlap on a low-activity street, the constraint between those agents would incur a cost, while routes that overlap on a high-activity street would generate a reward. Agents in distant regions would not share a constraint. If reward alone is used as a metric to select joint patrols, then all selected joint patrols could be the same, except for the action of one agent. This set of patrols would be repetitive and predictable to adversaries. If we pick some diverse joint patrols at random, they may be very low-quality patrols. Using *k*-optimality directly addresses such circumstances; *k*-optimality ensures that all joint patrols differ by at least $k + 1$ agents' actions, as well as ensuring that this diversity would not come at the expense of obviously bad joint patrols, as each is optimal within a radius of at least *k* agents' actions.

After introducing *k*-optimality, our second key contribution in this paper is addressing efficient resource allocation for the multiple JAs in a *k*-optimal set, by defining tight upper bounds on the number of *k*-optimal JAs that can exist for a given DCOP. These bounds are necessitated by two key features of the typical domains where a *k*-optimal set is applicable. First, each JA in the set consumes some resources that must be allocated in advance. Such resource consumption arises because: (i) a team actually executes each JA in the set, as in our patrolling example above, or (ii) the JA set is presented to a human user (or another agent) as a list of options to choose from, requiring time. In each case, resources are consumed based on the JA set size. Second, while the existence of the constraints between agents is known *a priori*, the actual rewards and costs on the constraints depend on conditions that are not known until runtime, and so resources must be allocated before the rewards and costs are known and before the agents generate the *k*-optimal JA set. In the patrolling domain, constraints are known to exist between patrol robots assigned to adjacent or overlapping regions. However, their costs and rewards depend on recent field reports of adversarial activity that are not known until the robots are deployed. At this point the robots must already be fueled in order for them to immediately generate and execute a set of *k*-optimal patrols. The resource to be allocated to the robots is the amount of fuel required to execute each patrol; thus it is critical to ensure that enough fuel is given to each robot so that each JA found can be executed, without burdening the robots with wasted fuel that will go unused. Consider another domain involving a team of disaster rescue agents that must generate a set of *k*-optimal JAs in order to present a set of diverse options to a human commander, where each option represents the best JA within a neighborhood of similar JAs. The commander will choose one JA for the team to actually execute. Constraints exist between agents whose actions must be coordinated (i.e. members of subteams) but their costs and rewards depend on conditions on the ground that are unknown until the time when the agents must be deployed. Here, the resource is the time the commander has to make the decision. Presenting too many options will cause the commander to run out of time before considering them all, and presenting too few may cause high-quality options to be omitted.

Because each JA consumes resources, knowing the maximal number of *k*-optimal JAs that could exist for a given DCOP would allow us to allocate sufficient resources for a given level of *k*. Unfortunately, we cannot predict this number because the costs and rewards for the DCOP are not known in advance. Despite this uncertainty, reward-independent bounds can be obtained on the size of a *k*-optimal JA set, i.e. to safely allocate enough resources for a given value of *k* for any DCOP with a particular graph structure. We first identify a mapping to coding theory, yielding bounds independent of both reward and graph structure. We then provide a method to use the structure of the DCOP graph (or hypergraph of arbitrary arity) to obtain significantly tighter bounds.

The third key contribution in this paper is to establish a connection to noncooperative settings by proving that our bounds for 1-optima also apply to the number of pure-strategy Nash equilibria in any graphical game on a given graph, which remains an open problem. In addition to their uses in resource allocation, these bounds provide insight into the problem landscapes that can exist in both cooperative and noncooperative settings.

2. *k*-OPTIMALITY

We introduce the notion of *k-optimality* as a metric that captures both relative quality and diversity when selecting a set of JAs. We begin with our model of the multi-agent team problem, which is a DCOP in which each agent controls a single variable to which it must assign a value. These values correspond to individual actions that can be taken by the agents. Subgroups of agents, whose combined actions generate a cost or reward to the team, define the constraints between agents. Because we assume that each agent controls a single variable, we will use the terms "agent" and "variable" interchangeably. More formally, for a set of agents $\mathcal{I} := \{1, \ldots, I\}$, the ith agent takes action $a_i \in \mathcal{A}_i$. We denote the joint action of a subgroup of agents $S \subset \mathcal{I}$ by $a_S := \times_{i \in S} a_i \in \mathcal{A}_S$ where $\mathcal{A}_S := \bigtimes_{i \in S} \mathcal{A}_i$ and the joint actions (JAs) of the entire multi-agent team by $a = [a_1 \cdots a_I] \in \mathcal{A}$ where $\mathcal{A} := \bigtimes_{i \in \mathcal{I}} \mathcal{A}_i$. The team reward for taking a particular JA, a, is an aggregation of the rewards obtained by subgroups in the team: $R(a) = \sum_{S \in \theta} R_S(a) = \sum_{S \in \theta} R_S(a_S)$ where S is a minimal subgroup that generates a reward (or incurs a cost) in an n-ary DCOP (i.e. a constraint), θ is the collection of all such minimal subgroups for a given problem and $R_S(\cdot)$ denotes a function that maps $\mathcal{A}_S$ to $\mathbb{R}$. By minimality, we mean that the reward component R_S cannot be decomposed further. Mathematically: $\forall S \in \theta, R_S(a_S) \neq R_{S_1}(a_{S_1}) + R_{S_2}(a_{S_2})$ for any $R_{S_1}(\cdot) : \mathcal{A}_{S_1} \to \mathbb{R}, R_{S_2}(\cdot) : \mathcal{A}_{S_2} \to \mathbb{R}, S_1, S_2 \subset \mathcal{I}$ such that $S_1 \cup S_2 = S, S_1, S_2 \neq \emptyset$. It is important to express the constraints minimally to accurately represent dependencies among agents.

To evaluate JA sets, specifically JAs with respect to each other, we need notions of neighborhood and distance among JAs. For two JAs, a and $\tilde{a}$, we define the following terms. The *deviating group* is $D(a, \tilde{a}) := \{i \in \mathcal{I} : a_i \neq \tilde{a}_i\}$, i.e. the set of agents whose actions in JA $\tilde{a}$ differ from their actions in JA a. The *distance* is $d(a, \tilde{a}) := |D(a, \tilde{a})|$ where $|\cdot|$ denotes the cardinality of the set. The *relative reward* of a JA a with respect to another JA $\tilde{a}$ is $\Delta(a, \tilde{a}) := R(a) - R(\tilde{a}) = \sum_{S \in \theta : S \cap D(a,\tilde{a}) \neq \emptyset} [R_S(a_S) - R_S(\tilde{a}_S)]$. In this summation, only the rewards on constraints incident on deviating agents are considered, since the other rewards remain the same. We assume every subgroup of agents G has a unique optimal subgroup joint action a^*_G for any context, where a context consists of a_{G^C}, the actions of the agents not in G, i.e. the complement of G. Mathematically, if $G \subset \mathcal{I}$ where $G \neq \emptyset$ and $G \neq \mathcal{I}$, then $\exists\, a^*_G \in \mathcal{A}_G \; s.t. \; R(a^*_G; a_{G^C}) > R(a_G; a_{G^C}) \forall a_G \neq a^*_G$. Here the notation $R(a_G; a_{G^C})$ is used to indicate the overall team reward generated when subgroup G takes the JA a_G with respect to a fixed context of a_{G^C}. The above assumption is natural for domains where rewards come from precise measurements, and is common in work on bounds and estimates for numbers of local optima [2] and Nash equilibria [11]. Given this assumption, we now classify a as a *k*-

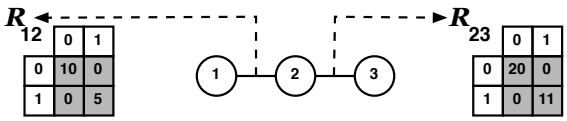

Figure 1: DCOP example

optimal JA or *k-optimum* if $\Delta(a, \tilde{a}) > 0 \ \forall \tilde{a}$ s.t $d(a, \tilde{a}) \leq k$. Equivalently, if the set of agents have reached a k-optimum, then no subgroup of cardinality $\leq k$ can improve the overall reward by choosing different actions; every such subgroup is acting optimally with respect to its context.

A collection of k-optimal JAs must be mutually separated by a distance $\geq k+1$ as they each have the highest reward within a radius of k. Thus, a higher k-optimality of a collection implies a greater level of relative reward and diversity. Let $A_q(I,k) = \{a \in \mathcal{A} : \Delta(a, \tilde{a}) > 0 \ \forall \tilde{a}$ s.t $d(a, \tilde{a}) \leq k\}$ be the set of all k-optimal JAs for a team of I agents with domains of cardinality q. It is straightforward to show $A_q(I, k+1) \subseteq A_q(I, k)$.

EXAMPLE 1. *Figure 1 is a binary DCOP in which agents choose actions from* $\{0, 1\}$*, with rewards shown for the two constraints (minimal subgroups)* $S_1 = \{1, 2\}$ *and* $S_2 = \{2, 3\}$*. The assignment* $a =$ [1 1 1] *is* 1*-optimal because any single agent that deviates reduces the team reward. However,* [1 1 1] *is not* 2*-optimal because if the group* $\{2, 3\}$ *deviated, making the assignment* $\tilde{a} =$ [1 0 0]*, team reward would increase from 16 to 20. The globally optimal solution,* $a^* =$ [0 0 0] *is k-optimal for all* $k \in \{1, 2, 3\}$.□

We now show, in an experiment, the advantages of k-optimal JA sets as capturing both diversity and high reward compared with JA sets chosen by other metrics. The lower half of Figure 2(a) shows a DCOP graph representing a team of 10 patrol robots, each of whom must choose one of two routes to patrol in its region. The nodes are agents and the edges represent binary constraints between agents assigned to overlapping regions. The actions (i.e. the chosen routes) of these agents combine to produce a cost or reward to the team. For each of 20 runs, the edges were initialized with rewards from a uniform random distribution. The set of all 1-optima was enumerated. Then, for the same DCOP, we found equal-sized sets of JAs using two other metrics. In one metric, the set of JAs with highest reward are included, and in the next, JAs were selected purely for diversity by the following method. We repeatedly cycled through all possible JAs in lexicographic order, and included a JA in the set if the distance between it and every JA already in the set was not less than a specified distance; in this case 2. The average reward and the diversity (expressed as the minimum distance between any pair of JAs in the set) for the JA sets chosen using each of the three metrics over all 20 runs is shown in the upper half of Figure 2(a). While the sets of 1-optima come close to the reward level of the sets chosen purely according to reward, they are clearly more diverse (T-tests for this claim showed a significance within .0001%). If a minimum distance of 2 is required in order to guarantee diversity, then using reward alone as a metric is insufficient; in fact the JA sets generated using that metric had an average minimum distance of 1.21, compared with 2.25 for 1-optimal JA sets (which guarantee a minimum distance of $k+1 = 2$). The 1-optimal JA set also provides significantly higher average reward than the sets chosen to maintain a given minimum distance, which had an average reward of 0.037 (T-test significance within .0001%.). Similar results with equal significance were observed for the 10-agent graph in Figure 2(b) and the nine-agent graph in Figure 2(c). Note also that this experiment used $k = 1$, the lowest possible k. Increasing k would, by definition, increase the diversity of the k-optimal JA set as well as the neighborhood size for which each JA is optimal.

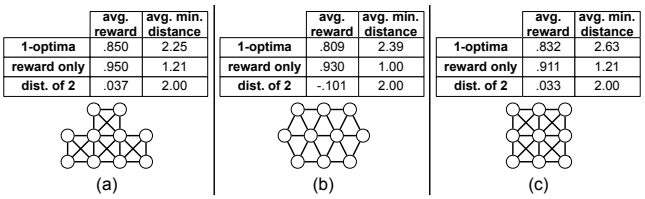

Figure 2: 1-optima vs. JA sets chosen using other metrics

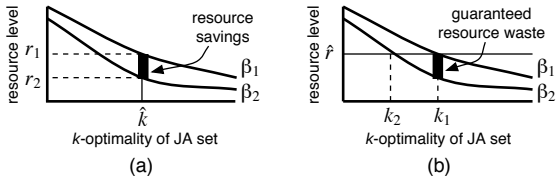

Figure 3: Hypothetical example illustrating the advantages of tighter bounds

In addition to categorizing local optima in a DCOP, k-optimality provides a natural classification for DCOP algorithms. Many known algorithms are guaranteed to converge to k-optima for some $k > 0$, including DBA [20], DSA [5], and coordinate ascent [17] for $k = 1$, MGM-2 and SCA-2 [9] for $k = 2$, and Adopt [12], OptAPO [10] and DPOP [13] for $k = I$. For $k < I$, random restarts of these "k-optimal algorithms" can be used to find sets of k-optimal JAs.

3. UPPER BOUNDS ON k-OPTIMA

Upper bounds on the number of possible k-optimal JAs, $|A_q(I,k)|$ are useful for two reasons: they yield resource savings in domains where a particular level of k-optimality is desired, and help determine the appropriate level of k-optimality to prevent guaranteed waste of resources (fuel, time, etc.) in settings with fixed resources.

First, a particular level of k-optimality may be desired for a JA set: a high k will include JAs that are more diverse, and optimal within a larger radius, but high-k algorithms have significantly higher coordination/communication overheads [12, 10, 9]; hence lower k is preferable under time pressure. Lower k may also be preferable if an agent team or a human user wants a more detailed set of JAs, for example, more joint patrols, more rescue options, etc. For a given level of k-optimality, bounds indicate the maximum resource requirement for any k-optimal JA set. Thus, tighter bounds provide savings by allowing fewer resources to be allocated *a priori* while ensuring enough will be available for all k-optimal JAs, regardless of the rewards and costs on the constraints. Figure 3 is a hypothetical example, with k on the x-axis and the number of resources to be allocated on the y-axis. β_1 and β_2 are two different upper bounds on the number of k-optimal JAs that can exist for a given DCOP. Part (a) shows how the tighter bound β_2 indicates that a resource level of r_2 is sufficient for all $\hat{k}$-optimal JAs, if each JA consumes one resource, yielding a savings of $r_1 - r_2$ over using β_1.

Second, if resource availability is fixed, tighter bounds help us choose an appropriate level of k-optimality. If k is too low, we may exhaust our resources on bad JAs (similar JAs with poor relative quality). In contrast, fewer k-optimal JAs can exist as k increases, and so if k is too high, available resources that could be spent on additional JAs are guaranteed to go unused. Tighter bounds provide a more accurate measure of this kind of guaranteed waste and thus, allow a more appropriate k to be chosen. In Figure 3(b), under fixed resource level $\hat{r}$, the looser bound β_1 hides the resources guaranteed to go unused when k_1 is used. This waste is revealed by β_2, with the thick line indicating the resources that, if allocated, will never be used, as there cannot exist enough k-optima to use them all; instead, we now see that using k_2 will reduce this guaranteed waste.

To find the first upper bounds on the number of k-optima for a given DCOP graph, we discovered a correspondence to coding theory [8]. In error-correcting codes, a set of codewords must be chosen from the space of all possible words, where each word is a string of characters from an alphabet. All codewords are sufficiently different from one another so that transmission errors will not cause one to be confused for another. Finding the maximum possible number of k-optima can be mapped to finding the maximum number of codewords in a space of q^I words where the minimum distance between any two codewords is $d = k + 1$. We can map JAs (complete DCOP assignments) to words and k-optima to codewords as follows: A JA a taken by I agents each with a domain of cardinality q is analogous to a word of length I from an alphabet of cardinality q. The distance $d(a, \tilde{a})$ can then be interpreted as a Hamming distance between two words. Then, if a is k-optimal, and $d(a, \tilde{a}) \leq k$, then $\tilde{a}$ cannot also be k-optimal by definition. Thus, any two k-optima must be separated by distance $\geq k + 1$.

Three well-known bounds [8] on codewords are Hamming: $\beta_H = q^I / \left(\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j\right)$, Singleton: $\beta_S = q^{I-k}$, and Plotkin: $\beta_P = \left\lfloor \frac{k+1}{k+1-(1-q^{-1})I} \right\rfloor$, which is only valid when $(1 - 1/q)n < k + 1$. Note that for the special case of $q = 2$, it is possible to use the relation $\beta_H(I, k, q) = \beta_H(I - 1, k - 1, q)$[8] to obtain a tighter bound for odd k using the Hamming bound. Now, to find a reward-independent bound on the number of 1-optima for three agents with $q = 2$, (e.g., the system in Example 1), we obtain $\min\{\beta_H, \beta_S, \beta_P\} = \beta_H = 4$, without knowing R_{12} and R_{23} explicitly.

Unfortunately, problems of even d (odd k), are not of interest for error-correcting codes, and β_H, the Hamming bound, is very loose or useless for DCOP when $q > 2$, e.g., for 1-optima (solutions reached by DSA) the bound is equal to the number of possible assignments in this case. Hence, for DCOP, we pursue an improved bound for $q > 2$ and odd k. β_H is derived by using a sphere-packing argument stating that the total number of words q^I must be greater than the number of codewords $A_q(I, k)$ multiplied by the size of a sphere of radius $\lfloor k/2 \rfloor$ centered around each codeword. A sphere $S_A(a^*, r)$ with center a^* and radius r is the set of JAs $\tilde{a}$ such that $d(a^*, \tilde{a}) \leq r$, and represents words that cannot be codewords (except for its center). It can be shown that $S_A(a^*, \lfloor k/2 \rfloor)$ contains exactly $\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j$ words. If k is even, the tightest packing occurs with spheres of radius $k/2$ and each word can be uniquely assigned to the sphere of its closest codeword. If k is odd, it is possible for a word to be equidistant from two codewords and it is unclear how to assign it to a sphere. The Hamming bound addresses this issue by using the bound for $k-1$ when k is odd, which leads to smaller spheres and a bound larger than necessary. This ignores the contribution of a word that lies on the "boundary" between several spheres. These boundary assignments can be appropriately partitioned to achieve a tighter bound on the number of k-optima for odd k, called the *Modified Hamming bound*.

PROPOSITION 1. *For odd k, $A_q(I, k) \leq \min\{A_1, A_2\}$ where*

$$A_1 = \frac{q^I - \binom{I}{(k+1)/2}(q-1)^{(k+1)/2}}{\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j}$$

$$A_2 = \frac{q^I}{\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j + \binom{I}{(k+1)/2}(q-1)^{(k+1)/2}(I^{-1})}$$

Proof. Any word that has Hamming distance $\lfloor k/2 \rfloor$ or less from a codeword belongs in that codeword's sphere, because belonging to more than one sphere would violate the code's distance requirement. Given an odd value of k, each codeword will have $\binom{I}{(k+1)/2}(q-1)^{(k+1)/2}$ words that are a distance of $(k + 1)/2$ away from it. It cannot claim all these words for its sphere exclusively, as they may be equidistant from other codewords. We do know however that each of these words can be on the boundary of at most I spheres (i.e. can be equidistant from at most I codewords) because they are of length I. Furthermore, each of these words can be equidistant from at most $A_q(I, k)$ codewords, i.e. the total number of codewords in the space. Thus, each codeword can safely incorporate $1/\min\{I, A_q(I, k)\}$ of each of these boundary words into its sphere without any portion being claimed by more than one sphere. Aggregating over all the words on the boundary, we can increase the volume of the sphere by $\binom{I}{(k+1)/2}(q-1)^{(k+1)/2}/\min\{I, A_q(I, k)\}$. Using the sphere-packing argument with the portions of the boundary words added to each sphere, if $A_q(I, k) \leq I$, we have

$$q^I \geq A_q(I, k)\left[\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j + \frac{\binom{I}{(k+1)/2}(q-1)^{(k+1)/2}}{A_q(I, k)}\right]$$

$$\Rightarrow A_q(I, k) \leq \frac{q^I - \binom{I}{(k+1)/2}(q-1)^{(k+1)/2}}{\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j} \equiv A_1,$$

and if $A_q(I, k) \geq I$, we have

$$q^I \geq A_q(I, k)\left[\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j + \frac{\binom{I}{(k+1)/2}(q-1)^{(k+1)/2}}{I}\right]$$

$$\Rightarrow A_q(I, k) \leq \frac{q^I}{\sum_{j=0}^{\lfloor k/2 \rfloor} \binom{I}{j}(q-1)^j + \binom{I}{(k+1)/2}(q-1)^{(k+1)/2}(I^{-1})} \equiv A_2.$$

We have $A_q(I, k) \leq I \Rightarrow A_q(I, k) \leq A_1$ and $A_q(I, k) \geq I \Rightarrow A_q(I, k) \leq A_2$. We can show that $A_1 \odot I \Leftrightarrow A_2 \odot I$, $\forall \odot \in \{<, >, =\}$. Furthermore, $A_1 \odot I, A_2 \odot I \Leftrightarrow A_1 \odot A_2$. Thus, when $A_1 \leq I$, then $A_2 \leq I$ and $A_1 \leq A_2$. So, $A_q(I, k) \leq A_1 = \min\{A_1, A_2\}$ when $A_1 \leq I$. And, when $A_1 > I$, then $A_2 > I$ and $A_1 > A_2$. So, $A_q(I, k) \leq A_2 = \min\{A_1, A_2\}$ when $A_1 > I$. Therefore, $A_q(I, k) \leq \min\{A_1, A_2\}$.■

We call the Modified Hamming bound β_{MH} and define $\beta_{HSP} = \min\{\beta_H, \beta_S, \beta_P, \beta_{MH}\}$, including the relation for β_H for $q = 2$; i.e. β_{HSP} gives the best of all the (graph-independent) bounds so far.

4. GRAPH-BASED ANALYSIS: *k*-OPTIMA

The β_{HSP} bound and its components depend only on I, k and q, regardless of how the team reward is decomposed onto constraints; i.e., the bounds are the same for all θ. For instance, the bound on 1-optima for Example 1 (found to be 4 in the previous section) ignored the fact that agents 1 and 3 do not share a constraint, and yields the same result independent of the DCOP graph structure. However, exploiting this structure (as captured by θ) can significantly tighten the bounds on $\{|A_q(I, k)|\}_{k=1}^{I}$. In particular, in obtaining the bounds in Section 3, pairs of JAs were mutually exclusive as k-optima (only one of the two could be k-optimal) if they were separated by a distance $\leq k$. We now show how some JAs separated by a distance $\geq k + 1$ must also be mutually exclusive as k-optima.

We define $D_G(a, \tilde{a}) := \{i \in G : a_i \neq \tilde{a}_i\}$ and $V(G) := \cup_{S \in \theta : G \cap S \neq \emptyset} S$. Intuitively, $D_G(a, \tilde{a})$ is the set of agents within the subgroup G who have chosen different actions between a and $\tilde{a}$, and $V(G)$ is the set of agents (including those in G) who are a member of some constraint $S \in \theta$ incident on a member of G (e.g., G and the agents who share a constraint with some member of G). Then, $V(G)^C$ is the set of all agents whose contribution to the team reward is independent of the values taken by G.

PROPOSITION 2. *Let there be a JA $a^* \in A_q(I, k)$ and let $\tilde{a} \in A$ be another JA for which $d(a^*, \tilde{a}) > k$. If $\exists\, G \subset \mathcal{I}$, $G \neq \emptyset$ for which $|G| \leq k$ and $D_{V(G)}(a^*, \tilde{a}) = G$, then $\tilde{a} \notin A_q(I, k)$.*

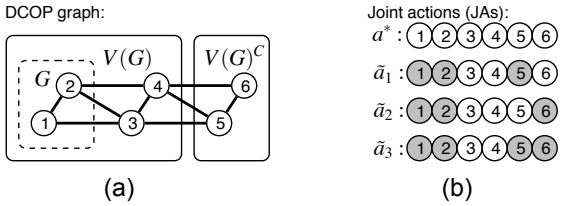

Figure 4: A visual representation of the effect of Proposition 2.

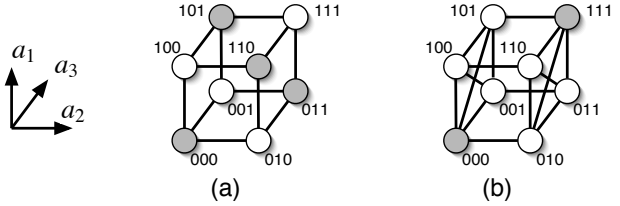

Figure 5: Exclusivity graphs for 1-optima for Example 1 with MIS shown in gray, (a) not using Proposition 2 and (b) using it.

Proof. Given a^*, $\tilde{a}$, and G with the properties stated above, we have that $\forall a : d(a^*, a) \leq k$, $\Delta(a^*, a) > 0$. If a is defined such that $a_i = \tilde{a}_i$ for $i \in V(G)$ and $a_i = a_i^*$ for $i \notin V(G)$, then $D(a^*, a) = G$ and $d(a^*, a) \leq k$ which implies

$$\Delta(a^*, a) = \sum_{S \in \theta : S \cap D(a^*, a) \neq \emptyset} R_S(a_S^*) - R_S(a_S) = \sum_{S \in \theta : S \cap G \neq \emptyset} R_S(a_S^*) - R_S(a_S)$$
$$= \sum_{S \in \theta : S \cap G \neq \emptyset} R_S(a_S^*) - R_S(\tilde{a}_S) > 0.$$

If $\hat{a}$ is defined such that $\hat{a}_i = a_i^*$ for $i \in V(G)$ and $\hat{a}_i = \tilde{a}_i$ for $i \notin V(G)$, then $D(\tilde{a}, \hat{a}) = G$ and $d(\tilde{a}, \hat{a}) \leq k$, and

$$\Delta(\tilde{a}, \hat{a}) = \sum_{S \in \theta : S \cap D(\tilde{a}, \hat{a}) \neq \emptyset} R_S(\tilde{a}_S) - R_S(\hat{a}_S) = \sum_{S \in \theta : S \cap G \neq \emptyset} R_S(\tilde{a}_S) - R_S(\hat{a}_S)$$
$$= \sum_{S \in \theta : S \cap G \neq \emptyset} R_S(\tilde{a}_S) - R_S(a_S^*) < 0,$$

thus, $\tilde{a} \notin A_q(I, k)$ because $\Delta(\tilde{a}, \hat{a}) < 0$ and $d(\tilde{a}, \hat{a}) \leq k$.■

Proposition 2 provides conditions where if a^* is k-optimal then $\tilde{a}$, which may be separated from a^* by a distance greater than $k+1$ may not be k-optimal, thus tightening bounds on k-optimal JA sets. With Proposition 2, since agents are typically not fully connected to all other agents, the *relevant context* a subgroup faces is not the entire set of other agents. Thus, the subgroup and its relevant context form a view (captured by $V(G)$) that is not the entire team. We consider the case where a JA $\tilde{a}$ has $d(a^*, \tilde{a}) > k$. We also have group G of size k within whose view $V(G)$, G are the only deviators between a^* and $\tilde{a}$ (although agents outside the view must also have deviated, because $d(a^*, \tilde{a}) > k$). We then know that $\tilde{a}$ contains a group G of size k or less that has taken a suboptimal subgroup joint action with respect to its relevant context and thus $\tilde{a}$ cannot be k-optimal, i.e. if the group G chose a_G^* instead of $\tilde{a}_G$ under its relevant context $V(G) \setminus G$ for $\tilde{a}$, then team reward would increase.

Figure 4(a) shows G, $V(G)$, and $V(G)^C$ for a sample DCOP of six agents with a domain of two actions, white and gray. Without Proposition 2, $\tilde{a}_1$, $\tilde{a}_2$, and $\tilde{a}_3$ could all potentially be 2-optimal. However, Proposition 2 guarantees that they are not, leading to a tighter bound on the number of 2-optima that could exist. To see the effect, note that if a^* is 2-optimal, then $G = \{1, 2\}$, a subgroup of size 2, must have taken an optimal subgroup joint action (all white) given its relevant context (all white). Even though $\tilde{a}_1$, $\tilde{a}_2$, and $\tilde{a}_3$ are a distance greater than 2 from a^*, they cannot be 2-optimal, since in each of them, G faces the same relevant context (all white) but is now taking a suboptimal subgroup joint action (all gray).

To explain the significance of Proposition 2 to bounds, we introduce the notion of an *exclusivity relation* $E \subset \mathcal{I}$ which captures the restriction that if deviating group $D(a, \tilde{a}) = E$, then at most one of a and $\tilde{a}$ can be k-optimal. An *exclusivity relation set* for k-optimality, $\mathcal{E}_k \subset \mathcal{P}(\mathcal{I})$, is a collection of such relations that limits $|A_q(I, k)|$, the number of JAs that can be k-optimal in a reward-independent setting (otherwise every JA could potentially be k-optimal). In particular, the set $\mathcal{E}_k$ defines an *exclusivity graph* H_k where each node corresponds uniquely to one of all q^I possible JAs. Edges are defined between pairs of JAs, a and $\tilde{a}$, if $D(a, \tilde{a}) \in \mathcal{E}_k$. The size of the maximum independent set (MIS) of H_k, the largest subset of nodes such that no pair defines an edge, gives an upper bound on $|A_q(I, k)|$. Naturally, an expanded $\mathcal{E}_k$ implies a more connected exclusivity graph and thus a tighter bound on $|A_q(I, k)|$.

Without introducing graph-based analysis, β_{HSP} for each k provides a bound on the MIS of H_k when $\mathcal{E}_k = \bigcup_{E \subset \mathcal{I} : 1 \leq |E| \leq k} E$. This set $\mathcal{E}_k$ captures only the restriction that no two JAs within a distance of k can both be k-optimal. Consider Example 1, but with unknown rewards on the links. Here, the exclusivity relation set for 1-optima without considering the DCOP graph is $\mathcal{E}_1 = \{\{1\}, \{2\}, \{3\}\}$, meaning that no two JAs differing only by the action taken by either agent 1, 2, or 3, can both be 1-optimal. This leads to the exclusivity graph in Figure 5(a) whose MIS implies a bound of 4.

The significance of Proposition 2 is that it provides additional exclusivity relations for solutions separated by distance $\geq k+1$, which arise only because we considered the structure of the DCOP graph, which will allow a tighter bound to be computed. This graph-based exclusivity relation set is $\widetilde{\mathcal{E}}_k = \bigcup_{E \subset \mathcal{I} : 1 \leq |E| \leq k} \bigcup_{F \in \mathcal{P}(V(E)^C)} [E \cup F]$ which is a superset of $\mathcal{E}_k$. Additional relations exist because multiple exclusivity relations ($\bigcup_{F \in \mathcal{P}(V(E)^C)} [E \cup F]$) appear the same to the subgroup E because of its reduced view $V(E)$. Now, for Example 1, the exclusivity relation set for 1-optima when considering the DCOP graph is $\widetilde{\mathcal{E}}_1 = \{\{1\}\{2\}, \{3\}, \{1, 3\}\}$, which now has the additional relation {1,3}. This relation, included because of the realization that agents 1 and 3 are not connected, says that no two JAs can both be 1-optimal if they differ only in the actions of both agent 1 and agent 3. This leads to the exclusivity graph in Figure 5(b) whose MIS implies a bound of 2. Algorithms for obtaining bounds using $\widetilde{\mathcal{E}}_k$ will be discussed in Section 6.

5. APPLICATION TO NASH EQUILIBRIA

Our graph-based bounds can be extended beyond agent teams to noncooperative settings. It is possible to employ the same exclusivity relations for 1-optimal DCOP assignments to bound the number of pure-strategy Nash equilibria in a graphical game (of the same graph structure) using any of our bounds for $|A_q(I, 1)|$. Bounds on Nash equilibria [11] are useful for design and analysis of mechanisms as they predict the maximum number of outcomes of a game.

We begin with a set of noncooperative agents $\mathcal{I} = \{1, \ldots I\}$, where the ith agent's utility is $U^i(a_i; a_{\{\mathcal{I} \setminus i\}}) = \sum_{S_i \in \theta_i} U^i_{S_i}(a_i; a_{\{S_i \setminus i\}})$ which is a decomposition into an aggregation of component utilities generated from minimal subgroups. Note that the combination of actions taken by any subgroup of agents may generate utility for any agent i, therefore the subgroups are denoted as S_i rather than S, as in the cooperative case, where the utility went to the entire team. The notation a_i and $a_{\{G \setminus i\}}$ refers to the ith agent's action and the actions of the group G with i removed, respectively. We refer to a as a joint action (JA), with the understanding that it is composed of actions motivated by individual utilities. Let the *view* of the ith agent in a noncooperative setting to be $V(i) = \cup_{S_i \in \theta_i} S_i$. The deviating group with respect to G is: $D_G(a, \tilde{a}) := \{i \in G : a_i \neq \tilde{a}_i\}$. Assuming every player has a unique optimal response to its context, then if a^* is a pure-strategy Nash equilibrium, and $d(a^*, a) = 1$,

$i = D(a^*, a)$, we know that $U^i(a_i^*; a^*_{\{\mathcal{I}\setminus i\}}) > U^i(a_i; a^*_{\{\mathcal{I}\setminus i\}})$ and a is not a pure-strategy Nash equilibrium. However, applying the graph (or hypergraph) structure of the game, captured by the sets $\{\theta_i\}$, we get exclusivity relations between JAs with distance > 1 as follows.

PROPOSITION 3. *If a^* is a pure-strategy Nash equilibrium, $\tilde{a} \in A$ such that $d(a^*, \tilde{a}) > 1$, and $\exists i \in \mathcal{I}$ such that $D_{V(i)}(a^*, \tilde{a}) = i$, then $\tilde{a}$ is not a pure-strategy Nash equilibrium.*

Proof. We have $U^i(\tilde{a}_i; \tilde{a}_{\{\mathcal{I}\setminus i\}})$

$$= \sum_{S_i \in \theta_i} U^i_{S_i}(\tilde{a}_i; \tilde{a}_{\{S_i \setminus i\}}) = \sum_{S_i \in \theta_i} U^i_{S_i}(\tilde{a}_i; a^*_{\{S_i \setminus i\}})$$
$$< \sum_{S_i \in \theta_i} U^i_{S_i}(a_i^*; a^*_{\{S_i \setminus i\}}) = \sum_{S_i \in \theta_i} U^i_{S_i}(a_i^*; \tilde{a}_{\{S_i \setminus i\}}) = U^i(a_i^*; \tilde{a}_{\{\mathcal{I}\setminus i\}}).$$

The first and last equalities are by definition. The second and third equalities are because $D_{V(i)}(a^*, \tilde{a}) = i$. The inequality is because a^* is a pure-strategy Nash equilibrium. The result is that $\tilde{a}_i$ is not an optimal response to $\tilde{a}_{\{\mathcal{I}\setminus i\}}$ and thus cannot be a Nash equilibrium. ■

Proposition 3 states that a^* and $\tilde{a}$ cannot both be Nash equilibria if $\exists i$, $D_{V(i)}(a^*, \tilde{a}) = i$, which is identical to the condition that prevents two JAs (in a team setting) from being 1-optimal. The commonality is that in both the cooperative and noncooperative settings, agents have optimal actions for any given context, and in both settings there is a notion of relevant context, $V(i) \setminus i$, which can be a subset of other agents $\{\mathcal{I} \setminus i\}$. The difference is that the views are generated in different manners: $V(i) = \cup_{S \in \theta : i \cap S \neq \emptyset} S$ in a cooperative setting, while $V(i) = \cup_{S_i \in \theta_i} S_i$ in a noncooperative setting. Given the views, we can generate the exclusivity relation set in the same manner, $\mathcal{E}_1 = \bigcup_{i \in \mathcal{I}} \bigcup_{F \in \mathcal{P}(V(i)^C)} [i \cup F]$. Given the exclusivity relation set, we can create an exclusivity graph for a noncooperative setting in a fashion similar to the one in Section 4. Thus, the bound on the number of Nash equilibria for a noncooperative graphical game is identical to the bound on 1-optimal JAs for a cooperative DCOP, if both share the same exclusivity relation set $\mathcal{E}_1$.

6. GRAPH-BASED BOUNDS

As seen earlier, the graph structure expands the exclusivity relation set for k-optimality in cooperative (DCOP) settings and Nash equilibria in noncooperative (graphical-game) settings. This set defines exclusivity graph H_k whose maximum independent set (MIS) provides a bound for the number of k-optimal JAs (or alternatively, for the number of Nash equilibria). Finding the size of the MIS is NP-complete in the general case [1], so we investigated heuristic techniques to obtain an upper bound on $|A_q(I,k)|$. We observe that any fully-connected subset (clique) of H_k can contain at most one k-optimum. Thus, the number of cliques in any clique partitioning of H_k also provides an upper bound on $|A_q(I,k)|$, where a partitioning yielding fewer cliques will provide a tighter bound. Hence, our first approach is the polynomial-time F_{CLIQUE} clique-partitioning algorithm, shown in [7] to outperform several competitors.

Our second heuristic technique to find a graph-based bound is Algorithm 1, the *Symmetric Region Packing bound*, β_{SRP}, which uses a packing method analogous to Proposition 1, where each k-optimum claims a region of the space of all possible JAs (the nodes of H_k). Because these regions are constructed to be disjoint and have identical volumes, dividing the space of all JAs by this volume yields a bound. Figure 6 shows β_{SRP} computed for 1-optima for Example 1. We choose an arbitrary JA $a \in A$ which we assume to be k-optimal (a = [0 0 0] in Figure 6), around which we will construct a region claimed by a.

Applying the exclusivity relations from $\widetilde{\mathcal{E}}_k$, we generate a set $B(a) = \cup_{E \in \widetilde{\mathcal{E}}_k} f(a, E)$ where $f(a, E)$ yields the JA that is excluded

Algorithm 1 for Symmetric Region Packing (SRP) bound

```

from being k-optimal by a and E. The first two rows of Figure 6 show $\widetilde{\mathcal{E}}_1$ and the set B([0 0 0]). Applying the exclusivity relations again for each $b \in B(a)$, and discarding JAs already included in a or $B(a)$, we generate a set $\overline{B}(b) = \cup_{E \in \widetilde{\mathcal{E}}_k} f(b, E)$ which contains all JAs that potentially exclude b from being k-optimal. In Figure 6, we apply $\widetilde{\mathcal{E}}_1$ to find $\overline{B}(b)$ for all $b \in B(a) = \{[1\,0\,0], [0\,1\,0], [0\,0\,1], [1\,0\,1]\}$ where the grayed out JAs are those discarded for being in $\{a\} \cup B(a)$. To ensure that the region that a claims is disjoint from the regions claimed by other k-optima, a should only claim a fraction of each $b \in B(a)$. This can be achieved if a shares each b equally with all other k-optima that might exclude b. These additional k-optima are contained within $\overline{B}(b)$. However, not all $\overline{b} \in \overline{B}(b)$ can actually be k-optimal as they might exclude each other. If we construct a graph $\overline{H}_k(b)$ with nodes for all $\overline{b} \in \overline{B}(b)$ and edges formed using $\widetilde{\mathcal{E}}_k$, and we find M_b, the size of the MIS, then a can safely claim $1/(1 + M_b)$ of b. We again use clique partitioning to safely estimate M_b. In Figure 6, for b = [0 1 0], $\overline{B}$([0 1 0]) leads to a three-node, three-edge exclusivity graph $\overline{H}_k$([0 1 0]). By adding the values of $1/(1 + M_b)$ for all $b \in B(a)$ (plus one for itself), we obtain that a can safely claim a region of size 3, which implies $\beta_{SRP} = \lfloor 2^3/3 \rfloor = 2$. Algorithm 1's runtime is polynomial in the number of possible JAs, which is a comparatively small cost for a bound that applies to every possible instantiation of rewards to actions. An exhaustive search for the MIS of H_k would be exponential in this number (doubly exponential in the number of agents).

7. EXPERIMENTAL RESULTS

We performed five evaluations in addition to the experiment described in Section 2. The first evaluates the impact of k-optimality for higher values of k. For each of the three DCOP graphs from Figure 2(a-c), Figure 7(a-c) shows key properties for 1-, 2- and 3-optima. The first column of each table shows $|\tilde{A}|$, the size of the

	$\lvert\tilde{A}\rvert$	avg. reward
1-opt.	10	.850
2-opt.	55	.964
3-opt.	175	.993

(a)

	$\lvert\tilde{A}\rvert$	avg. reward
1-opt.	10	.809
2-opt.	55	.961
3-opt.	175	.986

(b)

	$\lvert\tilde{A}\rvert$	avg. reward
1-opt.	9	.832
2-opt.	45	.977
3-opt.	129	.982

(c)

Figure 7: 1-optima vs. JA sets chosen using other metrics

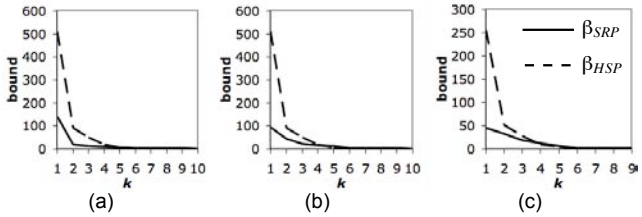

Figure 8: β_{SRP} vs. β_{HSP} for DCOP graphs from Figure 2

neighborhood containing all JAs within a distance of k from a k-optimal JA a, and hence of lower reward than a. For example, in the joint patrol domain described in Section 2, Figure 7(a) shows that, if agents are arranged as in the DCOP graph from Figure 2 (a), any 1-optimal joint patrol must have a higher reward than at least 10 other joint patrols. We see that as k increases, the k-optimal set contains JAs that each individually dominate a larger and larger neighborhood. The second column shows, for each of the three graphs, the average reward of each k-optimal JA set found over 20 problem instances, generated by assigning rewards to the links from a uniform random distribution. We define the reward of a k-optimal JA set as the mean reward of all k-optimal JAs that exist for a particular problem instance; each figure in the second column is therefore a mean of means. As k was increased, leading to a larger neighborhood of dominated JAs, the average reward of the k-optimal JA sets show a significant increase (T-tests showed the increase in average reward as k increased was significant within 5%.)

However as k increases, the number of possible k-optimal JAs decreases, and hence the next four evaluations explore the effectiveness of the different bounds on the number of k-optima. For the three DCOP graphs shown in Figure 2, Figure 8 provides a concrete demonstration of the gains in resource allocation due to the tighter bounds made possible with graph-based analysis. The x axis in Figure 8 shows k, and the y axis shows the β_{HSP} and β_{SRP} bounds on the number of k-optima that can exist. To understand the implications of these results on resource allocation, consider a patrolling problem where the constraints between agents are shown in the 10-agent DCOP graph from Figure 2(a), and all agents consume one unit of fuel for each JA taken. Suppose that $k = 2$ has been chosen, and so at runtime, the agents will use MGM-2 [9], repeatedly, to find and execute a set of 2-optimal JAs. We must allocate enough fuel to the agents *a priori* so they can execute up to all possible 2-optimal JAs. Figure 8(a) shows that if β_{HSP} is used, the agents would be loaded with 93 units of fuel to ensure enough for all 2-optimal JAs. However, β_{SRP} reveals that only 18 units of fuel are sufficient, a five-fold savings. (For clarity we note that on all three graphs, both bounds are 1 when $k = I$ and 2 when $I - 3 \leq k < I$.)

To systematically investigate the impact of graph structure on bounds, we generated a large number of DCOP graphs of varying size and density. We started with complete binary graphs (all pairs of agents are connected) where each node (agent) had a unique ID. To gradually make each graph sparser, edges were repeatedly removed according to the following two-step process: (1) Find the lowest-ID node that has more than one incident edge. (2) If such a node exists, find the lowest-ID node that shares an edge with it, and remove this edge. Figure 9 shows the β_{HSP} and β_{SRP} bounds

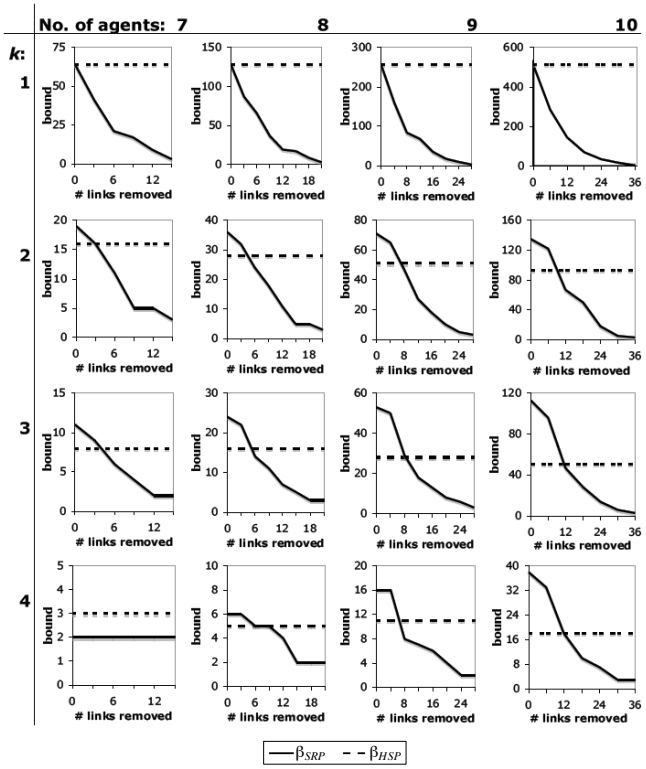

Figure 9: Comparisons of β_{SRP} vs. β_{HSP}

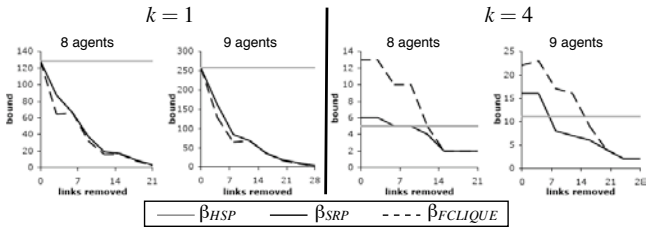

Figure 10: Comparisons of β_{SRP}, β_{HSP}, $\beta_{FCLIQUE}$

for k-optima for $k \in \{1, 2, 3, 4\}$ and $I \in \{7, 8, 9, 10\}$. For each of the 16 plots shown, the y axis shows the bounds and the x-axis shows the number of links removed from the graph according to the above method. While $\beta_{HSP} < \beta_{SRP}$ for very dense graphs, β_{SRP} provides significant gains for the vast majority of cases. For example, for the graph with 10 agents, and 24 links removed, and a fixed $k = 1$, β_{HSP} implies that we must equip the agents with 512 resources to ensure that all resources are not exhausted before all 1-optimal actions are executed. However, β_{SRP} indicates that a 15-fold reduction to 34 resources will suffice, yielding a savings of 478 due to the use of graph structure when computing bounds.

A fourth experiment compared β_{HSP} and β_{SRP} to the bound obtained by applying F_{CLIQUE}, $\beta_{FCLIQUE}$ to DCOP graphs from the previous experiment. Selected results are shown in Figure 10 for graphs of 8 and 9 agents. While $\beta_{FCLIQUE}$ is marginally better for $k = 1$, β_{SRP} has clear gains for $k = 4$. Identifying the relative effectiveness of various algorithms that exploit our exclusivity relation sets is clearly an area for future work.

Finally, Figure 11 compares the constant-time-computable graph-independent bounds from Section 3, in particular, showing the improvement of β_{MH} over $\min\{\beta_H, \beta_S, \beta_P\}$ for selected odd values of k, given three possible actions for each agent ($q = 3$). The x-axis shows I, the number of agents and the y-axis show s $100 \cdot (\min\{\beta_H, \beta_S, \beta_P\} - \beta_{MH}) / \min\{\beta_H, \beta_S, \beta_P\}$. For odd values of $k > 1$,

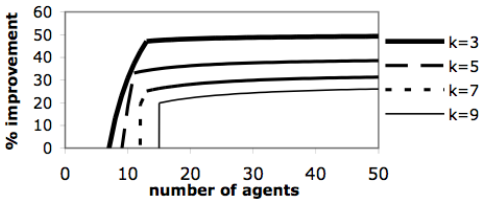

Figure 11: Improvement of β_{MH} on $\min\{\beta_H, \beta_S, \beta_P\}$

as I increased, β_{MH} provided a tighter bound on the number of k-optima. The most improvement was for $k = 3$; as I increased, β_{MH} gave a bound 50% tighter than the others.

8. RELATED WORK AND CONCLUSION

This paper provides a theoretical complement to the experimental analysis of local minima (1-optima) and landscapes in centralized constraint satisfaction problems (CSPs) [19] as well as incomplete DCOP algorithms [20, 9]. In contrast, we provide categorization and theoretical justification for k-optimality, bounds on the number of k-optima (both graph-independent and dependent), algorithms to compute graph-based bounds, and experimental analysis. We note that k-optimality can also apply to centralized constraint reasoning as a measure of the relative quality and diversity of solutions in a set. However, examining properties of solutions that arise from coordinated value changes of small groups of variables is especially useful in distributed settings, given the computational and communication expense of large-scale coordination.

Our research on bounding k-optimal solution sets for DCOPs is related to estimating numbers of local optima in centralized local search and evolutionary computing [2, 18]. The key difference is in the exploitation of constraint graph structure, not harnessed in previous work, to bound the number of optima.

Given that counting the number of Nash equilibria in a game with known payoffs is $\#\mathcal{P}$-hard [3], bounds have been investigated for particular types of games [11]. Graph structure is utilized in algorithms to expedite finding Nash equilibria for a given graphical game with known payoffs [6]. However, finding tight bounds on Nash equilibria over all possible games on a given graph (i.e., reward-independent bounds) remained an open problem.

In summary, in this paper, (1) we have introduced k-optimality as a metric that captures diversity and relative quality, properties desirable for evaluating sets of DCOP assignments, where each assignment represents a JA to be considered or executed. Finding bounds on k-optimal JA sets is useful for resource allocation problems associated with executing JA sets in sequence or presenting a JA set as a set of options. (2) We discover a correspondence to coding theory that yields bounds β_H, β_S, and β_P, independent of reward and graph structure and (3) introduce a tighter bound β_{MH} for odd k, all of which are computable in constant time. We introduced (4) a method to exploit DCOP graph structure to obtain tighter reward-independent bounds on the number of k-optima that can exist. (5) We also show that our method extends to noncooperative settings, as our bound for 1-optima in a DCOP can be used as a bound on the number of pure-strategy Nash equilibria in a graphical game of arbitary payoffs. Finally, (6) we develop techniques for computing bounds ($\beta_{SRP}, \beta_{FCLIQUE}$) using the graph-based exclusivity relation sets and (7) illustrate their utility on a diverse collection of graphs.

ABSTRACT

Along with manifold advantages of distributed multi-agent systems, increased network traffic produced by highly communicative agents in large distributed systems has to be considered as their practical downside. We suggest to apply the programming paradigm of mobile agents to reduce this network overhead by allowing agents to meet at the same network node before commencing communication. A remote communication between two agents could then be replaced by one or two agent migrations, followed by local communication. Since only in trivial cases it is possible to decide at design time whether remote communication or agent migration with subsequent local communication would perform better, this decision has to be made at run-time based on environmental parameters and agents' past experience. We present an adaptive approach, which is inspired by a solution of the *El Farol* problem. Every agent forecasts the network load of the next communication step and applies a simple mathematical model to decide between the two alternatives at run-time. In addition, our approach does not only consider network load but also server load by enabling agents to dynamically forecast the number of agents migrating to a specific agent server. The approach is evaluated with simulation experiments in static and dynamic server load environments.

mobile agents, collective and emergent agent behaviour

1. INTRODUCTION

In most distributed multi-agent systems, communication and coordination between agents is based on asynchronous message passing. If agents are located on distant agent servers, sending messages between agents generates network traffic between the corresponding network nodes. As every network traffic causes higher execution time by network transmission and latency compared with a centralized solution, a trade-off between advantages of agent distribution and drawbacks regarding their execution time has to be considered. For example, a promising application area of multi-agent systems is the management of Grid services [8, 13, 14]. Agents can act as representative of a service instance and supplement the service's functionality by intelligent techniques for negotiating QoS parameters [12]. Multi-step negotiation based on the iterative contract-net protocol between widely distributed agents can impose high network overhead, which might question the applicability of negotiations at large. We believe that this important problem has not sufficiently been recognized by the agent community so far and current agent development methodologies do not provide solutions to this problem.

Mobile agents have been introduced as a paradigm for distributed systems, in particular to reduce network traffic by moving code close to the place where the data is. A mobile agent is a program that can migrate from one host to another host in a network of heterogeneous computer systems and fulfil a user-given task. It can autonomously work and communicate with other agents and host systems. During the self-initiated migration, the agent carries its code and some kind of execution state with it [4, 21].

Mobile agents are a solution of our scenario of negotiating agents, because both agents could decide to meet at the same agent server and then communicate only locally without generating any network traffic except of the migration. Mobile agents can not only reduce network load and increase application response time but can also improve reliability by making the application more robust against network failures and reduce power consumption in case of mobile devices. In the last years, many research groups have carried out empirical evaluations to evaluate which of these two paradigms

(remote communication or migration followed by local communication) performs best regarding network load and processing time in various application scenarios [15, 17, 18].

It is obvious to see that mobile agents can only produce lower network load, if, simply speaking, the mobile agent's code and state that have to be transmitted are not larger than the amount of data that can be saved by the use of a mobile agent. It depends on the message size, the code and state size, and the network environment to decide whether mobile agents perform better than remote communication. In the following, we call this the *migration decision problem*. Most current solutions of the migration decision problem are based on mathematical models of the application's network load using parameter estimations (e.g. the number of negotiation steps, average message size, etc.) and lead to a decision at design time. We believe that in most application scenarios it will be beneficial to address the migration decision problem at run-time, because only then all influencing parameters (network throughput, latency, request message size, code size) can be actually known.

In this paper we present an approach to solve the migration decision problem at run-time involving dynamic prediction of message sizes based on historical information about previous communication acts. The agents do not only forecast message sizes but also the load of the remote agent server that an agent would migrate to. Although an agent might opt for migration when considering only message sizes, a remote communication could be the better alternative if also server load is taken into account. Our solution is inspired by the concept of inductive reasoning and bounded rationality introduced by Arthur [1] and does not rely on additional communication between the agents to decide which agent should migrate to which agent server. It performs well for large and highly dynamic systems and can easily be adapted to various system sizes. In addition, the overall system performance is not affected in case of agents fail or leave the system.

The remainder of the paper is structured as follows: The next section gives an overview of the related work already done in the area of network aware programs. Section 3 describes the model for communication and coordination costs that is used for this work and our assumptions and constraints. It is following a section describing our simulations and the experimental validation of the simulation results. An outlook to the future work concludes the paper.

2. RELATED WORK

Current approaches for deciding between remote communication and agent migration are based on static mathematical analysis of the application and network models. We argue that such static approaches are not sufficient for all kinds of application and should be complemented by adaptive decision models which enable the agent to decide between remote communication and migration during run-time autonomously.

To illustrate our discussion, we use the following simple model. In the remote communication approach, agent A_1 sends a request message of size B_{req} to the remote agent A_2, which answers with a result message of size B_{res}. The amount of bytes that are sent over the network equals $B_{RC} = B_{req} + B_{res}$. In the migration approach, agent A_1, which contains code of size B_c and state information of size $B_s + B_{req}$ migrates to the remote agent server (here we confine

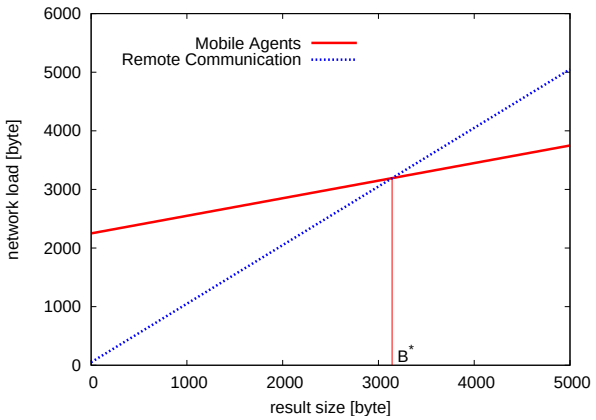

Figure 1: Evaluation of a simple mathematical model with [kB] $B_{req} = 50, B_c = 2000, B_s = 100, \varsigma = 0.7$ **and break-even point** $B^* \approx 3143$

to one mobile agent, instead of two as in the more general case mentioned in the previous section). At the remote agent server, the agent communicates locally with agent A_2, which does not produce any network load. Agent A_1 has code to filter or compress the reply message, so that only $(1-\varsigma)B_{res}$ must be carried to the agent's home agency. Note that the agent neither carries its code nor the request message back home, because the code is already available at the home server and the request message is no longer needed. However, state information must be sent back to the agent's home agency. Thus, the amount of bytes sent in the mobile agent approach equals $B_{MA} = B_c + 2B_s + B_{req} + (1-\varsigma)B_{res}$. When we evaluate this model using an artificial parameter setting, we see that there is a break-even point B^*, at which the migration overhead produced by mobile agents' code and state relocation is compensated by their ability for data reduction (compare Fig. 1).

Picco's approach is to estimate all influencing parameters and decide statically between these two design paradigms [16]. That approach is suitable for scenarios in which all the parameters are known to have constant size (e.g. the result message is a telephone number). Even if the size of parameters (e.g. the result size) are Poisson distributed with an expectation λ and $B^* \gg \lambda$ or $B^* \ll \lambda$ (i.e. the probability for a wrong decision is very low), a static decision is sufficient. In contrast, if B^* is close to λ or the distribution of reply sizes is not Poisson, changes over time or is simply unknown, a static decision on design paradigms is error-prone.

Another drawback of Picco's approach is that it does not take into account the possibility of a mixture of remote communications and agent migrations. It was already identified by Chia and Kannapan to be beneficial in terms of network load in the case of only two data servers [7]. Later, Strasser and Schwehm developed an algorithm to determine the optimal agent's itinerary of n data servers under the assumption of full knowledge [19]. In their approach, the agent only migrates to a subset of all data servers, whereas the other servers are accessed using remote procedure calls. The optimal agent itinerary depends on the size of requests and results, the number of communication steps and on the network quality between each pair of nodes. All these parameters are assumed to be estimated or known in advance.

Later, this approach was extended by a technique to provide information about network quality using distance maps before planning the optimal migration itinerary [20].

The second problem that has to be considered is the load of the agent server to which a mobile agent wants to migrate to. Even if a migration is beneficial from the perspective of network load, a migration has to be dismissed, if the destination agent server is already overloaded by other agents or server tasks. This problem has mainly been accounted from the server or system perspective so far. For example, Flüs [9] has proposed techniques for capacity planning of mobile agent servers and extended the Tracy [3] agent toolkit by techniques to avoid server overloading by refusing or queuing incoming agents. From a system perspective, the problem of load balancing between different agent servers is very important. Georgousopoulos et al. [10] present a load balancing mechanism based on a combination of state and model-based approaches. Cao et al. [5] describe a load balancing mechanism for Web servers based on the mobile agent paradigm.

A combined solution of both problems can be considered as a self-organizing approach to minimize network and server load of a multi-agent systems. To the best of our knowledge, there is no approach in the literature that combines both network load optimization and server load optimization so far.

3. MODEL DESCRIPTION

We model a distributed multi-agent system as a network of nodes $\mathcal{L} = \{L_1, \ldots, L_\mathrm{m}\}$ on each of which an agent server is running. The agent system comprises of agents $\mathcal{A} = \{A_1, \ldots, A_\mathrm{n}\}$, each located on its home agent server $h(A_i)$ at the beginning of its life-cycle. The map $\mathcal{P} : \mathcal{A} \rightarrow \mathcal{L}$ defines the location of each agent in general. Agents that are bound to large databases or otherwise immobile legacy systems are called stationary. All other agents are considered to be mobile.

Each agent has to process a list of communication steps $\mathcal{C} = \{c_\mathrm{i} \mid i : 1 \ldots p\}$ as part of its task. Each communication step $c_\mathrm{i} = \langle A_\mathrm{a}, A_\mathrm{b}, m_\mathrm{k}, m_\mathrm{j} \rangle_i$ defines that a request message m_k is sent from agent A_a (source) to agent A_b (destination), which responses with a reply message m_j. Each message m_k can be seen as an arbitrary sequence of bytes of the length $B_\mathrm{m}(m_\mathrm{k})$. The network cost for a remote communication step is calculated as follows:

$$B_{RC}(c_\mathrm{i}) = \begin{cases} 0 & if\ \mathcal{P}(A_\mathrm{a}) = \mathcal{P}(A_\mathrm{b}) \\ B_\mathrm{m}(m_\mathrm{k}) + B_\mathrm{m}(m_\mathrm{j}) & otherwise \end{cases} \quad (1)$$

Before each communication step, both involved agents (provided they are mobile) have to decide, whether to migrate from their current location $\mathcal{P}(A_\mathrm{i})$ to another location $\mathcal{P}(A_\mathrm{i})'$ before commencing the communication act. In the following we assume that both agents migrate to the same destination server. The network load only comprises of the cost for transferring the agents' code of size B_c and state of size B_s (which is equal to the size of the request message) but no costs for local communication. After the communication, both agents migrate back to their home agent servers (without code, because the code is already available at their home agent servers). Agent A_a carries back state information and results of size $(1-\varsigma)B_\mathrm{m}(m_\mathrm{j})$ with $0 \leq \varsigma \leq 1$, because the size of the original reply message could be reduced (e.g. filtered or compressed). The mobile agent communication network cost is calculated by

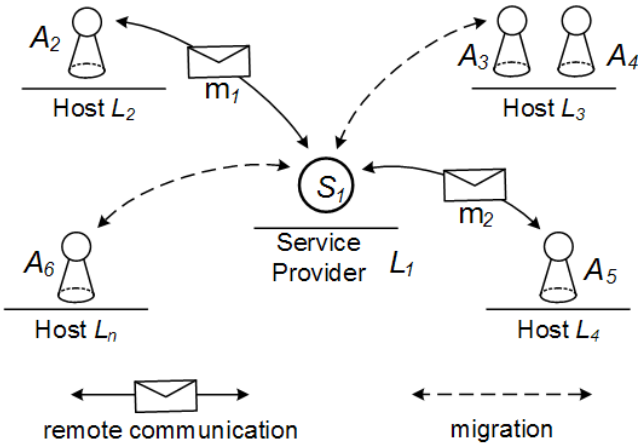

Figure 2: Communication model with multiple agents and a single server.

$$B_{MA}(c_\mathrm{i}) = \begin{cases} 0 & if \mathcal{P}(A_\mathrm{a}) = \mathcal{P}(A_\mathrm{b}) \\ B_c(A_\mathrm{a}) + B_\mathrm{m}(m_\mathrm{k}) + & \\ B_c(A_\mathrm{b}) + (1-\varsigma)B_\mathrm{m}(m_\mathrm{j}) & otherwise \end{cases} \quad (2)$$

if both agents are mobile. If only the sender agent is mobile, code transmission of agent A_b has to be disregarded.

The last formula is independent of the location of the destination agent server because we only consider network load and not transmission time at this stage. Formulas 1 and 2 can be used to decide between the two alternatives at run-time, provided that all message sizes are known. To further reduce the complexity of our model, we assume for our first experiments that all agents exchange messages with only one agent S_1, which is stationary and located on L_1, see Fig. 2.

4. TOWARDS EMERGENT MIGRATION BEHAVIOUR

4.1 Introduction – The El Farol Problem

We present a combined approach for reducing network load and agent server load, which is based on predicted environment parameters at run-time. As mentioned in the previous section, an agent has to decide before each communication step c_i between remote communication and agent migration. This decision must be based on limited knowledge, which only includes its own code size B_c and the request message size $B_\mathrm{m}(m_\mathrm{k})$. The size of the reply message $B_\mathrm{m}(m_\mathrm{j})$, the selectivity factor ς, and the current remote agent server load are not known in advance.

Naturally, we have to assume that neither of these values is distributed uniformly within their domain. In that case, there would be no chance to predict these values based on past experience. In order to apply machine learning algorithms for these values, they must render a certain pattern, for example some kind of probability distribution. One of our hypotheses is that in many application scenarios the reply size can be described by well-known distributions such as

Poisson or Gaussian distributions. It should be clear that this approach can be successfully applied to many application scenarios, for which a static analysis is possible as proposed by Picco [16] and Schwehm and Strasser [19]. In these cases, the reply message size, selectivity factor, and server load have a straightforward distribution (e.g. a constant value), which is easy to learn by our approach.

The prediction mechanism is inspired by inductive reasoning and bounded rationality principles introduced by Arthur [1] and demonstrated as solution of the El Farol bar problem. The original problem setting consists of 100 people to decide repetitively and independently, whether to go to the El Farol bar on a specific day of the week or not. All people have the same preference in order to decide: they will go to the bar, only if they expect less than 60 people to show up. Choices are unaffected from previous visits. There is no communication between people (e.g. to form coalitions or coordinate their decisions) and the only information available to every agent is the number of people that attended the bar in the past weeks.

Arthur's solution of the El Farol bar problem consists of a set of predictors for each patron, each able to forecast the number of patrons by applying very simple pattern based on past experience. At the beginning of the simulation, each person is assigned a randomly chosen set of predictors. In each step of the simulation the predictor that has performed best in the last week, is used to forecast the next number of attendants. The interesting result of Arthur's simulation shows a fast stabilizing process around the optimal number of 60 attendants. For more information about the El Farol bar problem, we refer to [6].

Our problem can be mapped to the El Farol bar problem by assuming agent S_1 (to which all communication is directed to) and its agent server to be the bar with limited resources. All other agents have to decide whether to migrate to that agent server or not. An agent will migrate only if the migration will reduce network costs and the destination agent server is not overloaded yet. The latter requirement can be simply modelled by a number of agents executed in parallel. We have to deal with similar effects as in the El Farol problem: if all agents believe that the server will not be overloaded, all agents will migrate and if all agents believe that the server will be overloaded, no agent will migrate – both experiences would invalidate the agents' beliefs in the environment.

The advantage of our approach is that no additional communication overhead is introduced because agents learn from their past experiences. In contrast to the original El Farol problem, we do not assume free information dissemination about the current server load to agents that did not migrate to the agent server recently. That is, only agents that have migrated to the agent server recently can benefit from up-to-date knowledge.

4.2 Network Cost Prediction

Each agent predicts environment parameters that are not know in advance but necessary for the migration decision based on its own historical data. For the prediction of message sizes and selectivity factors, this technique provides good results because we do not only use one predictor but a set of different predictors to provide a better accuracy.

The predictor that is used for the next prediction of the message size and the selectivity factor is called active predictor. After an agent has executed a communication step, its history information is updated with the measured values and all predictors will be rated again. The most accurate predictor in the last steps is chosen as the new active predictor because it is the most prospective for the next prediction. To reduce the computational overhead of the predictor evaluation, it is possible, to use the active predictor until it's relative error δ exceeds a pre-defined threshold.

As the migration decision of agent A_{j} based on the network costs is independent of any other agent A_{k}, it is fair to assign all agents the same set of predictors. Of course, the quality of the predictors influences the quality of the predicted values and it might be reasonable to introduce specialized predictors that can be applied to specific probability distributions. However, in our first experiments we were keen to learn about the quality of very simple predictors. Actually, it is not important to achieve a *correct prediction* of the environment parameters rather than making the *correct decision* based on the predicted values. The best predictor will be chosen automatically, while less accurate predictors will not be considered in the future.

For our experiments we have developed the following predictors:

- same value as n^{th}last communication step,
- moving average of last n steps,
- the trend of the last n steps,
- random value in the interval between current minimum and maximum,
- Poisson distribution based on the current history data.

4.3 Agent Server Load Prediction

Agent server load prediction differs slightly from message size prediction, because all agents compete for the same resource and agents' decisions regarding server load are dependent on each other. If all agents would predict the same resource load, than this would invalidate their beliefs. Therefore, it is important to ensure agents make different and adaptive decisions in their environment.

The selection of the active predictor differs from the technique presented previously. In contrast to the message reply size and selectivity prediction, the selection of the next server load predictor is not deterministic but has a level of uncertainty. The probability that a predictor is chosen as the new active predictor increases with the predictor's accuracy. The accuracy of a predictor is calculated from the number of correct and wrong decisions, i.e. the agent has predicted a not overloaded resource and decided to migrate.

Only the last n values are considered for calculation of the predictors accuracy because this allows a faster adaptation to changes. The number n can be configured by the agent designer. For every correct decision (the agent migrated and the resource was not overloaded), a predictor gets a positive rating. For a wrong prediction only the responsible active predictor gets a negative rating. To improve the learning process for new predictors and predictors with old historical values, they get a positive rating for correct predictions, but no penalty for wrong predictions, until they reach m predictions with $m \leq n$. The overall rating is the sum of all positive and negative ratings. The relative error of the prediction is not considered for the resource load prediction.

For example, if predictor P_1 predicted in 60% of the considered cases that the resource is not overloaded and the agent migrates to the resource while predictor P_2 predicted only 30% of the cases correct the probability of choosing P_1 is twice the probability of choosing P_2.

Usually, the agent bases the migration decision on local knowledge which means the resource load information is updated only if the agent migrates to the resource. Some experiments were conducted with global knowledge in which we updated the resource load information after every migration decision to learn about the differences.

The current approach uses a set of simple predictors, similar to the El Farol approach. Developed predictors include:

- n-period cycle predictor: predicts the same as n^{th}-last history value.
- moving average predictor: predicts the average of all values in a window of the last n history values.
- linear or non-linear predictors: predicts interpolated values the considers the last n history values.

4.4 Rule Based Configuration

For the strategic migration decision the agent uses a rule based decision system. The rules are based on the parameters provided by the message size and server load prediction to check which paradigm offers a better performance. Different rule sets can be configured to provide different configurations and priorities. The owner of an agent can decide which of the rule sets from a number of predefined rule sets are to be used for the decision making to meet different user preferences.

4.4.1 Data Collecting Phase

In the initial phase when agents have no (or not enough) historical data it is necessary to use a different type of predictors–not based on historical information and not predicting message size, but simply deciding between remote communication and migration, such as:

- Random migration strategy: The agent migrates with a given probability to the destination host.
- Always migrate strategy: The agent always migrates to the destination host. This is the fastest way to get required information for the learning phase.
- Never migrate strategy: The agent always uses remote procedure calls. In this case, the agent will never switch to the learning phase because no resource load information is updated.

After the agent has collected enough data so that at least some of the predictors are working, the agent switches to the working phase.

4.4.2 Learning and Working Phase

In the working phase, the agent uses the predicted data of message reply sizes, agent selectivity, and the expected agent server load based on local knowledge to come to a migration decision. Based on the rule set that reflects best the user preferences, an agent makes an autonomous decision which paradigm offers the highest benefit for the user.

- Minimal Network Load: Only the network load is considered for the migration decision. If the resource is crowded, the agent accepts waiting times.
- Balanced strategy: The agent will use migration when it offers benefit compared to RPC and the resource won't be crowded.
- Best Performance: Same as minimal network load, except that the migration probability increases linear with the age of the newest historical data or the average age of historical data in the sliding window, if the resource load data is out of date. This prevents that an agent create the habit not to migrate, if it has decided once like this. The predictor always predicts not to migrate, based on the same historical values.

5. EXPERIMENTAL VALIDATION

5.1 Outline

We have developed a first simulation test-bed in the Java programming language for a distributed multi-agent system independent of any specific agent toolkit. Our simulation environment enables different configurations of the number of agents, the number of communication steps for each agent, various distributions of reply sizes and selectivity factors for each agent, etc. The simulation uses an event-driven model to trigger agent activities. Network load equals the number of bytes transmitted without taking network protocol overhead (IP, TCP, application layer) into account. The latter will be considered in the near future, when the simulation environment will be re-designed to work with a well-known network simulation tool such as NS-2 or Omnet++. Network transmission time is modelled by taking bandwidth and latency between each pair of network nodes into account.

We have tested a number of different configurations of our simulation environment and for the evaluation we measured the following system metrics:

Reply size: The size of the reply message.

Selectivity factor: The agent's selectivity factor for the reply message.

Agent server load: The number of agents that attended the server in the last simulation step.

Several sets of experiments were conducted with different simulated configurations. We repeated each experiment several times and show results of representative experiments and some average values for illustration.

The first set of experiments focuses on the accuracy of message size and selectivity factor prediction. Both form the foundation for the strategic migration decision based on network load. The second set of experiments focuses on prediction of message size as well as agent server load, and investigates if and how fast agents can adapt to varying levels of server availability.

Usually we run experiments while varying only one parameter and keeping all other parameters constant. A detailed description of the simulation environment and the observed parameters follows in the next sections.

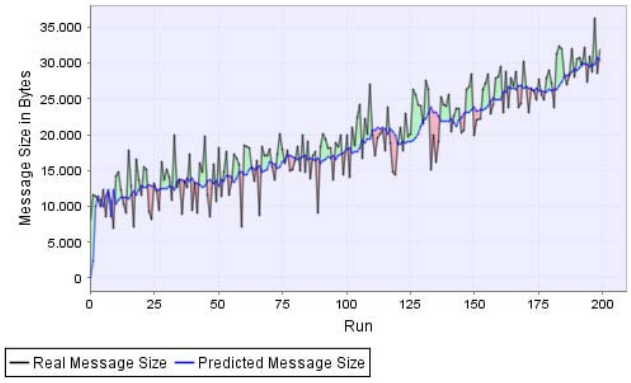

Figure 3: Comparison of the predicted message size and the real message size.

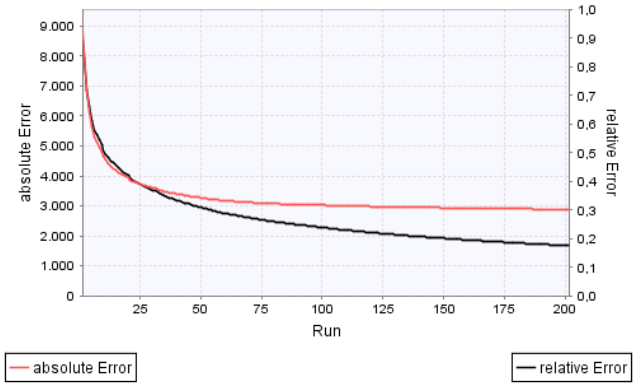

Figure 4: Average absolute and relative error of the reply message size prediction.

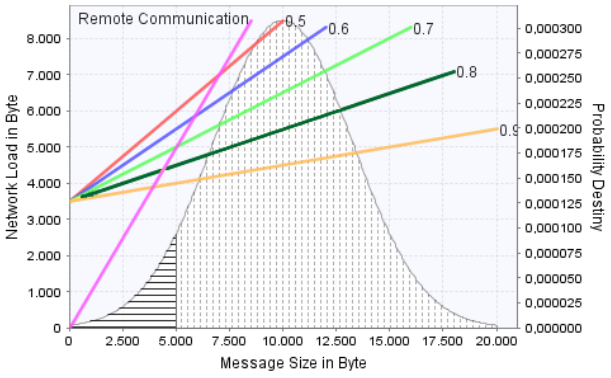

Figure 5: Comparison of mobile agent and remote communication paradigm.

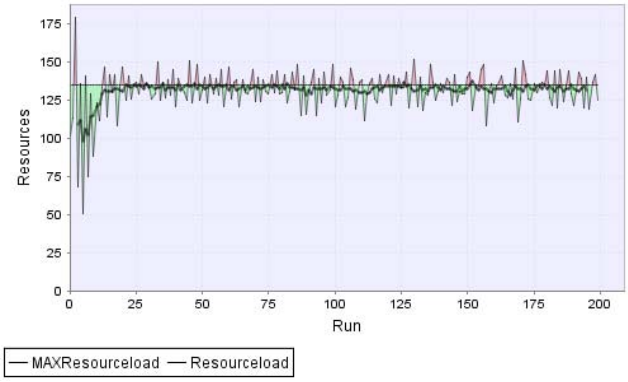

Figure 6: Development of server load for 200 cycles with resource limit of 135 units.

5.2 Message Size Prediction

In this section we report on results of message size and selectivity factor prediction. For this set of experiments we have selected different artificial Gaussian distributions of the message size with parameters $\mu = 5000$, 10000, 50000 Byte and $\sigma^2 = 10\%$, 20%, 40% of these mean values.

To validate the migration decision, we set the other parameters as follows: the agent size is 35 KByte, the agent performs 200 predictions using a set of 7 different predictors. The predictors for this experiment include 5 different period cycle predictors, a moving average predictor, and a linear predictor. Fig. 3 shows one example of message size prediction, in which the real message size is Gaussian distributed $N(10000Byte, 3250Byte)$ with an increasing mean value. We measured the absolute and relative error of the prediction and prediction correctness, i.e. whether the predicted value leads to the correct migration decision. Fig. 4 shows that the absolute error finally reaches 3000 KB and the relative error is below 20%.

In addition, we measured the cumulative values of these parameters. Figure 5 compares the network load of the remote communication and migration approach for different selectivity factors and message reply sizes for a representative message reply size distribution with $\mu = 10000$ $Byte$ and $\sigma = 32,5\% = 3250$ $Byte$. Considering only a statistical analysis of a fixed set of parameters and the given message reply size distribution, we can calculate that the break even point for the mobile agent paradigm with a selectivity of 70% is at 5000 Byte. An incorrect decision is made in less than 6,3% of all cases. We expect that real applications have certain patterns for the reply size distribution, and a small derivation.

5.3 Combined Prediction

In this section we report on results of combined message size and agent server load prediction mechanisms. In the first experiments we have selected a set of 200 agents with same agent resource requirements of 1 unit (memory, processor cycles). These agents want to use agent S_1 located on host L_1, which has available resources of $n = 135$ units. Fig. 6 shows the agent server load usage when the available server resources are constant. It can be seen that after only few executions, the average resource load balances below the maximum value. Only in few cases, the prediction over-estimates the real number of resources available. Fig. 7 shows that the number of migrations is similar for all agents. There is no group of agents that always migrates while other agents never migrate.

A second set of experiments uses the same parameters as the previous one, but the available server resources are varied at run-time after every 75 executions. The goal of this experiment is to see how fast the agents prediction mechanism can adapt to varying environmental parameter. We

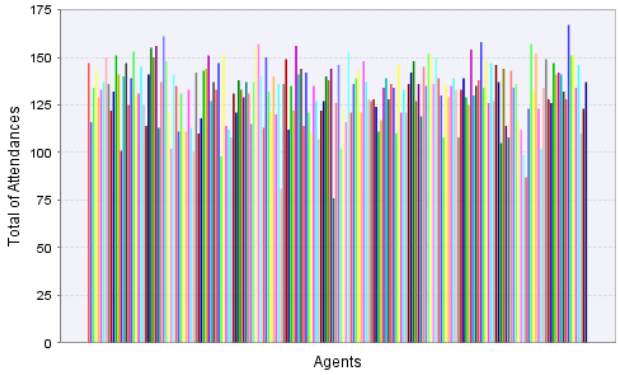

Figure 7: Attendance of mobile agents at the remote agent server for constant resource limit.

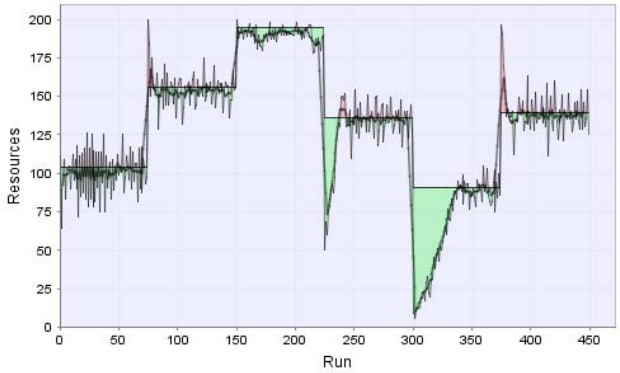

Figure 8: The adaptation of one server to varying resource capabilities.

set up an environment with different numbers of agents, and varying resource capabilities over time and measured the number of resources used by agents. We conducted experiments in which all agents have the same resource consumption as well as different resource consumption. Fig. 8 shows for one agent server that the adaption to varying server capabilities works surprisingly fast. Only in few cases, the available server capabilities are over-estimated, whereas in many cases the current server capabilities are close to the maximum values. In addition, Fig. 9 shows that even in the case of varying server resources the number of migrations is similar for all agents.

Finally, we tested two variants of updating the historical data of agents. At first, agents update their history values after every execution step, independent of having migrated to that server or not. This case resembles the original El Farol behaviour. Secondly, agents have limited and heterogeneous agent server load information. History values are only updated if an agent has migrated to the remote agent server.

Interestingly, the adaptive solution works better when agents have only limited and heterogeneous knowledge. Furthermore, the limited knowledge is preferred in real systems because it has no additional communication costs and it would be difficult to distribute resource information to potential agents.

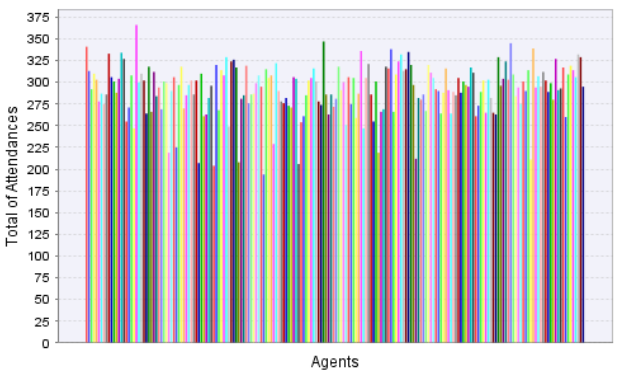

Figure 9: Attendance of mobile agents at the remote agent server for varying resource capabilities.

6. CONCLUSIONS AND FUTURE WORK

In this paper we have presented an approach for reducing communication overhead in a distributed multi-agent system by agent mobility at run-time. Our approach also considers system performance by balancing agent server load. Our approach is based on mobile agents that decide at run-time between remote communication and migration. It was inspired by inductive learning and bounded rationality principles. The prediction of the required environment parameters enables mobile agents to autonomously make a strategic migration decision and adapt to the dynamic environment. From a system perspective, this solution can be considered as a self-organizing mechanism to minimize network load and server load in a multi-agent system.

We have presented and evaluated a number of simulation experiments involving agents in static and dynamic server load environments. The results show that this new approach for strategic migration optimization based on inductive reasoning and bounded rationality principles is very promising and justifies further investigations. The advantages of this approach are its fast adaptability to different system sizes, its simplicity, and its easy extensibility. These are known advantages, although in this particular application area rarely used. With different rule sets, agents can be configured for different user preferences.

A possible improvement would be to share historical data between all agents of one agency in order to increase the learning speed and provide better predictions since historical data are up-to-date. After we have proven that this approach works fine with the event driven model we will upgrade our Java implementation. Our next step is to switch to a more realistic asynchronous simulation environment. The simple event-driven *multiple agents using one resource* approach will be extended with techniques for multiples resources. Agents will not only migrate to one agent server, but can freely migrate in the whole multi-agent system. Each agent will have a set of tasks to fulfil that need a certain amount of system capabilities. A set of system providers located on some of the servers offer services that also consume system capabilities. These services are used by each agent to fulfil its task either using remote communication or agent migration.

Our approach for optimizing network load in multi-agent systems must be supplemented in the longer run with tech-

niques to optimize the migration behaviour of mobile agents. In this paper we have assumed rather simple migration techniques (the agent carries all its code and data information), despite of already known techniques to optimize the migration strategy of mobile agents [2, 11].

ABSTRACT

Time-aware agents are agents capable of reasoning about their tasks duration and deadlines, and, more generally, to manage the temporal aspects of the execution of their tasks. We first focus on the case of agents in charge of long duration computations, sustaining that it is not acceptable for an autonomous agent to remain unaware of its environment for too long. We then consider deadline meetings when several time-aware agents share the same CPU. To achieve these goals, we recognize the importance of the artifact concept [16]. We introduce computational artifacts for long duration tasks and a coordination artifact for managing the CPU agenda and acting as an intermediary when agents negotiate CPU power. Control of computational artifacts is done thanks to a set of operating instructions dynamically computed by the coordination artifact.

1. INTRODUCTION

The context of this paper is the design of intelligent agents that make use of algorithms stemming from Artificial Intelligence research. For example, planification problems in cognitive agents make use of complex algorithms, often heuristic in nature.

Using such algorithms with very high complexity leads to execution times highly variable. A problem search space can have critical regions: for a small variation of input data, the computing time necessary to find the solution can tremendously vary and even become prohibitive. Processor resources needs are thus very fluctuating and difficult to anticipate. That concerns a lot of problems which are solved by using more or less powerful heuristics.

The implementation of such systems should take into account the following difficulties:

(i) agents may "lose consciousness". Even if involved in long duration tasks, agents should stay permanently aware of their environment and should be able to process information sent by others. On the contrary, an agent that have to execute long duration algorithms would be deconnected from the outside world and would not even realize that its calculation has become useless if a received but not processed message had said so. It would unnecessarily use CPU power that could be useful to other tasks or other agents.

(ii) agents may be unable to meet their commitments. The notion of commitment is essential to the rationality of agents in a multi-agent context. When time is concerned, an agent must be able to guarantee results within a given deadline, even if it means modifying its strategy, using an alternative algorithm or giving a solution of less quality, while respecting its deadlines.

(iii) agents may share the same CPU. This is most often the case that several agents of a MAS run on the same CPU and therefore have to share CPU power. In that case, it is very difficult to ensure that time constraints will be respected. Solution have to be found since it is generally unacceptable to assume that agents do not share the same CPU.

A natural solution to the previous difficulties would be to split agents having to achieve long duration computation in two or more parts:

(i) a "main agent", that would remain aware of its environment all the time and hence open to information coming from other agents,

(ii) one or more "computational agents" in charge of the long duration computations, the initial agent was concerned with.

It sounds like a good approach, but one may ask if these computational agents are really autonomous? Their purpose is to work on potentially long computations, so they can stay away from their environment for long periods of time. Worse, in order to manage the CPU sharing, the main agent would need some control facilities allowing it to suspend, restart or even completely stop the execution of its associated computational agents if necessary.

So even if this solution is technically the good one, one may legitimately be reluctant to call an agent an entity with such a damaged autonomy. The solution is to rely upon the notion of artifact proposed in [20, 17] in place of computational agents. An artifact is a first class entity of any MAS giving some kind of functionality that agents *use* to achieve their goals.

We will recall artifacts and their modeling in section 2.1 and explain in section 2.2 the way they are used for embodying our computational agents. We can already mention that even if it will solve the first difficulty previously stated (avoiding agent "lost of consciousness"), meeting deadline commitments and sharing CPU still remain an open problem. This is why we propose in section 3 to use a coordination artifact which will be in charge of determining time slices allocated to each computational artifact and providing the main agent with a set of operating instructions to control its artifacts. Section 4 explains the way the coordination artifact behaves. Section 5 gives results obtained on our implementation and section 6 discusses related and future works in the context of time management in MAS.

2. COMPUTATIONAL ARTIFACTS

We are interested in time-aware agents when they have to run one or several long duration tasks while being able to meet the deadlines they are committed to. It requires that the long duration tasks are run in processes separated from the one running the agent since, in the other case, the agent might lose control over its own behaviour, obliged to wait for the end of the tasks before taking any decision.

A straightforward (but costly) solution would be to run each task on a separate processor. Nonetheless, in most of the cases, CPU has to be shared and hence the agent must be able to control the tasks, that is to decide when to start, suspend, restart or cancel them in order to meet its own deadlines. Long duration tasks could be implemented as agents but one can legitimately wonder about the autonomy of an agent that can be externally controlled!

That every item of a multiagent system can be implemented as an agent is a point that has already been raised by Ricci, Viroli and Omicini [20, 17, 16], especially in the case of coordination agents. Their answer was to introduce *artifacts* as a first-class abstraction used to design and program those aspects of multiagent systems for which the agent abstraction is not suitable. We suggest that the same approach has to be adopted for the time-aware agents we are concerned with.

The following section 2.1 summarizes the *artifact* concept, directly borrowing from [20] the process algebra based formalism they introduced. Section 2.2 proposes the *computational artifact* as an abstraction for implementing the computational activities of time-aware agents.

2.1 The Notion of Artifact

As presented in [20], if agents are conceived as goal-governed or goal-oriented systems, an artifact is an entity an agent *uses* to achieve its goals. Artifacts provide a certain function that can be exploited as a service.

An artifact is characterized by:

- *a usage interface (UI):* defined in terms of a set of operations. These operations are of two kinds: action execution and perception about the completion of an action.
- *a set of operating instructions (OI):* the (formal) description of how agents can use the artifact.
- *a behavior specification:* the (formal) description of the internal behavior of the artifact.

Note that, taking the agent point of view, to exploit a coordination artifact means to follow its operating instructions, on a step-by-step basis. Thus, the agent does not have to know *how* the functionality is implemented.

We now briefly present the formal model introduced in [20] that makes use of a process algebra to express operating instructions. An instruction $I \in \mathcal{I}$ is expressed as:

$$I ::= 0 \mid !\alpha \mid \underline{\alpha} \mid ?\pi \mid I; I \mid I + I \mid (I||I) \mid \mathcal{D}(t_1, \ldots, t_n)$$

It is defined out from atomic instructions through structured instructions. Atomic instructions include the void behavior (0), the execution of an action α ($!\alpha$), an action α being started but not yet completed ($\underline{\alpha}$) and a perception π of action completion ($?\pi$). Structured instructions are the sequential composition of two instructions by operator ";", choice by "+", and parallel composition by "||". An instruction can also be an invocation $\mathcal{D}(t_1, \ldots, t_n)$ of antoher operating instruction. Several structural congruence rules that we do not mention here express commutativity and transitivity of previous operators.

Operating instructions evolve as the agent interacts with the artifact. The possible interaction acts $\delta \in$ are the execution of action α (α) and the perception π of the completion of α ($\alpha : \pi$):

$$\delta ::= \alpha \mid \alpha : \pi$$

This language can be given operational semantics. In the following rules, notation $I \xrightarrow{\delta}_{\mathcal{I}} I'$ means that OI state $I \in \mathcal{I}$ moves to new state $I' \in \mathcal{I}$ by the occurrence of interaction act $\delta \in$. Notation $[t/t']$ is used to indicate the substitution of t by t' in the continuation of instructions.

$I\|\|I'' \xrightarrow{\delta}_{\mathcal{I}} I'\|\|I''$	if $I \xrightarrow{\delta}_{\mathcal{I}} I'$	[PAR]
$I + I' \xrightarrow{\delta}_{\mathcal{I}} I''$	if $I \xrightarrow{\delta}_{\mathcal{I}} I''$ and $I' \not\xrightarrow{\delta}_{\mathcal{I}} I'''$	[ECH]
$I + I' \xrightarrow{\delta}_{\mathcal{I}} I'' + I'''$	if $I \xrightarrow{\delta}_{\mathcal{I}} I''$ and $I' \xrightarrow{\delta}_{\mathcal{I}} I'''$	[LCH]
$!\alpha; I \xrightarrow{\alpha'}_{\mathcal{I}} \underline{\alpha'}; [\alpha/\alpha']I$		[ACT]
$\underline{\alpha}; ((?\pi; I) + I'); I'' \xrightarrow{\alpha:\pi'}_{\mathcal{I}} [\pi/\pi'](I; I'')$		[COMP]

Rule [PAR] specifies that only one OI is followed at a given time. Rule [ECH] defines the semantics of exclusive choice: if I is executed, choices inside I' are excluded. Rule [LCH]

instead defines late choice: if interaction δ allows multiple choices, δ is executed and the choice is deferred to a forthcoming interaction. Rule [ACT] specifies that if α is the next action to execute, a specialization α' of α can be executed, propagating the corresponding substitution in the continuation of instructions. Rule [COMP] similarly deals with perception of the completion of an action.

Viroli and Ricci proposed in [20] an extension to the previous algebra to take into account the notion of timeout in OIs. The definitions of instructions and interaction acts are extended as follows:

$$I ::= \ldots \mid T(n) \mid \epsilon \qquad \delta ::= \ldots \mid \tau(m)$$

$T(n)$ is the timeout instruction, with parameter n being the duration of the timeout. ϵ is an error state the OI moves to when a timeout has expired while the OI was waiting for an interaction. $\tau(m)$ is the perception of m clock ticks. As for previous instructions, following rules give an operational semantics to the timeout instruction.

$$T(n); I \xrightarrow{\tau(m)}_{\mathcal{I}} T(n-m); I \quad \text{if } n > m \quad \text{[T-A-PASS]}$$
$$T(m); I \xrightarrow{\tau(n)}_{\mathcal{I}} \epsilon \quad \text{if } n \geq m \quad \text{[T-A-EXP]}$$
$$\underline{\alpha}; T(n); I \xrightarrow{\tau(m)}_{\mathcal{I}} \underline{\alpha}; T(n-m); I \quad \text{if } n > m \quad \text{[T-P-PASS]}$$
$$\underline{\alpha}; T(m); I \xrightarrow{\tau(n)}_{\mathcal{I}} \epsilon \quad \text{if } n \geq m \quad \text{[T-P-EXP]}$$
$$T(n); !\alpha; I \xrightarrow{\alpha'}_{\mathcal{I}} \underline{\alpha'}; [\alpha/\alpha']I \quad \text{[T-ACT]}$$
$$\underline{\alpha}; T(n); ((\pi; I) + I'); I'' \xrightarrow{\alpha:\pi'}_{\mathcal{I}} [\pi/\pi'](I; I'') \quad \text{[T-COMP]}$$

Rule [T-A-PASS] deals with time passing when a timeout is not yet expired and an action is to be made. When the timeout actually expires, rule [T-A-EXP] makes the OI moving to the error state ϵ. Rules [T-P-PASS] and [T-P-EXP] have the same purpose when a perception is expected: [T-P-PASS] deals with time passing and [T-P-EXP] makes the OI moving to error state ϵ when the timeout expires. Rule [T-ACT] removes the timeout when the agent decides to execute specialization α' of action α. Rule [T-COMP] acts the same way when a perception is made before the timeout expires.

2.2 Computational Artifacts Properties

A generic computational artifact (CA) is an artifact that is given a computational job to do on some input data, giving back either results or failure, depending on the input data. Such a computational artifact needs to be controlled during its processing by the agent it is associated with. We define the minimal usage interface as follows: possible actions are `start(input_data)`, `pause`, `restart`, `stop` and possible perceptions are `finished(result)` and `failure(error_info)`. According to the capabilities of the computational artifacts really being implemented in some application, we may extend this basic model. For example, if we want agents to have the possibility to ask the progress report of the task currently being executed or being regularly informed of the progress, the following action and perception will be added: `query_progress_report`, `progress_report`.

As we will see when trying to have several artifacts sharing the same CPU, we need mechanisms for time representation and manipulation. Timeouts proposed in [20] intuitively mean that the agent has to do an action or that a perception must occur *before* a given point in time. We also need the possibility to state that the agent has to do an action *after* a given point in time.

Hence, as for the timeout, we extend the definition of an instruction with the new atomic instruction $W(n)$. The following operational rules are added:

$$W(n); I \xrightarrow{\tau(m)}_{\mathcal{I}} W(n-m); I \quad \text{if } n > m \quad \text{[W-T-PASS]}$$
$$W(m); I \xrightarrow{\tau(n)}_{\mathcal{I}} I \quad \text{if } n > m \quad \text{[W-T-EXP]}$$

Rule [W-T-PASS] deals with time passing when the waiting time is not over. Rule [W-T-EXP] deals with the expiration of the delay imposed before being able to deal with next instruction. Note that there is no [W-ACT] rule. In the timeout case, an action can be started before the timeout has expired with rule [T-ACT]. Here, the agent cannot start an action before the end of the waiting time.

To clarify these notions, here is the example of an OI that may be used to control and interact with a computational artifact:

```
OI := W(10); !start(data);
  ((T(5); !pause; W(10); !restart; T(5); !stop)
    + ?finished(result)
    + ?failure(error_info))
```

The agent has to wait 10 time ticks before ordering the artifact to start its task with input `data`. Then, it has to order the artifact to pause within 5 time ticks and to restart no less than 10 time ticks later. Finally, if the work did not finish (normally or with an error) within 5 time ticks, the agent has to order the artifact to stop its computational task.

3. A COORDINATION ARTIFACT FOR CPU SHARING

In this section, we investigate the necessary coordination between agents to ensure meeting deadlines when they share a single CPU. We need an entity that can manage the CPU schedule and that can be used by agents to agree on the use of CPU power. As said before, this is typically where artifacts are useful. We thus define a coordination artifact called CPU Resource Sharing Artifact (CRSA) that generates operating instructions agents have to use to ensure all artifacts can meet their deadlines and which acts as an intermediary when agents negotiate CPU power.

Figure 1 reports the detailed definitions of the CRSA operating instructions. `Def_CA_Management` is the OI used by agents to interact with the CRSA when they have a computational job to give to a computational artifact, while `Def_Negotiation_Initiator` is the OI used during the previous process if the CRSA detects inconsistencies raised by adding the new computational task to the agenda. In this case, the `Def_Negotiation_Participant` OI is engaged so that other agents can propose to sacrifice a part of the CPU power they use.

Def_CA_Management. An agent which wants to delegate a computational job to a computational artifact first executes action `request(r_content)`. We consider that `r_content` is a term with four variables: an identifier `id`, an estimation `load` of the CPU power needed to finish the task, a list `t_c` of timing constraints the work has to respect and `ca_oi`, the OI that is the object of the request and which is bounded by the CRSA when no inconsistencies were found in the scheduling process. It waits for an answer from the CRSA

```
Def_CA_Management :=
  !request(r_content);T(r_timeout);
  ((?accepted(r_content);((r_content.ca_oi+0)||Def_CA_Management)+
   (?rejected(i_rejection);Def_Negotiation_Initiator(i_rejection));
     Def_CA_Management));Def_CA_Management

Def_Negotiation_Initiator(i_rejection) :=
  !start_negotiation(i_negotiation, i_rejection);  T(n_timeout);(
    ?negotiation_failed+
    ?negotiation_succeeded(i_negotation))

Def_Negotiation_Participant :=
  !get_sacrifice_request;(?finished+(?new_sacrifice_request(s_content);(
    T(s_timeout)+
    !refuse(s_content)+
    (!propose_sacrifice(s_content);(
       ?commit_sacrifice(s_content)+
       ?cancel_sacrifice(s_content))))));Def_Negotiation_Participant
```

Figure 1: CRSA Operating Instructions

Action	Precondition
request	B possible(r_content) & ¬B have_oi(r_content)
start_negotiation	B work_importance(r_content.id, s_content.imp) & B remain_work_load(r_content, s_content.load)
get_sacrifice_request	-
refuse	B ¬more_important(s_content, my_work)
propose_sacrifice	B more_important(s_content, my_work) & B can_sacrifice_work_load(s_content.load)

Perception	Effect
accepted	B have_oi(r_content.ca_oi)
rejected	-
negotiation_failed	B ¬possible(r_content)
negotiation_succeeded	B have_oi(i_negotiation.r_content)
new_sacrifice_request	-
commit_sacrifice	-
cancel_sacrifice	-

Figure 2: Semantic link between CRSA OI and agents mental state

for `r_timeout` time ticks. Answer can be an acceptance or refusal. In first case, the agent can decide or not to follow the OI `r_content.ca_oi` created by the CRSA. When a refusal is received, the agent tries to negotiate with other agents by following the OI `Def_Negotiation_Initiator`. In each case, a new call to `Def_CA_Management` is made so that the agent can do a new computational job request.

Def_Negotiation_Initiator. To simplify the negotiation process, we consider that agents have a common means of expressing the importance of a computational work, so that an agent that receives a proposal to sacrifice some CPU power can compare the importance of its works with the importance of the work it is asked to sacrifice for. The term `i_negotiation` contains the information of `r_content` and the information `imp`, calculated by the agent, that represents the importance of the requested work. The agent simply executes action `start_negotiation` and waits for an answer for `n_timeout` time ticks. If negotiation succeeds, the CRSA generates an OI to control the computational artifact and binds it to `ca_oi` in `i_negotiation`. Note that the initiator does not have any view on the negotiation process: is it managed by CRSA internal behavior.

Def_Negotiation_Participant. A participant to the negotiation protocol executes in a recursive way the action `get_sacrifice_request`. The perceptions associated to this action are `finished`, indicating that the participation of the agent to the protocol is over; and `new_sacrifice_request`, indicating that a new sacrifice request `s_content` is available. The term `s_content` contains information from `i_negotiation` and information `s_result`, calculated by the participant, on the sacrifice it can make. When a new sacrifice request is received, the agent has `s_timeout` time ticks to answer. It can refuse to sacrifice itself or it can accept, providing a proposal that will be used by the CRSA to verify if, with the sacrifice, the new task could be allocated. De-

pending on the case, the CRSA asks the agent to commit or to forget the proposed sacrifice.

Operating instructions, given alone, are not sufficient to agents. This is indeed necessary to give to agents enough information to understand the OI. We thus provide a link between the operating instructions and the agents mental state. Figure 2 describes this link in the case of our coordination artifact CRSA. We use the mentalistic semantics to actions and perceptions described in [20]. Preconditions in terms of agent beliefs are attached to OI actions and effects on agent beliefs to OI perceptions.

Preconditions of actions. An agent issues a request to the CRSA if it believes that it is possible to achieve the task (`Bpossible(r_content)`) and if it does not have an operating instruction to interact with the computational artifact yet (`¬Bhave_oi(r_content)`). Before starting a negotiation, it fills some fields in the `s_content` term (the importance and the needed load on CPU of its work). An agent refuses to sacrifice itself if it believes that its work is more important than the one in the request (`B¬more_important(s_content, my_work)`). On the contrary, it proposes to sacrifice itself if it believes that its work is less important. The proposition it does in this case depends on its beliefs of how much work load it can sacrifice (`Bcan_sacrifice_work_load(s_content.load)`).

Effects of perceptions. If an agent gets the perception that its request has been accepted or that the negotiation has succeeded, it believes that `r_content.ca_oi` is bound to a valid OI it can use to interact with a computational artifact (`Bhave_oi(r_content)`). In case the negotiation failed, it updates its mental state not to believe it is possible to do the requested task (`B¬possible(r_content)`).

4. CRSA BEHAVIOR SPECIFICATION

In this section, we describe the internal behavior of the CRSA. It mainly consists of a scheduling algorithm used to create the operating instructions it will return to agents. We overview the properties of such an algorithm, we give some information about how the scheduling is done and we give some examples of real generated operating instructions.

The scheduler that we need must have particular properties. It is constructed on top of the operating system scheduler. It can take into account (at its level) that several tasks can be carried out in parallel. It must manage differently agents, that are always active, and computational artifacts whose tasks have deadlines and therefore may be paused to ensure that other computational artifacts can meet their deadlines.

We consider that it is interesting to begin tasks as soon as possible. The behavior of a scheduler like Earliest Deadline First (EDF) [12], which will entirely execute the task whose deadline is the earliest and then turn to the next task, is not adapted to the resolution of a problem by various agents running different heuristics in parallel. In this kind of application, it is interesting to start the various heuristics as soon as possible and to stop the resolution as soon as one has found the required solution.

We model this scheduling problem with intervals and subintervals that split the scheduling horizon[4]. Each subinterval is characterized by the tasks which are allowed to run in it. In a subinterval containing n tasks, each task receives a share of $1/n$ of the CPU power in this subinterval. The scheduling problem is reduced to fixing the duration of each subinterval and is expressed as a linear program solved by the simplex algorithm.

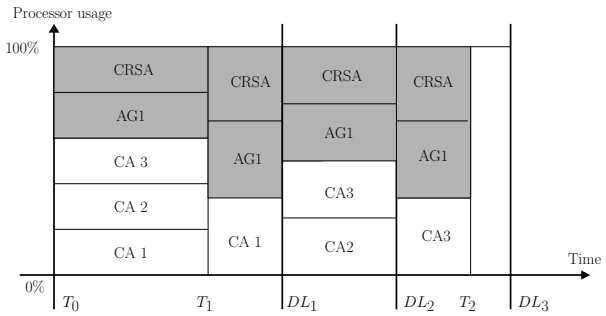

Figure 3: Schedule example

Figure 3 shows an example of such a schedule. There is an agent, the CRSA and 3 computational artifacts CA1, CA2 and CA3. Each computational artifact is assigned a task with respective deadlines DL_1, DL_2 and DL_3. We see that the main agent and the CRSA are considered to be always running (they are supposed to be fully time-aware), as they appear in each subinterval. The scheduler has determined that computational artifacts CA2 and CA3 could run until T_1 while ensuring that CA1 could respect its deadline DL_1. Here is the code of the OI generated by the CRSA for this example of schedule[1].

```
OI_CA1 := W(T0);!start(input_data);(
  (T(DL1);!stop)
  +?failure(error_info)+?finished(result))

OI_CA2 := W(T0);!start(input_data);(
  (T(T1);!pause;W(DL1);!restart;T(DL2);!stop)
  +?failure(error_info)+?finished(result))

OI_CA3 := W(T0);!start(input_data);(
  (T(T1);!pause;W(DL1);!restart;T(T2);!stop)
  +?failure(error_info)+?finished(result))
```

As this is not the main concern of the paper, we do not explain here all the details of the algorithm. The interested reader may find in [4] the algorithm details, explanations of implementation concerns and other examples of obtained schedules.

5. APPLICATION

We used the CPU resources sharing artifact previously described in a MAS which aim is to localize boats from an airplane by the sole use of the signal coming from the boat radars; it is then possible for the plane to stay hidden from the boats, which remain unaware of being spied. This procedure is called *passive localization*. It is useful in several practical situations such as the prevention of oil dumping from oil tankers – and also of course in lots of military applications.

[1]Note that, in this example, for simplicity reasons, we abuse notations for timeout and wait instructions by using absolute values of time points instead of durations as arguments to `T` and `W`. For example, we would rather use `T`($DL_1 - t_\alpha$) instead of T(DL_1) in `OI_CA1`, with t_α being the absolute time the last action was taken at.

The plane (the agent) gets the bearing of the boats on a regular basis corresponding to the periodicity of the boat radars. The bearings measured are imprecise of several degrees and possibly missing, due to the harsh operating conditions which generally prevail. This approach is comparable to goniometry but boats and plane are moving, which makes things really more difficult. The computation of a location for the plane is only possible when the plane is faster than the boats, which hopefully is generally the case. This speed difference is exploited by an interval propagation algorithm on continuous domain [10] which progressively narrows the possible area of the boats in combining measurements as and when they arrive. Interval propagation is especially well adapted for this task since it allows the incremental adjunction of constraints at each new measurement and also the use of non-linear constraints, in our case trigonometrical formulas.

Time-awareness is very important for an agent using such an algorithm since the duration of the computation might change dramatically due to possible slow convergence occurring in the propagation process [11]. Actions must be taken to avoid blocking the agent for a long time. Computational artifacts are a solution since they allow the uncoupling of the cognitive part of the agent and the time-unpredictable computation tasks it must carry out. It is then possible for the agent to decide whether or not the computation must be stopped, whether or not a new measurement must be considered...

Our system uses a proprietary Prolog-based interval constraint propagator (Interlog [3]) which makes it possible to specify a time contract when initiating a resolution step. When the contract expires, if the processing is not already achieved, Interlog stops and returns the present (interval) location of the corresponding boat. The agent can decide whether to resume the propagation and possibly improve the accuracy of the localization, or to introduce new constraints depending on the arrival or not of new measurements. Assuming that the period of the radar is known (which is practically the case after few measurements) it should be possible to meet the deadline requiring that the artifact is available when a new measurement arrives. Such a requirement is relevant since a new measurement conveys a more accurate information taking into account the last position of the boat and the plane. The new measurement is thus to be considered as soon as possible.

The problem is that the plane has to monitor several boats at the same time and hence several artifacts are competing for accessing the CPU. The number of boats under consideration can be chosen by the agent in order to ensure that all the required processing is feasible. Nonetheless, because of the de-synchronization between the radars of the boats (they all have their own period and run independently), it is impossible to guarantee the meeting of the deadlines without the use of a coordination mechanism such as the one proposed by the CRSA to manage the CPU.

More formally, the problem is the following:
Let B_i be the boats, the number of which can change over time, and p_i the period of the B_i radar (it is actually an upper bound since signals might be missing but it becomes more and more certain in the course of time).

When a new measurement j arrives for boat B_i, a new task $T_{i,j}$ is created, the deadline of which is: $DL_{i,j} = T + \tau_{i,j}$, with T the time of arrival and $\tau_{i,j}$ the processing duration.

Since few is known about processing duration, the same value PD is taken and used as a time contract (in CPU time) for the interval propagator for each new task. Hence: $\forall_i \forall_j : \tau_{i,j} = PD$.

At the end of the contract, a result is always available because, thanks to the monotonicity of the narrowing procedure used by the interval propagator, there is at anytime a valid interval encompassing the actual position of the boat that can be returned.

We ran experiments in a simplified version of the application described above to exhibit the benefits of the use of the CRSA in this application. We compared results obtained in the following cases:

- *when no coordination mechanism is used to manage the CPU power allocated to computational artifacts.* There is no guarantee that the computation for a measurement will be finished before a new measurement arrives. When this is the case, the artifact continues its computation until the time contract is reached and the new measurement is ignored.

- *when the CRSA services are used.* When the CRSA accepts to schedule a task, it guarantees that the computation will finish before the new measurement arrives. If the new task cannot be inserted in the schedule, the corresponding measurement is ignored.

We calculated in these two cases the percentages of measurements that were ignored. We used the following values for the parameters presented above:

- number of boats: 10,
- p_i: 5 to 30 seconds (real time),
- PD: 2 seconds (CPU time).

In the first case, 42% of measurements are ignored. Because of the de-synchronization between the radars, there are times when many measurements arrive almost at the same time, increasing the number of ignored measurements; some time later the CPU can be idlind for some seconds, all computations being finished and no new measurement arriving. The use of the CRSA coordination mechanism brings a significative improvement, with only 7% of ignored measurements and the CPU being constantly used.

6. RELATED AND FUTURE WORKS

In this section, we explore related work in time management in intelligent agent systems with the prospect of improving the notions and (formal) models that were used in this paper.

Time management is a transverse and vast concept in MAS [7]. From our point of view, it can be split into three concerns: *(i)* temporal reasoning, in which planning and scheduling are the two topics that interest us most, *(ii)* execution and monitoring and *(iii)* the link between these two phases. Item *(i)* is pointless if nothing is done to manage point *(ii)* and the most difficult problem is to unify these two viewpoints so that the modules that manage them can interoperate.

Time management already was a key point in Agent-0 [18]: the language allows agents to schedule commitments they

have to fulfill in the future and the framework is responsible of calling the corresponding actions when necessary. In Agent-0, there is a single control loop. On the contrary, InteRRaP [13] introduced several control layers that are respectively in charge of reactive behavior, planification and cooperation. There is a clear distinction between the three points of time management we cited before. To bridge the gap between temporal reasoning and execution and to allow temporal verifications, Concurrent MetateM[6] uses agent specifications that are directly executable, but is limited to reactive agents.

Several work as also been done to manage unpredictable hard and soft deadlines that are only known at execution time. The approach proposed by Adelantado et al. [1] to this problem uses two levels: a reactive meta-level that makes the agent aware of its environment and that controls the base level, which is *anytime* based. To our point of view, their approach cannot be applied to a wide range of applications because of the difficulty to find anytime algorithms for a particular problem. Moreover, our approach is based on *continuous* meta-level reasoning, which can give more flexibility than reactive approach, and the goal of computational artifacts is to embed legacy code that can have bad temporal properties.

To deal with this problem of deadline unpredictability, Lalanda et al. [9] propose to provide run-time flexibility to agents with multiple choices to realize an action. Agents have goals with hard or soft deadlines and goals have different priorities. The agents continually reason about their deadlines to choose the next action that they will execute. This reasoning is based on a scheduler that ensures deadlines meeting and a threshold based decision process to interleave the execution of the agent plans. Lalanda et al. applied their techniques to an office robot application. The robot is given tasks as book fetching and delivery, environment learning or environment inspection. The robot can decide to degrade its performance if it cannot fulfill all its goals. Our approach is more or less similar except that the tasks of our agents are computational tasks. We view time passing as the CPU time consumed by artifacts. They compete to use the CPU and agents have to cooperate to obtain the CPU power they need to meet their deadlines.

Omicini et al. describe in [15] an extension of the ReSpecT language to manage time in coordination artifacts. An extension of the well known *dining philosopher* problem is given as example. It manages the case when philosophers do not release back the chopsticks. The final coordination policy constraints the maximum time an agent can use the shared resources. Their approach is to allow *coordination artifacts* programs to contain timed instructions (wait, timeouts, timed insertions/deletions of reactions), while our approach is to allow *agents* reason about computation time passing and cooperate to achieve their goals.

An interesting field of research to improve this work is the one initiated by IMPACT [2] and extended by Temporal Agent Programs [5]. Interesting notions like checkpoints and history could be usefully exploited in our framework. More generally, having a formal model of algorithms used in computational artifacts is of great importance. This is the idea behind anytime computation [22]. However, finding an anytime algorithm to solve real-world problem is often impossible. Finding adaptable algorithms is nevertheless the good way to follow [8, 19]. Moreover, we must go towards flexibility. Agents must not be in a situation where they are unable to do anything. They need to have several choices to respect their temporal constraints and have the means to do the right choice [21, 14].

Last, but not least, MAS are distributed in nature. We have thus to extend our CPU Resource Sharing Artifact so that it can give information to agents about the load of other CPUs in order to let them decide to migrate.

7. CONCLUSION

In this paper, we investigated one aspect of time-awareness in multi-agent systems: being able to meet deadlines on heavily computational tasks in a context of CPU sharing, while remaining aware of the environment. We showed that modeling computational tasks with agents in this context is not satisfying. We used the notion of artifact developed in [20] to introduce computational artifacts, entities that provide computational functionalities to agents that use them to achieve their goals. As this is not sufficient to ensure deadlines meeting, we also introduced a coordination artifact (the CPU Resource Sharing Artifact) which purpose is to manage the CPU agenda and to act as an intermediary when agents need to negotiate to share the available CPU power. It is worth noting that the CRSA only centralizes information on the CPU agenda but does not decide anything when a conflict appears in the schedule. Agents keep entire control on the sacrifice decision process.

ABSTRACT

In order to achieve efficient progress in activities such as e-commerce and e-transactions in an open environment like the Internet, an agent must choose appropriate partner agents for collaboration. However, agents have no global information about the whole multi-agent system (MAS) and the state of the Internet; therefore, they must select the appropriate partners based on local knowledge and local observations. In this paper, using a multi-agent simulation, we discuss how total MAS performances are affected by local decisions when agents select partners to collaborate with. We also investigate how MAS performances change and how network structures between agents shift according to the progress of agents' local learning and observations. We then discuss the relationship between task load and agent network structure. This relates to estabilishing the optimum time when agents should learn about appropriate partners in an actual environment.

1. INTRODUCTION

Each agent in a multi-agent systems (MAS) must select the appropriate collaborative partner agent when assigning a task. The choice of an appropriate agent depends on the types of task and the agent's abilities and specialties. However, if there are still multiple candidate agents, the most efficient agent is preferable. Furthermore if deadlines have been set, the issue of performance/efficiency becomes dominant. For e-commerce on the Internet, for example, the selection of efficient agents (in this case, Web and database servers) provides smooth transactions for all customers. This also means that the computational resources provided by the e-commerce company are well-utilized.

The agents selected for collaborations are often memorized by a local agent for a certain period. This stored agent structure constitutes a kind of agent organization. Such an organization can avoid repeated searches for collaborating agents, retains the quality of the results, and enables agents to accurately estimate the finish time of given tasks for real-time requirements[3]. This suggests that the process by which agent teams are organized and the way appropriate partner agents are selected are important issues in designing MAS applications.

However, in an open environment like the Internet, complete information is not available; it is not possible to grasp the global states of the Internet and the complete states of the entire MAS working there. The efficiency of task execution by other agents depends upon their processing speed and load, and the communication bandwidth, traffic, and latency between agents. Hence, agents have to select appropriate (that is, efficient) partners based only on locally available information, which often contains uncertainties. This kind of local decision-making has already been used in Internet operations[2, 8, 9]. For example, Tenbin DNS[9] is an alternative DNS which, if it knows a number of servers that can provide the same content or functions, returns the IP address of the appropriate server for load-balancing and

for selecting the most efficient servers. Tenbin DNS selects servers based on local observations such as RTT (round trip time) using 'ping' or the average throughput between local hosts and target servers. A similar methodology is also used for Web server selection[2] and for route selection in multi-homed network environments[5, 6].

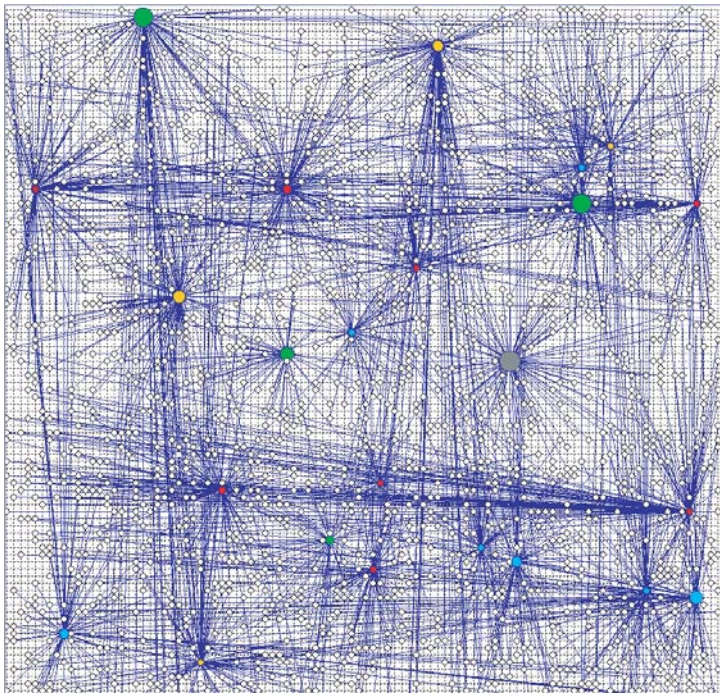
Here, another issue involved with scalability arises: when all agents select partner agents and form organizations based on local data, is the overall performance of the total MAS maximal or reasonable? ('Total' means not the performance of individual agents but the average performance of all agents.). This issue is important because the result is influenced by factors including task load, the agent's (CPU and processing) performance, communication costs, the agent's distribution across the Internet and the strategies of the agent's partner selections. For example, a high-performance agent a is identified as the best partner by many agents, and thus, is likely to be overloaded. This concentration worsens its observed performance data, so many agents will switch to other lower performance agents. Later, a will again be observed as a high-performance agent so they will switch to it again. Of course, these situations may depend on communication costs and the agent's *partner selection strategies (PSS)*. A number of studies have investigated how much the performance of each agent can be improved[2, 9]. From other global view points, for example, Gaston and DesJardins [4] propose an agent organizational network, and investigate what features are required to effectively form teams. To our knowledge however, there has been little research about how agents' local strategies and task loads influence the total performance of MAS and the structure of networks according to learning by individual agents.

The purpose of this paper is to show, using multi-agent simulation, how the total performance of a MAS improves or degrades when all agents statically, adaptively, or collaboratively select partner agents based on their local information. We also illustrate how the network of inter-agent structures (this network is simply called the agent network or hereafter, AN) changes and converges, and how the total performance changes according to the observed data, where an AN node corresponds to an certain agent and the edge between nodes a_1 and a_2 means that a_1 recognizes that a_2 is the appropriate agent to collaborate with. In this paper, we will first show that agents' PSSs affect the total performance and the structure of the agent network and that simple adaptation and collaboration with neighboring agents can effectively improve the total performance. Furthermore, the AN structures are heavily dependent on the frequency of the tasks occurring as well as the PSS. This result suggests that for the best performance the appropriate PSSs depend on the overall task loads.

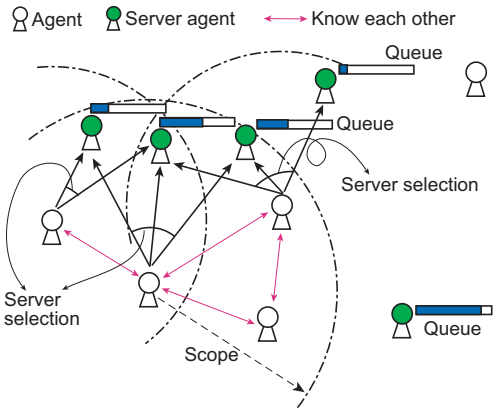
This paper is organized as follows: In the next section, the objective and settings of our multi-agent simulation are explained. Then, as a reference for subsequent experiments we will show the results of the first simple experiment. Next, we try to improve the number of dropped tasks and response time by changing some performance parameters. We also examine the effects of fluctuation in selecting the best server. Finally, we will discuss some implications for the control and design of MAS derived from these experiments.

2. AGENT SIMULATION

2.1 Objective



The objective of our simulation is to understand the structural changes of the agent network and to investigate the improvements and limitations of the total performance of the whole MAS when all agents make rational decisions about partner selection. Our simulation model consists of a set of agents $A = \{a_i\}$, and server agents $S = \{s_j\}(\subset A)$, which are able to execute a specific task T. When agent a_i has T, it assigns it to one of the servers that it knows, $S_i(\subset S)$. A PSS corresponds to the method whereby a_i selects s_j from S_i. To clearly understand the relationship between total performance and PSSs, we make the other parameters simple. For this purpose, we assume that all tasks are only of a single type. It is important to note that a server in this paper means an agent that can execute a specific task. Because we only consider a single type of task, the set of servers is static. In general, among the agents in a MAS, multiple tasks request each other, and different agents become servers for other tasks. We do not consider a simple client-server model but rather more flexible multi-agent models in which each agent selects appropriate partner agents depending on the task types from a local viewpoint.



On the actual Internet, one of the observable parameters concerning agents' performance is the response time (rt), which is the length of time between the agent requesting a task and the return of the result. We assume that smaller rt is better. Another parameter for evaluating agents is the number of dropped tasks, which indicates that the requested task is dropped (silently discarded) or refused (with notice), which also is better if it is smaller. Other parameters such as type of CPU and the number of queuing tasks in servers can also been used to evaluate agents, but these parameter values are not usually locally available, so they are not used for the evaluation of servers by agents in our experiments.

Hence, using the observed data, each agent learns which server's rt is expected to be the smallest. In our experiments, agent a_i calculates the average values of the observed response time of the known server s_j (let this value be h_i^j) and (usually) selects the best server, $arg\ \min_{s_j \in S_i} h_i^j$.

To evaluate the total performance of a MAS, we adopt the average value of the observed response time in all agents. This value is denoted by RT. Thus, our experiments demonstrate how RT changes when all agents try to make rt smaller. Another parameter for understanding the total MAS is the drop number, D, which is the total number of dropped tasks. Note that a smaller drop number is better but a drop is observed only when the MAS is overloaded. Therefore, the use of this value is restrictive.

To investigate the structure of relationships between an agent and its selecting server, we introduce the *agent network (AN)* whose nodes are agents or servers and whose links indicate that an agent has determines that a server is the best according to its PSS and local data. For a positive integer γ (= 1 for the default value), called the *selection number*, agent a_i selects γ servers as appropriate servers from S_i, then assigns the given task to one of the selected servers. We look into the *degree* of the server's node in the AN because the degree denotes the level of concentration of the task assignment, that is, how many agents identify that server as appropriate for assigning tasks. The distribution of the servers' degrees expresses the balance or deviation of the overall (and potential) task load. We also investigate how the distribution changes as the agents' observation and

Above: Simulation Environment.
This figure shows the settings of our simulation environment.

Left: A Screen Snapshot of our Simulation.
A small outlined circle corresponds to an agent and a filled circle to a server agent. The sizes of the filled circle express their queue length, so the larger circles are busier. A line between agent and server expresses that when the agent is given a task, the agent assigns it to the connected server with some probability. This snapshot of the simulation is scaled down: gridsize is 100x100 with torus topology, the number of agents is 2000, and the number of servers is 24.

Figure 1: Simulation Environment and Screen Snapshot of our Simulation.

learning progress.

Our simulation can acquire other parameters for understanding the whole MAS performance, such as average values of (1) *communication cost* C (the average RTT between agents and servers), (2) the *queuing time* Q (the average duration that the incoming task is queued for before execution), and (3) *CPU time* E (the average time for executing a task). Although these parameter values are not directly observable on the Internet, they can help to estimate internal AN changes. We assume that $RT = C + Q + E$ holds.

2.2 Simulation Environment

Our simulation (Fig. 1) generates 10000 agents that are randomly placed on points of a 150 x 150 grid plane with a torus topology. Of these, 120 agents are randomly selected to be servers (so the remaining 9880 agents will assign tasks to these servers). We also introduce the Manhattan distance to this grid.

For every tick, tl tasks are generated and given to tl randomly selected agents, where tl is a positive integer. tl is called the *task load*. We can naturally extend these settings for a positive non-integer tl, which means that the average number of statistically generated tasks in every tick is tl. This is denoted by tl task/tick or simply tl T/t, where we assume that 1 tick is 10 msec. Each agent a_i given the task immediately selects a server $s_j \in S_i$ using its PSS and sends the task to s_j. Server s_j processes the committed task and returns the result to a_i. Agent a_i can observe the response time for every task and calculate the average response time h_i^j that will be used in the next PSS.

All servers are assumed to have their own CPU capabilities: each server can process a task in 100 to 500 msec. All of the servers have different capabilities that are randomly assigned *a priori*. Once assigned, these capabilities are invariant. When a task arrives at server s_j, it is immediately executed if s_j has no other tasks. The result is then returned. If s_j has other tasks, the received task is stored in its local queue and the queued tasks are processed in turn. An agent can store 20 tasks in its queue. If a_i already has 20 tasks in its queue, the new task is dropped or refused.

The communication cost (time required to send a task) is assumed to be proportional to the distance between the agent and server and ranges from 10 to 120 msec. Of course, this maximal cost is also a parameter of the simulation environment, although it is not altered in any experiment in this paper, so that we might easily understand the effect of PPS based on local observation. Each agent has its own scope depending on distance (less than 14 in our experiments), so it initially knows and can communicate with all agents and servers within the scope. For all agents to compare servers' response times and to select the best (or better) one, they have to know at least two servers. If an agent knows none or only one server, it asks all known agents for known servers; by doing this, agents can initially know two to fifteen servers.

The experimental results of all our simulations are the average value of three independent experiments derived from a random number using three different seeds. The figures of degree distribution shown in this paper are only for one of the three experiments, but their diagrams are almost identical to the those of the other cases. In these three experiments, the total sum of the capabilities all agents express is that they can theoretically process 4.7 to 5.0 tasks every tick; of course, the actual total capabilities are influenced by the communication cost, the deviation of task allocation, and server distribution in the grid plane.

3. PRELIMINARY EXPERIMENT (EXP. 1)

In the first experiment (Exp. 1), agent a_i selects γ (= 1) servers from S_i using the following PSS.

(P1) a_i selects the server $arg\ \min_{s_j \in S_i} h_i^j$ with a probability of 0.9[1]. If there are multiple servers that have the best h_i^j, one of them is randomly selected.

(P2) Otherwise, a_i selects the server with the probabilistic distribution $Pr(s_j)$,

$$Pr(s_j) = (h_i^j)^{-l} / \sum_{s_k \in S_i} (h_i^k)^{-l} \qquad (E1)^1,$$

where, $l = 3$ in this experiment[1]. In the beginning, the agents have no observed data of known servers. Hence, agent a_i initially sets $h_i^k = 0$ for the known server s_k so that it first selects s_k with no observed data. Note that (P2) introduces *fluctuation* to some extent into the PSS, since an agent may select a server whose h_i^j is not the smallest.

In the cases of tl=1T/t and tl=4T/t, we measure the performance data, RT, C, Q and E, every 20,000 ticks (20K ticks). Fig. 2 shows how these values change over time. The data in Table 1 are the average values of these parameters during a 600K to 800K tick. Fig. 3 (ii) and (iii) illustrate the cumulative degree distribution (CDD) of AN at an 800K tick, and Fig. 3 (i) is the CDD of the initial state. Thus, the CDD gradually changes from (i) to (ii) (the case of 1T/T) or from (i) to (iii) (the case of 4T/t) in Fig. 3. The last column of Table 1 shows the performance data when only (P1) is adopted (so there is no fluctuation in server selection).

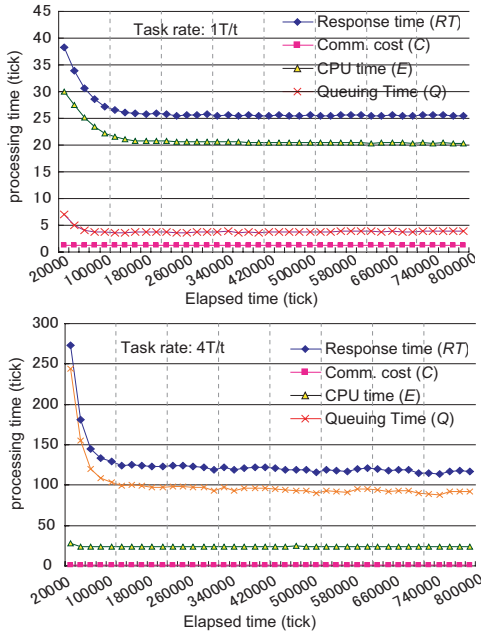


Figure 2: Total performance values (Exp. 1).

[1]We define probability 0.9 and $l = 3$ so that the server selection adequately fluctuates. Although there are a number of other ways to introduce fluctuation, we used (E1) for the first experiment. These values and expression are defined based on some experiments. We will show experimental results elsewhere when these values are changed.

Table 1: Observed performance values in Exp. 1.

Param.	0K (1T/t)	0K (4T/t)	800K (1T/t)	800K (4T/t)	4T/t (no fluct.)
RT	38.29	272.89	25.52	117.11	125.70
C	1.233	1.269	1.295	1.309	1.312
E	30.05	27.41	20.38	24.27	24.01
Q	7.01	244.20	3.85	91.52	100.38
D	0	11180.0	0	622.8	1780.1

The unit of value is a tick except D (number of tasks). 0K means the 'initial state' whose values are observed from 0 to 20K. The value of the columns at 800K are the average values of the parameters observed at every 20K ticks from 600K ticks to 800K ticks.

As indicated in Fig. 2, in this experiment the servers' performance became stable at around 120K ticks because the agents only know 2 to 15 servers, so all of them finished learning their performance. Agents select only local servers (since C hardly changed over time), so the global performance plateaus at an earlier stage. Though the theoretical capability of all servers is higher than 4T/t, approximately 600 tasks are dropped after learning. This implies that the servers' capabilities are underutilized.

The performance data are different depending on whether or not there is fluctuation as shown in Table 1. The fluctuation introduced in these experiments given by (P2) can improve average response time (RT) by 8% when tl = 4T/t. However when tl = 1T/t, this kind of improvement cannot be observed. The details are described later. Note that this experiment is similar to the one of the fixed-load case in [7], although there are many different settings; for example, the number of agents is quite large and communication costs are introduced in ours. The conflict vector in [7] corresponds to the degree of AN in ours; our experiment has more agents so it can show the structure of AN after learning.

In this experiment, the final total performance could have been further improved if all agents had known more servers. However, learning efficiency would have drastically dropped. For example, if all agents knew all 120 servers, they would require at least 1186600 (= $120 * 9880$) tasks to get performance data for all the servers. So in the case of 1T/t, it would take about 1200K ticks. In actuality, however, it would take more than 2400K ticks, because tasks are randomly assigned to agents. In practice, it is not feasible to know and attempt to use all servers on the Internet if the agents are in a massive MAS. This means that a more effective strategy for better knowing servers from a non-local viewpoint is required.

4. PERFORMANCE IMPROVEMENT AND STRUCTURAL CHANGES

We can consider a number of performance measures, but we first focus on the total drop number D in a MAS and try to reduce it. Using local information, we examine the following strategies to reduce D.

(S1) **Best two selection:** Set $\gamma = 2$. All agents select the best two servers every 500 ticks. When a task is given, the agent selects one of two servers using probability (E1) and sends it the task.

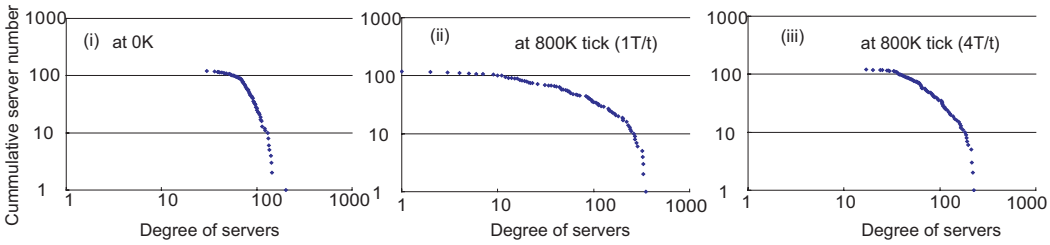

Figure 3: Cumulative degree distribution of servers.
Each point (x, y) indicates that there are y servers whose degrees are more than or equal x.

Table 2: Observed performance values in Exp. 2.

	(S1)	(S2)	(S3)	(S4)
RT	134.08	118.22	153.21	117.00
C	1.305	1.309	1.306	1.307
E	24.81	24.28	24.89	24.36
Q	107.96	92.63	127. 02	91.33
D	729.1	594.5	180.3	420.1

The unit of value is a tick except D. All data are the average values of the corresponding parameters observed every 20K ticks from 600K ticks to 800K ticks. $tl = 4$ T/t.

(S2) **Retransmission:** If their queues are full, the servers do not drop but rather refuse the requested task. The requesting agent resends the task to the server again. Agents will repeat this process five times, but if all five requests are refused, the agent gives up (drops) the task.

(S3) **Alternate selection:** Agents adopt both (S1) and (S2). The main difference is that agents have the top two servers, so after a task is refused, it may be sent to another server.

(S4) **Penalty:** This strategy is the same as (S2) except for introducing the penalty of refusal which is calculated as follows: Add double the RTT to the observed response time. This worsens the rt of the refusing server, so the agent may select another server the next time.

Table 2 shows the results of the second experiment, Exp. 2, whose tl is 4T/t. Comparing Tables 1 and 2, all performance values show only a small change in (S1) and (S2), and especially RT and D get worse in (S1). Even if an agent knows the second best server in (S1), it is probable that the server is the best for a number of other agents, so the drop rate does not decrease. Additionally, the agent requests the second best server, so the value of E (and of Q) also gets worse. Strategy (S2) is not a useful tactic for reducing D; although, after a task is refused, an agent requests it of the same server, there is a high probability that it will be refused again because with 4T/t the server's queue is likely to be still full. Note that if the agent can wait for a longer time D may become smaller, but there is a trade-off between the probability of refusal and the waiting time.

However, strategy (S3) can effectively reduce D. Alternately requesting a task of two servers simply halves the probability of refusal. Instead, RT gets larger; this implies that more tasks are stored in agents' queues, so Q also increases. Finally, strategy (S4) can only improve RT and D a little bit. We expect that this kind of penalty works well when servers are placed non-uniformly and the agents in the area where servers are sparsely settled observe more refusals so they then try to access more distant servers. The figures of cumulative degree distribution for (S1) – (S4) are not shown in this paper, but their characteristics are the same as those in Fig. 3 (iii).

4.1 Collaboration with neighbor agents

The experiments in the previous section aimed at reducing D, but the total response time RT and queuing time Q increased. These strategies kept all agents waiting for a longer time. In this section, we aim to reduce RT and Q.

The performance of the simple server selection strategies used in Exps. 1 and 2 depends on the size of the known servers. Agents that know more servers can choose more capable ones. However, the more servers the agent know, the more inefficient their learning performances are. So, a more effective and efficient strategy for agents to acquire good servers is required.

A practical strategy in the network environment is the recommendation of good servers by neighboring agents. Each agent learns the expected servers' capabilities from their local viewpoint so they can recommend to other agents the best or better server based on their observations. The basic idea is that it is possible for the better servers of neighboring agents to also be good servers for other agents. This strategy works as *collaborative filtering* using server evaluations.

To achieve this collaboration, we add the following PSS, (P3) between strategies (P1) and (P2).

(P3) With a probability of 0.01, an agent a_i randomly selects a known agent, and asks it to recommend a 'good server' s_n. If a_i already knows s_n, this recommendation is ignored. If not, a_i adds s_n to its set of known agents (so $h_i^n = 0$).

An agent that is asked to recommend a server selects a 'good server' using probability distribution (E1). The experimental results using (P1)–(P3) for 1T/t and 4T/t are shown in Table 3 and Fig. 5 (this experiment is referred to as Exp. 3). The cumulative degree distributions of Exp. 3 are illustrated in Fig. 4.

Table 3 shows that both RT and D are improved. This implies that server recommendation is an effective strategy for total MAS performance. Compared with Table 1, Exp. 3's C becomes larger – this indicates that agents assign their tasks to more distant but more efficient servers (E becomes

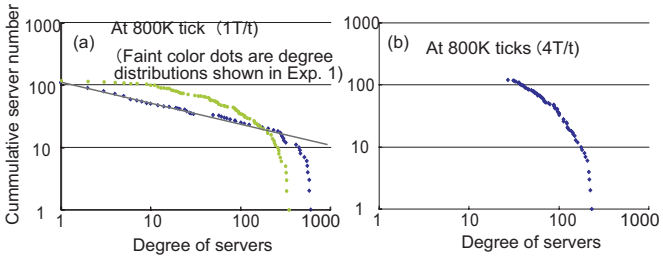

Figure 4: Cumulative degree distribution at 800K (Exp. 3).

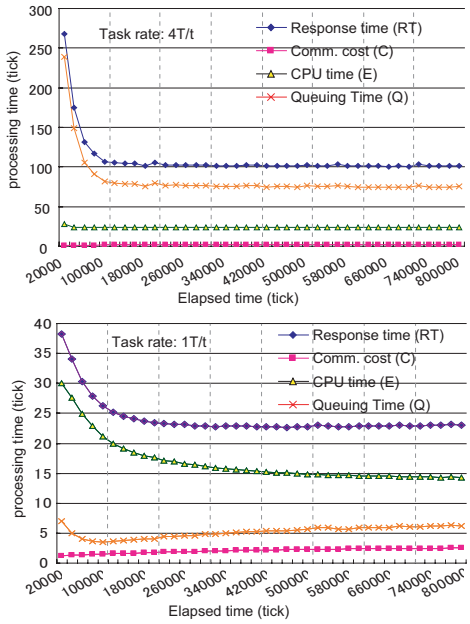

Figure 5: Total performance values (Exp. 3).

slightly smaller). The biggest difference between Exp. 1 and 3 is that the cumulative degree distribution for 1T/t follows the power distribution in Exp. 3, though it follows an exponential distribution in Exp. 1. It seems that the recommendation of good servers works like the preferential attachment in the Barabasi-Albert model[1]. However, there are some differences. For example, in our experiments, (1) all agents re-evaluate the recommended servers from their viewpoints, (2) the server becomes more inefficient if more agents assign their tasks to it, and (3) the communication costs prevent agents from accessing distant servers. So we argue that the server recommendation by agent collaboration (that is, by collaborative filtering) with local evaluation may be another mechanism for expressing the power low in the servers' degree distribution when the workload is low. Note that the cut-off in Fig. 4 (a) appears because of the limited numbers of agents in our simulation setting.

Table 3: Observed performance values in Exp. 3.

	1T/t	4T/t	4T/t with (S3)
RT	22.99	101.33	98.91
C	2.449	2.420	2.420
E	14.43	24.00	24.05
Q	6.11	74.91	72.45
D	0	309.6	0.17

The unit of value is a tick except D (number of tasks). All data are the average values of the corresponding parameters observed every 20K ticks from 600K ticks to 800K ticks.

At 800K ticks, the number of the agents' known servers ranges from 3 to 20 and increases by about 5.5 on average. This number is much smaller than 120, which is the total number of servers in this simulation. Therefore, we can say that the collaborative filtering described here is an effective learning method in our simulation setting.

Additional observations of Fig. 5 and Table 3 are:

- When tl is 1T/t, collaborative filtering produces a task concentration at higher capability servers and thus the number of servers whose degrees are small also increases. This concentration results in highly efficient total performance because the task load is low, which means that Q is still small.

- When tl is 4T/t, there is little difference between the degree distributions of Exp.1 and Exp. 3. However, Tables 1 and 3 express a difference in RT values. Comparing E values, agents did not find high capability servers, but we can understand from the C values that agents allocate their tasks to distant servers. A decrease of Q and D indicates that agents achieve load-balancing across wider regions.

Fig. 5 (b) demonstrates that RT becomes stable at an earlier time, but E, Q, and C still change around 800K ticks when $tl = 1$. This implies that the AN structure constantly changes; the degree distribution gradually changes to express power laws through this structural change.

Finally we want to point out that the collaborative filtering and strategy (S2) in Exp. 2 improves performance for different reasons if we compare Tables 2 and 3. Therefore, we additionally experimented with total performance and strategy by combining them. These results are shown in the final column in Table 3, which expresses the best performance in our experiments.

4.2 Fluctuations and Performance

The probabilistic distribution (E1) in Exp. 1 introduces a small fluctuation into the server selection decision because there is the small possibility of selecting a known server that is not the best. The last column in Table 1 shows the performance data if this fluctuation is excluded (that is, only (P1) is used) when tl is 4T/t. This data show that the fluctuation can reduce RT by 7.3%, Q by 9.7%, and D by 186%. We think that these differences are considerable.

However, this improvement by fluctuation appears only when tl is near four. The data (a) in the two graphs of Fig. 6 illustrate the distributions of $RT' - RT$ and $D' - D$in Exp. 1 over various tl ranging 0.5 to 5.2 T/t, where RT' and D' are the average of the whole response time and the number of total dropped tasks when no fluctuation was introduced (that is, (P2) was not used). The left graph in Fig. 6 shows that when $tl \leq 2.5$ the difference of RT and

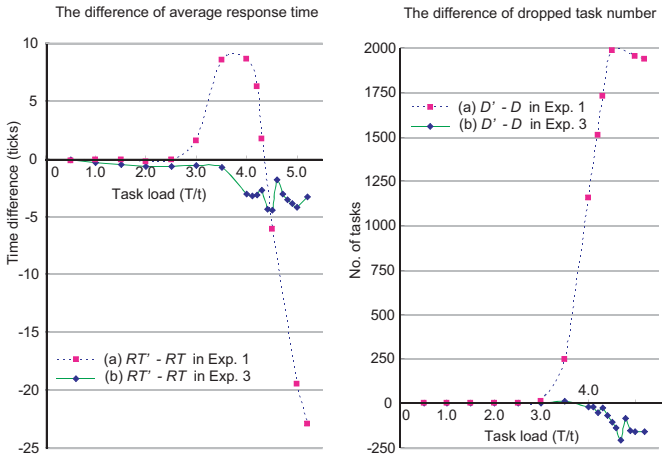

Figure 6: Performance differences (Exp. 4).

These graphs show the difference in the average response times and the number of dropped tasks when fluctuation is introduced and when it is not. Both RT and D are better if they are smaller, so if $RT' - RT$ $(D' - D)$ is positive, the fluctuation positively affects the average of the total response time (the number of dropped tasks).

RT' is almost zero (or more precisely, slightly negative). Then, fluctuation (by P2) can improve the average response time between 2.5 and 4.4, but worsens it when $tl \geq 4.4$. However, D is always better if fluctuation is introduced. We must note again that the theoretical total performance of all servers in our experiments varies from 4.7 to 5.0 and the average value is 4.86.

These figures show that the agents' best selection is not accurate when $2.5 \leq tl \leq 4.4$ in this experiment although agents select, in both cases, the best server within a restricted scope, which is the set of initially given servers. This implies that there is more uncertainty in server selection, in this range of tl. When the total load is low, the agent's PSS without collaborative filtering is relatively accurate, because all servers' queues have enough vacancies so that their observed capabilities are mainly affected by the servers' capabilities. A similar situation also appears when $tl \geq 4.4$, because when all servers' queues are almost full the observed data simply reflects their capabilities. When $2.5 \leq tl \leq 4.4$ however, the observed data are mixed with the capabilities and the queue lengths, which float over time. Therefore, the server observed to be the best may not be the best with higher probability in the next timing of the task assignment. Note that regardless of whether or not fluctuation is introduced, an agent selects servers only from the set of the initially known servers.

This uncertainty is eliminated to some extent when agents employ PSS with collaborative filtering. The graphs (b) in Fig. 6 show $RT' - RT$ and $D' - D$ in Exp. 3. As opposed to the previous case, the fluctuation worsens the total performance and the number of dropped tasks when $tl \geq 4$; this intuitively feels natural. This result implies that the collaborative filtering offers agents a more accurate and scalable decision-making process for selecting appropriate partner agents.

Table 4: Change task rate at 800K tick (Exp. 5).

	1→ 4T/t w/o CF	4→ 1T/t w/o. CF	1→ 4T/t w/ CF	4→ 1T/t w/ CF

5. DISCUSSION

In real applications, selecting the appropriate agents for task allocation is quite important. We discuss this issue by taking into account our experimental results.

Effect of prior learning

Load-balancing should be achieved when the total load of the MAS is heavy. However, although agents' prior learning to identify the best way to assign specific tasks when the global MAS state is normal (that is, when the load is not heavy), it has little or no effect on performance improvement. One of our findings in both Exp. 1 and 3 was that the AN structures are quite different depending on the task load tl. Especially, Fig. 4 (Exp. 3) shows that the features and their degree distributions are different in the cases of 4T/t and 1T/t; one is exponential and another is a power-law. This implies that the agents' local decision about which server is the best is also affected by the total task load.

In Exp. 5, we switched the task load 1T/t to 4T/t at the 800K-th tick and vice versa; these results are shown in Table 4. Comparing this table and Table 1, the performance values are almost back to the values found in early stages in all cases. So, we can conclude that agents should learn the best partner agent when the MAS is totally overloaded.

Compatibility with conventional programs

Our experiments show that observation and learning by each agent, especially collaborative filtering, play an important role in achieving efficient and effective partner selection. Actually, some systems described in Section 1 such as TenbinDNS and IPv6 route selection decide their preferences based on these kinds of observations without collaborative filtering. This learning-based load-balancing is more effective than static, random, and round-robin-based methods.

Furthermore, strategy (S3) in Exp. 2 can realize more efficient load-balancing with collaborative filtering as shown in Table 3. Although strategy (S3) in Exp. 2 seems to be a natural extension of (S1) and (S2), it is not easy to deploy this function for a number of reasons. First, in real applications, modifying legacy and existing programs is avoided; for example, the previously mentioned approach of load balancing by DNSs and proxies was chosen for this reason. Normal software such as a Web browser makes a query to the local DNS to resolve the IP address from the server's name. The result is then cached for a while (because this function is provided by the OS). Therefore, agents do not change their accessing servers.

The second reason is that agents have to understand the context of the (distributed) processes running on them in order to flexibly change their accessing partners. For exam-

ple, when buying goods using an e-commerce application, if a Web browser were to reconnects to another Web server that provides the same functions during the writing of an address or credit card number, it could cause some inconsistencies. More importantly, it could create an opportunity for user information to be stolen or illegally accessed. Thus, agents cannot change the server even if the server becomes overloaded during an interaction. We assume that (S1) and (S2) can be implemented in actual environments, but that it can only slightly improve the total MAS performance. Therefore, such a strategy (S3) should be implemented in future agent programs.

Rational decision and fluctuation

In general, an agent is required to make rational decisions according to its local knowledge which may contain uncertainty. However, this decision should be made with the consideration of accurate knowledge. Our experimental results regarding the effects of fluctuations indicate that the best selection does not always lead to the best performance. When all agents do not adopt collaborative filtering, it is better that agents sometimes select the second or third best server. However, when they adopt collaborative filtering, their rational decisions usually lead to a better performance.

Our experiments and discussion suggest that collaborative filtering can provide a more accurate view for rational decision-making. Collaboration is indispensable because it can eliminate some of the uncertainties contained in local knowledge. Rational decisions are required in multi-agent design but they must be based on accurate information about non-local information, otherwise the rationality is uncertain.

For more accurate rational decision-making, information about network and other agents' states is important. As shown in Exp. 3, collaborative filtering can achieve effective PSS. This suggests that MAS design should take into account the structure and (dynamic) performance of the Internet. Looking again at the example of DNS-based load-balancing, collaborations with other DNSes in the same autonomous system (AS) or neighboring AS's must be useful. However, Exp. 5 implies that this kind of learning through collaborative filtering in mismatched situations makes the performance worse. In this case, it is better that agents know network traffic and other agents' loads. To form appropriate MAS organizations for problem solving, we believe that MAS infrastructure that has the view of Inter- and Intra-AS structures (that is, routing) and (predicted) traffic, is necessary for future MAS design[10, 11].

6. CONCLUSION

In this paper, we investigated whether agents' local strategies for selecting partner agents that are committed a specific task affect the total performance of an entire MAS. In particular, we focused on the structure of agent networks that vary according to the task load. Then, we discussed a number of findings from the experimental results: (1) learning partners by observation must be derived from the observed data gathered in the same/similar situation, (2) for more precise learning, each agent has to take into account the states of network and other agents, and (3) rational decisions by agents do not provide the best performance when the task load is at or near the critical point for total MAS capabilities.

Only a few years ago, the communications bandwidth of the Internet was narrow. Hence, to provide effective and efficient access to the (Web) servers, it was important to place them at the sites near customers or at major network ISPs. However, recent communication technologies can provide a 1M to 100M line to each home, and the communication bottleneck tends to move to the server side, because they must process a large number of requested tasks. In such an environment, it is necessary for an agent to select high-performance partners rather than closer partners. In designing a MAS, we must consider how each agent finds other agents to assign tasks. Each agent's decision, based on local information, can be improved by careful local observation and learning. This can realize more efficient MAS operation. However, our experiments show that the simple local observation and learning may not be scalable when all agents do the same thing. Collaboration, such as collaborative filtering, plays an important role in achieving more scalable load-balancing.

ABSTRACT

Super-peer networks have been proposed to address the issue of search latency and scalability in traditional peer-to-peer (P2P) networks. In a super-peer network, instead of having a fully distributed systems of peer nodes with similar or comparable capabilities, some nodes that possess considerable computing power and resources are designated as super-peers. Each super-peer acts as a server for multiple client peers under it. This hierarchical structure of a super-peer network improves the performance of a super-peer network over traditional P2P networks by handling most search queries between the few super-peer nodes, thereby reducing overall network traffic and improving search latency. In this paper, we address the problem of mutual selection by super-peers and client peers. In particular, we evaluate alternative decision functions used by super-peers to allow new client peers to join the cluster of clients under it. We experiment with peers with known resources and demands. By formally representing and reasoning with capability and query distributions, we develop peer-selection functions that either promote concentration or diversification of capabilities within a cluster. We evaluate the effectiveness of these different selection functions for different environments where peer capabilities are aligned or are independent of their queries. We offer insight and analysis on the effects on inter and intra-peer bandwidth consumption which will allow a super-peer to adopt appropriate peer-selection functions given their expectations about the environment.

1. INTRODUCTION

Current research in peer-to-peer (P2P) networks mainly focuses on the capacity of the network to provide efficient search capabilities, to treat queries in a timely and accurate fashion, and to maximize the bandwidth to transfer data between peers. Super-peer networks [3, 5, 13] have been proposed to improve the search latency and scalability of traditional P2P systems. Instead of having a fully distributed system of peer nodes with commensurate computing capabilities and resources, a super-peer network comprises of a hierarchical arrangement of nodes with different computational capabilities. A super-peer network is a two-tiered structure: one level consists of super-peer nodes that have considerable computing capability and resources, with each super-peer managing operations such as searching and query forwarding for multiple client peers under it. The benefits of this architecture, compared to a fully decentralized approach, is an improvement in search latency and scalability as most queries are routed between the few super-peers or between client peers under one super-peer. In particular, a peer no longer needs to handle the network traffic associated with every search query. A super-peer, however, can become a bottleneck for its clients: it handles incoming and outgoing queries on their behalf, which requires maintenance of an accurate description of all clients.

Under the assumption that all peers are contributing to the community, [13] gives advice for building efficient super-peer networks. An open problem here is the choice of a super-peer when a new peer joins the network. A super-peer can accept or decline a join request from a new peer. In [5], the design of the network corresponds to ontologies. The idea is to cluster peers falling in the same category so as to make search more efficient in a semantic peer-to-peer network. As a result, super-peers will have similar clients. For example, it is possible to create a community of super-peers hosting computer science related information. Each super-peer could correspond to an area of computer science, say language, operating system, artificial intelligence (AI), etc. and the peers of the super-peer corresponding to AI could host information about agents, planning, Bayesian inference, etc. Depending on the need or the knowledge of the new peer, a similarity measure or the use of an ontology can dictate which super-peer the new peer should register with. [5] prescribes a structured network organization such as a hypercube that determines the topology of client peers under a super-peer. However, the problem of network organization becomes challenging and difficult to design a-priori if we consider unstructured P2P networks. Hence, we are interested in studying decision functions that super-peers and peers can use to mutually select each other and the effects of such decision functions on peer cluster composition.

Consider the case where a super-peer can answer a query from one of its clients by using its other clients. There may not be any

need to send a query to other super-peers. Hence, in addition to not having to coordinate search with other super-peers, answering a query by another peer in the cluster decreases the traffic between super-peers. This phenomenon can be highlighted by considering super-peer networks where each cluster is quasi-self-sufficient: each query being almost always answered by peers from the same cluster. The research question is how to form clusters of clients to significantly decrease the traffic between clusters. Should a super-peer seek heterogeneity of interest and capabilities of its peers, or should it attempt to build a community of peers having similar interests and capabilities.

In this paper, we want to dynamically build the network of super-peers from a fully distributed network. We want to ensure that peers are contributing to the community. To this end, we use a reciprocity based mechanism to promote collaboration between the super-peers. We use a cost function to capture the preference of intra-cluster data transfer over inter-cluster data transfer. We consider that peers are defined both by their interests, which are used to generate queries, and their knowledge or competencies, that are used to answer queries. We believe that in the real world, knowledge and competencies are often aligned: interest in a subject leads to an increase knowledge in that topic. In such situations, peers with similar interests should be able to sustain self-sufficient communities, needing the help of other clusters only rarely. On the other hand, if interest and knowledge are not aligned, it might be preferable to create heterogeneous groups where peers have complementary knowledge and interests. We want to study how the joining decisions affects cluster compositions and the total cost of answering queries. In particular, we consider both environments where agents have similar interest and knowledge, and environments where interest and knowledge are not correlated.

2. RELATED WORK

P2P systems have become an area of active research and development because of the popularity of online resource sharing services such as Freenet [1], Gnutella [2], Napster [4] and SETI@home [9]. Resource management in P2P networks has been an important and challenging issue for researchers. The most common techniques for P2P resource management include structured P2P networks that employ distributed hash tables (DHT). In DHTs, resources are strategically placed on nodes to improve resource availability and enable rapid lookup [7, 10, 14]. In DHTs each node and resource is associated with a key computed from a hash function. A mathematical function [6, 11] is then used to strategically place resources in different nodes to preserve the network topology and balance the network load throughout the system. However, DHTs require additional overhead in the form of updates to local hash tables within a node when nodes and resources join or leave the network, and, forwarding the updates to neighboring nodes.

Yet another mechanism for P2P resource management is super-peer networks [12, 13] that uses a tiered network structure within an unstructured P2P network. In a super-peer network, some nodes act as super-peers or managers that supervise and coordinate the operation of several peers or clients under them. Super-peers maintain meta-information about peers supervised by them. A super-peer can interact with the peers its supervises and with other super-peers to route search queries and implement load balancing algorithms. In super-peer networks, a peer wishing to search for a resource contacts the super-peer supervising it with the search request. The super-peer first searches for the resource within other peers supervised by itself. If the resource is not found within its supervised peers, the super-peer directs the search query to other super-peers. Each super-peer that receives a search request from another super-peer searches for the resources within its supervised peers and responds to the super-peer that initiated the query at the super-peer level if the resource is found. The super-peer that initiated the super-peer level query then forwards the resource-found response to the peer under it that originated the query. In [5], the super-peer framework has been implemented within a structured P2P network. DHT-based algorithms are used to determine the network topology and resource placement within the network. Database schema based techniques are also used to organize the content on different peers. In [3], a protocol for dynamically updating the topology of a super-peer network is described. Super-peers exchange meta-information about peers with each other to reconfigure the network and achieve load balancing. In contrast to these research, our paper describes mechanisms that can be used by peers and super-peers for mutual selection within an unstructured P2P network.

3. SUPER-PEER NETWORK MODEL

In this section, we describe our model of the peer-to-peer system and the query protocol. We assume a fully connected network of super-peers, which allows a super-peer to be contacted directly, i.e., a query can be targeted to a precise set of peers. Each super-peer manages a cluster of client peers.

Each peer is defined by its interests and its competence in providing information to other peers. The interests are used to generate queries, and the competencies are used to answer queries. We will investigate two kinds of environments: one where competencies and interests are the same, the other where they are not correlated. Each resource is indexed by a set of interests or keywords and peers can query for a resource based on its associated interest set. Interests are represented as words (character strings). We have used a hash function to map the different interests to a natural number in the range $\mathcal{S} = [0..dim]$. Every peer uses the same hash function to ensure uniformity in the interpretation of interests across the network. This allows us to model the competence and interest on a one-dimensional line. The interests of a peer are represented by a probability distribution function $\mathcal{I}$ over $\mathcal{S}$. Peaks on $\mathcal{I}$ represents the main interests of a peer. The competence of the peer is represented by a function $\mathcal{C}$ which, given a point q in $\mathcal{S}$, output the probability $\mathcal{S}(q)$ of answering a query for that input. We have chosen this approach to produce a static description of the peers' interests and capabilities that facilitates analysis and experimentation. This would not be possible if peer capabilities were represented for example by a dynamic database of resources.

A super-peer has the responsibility to handle queries from its clients and other super-peers. It maintains a balance of help over the past interactions with other super-peers, and with its own peers. Each time a peer answers a query from another peer, it incurs a cost proportional to the amount of data transferred. We assume that transfer of data within a cluster is cheaper than transferring data between cluster. In order to promote contribution of other super-peers, the balance of cost is used in a probability-based mechanism to make the decision [8] of answering or not answering queries from other super-peers. A super-peer wants to minimize the cost incurred by its own clients by promoting intra-cluster communication. If a super-peer or one of its peers does not collaborate sufficiently, the super-peer can decide to block their future queries until the balance improves.

We address the dynamic formation and update of peer clusters by evaluating alternative joining decision mechanisms that are function of the interest and competence of the new peer and the existing clusters. We require a new peer to reveal an estimate of its interests and competencies. Because of the trust mechanism used by the super-peer to track its actual performance, there is a disincentive to

misrepresenting one's competence or interest. Though we assume that peers can generate their competence and interest vector, we note that this may not be a simple task. In addition, we assume that the super-peer is also a peer, and it can ask as well as answer queries.

3.1 Cost and Reciprocity Framework

The cost metric is a function of the volume of data transferred and whether the communication is intra or inter clusters. We use two rates: c_l for intra-cluster communication and c_w for inter-cluster communication. The difference in cost models a search cost incurred by the super-peer when it needs to deal with the other super-peers.

Each super-peer records the past interactions of help with the other super-peers. For a super-peer i, a super-peer j maintains:

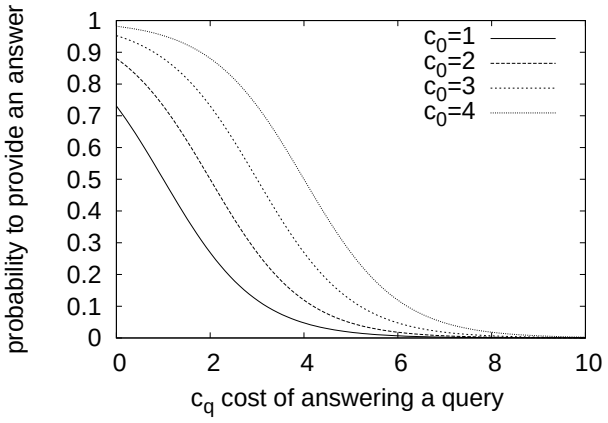
- credit $c(i,j)$, i.e., cost of the help received by j from i.
- debit $d(i,j)$, i.e., cost of the help provided by j to i.
- balance $b(i,j) = d(i,j) - c(i,j)$

To determine whether to answer a query q from super-peer i, super-peer j peer first obtain the cost c_q of answering q using its knowledge about the capabilities of its client peers. It then calculates the probability of responding to the query as

$$P(i,j,q) = \frac{1}{1 + e^{\frac{c_q - b(i,j) - c_0}{\tau}}},$$

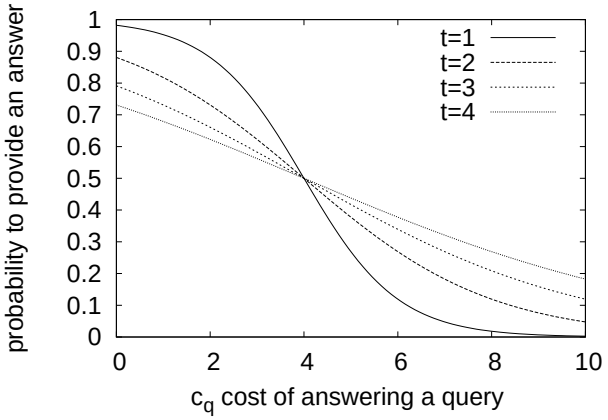
where c_0 is the initial inclination to help and τ controls the shape of the probability function. The super-peer will sample this probability to decide whether to help or not the other peer. If c_0 is large, the super peer is more inclined to help other super-peers. In Figure 1(a) and 1(b), we present the probability to answer a query with respect to its cost. In Figure 1(a), we study the effect of c_0 on the probability function. The higher the cost, the less likely it is to provide an answer. In addition, the higher the value of c_0, the more likely it is to answer a query. In Figure 1(b) we vary the value of τ for a fixed value of c_0: large value of τ make the probability function to answer a query quasi-linear in the cost, when small values of τ gives a logistic shape to the function: high probability of answering a query for low cost, low probability for high cost.

3.2 Query generation and Response Protocol



The following describes the different aspects of the query generation and response process:

Query generation: A query corresponds to one point q in $\mathcal{S}$, the interest space. A peer generates a query by sampling its probability distribution $\mathcal{I}$. The message containing the query also contains the address of the requesting peer and its super-peer.



Query-answering capability: The client has an answer to q with a probability $\mathcal{C}(q)$, and do not have an answer with probability $1 - \mathcal{C}(q)$.

Replying to a query q: A super-peer answers a query by sending a message, r_a containing its address, the address of one of its clients, a, that will answer q, and the associated cost. The clients are then responsible for opening a connection between themselves and transfer the data.

Protocol: The protocol for the interaction of the source of a query and the responder is as follows:

(a) Variation of c_0.

(b) Variation of τ.

Figure 1: Influence of c_0 and τ on the probability to help.

1. an initiator peer P_q generates a query q and sends it to its super-peer $SP(P_q)$.
2. $SP(P_q)$ checks its database to find if one of its clients can answer q. We consider that a super-peer has accurate knowledge of the capabilities of its client peers. In our model, this is implemented by $SP(P_q)$ sampling the probability $\mathcal{C}_i(q)$ to determine whether the peer i can answer the query q or not. If one of the clients under $SP(P_q)$ can answer the query, the query is forwarded to that client. If more than one client can answer q, the super-peer chooses the one with the highest balance (download minus upload volume). This allows the super-peer to distribute the load of query answering between its client peers and maintain the satisfaction level of peers.
3. If the clients of $SP(P_q)$ cannot answer the query, $SP(P_q)$ broadcasts the query to other super-peers. When another super-peer SP_a receives a query from $SP(P_q)$ it performs the following steps:
   (a) SP_a determine whether one of its client peers can an-

swer the query. Again, this is implemented by sampling the probability $C_i(q)$ for each of its peer i. If some peers can answer the query, SP_a picks the peer P_a with the highest balance as described above. If no client can answer the query, then SP_a cannot answer the query.

(b) If some client can respond to the query, SP_a uses the reciprocity framework (Section 3.1) to decide whether or not to provide the answer.

(c) If SP_a decides not to answer, an empty message is sent.

(d) If SP_a decides to help, it forwards the query to P_a, and sends a reply r_a to $SP(P_q)$. The reply message contains the address of the peer that will answer the query and the associated cost. At this time, SP_q may or may not use this answer, hence SP_a does not update its balance of yet at this time, it will wait a notification that its peer has provided an answer (see step 4)

$SP(P_q)$ gets all the reply messages, r_a, from all the super-peers. It chooses to use the answer provided by the super-peer SP_a with the highest balance, i.e., it picks the super-peers that owes the most. $SP(P_q)$ updates its balance with SP_a and forwards the reply message to P_q.

4. When P_q receives the reply, it directly contacts the answering peer P_a and transfers the data. At the end of the transfer, P_a notifies its super-peer about the transaction so that SP_a can update its balance with $SP(P_q)$.

3.3 Mechanisms for cluster formation

We assume the existence of a network of super-peers. The peer nodes enter the system one at a time and are assigned to one of the super-peers by the process described below. Once assigned, a peer-node does not change its super-peer.

3.3.1 Random peer assignment

As a baseline scheme for comparison we consider a random assignment of new peers to any of the super-peers.

3.3.2 Negotiated peer assignment

We consider three negotiated mechanisms. In each of these methods new peers negotiate with existing super-peers and final assignment is made by mutual selection.

When a peer seeks to join a cluster, it sends its capability and interest information to all super-peers. The super-peers estimate the "usefulness" of having this new peer in their cluster and reply with the estimate. The peer greedily chooses to join the super-peer that provided the best estimate. To measure this "usefulness", we consider three metrics:

Competence alignment: By using this metric, a super-peer seeks peers that have similar competence, which improves the probability of answering queries on particular topics. The super-peer builds the aggregate competence vector of its cluster of client peer nodes where the aggregate competence of a cluster for a given domain is the probability that at least one peer answers the query. Consider that a super-peer has n client peers, and let $c_{i,j}$ denote the probability of the ith peer to answer a query for the jth domain in the competence space $\mathcal{S}$. The probability for at least one peer to answer the query is

$$c_j = 1 - \Pi_{i=1}^{n}(1 - c_{i,j}), j \in [1..dim].$$

The metric returned is the Euclidean distance between the aggregate competence of the cluster and the competence of the entering peer. The smaller the distance, the better the offer made to the peer.

Competence diversity: With this metric, a super-peer seeks to form a heterogeneous group able to answer the most diverse range of queries. For example, a peer who does not bring any new expertise to a cluster is of little interest. The super-peer computes the probability of answering a query about each domain in $\mathcal{S}$ in the absence or presence of the requesting peer. The difference is the measure of the impact of the peer on the group. The "usefulness" metric sent to the requesting peer is:

$$\Delta = \frac{1}{dim}\sum_{j=1}^{dim}\left(c_j^+ - c_j\right),$$

where dim is the dimension of $\mathcal{S}$, c_j (resp c_j^+) is the aggregate probability of the cluster (resp the cluster and the peer) to answer a query about the jth domain in $\mathcal{S}$ (we assume a uniform distribution of queries over $\mathcal{S}$). A super-peer seeks peers with higher Δ value. The peer chooses the super-peer with the largest Δ.

Competence and interest complementarity: By using this metric, a super-peer seeks peers that can answer queries from the current cluster and vice versa. When this metric is used, peers and super-peers use a two-step interaction protocol: the super-peer will first evaluate the ability of the peer to answer queries from the cluster's member. If this likelihood is above a threshold, the super-peer will send the likelihood for cluster's members to answer a query from the new peer. We now present more details of this process. First the peer sends its competence vector so that the super-peer can estimate the potential of this peer to answer a query issued by current cluster members. The super-peer invites a peer only if it can bring sufficient new expertise to the cluster. If the probability of answering queries from its cluster exceeds a fixed threshold ϵ_u, the super-peer responds favorably to the peer. The peer replies to interested super-peers and sends them its interest vector. The super-peers return the probability of the cluster to answer a query issued by the new peer. The entering peer chooses the super-peer with the highest likelihood of answering its query. Let q denote the interest probability distribution and let c denote a competence vector. The probability that a peer or cluster with a competence c can answer a query from a peer or cluster of interest q is $\sum_{i=1}^{d} q_i c_i$. In a nutshell, the super-peer accepts beneficial peers, and the peer joins the most promising super-peer, i.e. one that is most likely to able to answer its queries.

4. EXPERIMENTAL RESULTS

To evaluate the relative effectiveness of above mentioned cluster formation mechanisms, we simulated different environmental configurations. We generated the interest and the competence of the peers assuming the existence of a preponderant domain of competence and a preponderant domain of interest, which need not be identical. When they are identical , i.e., competence and interest are aligned, we have peers knowledgeable about a particular topic and wanting to know more about that topic. When the preponderant topics are different, i.e., competence and interest are not aligned, we have peers that have knowledge in a domain and wanting to learn about a different domain. In Figure 2, we present a typical competence vector of a peer. The algorithm for generating a competence vector for a peer is presented in Algorithm 1. The interest vector is generated in a similar way, and is normalized to meet the requirements of a probability distribution. We have experimented with two types of peers: when interest and competence are aligned and when they are not correlated. In all experiments we ensure that the preponderant competence and interest are drawn from a uniform distribution.

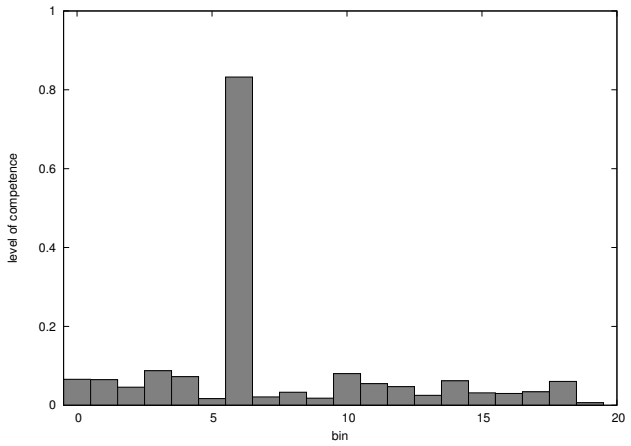


Figure 2: Example of the competence vector of one peer.

Algorithm 1 Form competence vector c for peer p.

p_{high}, p_{low} and v are given
for $i = 1$ to d **do**
  $\epsilon \leftarrow$ normal(0,1)
  if main interest of p is i **then**
    $c_i \leftarrow p_{high} + \epsilon v$
  else
    $c_i \leftarrow p_{low} + \epsilon v$

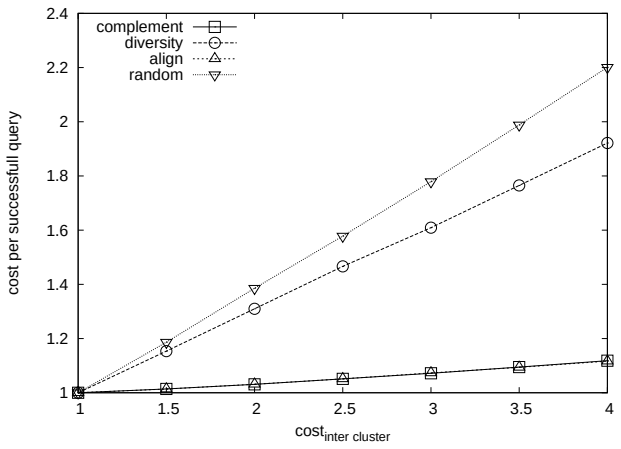
4.1 Settings

The results presented in this section are averaged over 20 different assignments of the peers to the clusters (the order of introduction of the peers is different). For each assignment, we ran the simulation 5 times, varying the order of the peers asking queries. Each simulation consists of generating 10,000 queries. For each query, a peer is chosen randomly, and its interest distribution is sampled to generate the query type. There is a fixed number of super-peers, one for each domain, and the number of peers varies between 20 and 300.

4.2 Influence of the cost difference between intra and inter cluster communication

We study first the influence of the cost difference between intra and inter cluster communication on the environment where interest and competence are aligned. For these experiments, the reciprocity framework is initialized with $\tau = 1$ and $c_0 = c_{inter}$, i.e. initially, the super-peer is inclined to answer one query issued from another super-peer with a probability of 0.5. In Figure 3, we present results from experiments with a system of 500 peers, 50 super-peers and 50 different domains. The cost for communication within the group is fixed to 1.0 per query.

Since for a given peer, the preponderant competence and interest domains are the same, the optimal assignment occurs when peers with the same preponderant domain are grouped in the same cluster. They are likely to answer most queries of other members of the cluster, thus minimizing total cost of answering queries. Requesting the help of peers from other clusters is needed when a query is outside the preponderant domain, which is much less frequent. Under these conditions, the join function promoting complementarity between peers and the join method based on the alignment of the competence produce best performance. We noticed that as the size of a cluster increases, the cost increases slightly. Even if all the cluster's peers have the same main expertise, the probability of answering other types of queries also increases, which may "mislead" the assignment of some peers entering later. These peers cause the performance to drop, i.e. the cost to increase; since the query of these late entering peers is less likely to be answered by the cluster's member. Surprisingly, promoting the diversity of competence in the cluster performs better than random assignment. The use of a diversity based mechanism should be costly since it is unlikely to have two peers with the same interest/competence coexisting in the same cluster. The relative better performance compared to random is due to the existence of few larger clusters that are more capable of being self-sufficient.



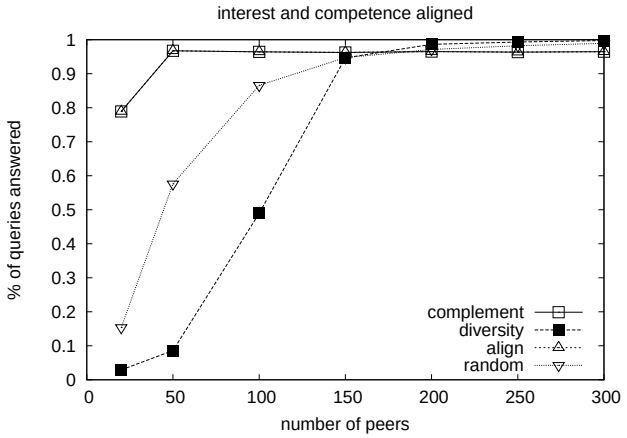


Figure 3: Influence of the cost ratio between inter and intra cluster communication on average cost of answering a query with different cluster formation mechanisms.

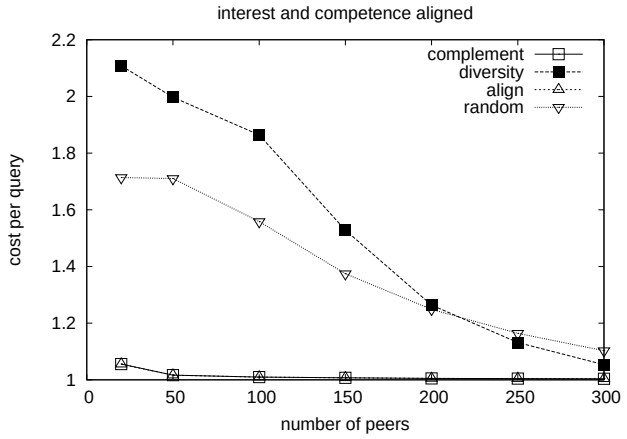
4.3 Influence of the number of peers

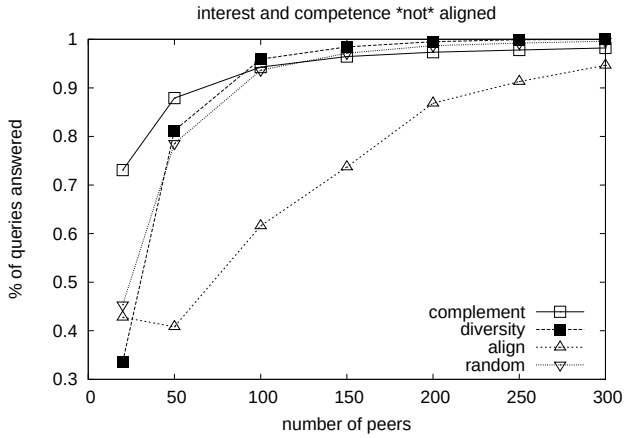


For the rest of the study, we fixed the ratio of the cost of inter and intra-cluster communication to 2.5 where the cost to communicate one answer within a cluster is set to 1.0. In the next set of experiments, we fixed the dimension of the interest space and the number of super-peers to 10. We study the influence of the number of peers in the system both in environment where competence and interest are aligned and when these are not correlated. Our first metric is the average cost of a query. If it is 1.0, all the queries are answered within the cluster. The second metric is the percentage of queries answered (see Section 3.2). A query may not be answered for multiple reasons. First, when a peer p answers a query about domain $i \in \mathcal{S}$, the distribution $\mathcal{C}(i)$ is sampled. Even if i is the domain of expertise of p, it may not get the answer and no one else may be able to answer. In addition, a peer might be capable of answering the query, but the super-peer may block the query because the requesting peer has a low balance.

The results when the competence and interest of a peer are aligned are presented in Figure 4. The complement-based and the alignment-based join functions produce clusters of peers with similar expertise and are performing the best in this environment (the corresponding curves are overlapping). As peers generate queries in their area of interest, other peers in the same group can answer these queries with a high probability and hence they do not require help from other super-peers, keeping the cost low. For a small number of peers in the system, the join function based on diversity is performing worse than random assignment. This is because all the peers in the cluster have different competence/interest, and they have a

small probability of answering queries from the other peers of the cluster. When the number of peers is high, each group contains sufficient number of experts of each type in each cluster to answer queries issued by any peer and hence the performance of clusters generated by all mechanisms become equivalent. This is shown both by an increase in the success rate of answering queries and a corresponding decrease in the cost per query.

(a) Success Rate



(b) Cost

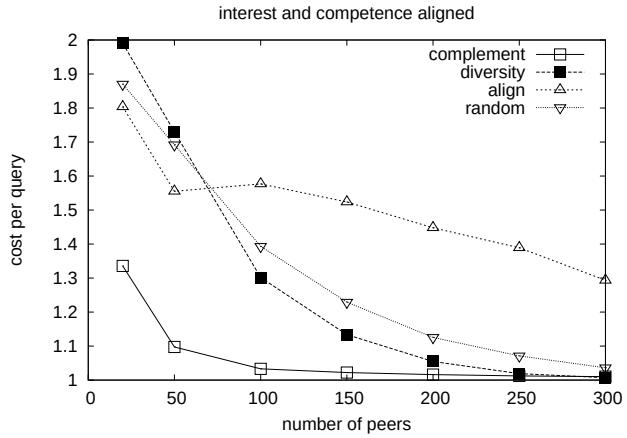


Figure 4: Influence of the number of peers when interest and competence are aligned.

When the preponderant competence and interest of a peer are not correlated, the join function based on complementarity is still performing much better with a small number of peers in the system (see Figure 5). The first significant difference with the previous scenario is that the alignment-based join method is performing much poorer: as peers with the same main expertise do not necessarily have the same main interest, a cluster made of peers with the same main expertise will require the help from many other clusters. The second main difference is that the diversity-based join function takes less number of peers in the system to perform as well as any other scheme. The promotion of diversity in the cluster formation increases the probability of answering any kind of query by another member of the same cluster, which is the key requirement here.

From the above scenarios, the main conclusion to be drawn is that the join method based on complementarity is performing as well as any other selection method over all scenarios. This mechanism appears robust to scale and to competency-interest alignment of peers. The inherent reciprocal benefit consideration underlying this cluster formation scheme enables such clusters to be largely "self-sufficient" in most environments, thus increasing query answering rate and reducing the cost for answering queries.

(a) Success Rate

(b) Cost

Figure 5: Influence in the number of peers when interest and competence are not aligned.

5. CONCLUSIONS

We have investigated the effects of different join-decision-functions on the performance of super-peer networks. Super-peers are responsible to find other peers which can provide an answer to a query, either by using peers from its pool of clients, or by requesting help from other super-peers. Super-peers use a reciprocity mechanism to ensure that there are no free-riders in the system. Each super-peer also ensures that all its client peers are contributing by enforcing load balancing within its cluster of client peers.

We use a probability function to model the competence and probability distributions to model the interest of a peer. Under these conditions, we found out that forming peers based on complementarity between a new peer and a cluster reduces cost of answering and increases success. However, this join method, unlike the others, is a two-step process. Looking for diversity to form a cluster can also be beneficial when there is no correlation between the competence and the interest of a peer. However, when interest and query is aligned, alignment of competence in a cluster is preferable to competence diversity. As the number of peers in each cluster increases, however, the performance difference between the different cluster formation mechanisms monotonically decreases.

We plan to study the effect of the relative ratio of the number of super-peers to the number of capability and interest types. In this paper, agents do not change clusters; we plan to investigate dynamic cluster dissolution and reorganization schemes. Another limitation in the current work is the static interest and capability vectors for peers. We believe that in a number of domains both capabilities and interests of peers can vary over time. That dynamism presents a significant challenge to developing adaptive schemes that will continue to maintain the performance of peer clusters. We will investigate predictive cluster selection schemes to address this critical issue.

ABSTRACT

What if traffic lights gave you a break after you've spent a long time waiting in traffic elsewhere? In this paper we examine a variety of multi-agent traffic light controllers which consider vehicles' past stopped-at-red histories. For example, a controller might distribute credits to cars as they wait and award the green light to lanes with the most credits, allowing cars to keep the credits they accumulate during travel. Such history-based controllers are intended to provide a kind of global fairness, reducing the variance in mean time spent waiting at lights during trips. We compare these controllers against other multi-agent controllers which only consider present information, and discover, among other things, that while the history-based controllers are among the most robust, they often unexpectedly provide more efficiency than fairness.

1. INTRODUCTION

You have just spent a long time downtown stopped in gridlocked traffic. As you travel home, shouldn't traffic light controllers recognize this fact and award you the green light, to spread the pain more evenly? This is the idea behind history-based traffic control. Such a traffic controller would take into consideration a vehicle's past stopped-at-red history elsewhere, increasing the fairness with which vehicles are dealt globally on a per-trip basis.

Fairness can be a highly desirable trait: citizens of a town may desire a system which attempts to give every driver approximately the same percentage of waiting-time. But with a few exceptions [13, 15, 18], the literature has instead largely focused on some notion of system-wide *efficiency*, which might translate into lower emission levels, higher average speed, lower probability of stopping, etc. We imagine this lack of study is because fairness is not an easy thing to implement with existing hard-wired traffic controllers. But if one instead views these controllers in a multi-agent context, with vehicles (and their histories) traveling from controller-agent to controller-agent, then a variety of history-based methods become evident which we will argue notionally provide a kind of fairness. In this paper we compare various multi-agent traffic controllers, including history-based ones, and examine the degree to which they are fair and/or efficient.

The idea behind multi-agent traffic control is to develop a good emergent macro-level traffic-control behavior out of the micro-behaviors of the individual traffic lights. But traffic lights typically "live in the now": they know little of where specific vehicles have been and where they plan to go. At best, such controllers may use past historical information about vehicles in the aggregate, and perhaps heuristic information about likely future traffic patterns. Some past work [21, 22] has explored what happens when traffic light controllers are instead told of trip plans by the drivers: but we think it may not be reasonable to demand such information of the drivers. However, it *is* plausible to collect information about vehicles' immediate past histories to help inform the controllers, given reasonable privacy restrictions. This allows traffic controllers to communicate with one another, in some sense, through the immediate histories of cars as they travel from intersection to intersection.

We introduce this notion of historical fairness by allowing cars to store "credits" they receive when waiting at red lights, and cash the credits in when passing through intersections. Traffic lights base their decisions on the credits of various cars at the intersection. We also examine history methods which consider the mean waiting time the vehicles have spent at intersections so far along their respective trips. We compare these various methods against two non-history-based methods from the literature: one awards the green light to the lanes with more cars, and the other one prefers the lanes where cars have spent the longest time waiting.

In focusing on the effect of using "history" from a multi-agent perspective, our simplified experimental setup ignores a variety of important game theoretical and modeling issues which may be useful to study in the future. For example, we treat drivers as non-adaptive entities, while real drivers have varying risk attitudes and exhibit adaptive behavior, all of which present complex, difficult-to-model issues [14, 16, 19]. Even so, we believe that the concept of credits as history may be useful in the abstract in various other multi-agent scenarios involving, among other things, network resource allocation [23], package delivery, etc.

As we discuss later in the paper, our history-based traffic control methods perform well, but often in surprising ways. Notably, though they were designed to provide fairness, several unexpectedly reside in the *efficiency* side of the efficiency-fairness spectrum!

The paper is organized as follows: Section 2 discusses related work. Section 3 introduces our simulation model. Section 4 describes the various traffic-control micro-behaviors in the study. The experiments, comparison metrics, and experimental results are given in Section 5, followed by conclusions in Section 6.

2. RELATED WORK

In this paper we will refer to the traffic controller of an entire intersection as a *traffic light*. A traffic light *pattern* is a combination of red and green lights for each incoming lane that prevents cars from crashing into one another. The interval of time allotted to a pattern is called a *phase*.

The most common metrics used in the traffic light literature are *waiting time* [1, 8, 9, 12, 18, 22], *delay* (the difference between the minimum possible travel time and the actual travel time, including acceleration and deceleration delays) [5, 15, 20], and *travel time* [1, 8, 9, 15]. Other popular metrics are *percentage of stopped cars* [11, 20], *density of cars* [3, 7, 6, 10] and *global flow* [2] (global density times average speed).

One may view efficiency and fairness as the mean and variance, respectively, of these various metrics. Nearly all the literature has concentrated on efficiency (the mean); and fairness has been only lightly studied. Exceptions include: Liu et al [15] analyzed their controllers' efficiency and fairness separately; and Krogh et al [13] and Montana and Czerwinski [18] combined the two into a single measure.

The notion of "fairness" used in Liu et al deals with cars waiting at a single isolated intersection. The cars' delays are averaged per lane[1] and the fairness is the standard deviation of the lanes' expected delays. We instead are interested in fairness (and efficiency) spread throughout a multi-traffic-light system. Thus our efficiency and fairness measures will be largely based on the mean of waiting times at the intersections along a vehicle's trip. This is the "trip waiting time" metric used in [21, 22], but normalized by the number of intersections in the trip.

It is worthwhile mentioning a very popular paradigm in urban traffic control, the "green wave," which coordinates traffic lights so that cars traveling at a certain speed go across those intersections without stopping. The green-wave phenomena cannot be achieved along all streets simultaneously, so traditionally it is used for heavy-flow arteries with light flow intersecting streets. A more general approach is to dynamically decide the sets of intersections that should coordinate. For example in [6] the traffic lights run a distributed constraint satisfaction algorithm to get ad-hoc green-waves.

There have been some efforts to achieve green-waves with implicit communication through density or flow. The idea is to provide an emergent green wave through coordinated behaviors. Bazzan's [3] traffic lights are self-interested agents that learn to coordinate with their neighboring traffic lights by playing coordination games. Gershenson's [11] basic control method changes to green when the total time spent by cars approaching or waiting at the red light exceeds a given threshold. Large enough "platoons" of cars move from light to light, causing it to turn green by their sheer mass, resulting in emergent green waves. This notion is closely related to our new history-based methods presented later.

[1]The authors actually used the concept of a *movement*, which is an incoming lane or a group of incoming lanes sending cars in the same direction.

3. THE URBAN TRAFFIC MODEL

We use a network model to simulate traffic flow. Nodes in the network are intersections, each one manned by a traffic light. Edges in the network are one-way road segments, each with a specified length, connecting intersections. Two-way road segments are modeled by using two edges, one in each direction.

On this network travel cars. When a car starts along an edge, it waits for a period of time equal to how long it would take to drive along the road to the next intersection. At that point it emerges and is placed into one of several queues depending on its desired action at that intersection. More formally, for each pair of edges $\langle a, b \rangle$ at an intersection, there is a queue $a \rightarrow b$ into which cars emerging from the edge a are placed while they wait for permission to start traveling on b. Queues may be thought of as the intersections' various turn and go-straight lanes of movement.

Our motivation for using a course-grained network of queues, rather than a fine-grained cellular-automaton-style grid of cells, is twofold. First and foremost, it permits the simulation to run much faster. Second, it allows us to choose whether or not to model individual road segments' capacities (we have declined to do so[2]). We also believe that a similar network structure may be applicable to other relatively unrelated domains, such as entry/exit policies for internet routers [23].

This means that the simulation is neither micro-level nor macro-level. Unlike in [2, 11, 21, 22], we do not explicitly model the movement of cars along road segments. We also make many simplifying assumptions a micro-level model would not make: for example, our cars all run at the same speed regardless of traffic density or road capacity. Further, as we do not consider road capacity, we only examine traffic flow difficulties due to long waits at stoplights. However, we do model cars and traffic lights explicitly, rather than treating them as flow in a macro-level dynamical systems model.

There is a constant number of cars traveling at any time along the streets, each following a predetermined *trip* from an origin intersection to a destination intersection. At the start of the simulation, cars' starting points are randomly chosen from the set of intersections. As a car's trip begins, the car is simply placed on its first edge, and when it completes its last edge, its trip is over (thus the car is not involved in queues at its start or destination). After a car has completed its trip, its former destination becomes the origin of the next trip, and a new destination is chosen at random from among all intersections (excluding the origin). After a trip destination is selected, drivers choose from among two ways to plan the trip route. With 40% probability, drivers will build a trip by incrementally adding to the path a randomly-selected intersection from the set of neighbors that minimize the remaining distance to the destination. With 60% probability, the driver will choose a shortest path with the fewest turns (at most one turn for a two way orthogonal street grid); when there are two such solutions, the driver selects the one whose turn takes place furthest from the city center. The intuition here is that the center of the city is so crowded (mostly with drivers using the first behavior), that there are some drivers who (modeled with the second behavior) prefer to avoid it.[3]

Intersections. Every twenty seconds (in simulation time), each traffic light individually considers whether to change its pattern. A traffic light may choose between every possible pattern (meaning

[2]Specifying capacities is more realistic, but unless the drivers are capable of re-routing, capacities can produce artificial deadlocks.

[3]We recognize that in a more sophisticated scenario, drivers would base routes on previous experience and common places to travel [21, 22].

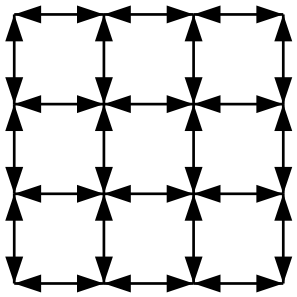

Figure 1: Example (4x4) Street Layout.

maximal set of *non-conflicting* queues). Two queues are said to conflict if cars leaving those queues might collide, either because cars in each queue are entering the same edge, or because the car trajectories intersect with one another. In the intersection $\begin{smallmatrix} & a & \\ c & & d \\ & b & \end{smallmatrix}$ between road segments a, b, c, and d, the queue $a \rightarrow b$ conflicts with, among others, the queues $c \rightarrow d$ (obviously), $c \rightarrow b$ (because they both enter b), and $b \rightarrow c$ (because, assuming drivers drive on the right-hand side, $b \rightarrow c$ cars turn into the $a \rightarrow b$ traffic). On the other hand, $a \rightarrow b$ does not conflict with $a \rightarrow c$, $a \rightarrow d$, $b \rightarrow a$, $d \rightarrow a$, or $b \rightarrow d$. It also does not conflict with $c \rightarrow c$, $d \rightarrow d$, or $a \rightarrow a$ either, but in this paper paths do not make U-turns, so these queues are always empty.

If a queue awarded the green light was not awarded one in the previous phase (its light was red then), it must wait for 5 seconds while conflicting queues clear the intersection (obstensibly during their yellow light period) before the green light may commence. Thus a light changing from red to green has only a 15-second green period, while a light staying green has a 20-second green period. While a light is green, cars waiting in the corresponding queue are removed one by one and permitted to enter the intersection with a three-second "acceleration penalty" corresponding to getting back up to speed after being stopped at the light. Thus in a 15-second green period five cars can traverse the intersection, but during a 20-second green period six cars can do so. If a car is approaching an intersection and the appropriate queue is empty, the car is allowed to go through at full-speed (with no 3-second penalty). The limit of five (six) cars going through per phase and per lane applies to any combination of cars removed from the queue and cars finding the queue empty and going through full speed.

In our model, all roads are two-way streets, laid out along an orthogonal mesh akin to a downtown city grid (see Figure 1). The blocks are squares, each 0.25 miles on a side. The traffic lights have 0.125 mile sensor ranges, inside which they may discern approaching cars and their desired intersection queues (imagine that turn lanes start 0.125 miles out and sensors are positioned where they start). All cars travel at 25 mph, so they need 36 seconds to cover the segment between two intersections. Regardless of whether they go straight or turn, all cars need exactly 5 seconds to traverse the intersection (not including the acceleration penalty).

4. THE TRAFFIC LIGHT CONTROLLERS

We divide the traffic light controller function into two subfunctions. The first subfunction assigns a *score* to each pattern. The second subfunction selects the winning pattern based on the patterns' scores.

The second subfunction uses one of two winner-selection methods: a deterministic method and a stochastic method. In the deterministic method, the pattern with the highest total score is the winner; in case of a tie, the winning pattern is the one with most cars in its queues; further ties are broken at random. The stochastic method uses *roulette selection*: the probability that a pattern will win is proportional to its total score. If all patterns have a score of 0, the pattern with more cars in its queues wins, and further ties are again broken at random. A light only bothers to select a new winner if cars are actually waiting at or approaching the intersection.

The first subfunction is called the *scoring function*, and assigns each pattern a score equal to the total points assigned to cars within the sensor range of the queues receiving the green light in that pattern. We examine the following score functions in combination with the aforementioned winner selection methods:

*Counting Cars (*CC*).* Each car yields one point. As a result, this controller defines scores simply as the total number of cars within the queues' collective sensor range. We include it as a baseline for our comparisons because it is the simplest and most intuitive adaptive traffic controller. Counting Cars was used in [4, 22].

*In-Range Time (*IRT*).* A car's points are equal to the length of time that has transpired since it was picked up by the queue sensors at the current intersection. This is a generalization of Gershenson's method [11], which only worked with two one-way road intersections. In-Range Time is also closely related to a notion of pheromones applied in [7]. There, cars deposit pheromones as they wait, and the traffic light controller makes a decision based on the total level of pheromones in each lane.

*Mean Waiting Time (*MWT*).* This is our first history-based method. The car's points are equal to its mean time spent waiting at intersections in its trip so far, including the current intersection.

*Previous Mean Waiting Time (*PMWT*).* This is our second history-based method. The car's points are equal to its average waiting time over the previous intersections of the trip but *not* including the current intersection. When at its first intersection of the trip, the car's score is the global mean waiting time over all intersections in that simulation run. In some sense, MWT$\approx$ PMWT + IRT.

*Credit Methods (*CREDIT*).* These are our final history-based methods. The car's points are defined as accumulated "credits" which it receives from, and pays back to, various traffic light controllers. There are four credit-disbursement methods, each a combination of the following two parameters:

- *How are cars compensated for receiving the red light?* If using the *general-sum policy*, after every phase (20 seconds), the cars in the lane of a red traffic light each receive one credit, and cars passing through a green light must pay the traffic light 5 credits or the car's accumulated credit wealth, whichever is smaller. If using the *zero-sum policy*, after every phase, cars passing through must again pay up to 5 credits as before, and the total credits paid to the intersection at that phase are in turn distributed evenly among cars in red-light lanes at that intersection. If no car is waiting at red, the zero-sum policy will not require a green-light car to pay anything.

- *How many credits does a car have initially?* At the start of a trip, a car's credit wealth is reset to either *10* or *100* credits.

The values for the parameters of the CREDIT controllers were chosen ad-hoc, and we made no effort to tune them. We note that CREDIT can easily accommodate emergency vehicles and public transportation by endowing special vehicles with unusual numbers of credits, or weighting their credits appropriately.

Table 1: Pareto fronts for all combinations of city size and workload level. The controllers using the stochastic selection are shown with a gray background, while no background is used for the deterministic selection controllers. The CREDIT variants are depicted as CR(E,P), where E is the initial endowment of credits and P is the policy (either *Z* for zero-sum or *G* for general-sum compensation).

5. EXPERIMENTS

We tested the traffic light controllers under different city grid sizes and demand levels (what we refer to as the *workload*: the number of cars on the streets). We experimented with two scenarios based on the size of the city grid: 4×4 and 10×10. As mentioned in Section 3, we used a closed model to generate the workload, so the number of cars was constant throughout a simulation run. In our experiments we chose the following workload levels: 31, 62, 125, 250, 500, 1000, and 2000. For the 10×10 scenario we also used 4000, 8000, and 16000.

All presented results are based on 100 independent runs for each combination of city grid scenario, workload level, and traffic light controller. We ran each simulation for 1000000 seconds (approximately 11.5 days of simulated time). The reason for such a large simulation length is the stochastic nature of the traffic light controllers and route selection, requiring a large sample to accurately compare the traffic light controllers. In order to eliminate the boundary conditions at the beginning of a run, we discarded the data for those trips finished within the first 500 seconds of each run. Simulations were performed using the MASON multi-agent simulation toolkit [17].

5.1 Comparison methodology

When a car reaches its destination, it reports its average waiting time over all intersections along the trip. This statistic is the normalized version of the average trip waiting time ("ATWT") used in [21, 22].[4] Of interest to us is the distribution of this statistic over all trips: we use the mean and standard deviation of the distribution as our measures of efficiency and fairness, respectively, in the system.

We used a pareto-dominance criterion to compare two methods: method *A* is superior to method *B* if it is at least as good in both metrics and better in at least one metric. By "better" we mean statistically significantly superior to, and by "at least as good" we will mean significantly superior to or not significantly distinguishable from. Since the efficiency and fairness of a controller are distribution samples, we needed a statistical analysis mechanism to assess the Pareto-dominance relationships. We used unequal-variance repeated t-tests with a Bonferroni-corrected significance level $\alpha = 2.31481 \times 10^{-6}$, which exceeded a 99% confidence in the correctness of the entire set of results presented in this paper.

5.2 Results

Table 1 contains the Pareto fronts for all the city size/workload level combinations. We have taken the liberty of spacing the items in the fronts so that occurrences of the same controller are on the same column. There is no special meaning behind this other than our attempt to make the table easier to read. See Figure 2 for representative examples of what the fronts actually look like.

Overall, the results are very promising for the CREDIT controller, as its variants appear in the Pareto fronts in all our scenarios but one (4×4 grid, 1000 load). In general, CREDIT seems to be a versatile controller, adapting well to both high and low workloads.

An analysis of Table 1 reveals some interesting observations. The most interesting one is that although we expected the history-aware controllers to be fair at the cost of efficiency, some variants proved to be more efficient than the history-oblivious controllers. Most unexpected is PMWT being the most efficient controller for the highest workloads. We did not expect this because PMWT ignores the waiting time information about the current intersection, which would provide efficiency, and uses only past information, which in some sense is the source of fairness. Also, we were surprised to find that the deterministic CREDIT variants are more efficient than MWT, even though the information used by the latter is more accurate then that used by the former.[5] Oddly, the situation is reversed in the stochastic versions of the controllers.

Another observation is that for (and only for) high enough workload levels, the stochastic selection controllers are consistently

[4]Using the *total* trip waiting time as our statistic would make drivers on a short trip expect the same total delays as the ones on very long trips, which we felt was unreasonable.

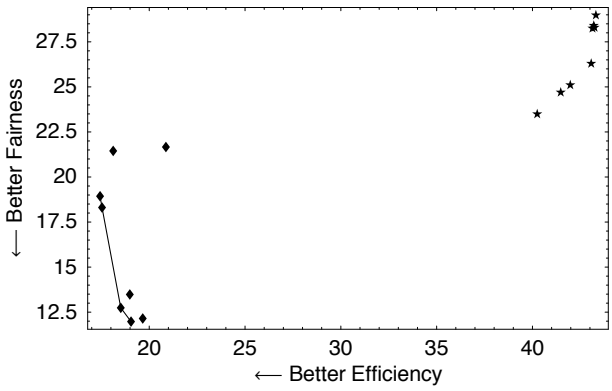
[5]The CREDIT controller cannot tell if a car has waited $k \times 20 + 2$ seconds or $k \times 20 + 18$ seconds. Also, if a queue is long enough, some of the cars waiting in it do not go through in a single 20-second green phase, yet are not compensated for waiting. Therefore a car's compensation is only a rough measure of the time spent waiting in the queue, as it ignores these "green phases."

more fair than the deterministic ones (see Figure 2(c) for a typical example). We observe this behavior starting at 1000 cars for the 4×4 grid and 8000 cars for the 10×10 grid. For these scenarios the drivers' expected waiting times per intersection are 2 and 3 minutes respectively, which we feel is not unrealistically high for a rush-hour traffic-jam situation. Why stochastic controllers would perform in this way is still unknown to us. Figures 2 reveal why stochastic controllers disappear from the front however: as workload drops, the deterministic controllers maintain their efficiency advantage but secure more fairness relative to the stochastic controllers.

There are a few other points worth mentioning. One can make a CREDIT variant more fair or more efficient by simply adjusting the initial endowment of credits. The larger the initial number of credits, the less likely a queue with fewer cars can outscore a queue with more cars, resulting in a less fair controller. At the limit, CREDIT with an endowment of infinity is roughly equivalent to CC, except for the tie situations. But CC is dominated in all the scenarios presented here, which leads us to the conjecture that fair tie breaking should not be ignored when designing a traffic light controller.

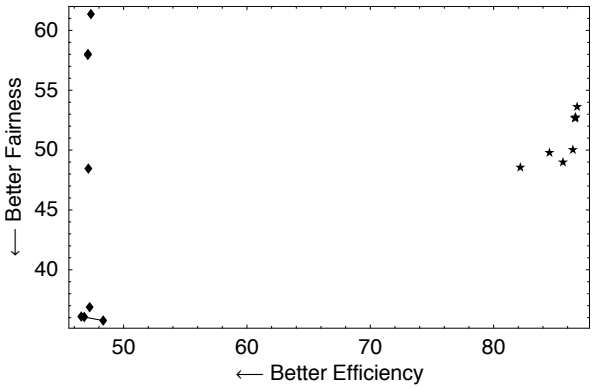
6. CONCLUSIONS

We have introduced the concept of trip-based fairness and showed a simple approach to incorporate it into traffic light control. We have implemented several controllers to investigate the effect of awarding the green light based on information regarding the cars' past experiences. The testbed we used was a meso-simulated two-way street grid scenario with uniform demand and a wide range of traffic loads. All controllers investigated here, however, work out-of-the box with any intersection set-up: arbitrary number and layout of one- and two-way streets, with and without shared lanes. Cars are not required to participate in the traffic control system: if a light senses a non-participating car, it might set up a proxy credit accumulator initiated with some mean credit amount, but which does not travel with the car when it leaves the intersection.



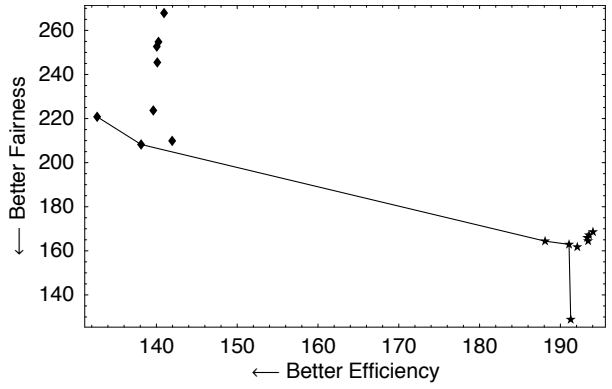
We expected the newly proposed controllers to be fair at the expense of efficiency, but they performed reasonably well in general, and some even turned out unexpectedly efficient (at the expense of fairness). More research is needed to gain a fuller understanding of the phenomena involved.

The data provided interesting (and often unexpected) results when dealing with overcrowded traffic conditions. Here, stochastic selection is a viable solution for improving fairness; and for the history-based methods, the cruder the use of information about the present, the more efficient the controller.



6.1 Future work

Presently our controllers work with a pre-set phase length. While this is not an unusual bias in the traffic light control literature, we think we should try to eliminate the phase length parameter or incorporate phase adaptation into the controllers.



The original inspiration for this paper was to allow the drivers to let the traffic lights know whether the drivers are in a hurry or not. We plan to investigate various auction-style methods for traffic light controllers. In these methods, the drivers are self-interested agents trying to resolve who goes first using a currency accepted at all traffic lights. The lights act as benevolent auctioneers, awarding green lights to those deserving it (able and willing to "pay") the most. When drivers are not in a rush they might choose to bid low and save some credits for the future. The resulting traffic controller system acts as a market, which hopefully requires less tuning because it is self adaptive.

(a) 2000 cars

(b) 4000 cars

(c) 8000 cars

Figure 2: Results for the 10×10 grid with different workloads: 2000, 4000 and 8000 cars. The deterministic controllers are represented as ♦ and the stochastic ones as ★; the lines connect the non-dominated controllers (see Table 1); the units on the plots' axes are seconds.

This is only a sample of future work for this domain. We think distributed traffic control is an attractive problem for multi-agent systems, with a broad, relatively unexplored research domain and a payoff in the form of immediate real-world impact. The area also presents a number of major research challenges: the number of cars and traffic-control devices on the road is huge, and the problem is highly decentralized with regard to vehicles and, more often than not, with regard to traffic-control devices. The humans in the vehicles co-adapt to one another and to traffic controllers. Dense traffic can produce emergent, unexpected phenomena. As such, we imagine this area may prove both fruitful and increasingly important in the future.

ABSTRACT

Techniques were developed in previous work for managing communication in a controlled satisficing manner in two layer distributed Bayesian Networks. DEC-MDPs were used to sequence the information transferred in order to guarantee the required confidence level. In this paper, we introduce multiple abstraction layers into the Distributed Bayesian Network as a way of carrying more useful information in transmitted data to further reduce the number of messages that need to be sent. An algorithm is developed to automatically generate appropriate abstraction data. Techniques are introduced to effectively incorporate this abstraction data set into the DEC-MDP framework. We show that the appropriate addition of abstraction data actions simplifies the DEC-MDP while reducing the expected communication cost. This work provides us with a formal view of the use of abstraction in agent cooperation and begins to give us an understanding of when the less abstract data needs to be transmitted.

1. INTRODUCTION

In complex distributed applications, such as distributed interpretation (DI), a problem is often decomposed into a set of subproblems and each subproblem is distributed to an agent who will be responsible for solving it. The existence of interactions between subproblems means that the agents cannot simply solve the subproblems individually and then combine local solutions together. In such systems, the amount of communication among agents may be very significant in order to guarantee global optimality or even global consistency. Thus, "satisficing" approaches have been developed that trade off optimality for reduced communication [4]. One approach is for agents to generate local solutions based on their own data and then transmit these high level solutions to other agents. Based on the consistency and credibility of these local solutions, new local solutions may be generated or more detailed data sent until a sufficient level of consistency and credibility has been achieved among the agents. An important characterization of such distributed protocols is how much communication is required and the likelihood that the solution will be the same as that generated by an optimal centralized algorithm which uses all available information.

Most approaches to managing communication trade off solution quality for reduced communication, but only from a statistical point of view. The behavior of the algorithms are often analyzed over a collection of problems to say that p percent of the time they will get the required solution quality q with an average amount of communication c [4].

Shen et al. [11] took this satisficing approach to the next step by designing a parameterized algorithm where one can predict, for a desired confidence level in the final solution, the expected amount of communication the agents need. They studied these issues in terms of a two layered Distributed Bayesian Network (DBN), as shown in Figure 1. A decision-theoretic framework was proposed to model this multi-agent coordination decision problem. A decentralized Markov Decision Process (DEC-MDP) [1] can be constructed from the Bayesian Network structure to find a joint communication policy that minimizes the expected communication cost.
Each agent needs to decide its communication actions based only on its local observations. The framework takes the amount of communication into account, as well as the quality of the final solution. The agents use only the necessary amount of communication to achieve the required level of solution quality.

In this paper, we introduce abstraction layers into the Distributed Bayesian Network as a way of carrying more useful information in one piece of transmitted data to further reduce the number of messages that need to be sent. In order to effectively use the abstraction technique, there are two questions that need to be answered: How to generate the abstract information to be transferred, and When to transfer the abstract information. To answer the first question, we present an algorithm that automatically generates

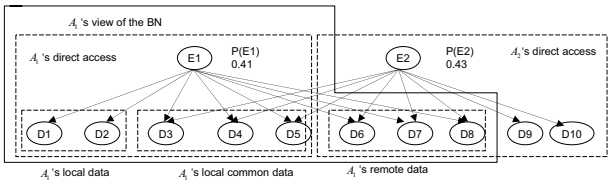

Figure 1: There are two events E_1 and E_2. Data $D_1, D_2, ...D_{10}$ are distributed between two agents. A_1 has access to $D_1, ...D_5$ and is responsible for solving E_1, while A_2 can see only $D_6, ...D_{10}$ and is responsible for solving E_2. The value of E_1 is dependent on A_1's data and vice versa. The objective is for A_1 and A_2 to decide what E_1 and E_2 are with required confidence while minimizing the expected communication cost.

appropriate abstraction data, which reduces the expected communication cost necessary to achieve the required confidence level. This is a greedy approach since the abstraction data enables the agent to immediately reach the desired confidence level. We chose this type of abstraction data because it is intuitive and straightforward to generate, yet it enables us to study the concept of abstraction and its use in reducing communication cost from a formal perspective. There are other forms of abstraction that can be potentially useful. For example, some abstraction data may contain useful information but is not sufficient to reach the confidence by itself. Other abstraction may be an intermediate interpretation result that can be incorporated into the local solution. We plan to look into these different types of abstraction in future work.

To answer the second question, we examine three different approaches to incorporate the new abstract communication actions to the existing DEC-MDP. The *all data action selection* approach allows abstract communication actions as well as the normal communication actions in all the states. The *abstraction data action selection* approach allows only the abstract communication actions in all the states. In the *hierarchical action selection* approach, before an agent has acquired all of the abstraction data, the agents are not allowed to transfer any of the information available at the next more detailed level. Experimental work demonstrates that the hierarchical approach simplifies the DEC-MDP while still reducing the expected communication cost. Furthermore, experiments on larger networks with multiple abstraction layers show that the hierarchical approach is able to solve more and larger networks than the other approaches and therefore is more suitable for scaling up the approach.

Most work studying communication in DEC-MDP and its related models studies synchronizing communication, where every communication action synchronizes the agents' views of the world state [8, 10]. In contrast, this work studies the problem of what to communicate, where only part of the local observation is transferred between the agents. Abstraction has often been used in hierarchical planning community to represent abstract plans that can be further refined into specific actions. In particular, Clement and Durfee [6] used summary conditions, a form of abstraction, to coordinate the concurrent interactions of plans at different levels of abstraction between agents. Abstraction has also been used in distributed diagnosis research to identify the sources of problem. Chung and Barrett [5] demonstrated how Boolean expressions can facilitate finding minimal cost diagnoses in linear time. However, neither work studies the tradeoff between abstraction and communication. In the original Distributed Problem Solving work [7], abstraction was used as a mechanism for controlling the information needing to be communicated. However, the use of abstraction was not formalized. Nor was there a clear understanding of when the lower level data needed to be transmitted. Carver and Lesser [3] studied the use of multiple levels of abstraction to reduce the necessary communication. Like [7], the abstraction layers were predefined and the use of abstraction was not formalized. In contrast, the algorithm we introduce allows the system to generate appropriate abstraction data automatically without predefinition. Our study of the addition of abstraction layers into the Bayesian networks and transferring abstraction data as actions in the DEC-MDP provides us with a formal view of the use of abstraction in the management of communication cost in a distributed problem solving system.

The next section formally defines the problem we study and summarizes the DEC-MDP model we developed to generate the communication strategy. Section 3 introduces the algorithm that automatically generates the abstraction data that when transmitted can greatly facilitate the achievement of the confidence level. Section 4 discusses how the abstraction data can be incorporated to improve the system performance. Section 5 extends the different approaches discussed so far to larger networks with multiple abstraction layers. We conclude with a discussion of future work.

2. PROBLEM DEFINITION AND DEC-MDP MODEL

In an interpretation system there is a set of observable data that is caused by some possible events, which agents do not have the means to directly observe. The agents need to observe the data and identify the events that are most likely the cause of them. In many environments, the problem is inherently distributed and the network is fairly large. In those cases, it is common to distribute not only the data but also the interpretation task among several agents. Inevitably, there is a close interaction between the agents since the local sub-problems an agent is responsible for are often dependent on some of the data collected by other agents. The existence of subproblem interaction means that the agents will need to communicate during problem solving. Therefore, agent communication strategies can have a major effect on the cost of problem solving.

We use a two-layer Bayesian Network to represent the problem structure (Figure 1). The top level nodes are the events that are the possible causes of the observed data, while the leaves are the raw data gathered by various agents. There are two agents, each of whom has direct access to only a part of the observable data. The interpretation task is distributed to the two agents as well with each agent responsible only for part of the overall problem. Additionally, an agent only has knowledge of the network structure that is directly relevant to its interpretation task. The agents can either request or send data. The objective is to identify the most likely interpretation of the causal events with a target level of confidence using as little communication as possible. For example, in Figure 1, there are two agents A_1 and A_2. A_1 is responsible for interpreting the event E_1 and therefore

knows about the part of the causal network that is relevant to E_1 . Out of the relevant data $D_1, ..., D_8$, it can directly observe only D_1 through D_5. D_6, D_7 and D_8 are *remote data* and may need to be transferred in order for A_1 to solve its local problem with confidence.

The **evidence** ϵ_{A_i} of an agent A_i are the values of the data that the agent has collected so far. They can be the values that are observed directly by that agent or acquired from the remote agent. An agent A_i is only able to find the most likely interpretation of the local events given its current evidence set, i.e., $MAPI(\epsilon_{A_i}) = argmax_h P(E_{A_i} = h|\epsilon_{A_i})$ [4]. Ideally the decentralized system should generate the interpretation that a centralized system will generate given the complete data values $MAPI(\epsilon^*_{A_i})$, where $\epsilon^*_{A_i}$ is the complete evidence set relevant to A_i. Unfortunately, with only partial knowledge of the relevant data values, it is not always guaranteed that the current local MAPI is the global MAPI. On the other hand, with the conditional probability table given by the BN, an agent can predict the probability of different relevant data configurations given its current evidence $P(\epsilon^*_{A_i}|\epsilon_{A_i})$. Hence we have the following definition.

Definition 1. **Confidence** *is the likelihood of the local MAPI being the global MAPI of E_A given the current known evidence of A.*

$$\begin{aligned} C(MAPI(\epsilon_A)) &= P(MAPI(\epsilon_A) = MAPI(\epsilon^*_A)) \\ &= \sum_{e \in \{\epsilon^*_A | MAPI(\epsilon_A) = MAPI(\epsilon^*_A)\}} P(e|\epsilon_A) \end{aligned}$$

What is important about the solution quality of a distributed system is not the likelihood of an event being the local MAPI, but whether the local MAPI agrees with the global MAPI, i.e., whether the decentralized system will generate the same result that a centralized system would. That is exactly what this definition of confidence achieves. Using confidence as a measurement of the solution quality of a decentralized system as compared to that of a centralized one, we can make a tradeoff between the quality of the solution and the communication cost. Another interesting and useful property of our definition of confidence is that it is guaranteed to reach 100% when the values of all the relevant data are known. As a result, a given confidence level can always be satisfied.

Given a problem structure in a two level BN such as the one in Figure 1 and a specified confidence threshold, we need to find a communication strategy. Such a communication strategy should specify what communication action each agent should take based on their current knowledge at each stage. In this paper we are considering only the case of synchronous communication. In other words, the two agents take turns to decide their actions in the sequence of $A_1, A_2, A_1, A_2, ...$ until the confidence threshold is reached.

Definition 2. *A* **communication strategy** $\pi_{\langle A_1, A_2 \rangle}$ *is a pair of policies π_{A_1} and π_{A_2}. Each policy π_{A_i} is a mapping from local evidence and communication history to a local action: $\pi_{A_i} : \epsilon_{A_i} \times H \rightarrow a_i$.*

There are three classes of actions for each agent: SEND, REQUEST and NULL. The content of the SEND and REQUEST actions at each stage are restricted by the communication history so far. An agent can send only the part of the local common data that the other agent has not yet acquired, and can request only a part of the remote data that it has no knowledge of. When the communication history indicates that it is not A_i's turn to act, the policy of that agent will always be NULL. A REQUEST action and its response by the other agent occur in the same stage. For example, in Figure 1, let us assume that initially $\epsilon_{A_1} = \{D_1 = 1, D_2 = 0, D_3 = 0, D_4 = 1, D_5 = 1\}$ and $H = \emptyset$. A valid action for A_1 at this step would be "SEND D_3 and D_4". It could also "REQUEST D_8 and D_9". On the other hand, since it is not A_2's turn, the only valid action for A_2 is NULL. The cost model for this framework is very general. Each communication has its own cost, based on its action class and the particular data sent. The only restriction is that the cost of a REQUEST must also include the cost of the immediate reply by the other agent. For example, in our experiments SEND costs 1 per data sent. A REQUEST action costs 1 for the request plus a reply cost equal to a SEND action of the same data. "REQUEST D_8 and D_9" would cost 3.

To summarize, the problem can be defined by a two level BN and a required confidence threshold t. The goal is to find a communication strategy $\pi_{\langle A_1, A_2 \rangle}$ that allows the agents to interpret their local events with a confidence greater than, or equal to t, i.e., $C(MAPI(\epsilon_{A_1})) \geq t$ and $C(MAPI(\epsilon_{A_2})) \geq t$, while minimizing the expected communication cost.

To solve this problem, we model it as a DEC-MDP. Unlike a centralized MDP, in a DEC-MDP the process is controlled by multiple agents, each with a different view of the current global state. At each time step the agents' observations together uniquely determine the global state, though frequently no one agent has this complete view. A local policy for an agent is a mapping from its local histories of observations to an action. The goal of a decentralized MDP is to find an optimal joint policy for all of the agents that maximizes the expected total reward.

We model our problem in the framework of a decentralized MDP as follows.

- Every global state is in the form of $s = \langle \epsilon^*, i \rangle$, where ϵ^* is all of the low level data values observed by the system, and i is an external feature that indicates it is A_i's turn to communicate. s_0 is a dummy start state $\langle \emptyset, 0 \rangle$. When all the sensors collect their data, the start state transitions to one of the possible real global states $\langle \epsilon^*, 1 \rangle$ before any communication takes place.
- Ac_1 and Ac_2 are action sets of the two agents. $Ac_i \in \{$ NULL, SEND x, REQUEST $y\}$, where x is a subset of the local common data of A_i and y is a subset of the remote data. When it is not A_i's turn to communicate, its action is the NULL action. A joint action $\langle Ac_1 \neq NULL, NULL \rangle$ transitions a state $\langle \epsilon^*, 1 \rangle$ to $\langle \epsilon^*, 2 \rangle$, and a joint action $\langle NULL, Ac_2 \neq NULL \rangle$ transitions a state $\langle \epsilon^*, 2 \rangle$ to $\langle \epsilon^*, 1 \rangle$. If at state s, both agents have reached confidence level t for its local interpretation task, i.e., when $C(MAPI(\epsilon_{A_i})) \geq t$, $i = 1, 2$, then s is a final state.
- P is a transition probability table. $P(s'|s, a_1, a_2) = P(\langle \epsilon^*, i \rangle | \langle \epsilon^*, j \rangle, a_1, a_2) = 1$ iff $i \neq j$. Otherwise, $P(s'|s, a_1, a_2) = 0$. As a special case, the transition probability from s_0 to $s = \langle \epsilon^*, 1 \rangle$ after both agents execute NULL action is $P(s|s_0, NULL, NULL) = P(\epsilon^*)$.

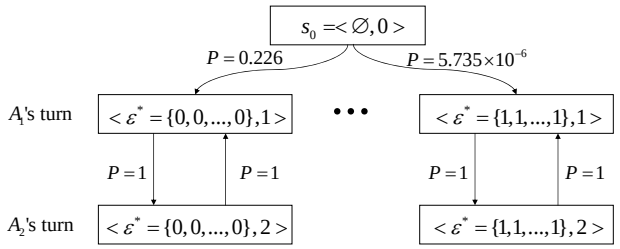

Figure 2: A portion of a typical decentralized MDP.

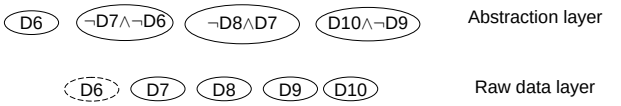
It can be calculated given the BN structure.

- R is a reward function. $R(s, a_1, a_2, s') = R(a_1, a_2) = -c(a_1) - c(a_2)$, where $c(a_i)$ is the cost of the communication action a_i, $i = 1, 2$.
- Ω_1 and Ω_2 are the sets of observations for the two agents. An observation $o_i \in \Omega_i$ is the data value just sent or received by A_i. As a special case, after s_0, each agent observes the values of its local data. An observation sequence $\overline{o}_i = \langle \epsilon^0_{A_i}, H \rangle$, where $\epsilon^0_{A_i}$ is the initial observation of A_i's local data set before any communication occurred in the system, and H is the communication history of the system.
- $O(s, a_1, a_2, s', o_1, o_2) = 1$ iff o_1 and o_2 are the new data sent or received by the agents after them taking actions a_1 and a_2 at state s. Otherwise it equals to 0.
- A local policy π_i for agent A_i is a mapping from the local observation sequence $\overline{o}_i$ to an action $a_i \in Ac_i$. A joint policy $\pi = \langle \pi_i, \pi_j \rangle$ is a pair of local policies, one for each agent.

For example, Figure 2 is the DEC-MDP built for the problem in Figure 1. A possible global state s when both agents just observed their local sensor data might be $\langle \{D_1 = 1, D_2 = 0, D_3 = 0, D_4 = 1, D_5 = 1, D_6 = 0, D_7 = 1, D_8 = 1, D_9 = 0, D_{10} = 0\}, 1\rangle$. The possible actions for A_1 are NULL, SEND x, and REQUEST y, where $x \subseteq \{D_3 = 0, D_4 = 1, D_5 = 1\}$ and $y \subseteq \{D_6, D_7, D_8\}$. Since it is not A_2's turn to communicate, its only action is NULL. If A_1 chooses REQUEST $\{D_7, D_8\}$, then the next state is $\langle \{D_1 = 1, D_2 = 0, D_3 = 0, D_4 = 1, D_5 = 1, D_6 = 0, D_7 = 1, D_8 = 1, D_9 = 0, D_{10} = 0\}, 2\rangle$ and both agents observes $\{D_7 = 1, D_8 = 1\}$. The observation sequence for A_1 is $\overline{o}_1 = \{\langle D_1 = 1, D_2 = 0, \ldots, D_5 = 1\rangle, \langle D_7 = 1, D_8 = 1\rangle\}$, and the observation sequence for A_2 is $\overline{o}_2 = \{\langle D_6 = 0, D_7 = 1, \ldots, D_{10} = 0\rangle, \langle D_7 = 1, D_8 = 1\rangle\}$. The policy π_i decides which action to take for each agent based on its current $\overline{o}_i$. Remembering the entire communication history H for both agents have two purposes. First, it includes the newly acquired evidence received from the other agent. Second, even for the agent who just SEND part of its own data without receiving any new evidence, it is important to remember this so that in the future it does not send the same information unnecessarily.

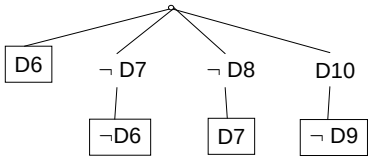
3. GENERATING THE ABSTRACTION LAYER

So far we have discussed two layer networks, which means that there are no intermediate abstraction data. Many domains, however, have structures that can be exploited to improve the performance of both local processing and inter-agent merging of evidence. Domain structure can result from a number of factors such as independencies among subsets of events or between events and certain data subsets and cases where only a fraction of the combinations of some data are informative. Many of these situations are best captured by using BNs that include intermediate nodes that lie between the event and data levels.



```
1.1 Input: agent A's view of BN, the values of
    the local data, the required confidence
1.2 Output: a set of logic expressions of the
    remote data that, if true, put the local
    confidence above the required confidence
1.3 Set DataList = all the remote data of A,
    potential = null
1.4 Initialize LogicTree
1.5 while DataList.next is not null do
        currentLeaf = DataList.next
        add currentLeaf and ¬currentLeaf as new
        children to LogicTree.root
        if confidence given currentLeaf ≥ required
        confidence then
            mark currentLeaf
            continue
        if confidence given ¬currentLeaf ≥
        required confidence then
            mark ¬currentLeaf
            continue
        if potential == null then
            potential.add(currentLeaf)
            potential.add(¬currentLeaf)
            continue
        for each p in potential do
            potential.add(addChildren
            (currentLeaf, p), addChildren
            (¬currentLeaf, p))
1.6 convert the marked part of LogicTree to a set
    of logic expressions and return it
1.7 addChildren (currentLeaf, p)
    begin
        Add p to LogicTree as a child of
        currentLeaf in a depth first fashion, check
        the confidence at every step. If confidence
        ≥ required confidence, stop going deeper
        into this branch and mark it.
        Output: the unmarked subtree of
        LogicTree starting from currentLeaf
    end
```

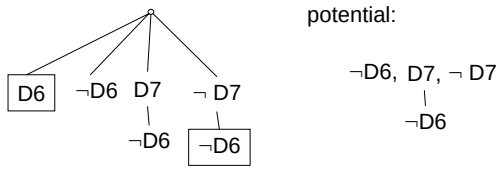
Algorithm 1: The algorithm for generating the abstraction layer



Research on learning Bayesian Networks from data [2, 9] focuses on finding the BN structure that best matches the collected data. These techniques are important in constructing the BN structure that represents the problem we are trying to solve. However, we need other methods to find an appropriate abstraction layer from the existing BN that, when transmitted from the remote agent, more efficiently conveys the necessary information to facilitate the local problem solving. In other words, this abstraction layer, when acquired, should be able to reduce the expected communication necessary to achieve the required confidence level.

(a) The action options for the *raw data action selection* approach

(b) The action options for the *all action selection* approach. The data that can be transferred are divided into two categories.



(c) The corresponding **LogicTree** to the abstraction data.

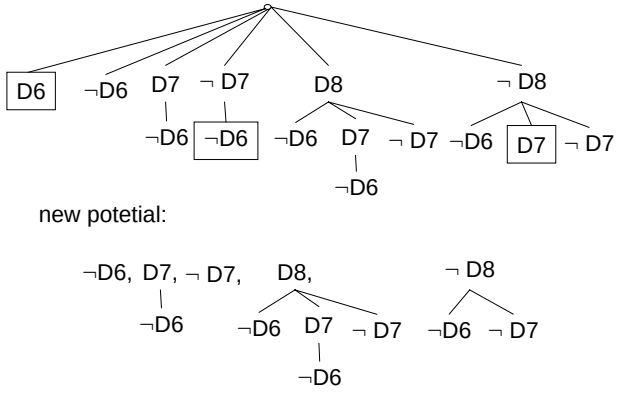


Figure 3: An example of the abstraction layer. Remote data includes $\{D6, \cdots, D10\}$. The required confidence level is 75%

We achieve this goal by developing an algorithm (Algorithm 1) that automatically generates an abstraction layer given a value combination of an agent's local data and the desired confidence level. The basic idea behind the algorithm is to find a set of logic expressions consisting of the remote data such that if at least one of the expressions is true the required confidence is reached. For example, an agent has 5 pieces of remote data $\{D6, \cdots, D10\}$ and needs to achieve a confidence level of 75%. In the original system, the only possible actions are to transfer some or all of these raw data. We will call this approach *raw data action selection*. However, if one or more of $D6$, $\neg D7 \wedge \neg D6$, $\neg D8 \wedge \neg D7$ and $D10 \wedge \neg D9$ are true, then the agent immediately has a local solution with a confidence level of 75%. These data carry more abstract information than the raw data themselves and therefore are more efficient, though the information is not as refined. If these data values can be acquired as well as the raw data, it can potentially yield huge savings on the communication cost. Additionally, the values of the abstraction data also give valuable information about what the values the raw data may have. For example, if the value of $\neg D7 \wedge \neg D6$ is transferred and is true, then the process can immediately terminate because the confidence level of 75% has been reached. If the value is false, even though the desired confidence level is not immediately achieved the agent does now have the knowledge that $D6$ and $D7$ cannot be false at the same time. This information can be retained by updating the BN. Figure 3(a) shows the action options of the *raw data action selection* approach for this example while Figure 3(b) shows the action options if the abstraction data can also be transferred.

The desired set of logic expressions can be generated by simply enumerating all of the possible combinations of the remote data values and selecting those that will enable the agent to reach its desired confidence level. Our algorithm improves efficiency by a logarithmic factor over the exponential brute force enumeration by reusing the subgraphs of logic expressions.

(a) **LogicTree** and **potential** before adding $D8, \neg D8$ to **LogicTree**.

(b) **LogicTree** and **potential** after adding $D8, \neg D8$ to **LogicTree**.

Figure 4: An example of the key step of Algorithm 1.

Figure 4 gives an illustration of an episode showing how the algorithm is run for the example in Figure 3. We use a tree, which we call a **LogicTree**, to keep track of all the data values examined so far. The nodes along the same path are connected by the $\wedge$ operator, and the different branches represent different value assignments. The marked branches are the ones that pass the confidence test, i.e., if true, the desired confidence level is reached. The set **potential** is used to keep track of the subtrees examined so far that did not pass the confidence test. Only the members of **potential** should be examined as a subgraph of longer expressions. Figure 3(c) shows the final **LogicTree** for this example.

If the values of all the remote data are acquired, the local confidence is guaranteed to reach 100%. Therefore, we limit the depth of the **LogicTree** to be less than the number of remote data. When the maximum depth is the number of remote data minus 1, the algorithm generates all of the expressions that have the desired property. Reducing the depth of the **LogicTree** results in a smaller number of abstraction nodes generated and therefore a smaller DEC-MDP. This tradeoff will be further discussed in the next section. In general, the number of abstraction data generated should be no more than the number of raw data. For each path in the **LogicTree**, we record the likelihood of the abstraction data represented by the branch being true, and we choose the n abstraction data with the highest likelihood of being true to incorporate into the DEC-MDP, where $n <$ the number of raw data.

When given a BN and a desired confidence level, the agent generates an abstraction layer for each raw data value combination and adds them to its action options for the states that have the corresponding raw data values. The expanded DEC-MDP can be solved to generate a communication strategy. We call this approach the *all data action selection*

approach. Since the raw data communication actions are competing with the abstraction actions, an agent chooses to transfer an abstraction data if and only if it will result in a lower expected communication cost than transferring any of the raw data. Therefore, the new system performance should be no worse than the original system in terms of the expected communication cost.

We compared the performance of the *all action selection* approach and the *raw data action selection* approach. The cost of sending a piece of abstraction data was equal to the cost of sending raw data. We used the Iterative Algorithm introduced in [11] to solve the DEC-MDP. We ran experiments on 100 problem structures with 2 high level events and 10 raw data (5 local to each agent) for different confidence levels. All of the networks were fully connected, which means that for both agents to have the complete evidence, 10 pieces of data needed to be transmitted. The corresponding curves in Figure 5 shows a comparison of the minimum expected communication cost generated by both systems. Column (a) in Table 1 shows the percent improvement in the expected communication cost when transmitting abstraction data in addition to the raw data. As shown, the *all data action selection* has a noticeable improvement over the *raw data action selection* approach. This illustrates that the addition of the abstraction data does help reduce the communication cost. The improvement is most significant when the required confidence is between 70% and 80%. When the confidence level is low, the expected communication cost is already low so that it is difficult to achieve a significant improvement. On the other hand, when the required confidence level is high, there are much fewer abstraction data generated resulting in a smaller improvement.

4. HIERARCHICAL ACTION SELECTION

Introducing the communication actions that transmit the values of the new abstraction data leads to both a larger state space and a larger action space for the generated DEC-MDP. As a result, the time needed to solve the new DEC-MDP can be significantly greater than the original DEC-MDP, which only has the raw data transmission as its actions. Column (c) in Table 1 shows the average time the *all data action selection* approach took to solve the DEC-MDP, where the average time needed for the *raw data action selection* approach equals 1.00. In this section, we introduce techniques that address this problem.

First we examine the case where the agents only transfer the abstraction data between them. We call this approach the *abstraction data action selection* approach. While the size of the DEC-MDP generated is often much smaller than that of the original DEC-MDP, one major drawback of this approach is that we can no longer guarantee that the required confidence level can be reached. Only when at least one of the abstraction data is true will the desired confidence level be reached. The corresponding curve in Figure 5 shows the expected communication cost achieved for the cases where the desired confidence level can be reached. When the required confidence level is high, there are fewer abstraction data generated, and therefore the expected cost is much lower than those of the two approaches we discussed in the previous section. Notice, however, that this is a false savings as the desired confidence level cannot always be reached, which is not reflected in the figure.

We seek to combine the advantages of the *all data action selection* approach and the *raw data action selection* approach so that we can save time on solving the DEC-MDP as well as guarantee the required confidence level. We achieve this by restricting legal actions for different states. Before an agent has acquired all of the abstraction data, the agents are not allowed to transfer any of the raw data. We call this approach the *hierarchical action selection* approach. An agent prefers to transfer abstraction data because it abstracts from multiple pieces of raw data and thus is a more efficient information carrier. Only when the acquisition of all of the abstraction data cannot achieve the desired confidence level will an agent start to acquire the raw data in order to get the necessary information.

Like the *all data action selection* approach, the *hierarchical action selection* approach guarantees that the desired confidence level can be achieved. Figure 5 illustrates the comparison of the performance of the approaches we have discussed. As we expected, the *all data action selection* approach performs the best. In fact, it generates the optimal solution for any DEC-MDP whose action space in-

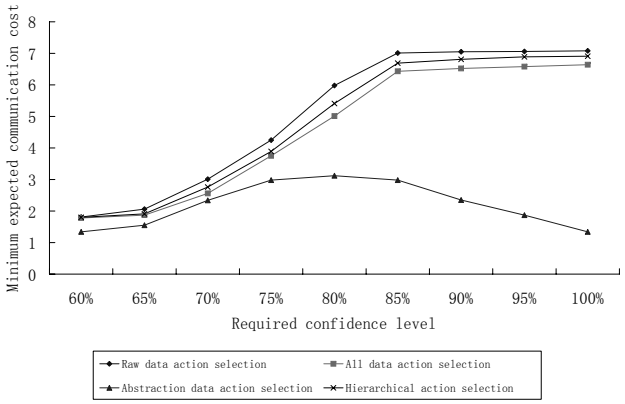

Figure 5: A comparison of the minimum expected communication cost given different action selections

required confidence	(a)	(b)	(c)	(d)
60%	1.66%	0.55%	1.25	0.89
65%	9.22%	7.28%	1.53	0.77
70%	14.95%	8.31%	1.49	0.69
75%	11.76%	8.47%	1.52	0.63
80%	16.22%	9.53%	1.61	0.59
85%	8.27%	4.56%	1.41	0.65
90%	7.52%	3.40%	1.21	0.77
95%	6.80%	2.41%	1.10	0.82
100%	6.21%	2.40%	1.09	0.87

Table 1: Performance compared to raw data action selection approach for single abstraction layer in a 2-10 network. (a) Expected communication cost improvement of *all action selection*. **(b) Expected communication cost improvement of** *hierarchical action selection*. **(c) Time needed to solve the DEC-MDP for** *all action selection* **normalized by that for raw data action selection. (d) Time needed to solve the DEC-MDP for** *hierarchical action selection* **normalized by that for raw data action selection.**

cludes transferring both the abstraction data and the raw data. On average, the *hierarchical action selection* approach outperforms the *raw data action selection* approach. However, there are cases where the *hierarchical action selection* approach requires more communication than the *raw data action selection* does. In those BNs, it is often the case that there is a low likelihood of any of the abstraction data being true. Column (b) in Table 1 shows the amount of improvement in the minimum communication cost the *hierarchical action selection* approach gains over the *raw data action selection* approach. The pattern is similar to that of column (a).

Column (d) in Table 1 shows the average time needed to solve the DEC-MDP for the *hierarchical action selection* approach normalized by the average time needed for the *raw data action selection* approach. It achieves substantial savings. Even though the *hierarchical action selection* approach does not reduce the size of the action space compared to the *all action selection* approach, it does reduce the number of legal actions available to any given state. This also decreases the size of the state space because H, the communication history, has fewer possibilities. These two factors combined together contribute to the time savings, and the larger the network is, the more substantial the savings should be. We plan to run more experiments on larger networks to verify this observation.

All of the experiments we have shown so far set the depth of the **LogicTree** in Algorithm 1 to be the number of remote data minus 1, i.e., 4. A shallower **LogicTree** will generate fewer abstraction data and result in a higher expected communication cost to reach the same confidence level. However, generating the abstraction layer and finding the communication strategy will take less time. Our future experiments will explore this tradeoff between computation time and communication cost as the depth is varied.

5. MULTIPLE LEVELS OF ABSTRACTION

The idea of varying the depth of the **LogicTree** leads to an interesting way of generating a hierarchy of abstraction data. We can modify Algorithm 1 to generate a set of abstraction data of different lengths. The more literals in the abstraction data, the more abstract it is, the more efficiently it carries information, and the less refined the information is.

Just like in the single abstraction layer case, there are different ways of incorporating multiple layers of abstraction data into the action space of the DEC-MDP. We did experiments on the all data action selection approach and the hierarchical action selection approach, and compared their performance to that of the raw data action selection approach. In the all data action selection approach, all the abstraction data of various length are added to the action space to compete with the raw data. In the hierarchical action selection approach, the agents transfer the most abstract data first. If the confidence level is not achieved, then the agents start transferring the next level of abstract data. This process goes on until the confidence level is reached.

We tested these approaches on networks of different sizes: 4 high level events and 20 low level data (4-20 networks); 6 high level events and 30 low level data (6-30 networks); 8 high level events and 40 low level data (8-40 networks). We generated two abstraction layers for each of the networks. Figure 6 shows the percentage of the networks we tested on

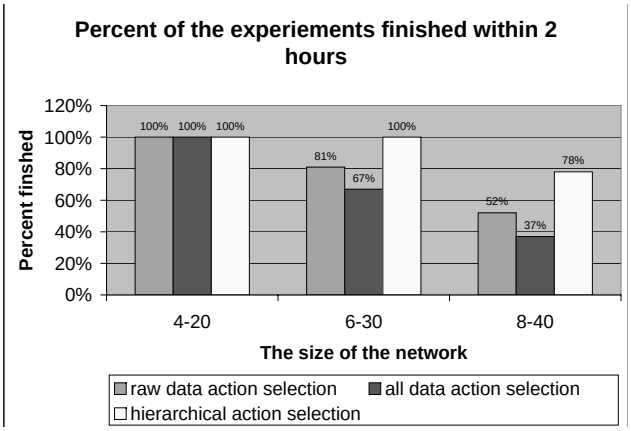

Figure 6: The percentage of the problems tested that each approach was able to finish solving within 2 hours.

required confidence	(a)	(b)	(c)	(d)
60%	3.87%	2.14%	1.33	0.91
65%	10.42%	8.19%	1.49	0.79
70%	16.01%	12.34%	1.52	0.62
75%	19.84%	15.62%	1.59	0.56
80%	18.26%	13.43%	1.71	0.49
85%	12.22%	9.53%	1.59	0.58
90%	8.49%	6.72%	1.39	0.68
95%	5.71%	4.43%	1.19	0.76
100%	4.23%	3.12%	1.10	0.78

Table 2: Performance compared to the raw data action selection approach for multiple abstraction layers in a 6-30 network. (a) Expected communication cost improvement of *all action selection*. (b) Expected communication cost improvement of *hierarchical action selection*. (c) Time needed to solve the DEC-MDP for *all action selection* normalized by that for raw data action selection. (d) Time needed to solve the DEC-MDP for *hierarchical action selection* normalized by that for raw data action selection.

that each of the three approaches was able to finish within two hours. It shows that hierarchical action selection approach was able to finish the policy search better than either of the two other approaches. The larger the network, the bigger an advantage the hierarchical approach has over the other two. Table 2 shows the performance comparison of the all data action selection approach and hierarchical action selection approach over the raw data action selection approach. The data is shown only for the 6-30 networks for which all of the three approaches finished searching for the optimal policy. The first abstraction layer is composed of the abstraction data with no more than 5 literals, and the second layer is composed of the abstraction data with no more than 10 literals and greater than 5 literals. The results show a similar pattern as those of the single abstraction layer experiments. The all data approach is not practical for large networks or more than a few abstraction layers, since it substantially expands both of the state space and action space of the DEC-MDP. However, it does give a

lower expected communication cost than the raw data action selection approach when it can solve the problem. On the other hand, the hierarchical approach proves to be more effective than both the raw data action selection approach and the all data action selection approach. It is able to solve more and larger networks, and on average it takes much less time. Furthermore, for the networks that both approaches were able to finish the policy search, the solution generated by the hierarchical action selection approach has a lower expected communication cost on average than that generated by the raw data action selection approach.

6. CONCLUSIONS AND FUTURE WORK

In this paper we investigated the techniques of transferring abstraction data in addition to raw data in Distributed Bayesian Networks to reduce the required communication cost. We introduced an algorithm that automatically generates appropriate abstraction data that facilitates the achievement of the required confidence level and reduces the necessary communication cost. We also discussed approaches to incorporate the new abstraction data into the DEC-MDP framework effectively. Both the improvement in the minimum expected communication cost and the time savings in solving the DEC-MDP make the *hierarchical action selection* an attractive approach, especially for the systems which require a mid-ranged confidence level. We further extended the different action selection approaches to larger networks and multiple abstraction layers. The hierarchical action selection approach was shown to be able to solve problems with larger networks than the other approaches.

This work allows us to look at the use of abstraction to reduce communication cost from a formal perspective. The *hierarchical action selection* approach defines when and how the abstraction data and the raw data should be transferred in the communication process. The addition of transferring abstraction data to the communication actions can be extended to reduce the communication cost of other Cooperative Distributed Problem Solving (CDPS) applications as well. Though the algorithm that we used to generate the abstraction data is specific to the DBN used to represent the DI problems, given a CDPS problem with specific semantics, there often is abstraction data that can be generated and used to transfer information more efficiently. The hierarchical action selection approach then can be used to incorporate this abstraction data to further minimize the communication cost.

We plan to do more experiments with larger networks, and we predict that the savings of the *hierarchical action selection* approach shown in this paper will be more significant for larger networks. The influence of different depths of **LogicTree** in Algorithm 1 on the system performance will also be investigated. In this work, we looked at one particular type of abstraction. There are other forms of abstraction that can be potentially useful. For example, some abstraction data may contain useful information but is not sufficient to reach the confidence by itself. Other abstraction may be an intermediate interpretation result that can be incorporated into the local data. We plan to look into these different types of abstraction in future work. We also intend to investigate other techniques in generating multiple layers of abstraction data, such as different levels of intermediate interpretation results.

ABSTRACT

Intelligent software personal assistants for human organizations are an active research area within the multiagent community. However, while many capabilities for these software personal assistants are imagined or already developed, there has been no quantification of how an organization's performance is improved by software personal assistants. Moreover, while intuitively organizations will adapt to take advantage of the new technology, there has been no work looking at how organizations should or will change in response to the new technology. This paper presents a first step toward addressing this oversight. Specifically, a computational model of the working of an organization and how software personal assistants will affect that organization is developed that allows effects of software personal assistants to be modeled. By varying the potential capabilities of the software personal assistants and the structure of the organization, we can explore the impact of the technology. Our results show that managing task contingencies can greatly improve organizational performance by as much as 45%.

Keywords

Organizational Design, Personal Software Assistants

1. INTRODUCTION

A variety of recent agent research has focused on developing techniques for building intelligent software personal assistants (SPAs) for humans in complex organizations. Each human in the organization will have his or her own SPA which is anticipated to have a wide variety of capabilities from scheduling joint activities[19, 23, 11, 21], monitoring and reminding individuals of key timepoints[7, 4], sharing key information[23, 20], assisting in negotiation decision support[14], and even ordering lunch[7]. Just as previous technological innovations have revolutionized human organizations, SPAs are likely to revolutionize the way organizations ranging from first responders to the military to commercial enterprises organize their joint activities. However, despite much research into enabling technologies, there have been no previous efforts to understand how human organizations might utilize the technology. Moreover, it is not even well understood which SPA capabilities are most useful for improving the effectiveness and efficiency of an organization.

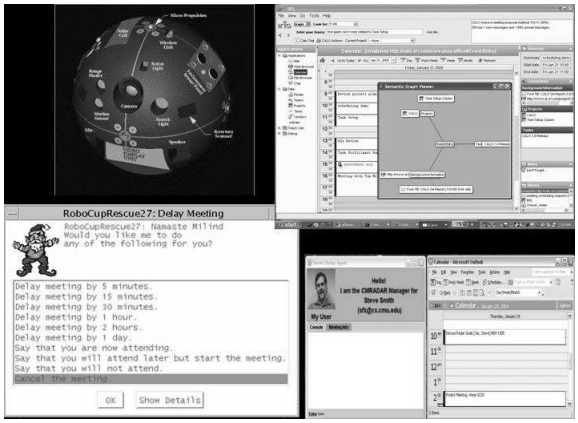

Figure 1: A sampling of SPA technology. Clockwise from upper right: CALO, RADAR, Electric Elves, PSA.

Outside of the multiagent community, organizations and their adaption to technological change has been extensively studied. Some research, particularly within economics, uses abstract analytical models to determine optimal features of an organization given the task for which it is designed[12, 10, 3]. Other work, often in sociology, attempts to develop analytic models to explain observed phenomena[5, 17]. Unfortunately, such analytic models are typically too abstract to model the subtle effects of SPA technology. One sub-field of research focuses on design and adaption of human organizations[5], but has not looked specifically at the impact of new technology on those organizations. Within the multiagent community, researchers such as Dignum[9], Horling[13] and Dastani[8], have developed interesting techniques for modeling organizations. As these languages mature they will play an important, complementary role to this work. Hence, while organizations are extensively studied, no work specifically allows quantification of the impact of SPAs on an organization.

In this paper, we present our initial efforts at modeling the impact of SPAs on human organizations. The aim is to provide SPA developers with input on which capabilities are most likely to be useful and to provide SPA adopters with input on how to best apply the technology. Specifically, we are interested in organizations configured for a particular large scale task, e.g., response to a major disaster or a military operation, where SPAs such as the DARPA COORDINATORS assistants[23] may be deployed. Since SPA capabilities typically affect detailed work activities and their broader influence is unclear, we must model the organization at a fine grained level of detail, capturing, for example, message paths, decision making, times, etc, in order to see their effects. An abstract simulation environment takes proposed organizations and tasks to be performed by that organization and computes key properties of task execution, including how well and how quickly the organization performed the task and how robustly it handled individual failures. The simulation captures important aspects of the operation of the organization, such as non-determinism and individual cognitive limits, but abstracts away domain level details, making it feasible to evaluate many instances.

In our computational model, SPAs are represented as changing and relaxing constraints on human cognition. With reference to ongoing projects and previously published literature about SPA technology, we identified four key capabilities that are being developed and inferred how these would alter how a person operates in an organization. For example, several key technologies[23, 4] will have the effect of increasing the speed with which an individual in an organization will be able to make decisions. The model of the organization allows the impacts of capabilities to be considered individually or in combination.

To quantify the impact of SPAs on an organization, we generated a large number of different organizational structures and evaluated the performance of each organizational structure with and without combinations of SPA capabilities. This general approach was used for two reasons. First, it enabled us to quantify the impact of SPAs on the organization by measuring the difference in performance between organizations with and without SPAs. Specifically, we found that managing contingencies to prevent actor overload improved performance most significantly, allowing a 45% performance improvement over an organization without SPAs. Second it allowed us to compare the performance of different organizational structures to determine what changes may be needed to leverage SPA technology. We found that the types of hierarchies currently used by many organizations remains effective in the presence of SPAs.

2. RELATED WORK

The effect of information technology on human organizations has been a focus of considerable research, especially in business and organization theory[5, 17, 1]. While it is generally assumed that the deployment of such technology in an organization reduces coordination costs and enhances performance[16], other research[6] indicates that the adoption of information technology can have unexpected and deleterious effects. It is thus essential to consider the interactions between proposed technology and the dynamics of the organization deploying that technology.

Even in cases where the adoption of information technology improves organizational efficiency, the underlying organizational structure must often change in order to realize the full benefits. Two notable and well-studied such technologies are electronic marketplaces in supply chain management[17] and e-mail for communication and coordination[1]. While the organizational adaptations needed to leverage those technologies are now understood, there is to date no research on the organizational changes necessary to most fully exploit the newer technology of SPAs. Research on SPAs has instead focused on issues of actually building and deploying such complex software systems, in domains ranging from military applications[23] to disaster response[20] to office scheduling and collaboration[7, 19] to space environments[4]. Studies involving agents actually assisting human teams perform tasks have been performed[22, 7], but such an approach is impractical for studying the effects of agents on large organizations, and also require the SPA to already be built.

Organizational research in the multiagent community has tended to focus on modeling organizations in order to guarantee logical properties during execution[9]. While important for a complete understanding of organizational behavior and the successful integration of agents into human organizations, this approach does not specifically address the impact of SPAs, and also neglects quantitative evaluation of organizational performance. Recent work[13] addresses the issue of quantitative evaluation, but is focused primarily on organizational modeling as opposed to design, and still does not specifically take into account SPAs.

3. PROBLEM

We represent an organization of human actors that perform tasks and communicate in order to make decisions. Successful execution of sensing tasks yields information that is used as input to making decisions. This abstraction describes a wide variety of real-life organizations, from military units that detect and eliminate enemy threats, to businesses that identify customer needs and reallocate investments.

A number of assumptions govern the behavior of actors in our model:

- An actor that attempts to perform a task may *fail*. The actor cannot try to perform the task again.
- Tasks have fixed execution durations during which time they must be performed, uninterrupted.
- Actors can perform only a limited number of tasks simultaneously. In particular, an actor can only perform a single sensing task at a time, or 3 decision-making tasks at a time. Actors cannot simultaneously perform sensing and decision-making tasks. An actor who attempts to exceed these limits becomes overloaded and cannot perform *any* tasks.
- Actors can only transmit information along predetermined communication links.
- Actors are bounded in the number of communication links they can maintain. Each actors can have at most max_{in} incoming communication links and max_{out} outgoing communication links.
- Communication takes a fixed amount of time.
- Actors can only perform decision tasks if they have all the required information.

We do not explicitly represent SPAs in the organization, but instead model their effects as changes in organizational constraints and parameters. For example, the presence of SPAs may be modeled by increasing the communication speed from a baseline for an organization without SPAs.

Formally, an organization O is a tuple

$$O = \langle A, T, I, Prov, Req, Cap, Fail, G, speed_d, speed_c, M, d \rangle$$

with the following components:

- $A = \{a_1, a_2, \ldots, a_m\}$: the set of human actors in the organization
- T: the set of tasks to be performed by the actors. Tasks are partitioned in two orthogonal ways:
  - $T = T_P \cup T_C$
    - $T_P = \{t_1, t_2, \ldots, t_n\}$: the set of *primary tasks* to be performed.
    - $T_C = \bigcup_{t_i \in T_P} C_i$: the set of *contingencies* to be performed in case of task failures.
  - $T = T_D \cup T_S$
    - T_D: the set of *decision-making tasks* that require information to be performed.
    - T_S: the set of *sensing tasks* that provide information when successfully performed.
- $I = \{I_1, I_2, \ldots, I_l\}$: the set of information produced by sensing tasks and used by decision tasks.
- $Prov : T \rightarrow \mathcal{P}(I)$: the information provision function mapping (sensing) tasks to the set of information provided by successfully completing the (sensing) task.
- $Req : T \rightarrow \mathcal{P}(I)$: the information requirement function mapping (decision-making) tasks to the set of information required to perform the (decision-making) task.
- $Cap : A \times T \rightarrow [0, 1]$: the capability function indicating how well actors perform tasks.
- $Fail : A \times T \rightarrow [0, 1]$: the failure function indicating the probability actors will fail at performing tasks when attempted.
- G: the directed graph with actors as vertices and directed edges indicating possible communication paths between actors.
- $speed_d$: the rate at which an actor can make a decision.
- $speed_c$: the speed of communication.
- M: the assignment matrix of primary tasks and contingencies to actors. Each primary task and contingency must be assigned to exactly one actor.
- d: the deadline by which time all decisions must be made in order for the organization to succeed.

For each primary task $t_i \in T_P$, there exist 0 or more contingencies, $C_i = \{c_i^1, c_i^2, \ldots, c_i^{k_i}\}$. The contingencies are pre-determined backup tasks that are invoked in case of task failure, and are ordered by preference. Hence contingency c_i^1 must be performed if primary task t_i fails, and contingency c_i^2 must be performed if contingency c_i^1 fails, and so on. The set of all contingency tasks is written $T_C = \bigcup_{t_i \in T_P} C_i$.

3.1 An Organization Model

The directed graph G in the specification of the organization describes the structural communication links that exist between members of the organization. The vertices of G are the actors in A. A directed edge from $a_i \in A$ to $a_j \in A$ indicates that a_i can transmit information to a_j. A path through G must exist from one actor to another when the first supplies information to the second, i.e., a path must exist from two actors a_i and a_j if $M(a_i, t) = 1$ and $M(a_j, t') = 1$ and $Prov(t) \cap Req(t') \neq \emptyset$. Communication will actually occur on the edges of G if it falls on a path required for delivering information.

Notice that tasks in T_C may not actually be performed, hence edges in G that only transmit information for these tasks may not actually be used. Moreover, even those edges that are on paths required for tasks in T_P may not be used if the actor performing the task fails, since a contingency would then be invoked. Hence we distinguish between two graphs, G and $\bar{G}$. We refer to G as the potential structure graph, since it must contain all the edges that could be required for any possible combination of tasks and contingencies. $\bar{G}$, on the other hand, is called the *instantiated structure* and only contains those edges that are actually being used given the current set of tasks and contingencies.

Human cognitive limitations restrict the number of contacts a person can effectively handle. We model this as constraints on the potential structure graph G. In particular, we bound the in- and out-degrees of the actors in G: $\forall a \in A$, $indegree(A) \leq max_{in}$ and $outdegree(A) \leq max_{out}$.

3.2 Execution

The actors attempt to perform primary sensing tasks assigned to them in M. For any primary task failure, contingencies are invoked as described in section 3. If an actor a succeeds at a sensing task t_s (whether it is a primary task or contingency), the actor gains information $Prov(t_s) \subseteq I$. This information has an associated quality which we denote by $Qual : I \rightarrow [0, 1]$. For all $I_j \in Prov(t_s)$, we let

$$Qual(I_j) = Cap(a, t_s) \in [0, 1] \tag{1}$$

The actor then transmits the newly learned information to any neighbors as defined in G. These neighbors store the information in their personal knowledge bases and also in turn propagate the information to their neighbors.

When an actor assigned a decision-making task gains all the information required to make the decision, either from other actors or by performing the sensing tasks itself, it attempts to perform the decision (which can fail). If the actor succeeds, the decision is made with a quality that depends both on the capability of the decision-making actor and the quality of the provided information, and the organization gets reward for making the decision. This reward is denoted $Reward : T_P \cap T_D \rightarrow [0, 1]$. For a decision-making task t_d successfully performed by actor a, if $t_d = t_i \in T_P$ or $\exists t_i \in T_D$ with $t_d = c_i^r \in T_C$, reward is given by

$$Reward(t_i) = Cap(a, t_d) \left(\sum_{I_j \in Req(t_d)} Qual(I_j) \right) \tag{2}$$

where $Qual(I_j)$ is defined above in equation 1. The total reward earned by the organization will be one measure of organizational performance, as described next.

3.3 Objective Function

The "performance" of an organization is complex and multi-attributed. In this work, we focus on three specific measures.

- *Success Rate* This is a measure of how well the organization handles individual failure and is calculated as the fraction of the time the organization makes all of the decisions represented in T_D before the deadline d.
- *Reward* This is a measure of how well the organization makes decisions when it succeeds, and is calculated:

$$\sum_{t_d \in T_D \cap T_P} Reward(t_d)$$

  where $Reward(t_d)$ is given by equation 2 in section 3.
- *Speed* This is a measure of the organization's efficiency and is calculated as the difference between the deadline time d and the time at which the last task finishes execution.

The overall objective function used for performance is a weighted sum of these three metrics.

4. EXPERIMENTAL SETUP

We evaluated a large number of organizations with a variety of organizational structures. The basic experimental setup was as follows:

- 20 human actors.
- 44 total primary tasks and contingencies.
  - 4 decision tasks, each requiring information provided by 3 distinct sensing tasks.
  - Each decision task had 1 contingency.
  - Each sensing task had 2 contingencies.
- Performance function: each metric (success rate, reward, and speed) was normalized prior to weighting. The weights were:
  - Success rate weight = 5
  - Reward weight = 1
  - Speed weight = 1

We tested 9 types of organizational structures. These 9 types of structures can be grouped into 4 broad classes:

- Ring. Actors form a a singly linked cycle. If actors can link to more than one actor (i.e., $max_{out} > 1$), actors form at regular intervals across the ring to minimize the average path length to every actor.
- Regular hierarchy. Actors form a full n-ary rooted tree, where n is the span of control. We tested hierarchies with three spans of control:
  - RH3: regular hierarchy with span of control of 3.
  - RH4: regular hierarchy with span of control of 4.
  - RH5: regular hierarchy with span of control of 5.

  Every actor in a regular hierarchy has one outgoing link and a fixed number of incoming links, so this structure is invariant to changes in max_{out} and max_{in}. Note, however, that max_{in} must be greater than or equal to the span of control for a regular hierarchy to be allowed.
- Scale free network. These were generated according to [2]. A small initial set of actors were chosen and the remaining actors were added sequentially, with each adding max_{out} directed links to the actors already in the graph. Link formation was done preferentially to actors with higher connectivity. No actor was allowed to have more than max_{in} incoming links.
  - SF: linking preference was proportional to the in-degree of the target actor.
  - SFpreR1: each actor in the initial set added an edge at uniformly at random to another actor in the initial set before generation began. Preferential linking was by in-degree.
  - SFB: linking preference was proportional to the total degree (in-degree + out-degree) of the target actor
  - SFBpreR1: each actor in the initial set added an edge at uniformly at random to another actor in the initial set before generation began. Preferential linking was by total degree.
- Random graph (Rand). max_{out} links were added randomly from each actor to other actors. No actor was allowed to have more than max_{in} incoming links.

4.1 Baseline Performance

In the baseline configuration, $max_{out} = 1$ and $max_{in} = 4$. Note that this meant that actors in ring structures did not have any links across the ring. In addition RH5 could not be used in the baseline configuration since actors in RH5 must have 5 incoming links, which exceeds the constraint on max_{in}.

Figures 2 – 4 show organizational performance as described in section 3.3. Figure 2 shows the success rate component, Figure 3 shows the reward component, and Figure 4 shows the speed component. Baseline performance is depicted by black columns labeled "No SPAs".

Observe that the regular hierarchies show the highest success rates in Figure 2. This is because there is a high congruence between hierarchical structure and the decision making problem we are considering: actors lower in the hierarchy perform sensing tasks, and they transmit information upward to decision-making actors. The structure of the organization naturally constrains the flow of information to the actors needing that information. The root actor will eventually have all information gained by actors in the organization, and is thus well placed to make decisions or to perform contingencies for decision-makers lower in the hierarchy.

In contrast, ring structures show the lowest success rate. This is because of the lack of congruence between the ring structure and the problem. Because the ring structure is strongly connected, all actors eventually gain any information gained by any actor. However, there is no structural force to encourage the specialization of actor, and so many actors overload by attempting to simultaneously perform sensing contingencies and make decisions.

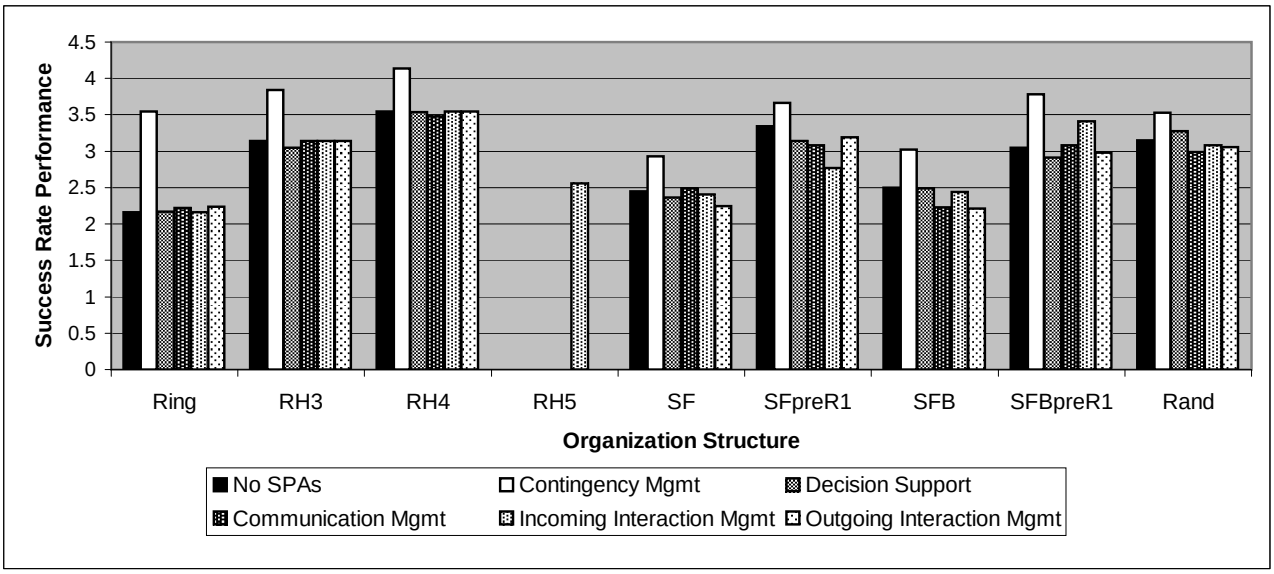

Figure 2: Success rate contribution to performance.

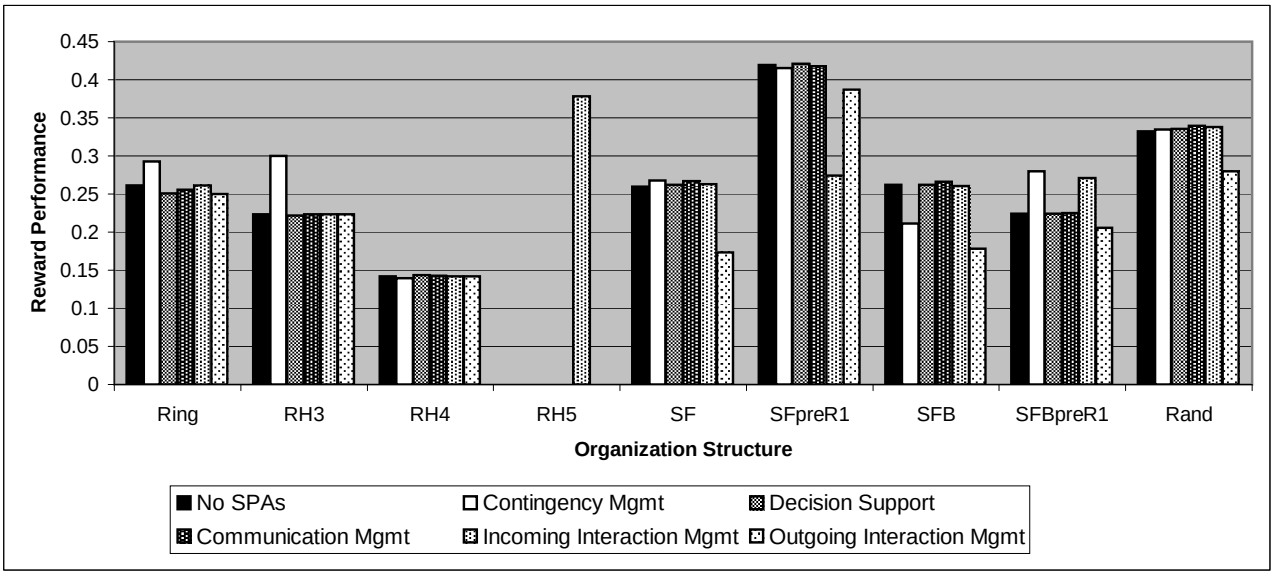

Figure 3: Reward contribution to performance.

Ring structures also show the lowest speed in Figure 4. This is because actors are only allowed a single outgoing link. Thus there are no edges crossing the cycle. As a result, the diameter of the ring structure is linear in the number of actors, while it is logarithm in the number of actors for the other structure types.

Results presented in the next section will detail how performance changes in the presence of SPAs.

5. MODELING PERSONAL ASSISTANTS AND RESULTS

The capabilities of SPAs are generally being designed to overcome perceived cognitive limitations of humans that are thought to limit the performance of an organization[22, 23, 4]. In this section, we describe four such limitations and the models of SPA capabilities — contingency management, decision support, communication management, and interactor interaction management for information sharing — that might overcome these limitations. We also present experimental results showing the effect of these capabilities on organizational performance in figures 2 – 4.

Many other SPA capabilities (and corresponding cognitive limits) might have been modeled. We focused on this initial set because there was active research in the field on developing these capabilities. Moreover, we selected SPA capabilities that appeared most suited to the special purpose organizations that are the focus of this paper. Future work will expand the scope of SPA capabilities, including to those where there is not yet active research.

5.1 Managing Task Contingencies

An SPA may manage contingencies in order to prevent its actor from being overloaded. Instead of invoking contingencies only when a domain-level failure is suffered, the SPA may monitor the actor's current status and workload and automatically invoke contingencies for any tasks that would overload the actor. Similar approaches have been developed or proposed for SPAs in other environments[7, 15]. Intuitively, these SPA capabilities should make the organization more robust to individual failure. Moreover, we hypothesize that it will be possible for the organization to arrange itself such that more capable team members will be involved in more contingencies, since their task performance provides the most reward to the whole organization. Managing contingencies or assigning roles has been a key area of research, but this is the first work that attempts to quantify the benefit of such a capability on an organization and understand how the organization may change to leverage this capability.

The results of adding contingency management capabilities to the simulated organizations are shown in figures 2 – 4 in the white columns labeled "Contingency Mgmt". From Figure 2, it is clear that contingency management greatly improved the success rate for all tested organization structures. It was particularly effective in improving the success rate of the ring structure, which is especially prone to actor overload: the success rate of the ring structure improved by 64%, while the success rate of RH4 improved by only by only 16%. This large gain translated into an overall gain in performance of 45% for the ring structure, against an average performance gain of 17% for all structures.

As shown in Figure 3, the addition of SPA-managed contingencies also improved the reward obtained by some of the organizations, in accordance with our hypothesis. For example, reward increased by 24% for SFBpreR1 and 34% for RH3. The only structure that lost reward was SFB, which saw reward decrease by 20%.

5.2 Decision Support

As introduced above, a key cognitive constraint on humans in an organization is the number of decisions that can be effectively made in a limited amount of time. SPAs could relax this constraint in a variety of ways, e.g., taking over routine tasks to provide more time for "decisions"[18, 20] or collating and presenting information in a way that speeds up the actual decision-making process[15]. Without reference to specifically how it is done, in the computational model of the organization, we simply allow a person to effectively make more decisions in the same period of time, if they have access to SPA technology, by doubling $speed_d$, the speed of making decisions.

The performance of organizations with this capability is shown in figures 2 – 4 in the columns labeled "Decision Support". We expected that this capability would impact the success rate and the speed of execution, It would affect the success rate because each decision would have execute more quickly, thereby reducing the amount of time that the actor may be overloaded. It would also increase the speed of execution directly. Both these factors turned out not to have noticeable impacts of performance because the decision duration was already quite low, especially in comparison to the deadline (which was used to normalize the speed metric). When modeling other problems this capability may yet prove to be significant and merits further study.

5.3 Communication Management

Wired and wireless networks upon which much communication in an organization travels is amazingly fast in contrast to human communication speeds. However, in most cases, people are still required to input information and subsequently process received information. The input and output time is subject to human limitations and is fast becoming (if it is not already) the bottleneck in intra-organization communication, and could be alleviated by SPAs.

We modeled this capability by doubling the communication speed in the organization. The effects on performance can be seen in figures 2 – 4 in the columns labeled "Communication Mgmt". This capability had little effect on either success rate or reward. As shown in Figure 4, it also had only small but noticeable effect on the speed of most organizations, increasing average speed by 8%, because they already displayed efficient communication. As expected, however, this capability had a substantial impact on ring-structured organizations, with a speedup of 29%.

5.4 Managing Interactions for Information Sharing

The rate at which decision-makers in an organization can effectively make decisions is limited by two key factors: (i) their ability to get the appropriate information to make required decisions and (ii) their innate processing speed for making those decisions (see section 5.2). The cognitive load of managing incoming information from others in the organization and directing outgoing information to others is a constraint that may be relaxed by SPA technology[15, 17]. Specifically, a decision-maker may be able to handle input

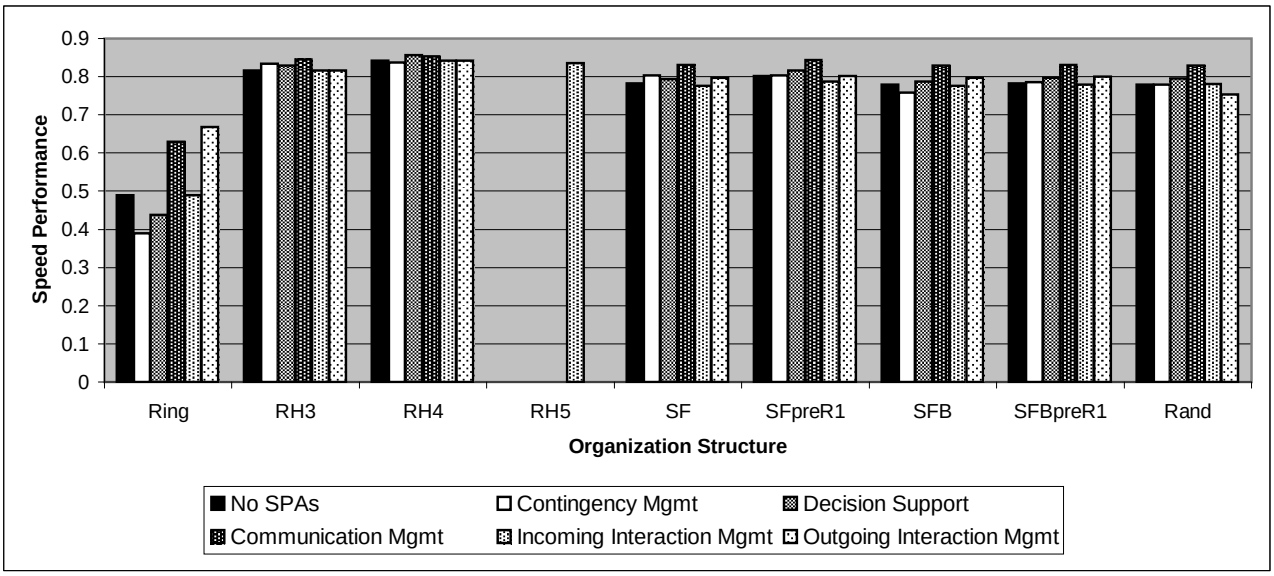

Figure 4: Speed contribution to performance.

from a greater number of members of an organization and hence, either get more direct access to that information or make more decisions. For example, the CEO of an organization needs information from all over parts of the organization to make key strategic decisions. However, it is cognitively and organizationally infeasible for a person to directly receive input from a large number of people[5]. Hence, in the case of the CEO, that information must pass through a small number of department heads, both delaying the information and potentially distorting it. Conversely, suppliers of information are limited in how many others they can provide information to, requiring organizational structures that channel information and introduce delays and distortion. SPA technology could allow information suppliers to more directly communicate with the decision-makers requiring their information.

The effect of managing interactions was modeled by changing the values of max_{in} and max_{out}. max_{in} was increased from 1 to 2, and max_{out} was increased from 4 to 5. We considered the two effects separately, with the resulting performance shown in figures 2 – 4 by the columns marked "Incoming Interaction Mgmt" and "Outgoing Interaction Mgmt", respectively.

It is important to note that unlike the other capabilities tested, interaction management related directly to the organizational structure by allowing actors to form more links. Some structural classes were completely unaffected by such changes. For example, in a regular hierarchy, each actor has a single outgoing link, and a fixed number of incoming links (bounded above by max_{out}), and so changing max_{out} had no effect on regular hierarchy performance. Similarly, increasing max_{in} had no effect on the ring structure performance. However, increasing max_{out} allowed actors in the ring structure to add links crossing the cycle, which reduced the diameter of the graph by half. This translated into impressive gains in speed of 36%, as shown in Figure 4.

The increase of max_{in} from 4 to 5 allowed us to test a new regular hierarchy, RH5, in which actors had a span of control of 5. This structure had a poor success rate, lower than that of both RH3 and RH4, as shown in Figure 2. This is because the hierarchy of RH5 was too shallow; there were too few interior actors to make all the decisions and so they are being overloaded.

5.5 Multiple Capabilities

We also tested the organizations with different combinations of SPA capabilities. Because there are four capabilities (those described in subsections 5.1 – 5.4), with information sharing including two distinct effects, there are a total of 32 distinct combinations of capabilities. Figure 5 shows the performance breakdowns of the SFpreR1 scale free structure for all combinations of our SPA capabilities; the number of capabilities in the combination increases along the x-axis, from no capabilities on the left to all capabilities on the right. It is clear that not all combinations of capabilities have equal effects on performance, and many (including the combination of all capabilities) even negatively impact performance. This emphasizes the need to carefully select SPA capabilities to fit the organization.

Several of the effects seen in the individual capability experiments were evident in this experiment as well. For instance, managing contingencies to prevent actor overload provided substantial gains in organizational performance. Also, managing interactions frequently decreased performance by encouraging flatter, bushier structures. The resulting decrease in levels of redundancy that can be exploited through the assignment of contingencies leads to higher chances of actor overload.

Managing contingencies can offset this increase, as shown by the best performing organization using contingency management, communication management, and incoming interaction management. In this case, the increased number of incoming links allow a more capable actors to make decisions, yielding higher rewards. Speed is also increased both directly by communication management, and indirectly because of the bushier structure. This sort of interplay between capabilities is important to take into account when evaluating and designing SPAs.

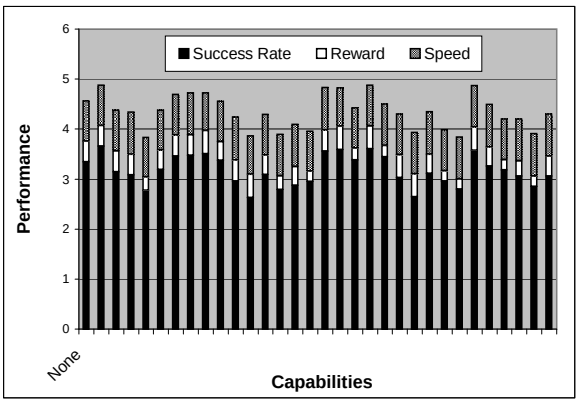

Figure 5: Performance breakdown of organization with scale free structure for all combinations of SPA capabilities.

6. CONCLUSIONS

We have taken an initial step toward identifying the ways in which intelligent personal assistants will impact the performance of human organizations. We have hypothesized a number of possible capabilities of SPAs, evaluated their effect on performance, and shown that the structure of the underlying organization has a substantial effect on the effectiveness of the SPA in improving performance. Our results indicate that SPAs can substantially improve organizational performance by flexibly managing pre-planned contingencies in order to reduce actor overload. However, the effects of the SPAs are far from dramatic and do not impact all structures evenly. Significantly, more work will be required to understand precisely when SPAs are useful. More importantly more analysis should be performed to determine what SPA capabilities might make a dramatic impact.

ABSTRACT

This paper presents a framework for robustly recognizing physical team behaviors by exploiting spatio-temporal patterns. Agent team behaviors in athletic and military domains typically exhibit an observable structure characterized by the relative positions of teammates and external landmarks, such as a team of soldiers ambushing an opponent or a soccer player moving to receive a pass. We demonstrate how complex team relationships that are not easily expressed by region-based heuristics can be modeled from data and domain knowledge in a way that is robust to noise and spatial variation. To represent team behaviors in our domain of MOUT (Military Operations in Urban Terrain) planning, we employ two classes of spatial models: 1) team templates that encode static relationships between team members and external landmarks; and 2) spatially-invariant Hidden Markov Models (HMMs) to represent evolving agent team configurations over time. These two classes of models can be combined to improve recognition accuracy, particularly for behaviors that appear similar in static snapshots. We evaluate our modeling techniques on large urban maps and position traces of two-person human teams performing MOUT behaviors in a customized version of Unreal Tournament (a commercially available first-person shooter game).

1. INTRODUCTION

In certain domains tasks are too complicated to be performed by individual agents and must be achieved through the coordinated efforts of a group of agents over a period of time. To analyze performance of these tasks, we need to extend existing behavior recognition formalisms to accommodate group behaviors. Due to the increase in number of actions generated, assuming that each agent is simultaneously executing actions, team behaviors have a more complicated *temporal* structure than single agent behaviors. However team plans involving physical movement also possess a distinctive *spatial* structure, characterized by the relative positions of teammates and external landmarks, that can be exploited to classify team behaviors. This paper presents a framework for constructing spatio-temporal models to robustly recognize physical team behaviors from position traces of the agents' movement.

We demonstrate our method in the domain of MOUT (Military Operations in Urban Terrain) team planning to recognize military team behaviors customarily performed by human soldiers while moving through an urban environment. Examples of team behaviors include building entry, perimeter guarding, opponent flanking, and formation movement, such as stacked and bounding overwatch.[1] Although this paper focuses on MOUT team behaviors, our algorithms are also applicable for recognizing team behaviors in other military, robotic, and athletic domains.

In this paper, we present two classes of spatial models and illustrate how they can be used to robustly recognize team behaviors in the presence of spatial variations, noise, clutter, and human variability in behavior execution.

team templates: models encoding static spatial relationships between team members and external landmarks. These models are composed of the relative positions of map entities and can be generalized to different geographic layouts using similarity transforms. To efficiently identify team templates over large map areas without using exhaustive search, we employ an efficient randomized search technique, RANSAC (Random Sampling and Consensus) [4].

spatially-invariant HMMs: a set of Hidden Markov Model classifiers applied over short overlapping time windows to identify temporal patterns in agent team configura-

[1]See Section 3 for more details on MOUT team behaviors

tions. By representing the agents' positions in a canonical reference frame, the classifier is robust to certain spatial variations.

We evaluate our modeling and recognition techniques on two different types of data: 1) large urban simulation battle maps and 2) position traces of two-person human teams performing designated sequences of MOUT behaviors in a customized version of Unreal Tournament (a commercially available first-person shooter game).

2. RELATED WORK

Previous work on team behavior recognition has been primarily evaluated within athletic domains, including American football [6], basketball [7], and Robocup soccer simulations [14, 15]. Recognition for military air-combat scenarios has been examined in the context of event tracking [18] and teammate monitoring [8], Finally, a general framework for multi-agent plan recognition (Hierarchical Multiagent Markov Processes) [16] has been demonstrated for a single pair of humans moving around a laboratory.

The research described in this paper focuses on the pattern classification aspect of team behavior recognition—how to systematically model and identify complex spatio-temporal patterns that are created by agent team behaviors. Most previous research in the area of team behavior recognition either leverages the existence of domain-specific features to classify spatial patterns [6, 7] or relies on identifying temporal patterns in behavior sequences [18, 8, 16], largely ignoring implicit spatial information. For many athletic behaviors, researchers have been able to exploit simple region-based or distance-based heuristics to build accurate, but domain-specific classifiers. Based on the premise that all behaviors always occur on the same playing field with a known number of entities, it is often possible to discretize the playing field into grids [15] or typed regions (goal, scrimmage line) [6] that can be used to classify player actions. Prior work on spatial representations for the MOUT domain [2, 11] only addresses the problem of behavior generation, not recognition.

3. MOUT DOMAIN

MOUT (Military Operations in Urban Terrain) scenarios involve moving teams of soldiers and vehicles through heavily-cluttered urban areas to accomplish high-level strategic objectives. A common task performed by human soldiers is building clearing, during which a firing-team of soldiers must enter a building and clear it of enemy occupants and hazards; the challenge is to explore unknown areas while constantly remaining in a defensible position against enemy attack. To achieve this, soldiers move through the urban terrain using set procedures that maintain a defensive position while still propelling the team forward.

The cognitive task analysis of building clearing given in [12] emphasizes the importance of spatial cues in the soldiers' decision making process. Features such as proximity to other buildings, opportunities for cover, open spaces, windows in the building, street layout, fortifications, height of buildings, locations of stairways, obstacles, potential booby-traps, and doors, are critical cues that expert human decision-makers must take into account while performing the task. Certain team behaviors are triggered by the spatial characteristics

Figure 1: MOUT scenario in customized Unreal Tournament environment from spectator viewpoint. A pair of human players control soldiers A and B as they execute the procedure for traversing a T-shaped intersection. The bot models and animations were modified to conform to the appearance of real human soldiers rather than the larger-than-life UT fantasy fighter models.

of the terrain; for instance, firing-teams have special procedures for moving through L-shaped and T-shaped street intersections. In these cases, we hypothesize that static spatial configurations, such as the ones described in our team template models, are highly predictive of the teams' actions.

However, there are some cases, particularly for smaller two-soldier subteams, in which static spatial configurations, by themselves, lack predictive power. The second part of the paper focuses on the three such behaviors, stacked movement, bounding overwatch, and buttonhook entry commonly used during the building clearing task. These behaviors are difficult to identify solely on the basis of static snapshots due to their spatial similarities (see Figure 3).

During stacked movement the purpose is to move the team in such a way that their gun angles completely span all possible areas of approach; the team moves slowly and in synchrony. For moving through open areas or intersections, this approach is less feasible since it's difficult to cover all possible threatened areas. In this case, the bounding overwatch behavior is used; one soldier moves forward while the other remains stationary. The buttonhook entry is similar to bounding overwatch; one soldier moves through the doorway hugging the wall while the other soldier waits and guards. After the entry is clear, the second soldier moves through the doorway hugging the opposite wall. To recognize these behaviors, our classifier needs to exploit the temporal information in behavior sequences in conjunction with spatial information on the position and velocities of team members in a way that is robust to geographic variations that modify the execution of the behavior.

4. METHODS

In this section, we present our methodology for developing spatial models and using them to classify instances of team behavior. Section 4.1 discusses the representation and

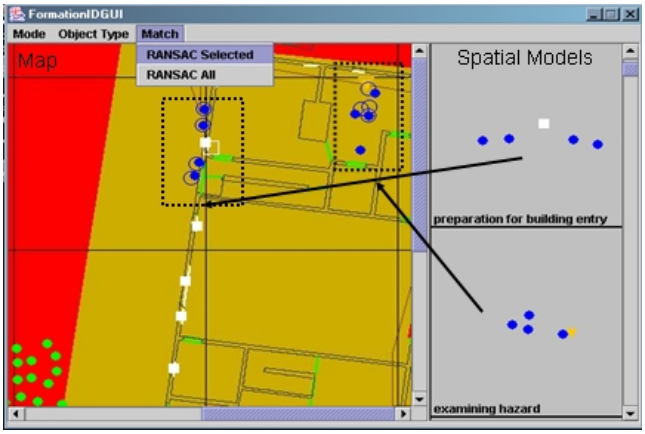

Figure 2: Spatial model authoring and matching system. The library of previously created spatial models are shown to the right of the screen; the left side of the GUI displays an annotated map to be analyzed. A fire team of soldiers (blue circles) examining a hazard (orange inverted triangle) are displayed on the map; a second fire team prepares to enter the building through the door (marked by the white rectangle). Our matching technique successfully associates both groupings of soldiers with the correct spatial models; hollow circles and rectangles show the locations of the entities as predicted by model projection.

authoring of team templates to encode static spatial relationships between team members and external landmarks. Section 4.2 provides an overview of the randomized search technique, RANSAC (Random Sampling and Consensus) that we use to efficiently and robustly identify these templates over large simulation map areas without resorting to exhaustive search. In Section 4.4 we describe the Unreal Tournament simulation environment that we use to collect data from pairs of human subjects performing the three types of statically-similar team behaviors (bounding overwatch, buttonhook entry, stacked movement). Finally, Section 4.5 presents our procedure for converting agent position traces into the canonical representation used by our Hidden Markov Model classifiers (Section 4.6).

4.1 Team Template Representation

To model team behaviors, we developed a tool that enables the author to describe behaviors by designating a set of characteristic spatial relationships that commonly occur during the execution of a behavior. Once a library of spatial models has been constructed, they can be used to classify formations of MOUT entities on a 2D annotated urban map. If labeled training data of team behaviors exists, these team templates could potentially be learned from data using a supervised classifier; however all the experiments described in this paper were created with the authoring interface shown in Figure 2.

Each team template contains the following attributes:

behavior name: Behaviors are represented by collections of spatial models; however no particular temporal structure, or execution order, is attached to the collection. Each spatial model can only belong to a single behavior; we do not include models which appear in a large set of behaviors since they are unlikely to help in discriminating between multiple behaviors.

spatial position of relevant entities: Entities are represented by a single (x,y) coordinate of their centroid; larger entities are represented as groups of points connected by visibility constraints.

entity type: For our library of MOUT behaviors, we designated eleven types of entities including person (unknown), civilian, teammate, opponent, hard cover, soft cover, empty area, windows, intersections, doorways, hazards, and objectives.

One consideration in developing models is generalization—how well do models developed for one scenario match behaviors executed in a different spatial layout? Without generalization it becomes impractical to exhaustively enumerate all possible spatial relationships that can occur across different maps. To solve this problem, we define a set of legal transforms to project models to new spatial layouts and score the quality of the match. We define the set of legal transforms to be the class of similarity transforms (rotation, translation, and scaling); these can be parameterized in homogeneous coordinates as follows:

$$\mathbf{T} = \begin{bmatrix} s\cos(\theta) & s\sin(\theta) & x \\ -s\sin(\theta) & s\cos(\theta) & y \\ 0 & 0 & 1 \end{bmatrix}$$

where θ is the angle of rotation, s is a scale factor, x is the x-translation, and y is the y-translation. This formulation can easily be extended to model three dimensional transforms by increasing the matrix to 4×4. The next section describes a robust and efficient technique for searching the space of possible transforms.

4.2 Efficient Template Matching

Given a set of spatial models and valid transforms, the problem of determining which spatial models are applicable to the current map can be solved by searching the space of potential transforms and models to find all the combinations of model plus transform that result in a match of sufficient quality. A commonly-used approach is exhaustive template matching [1]. Each template is applied to all possible locations in the map using a sliding window; the distance function is calculated over the window area and those matches that score under the threshold are retained. This process is exhaustively repeated for a range of scales and rotations, over all models in the library. Unfortunately this process is time consuming, scales poorly to higher dimensional transforms, and is sensitive to noise, occlusion and misalignment.

Instead, we employ a statistically-robust technique, Random Sampling and Consensus (RANSAC) [4], to efficiently sample the space of transforms using hypotheses generated from minimal sample sets of point correspondences. The algorithm can be summarized as follows:

hypothesis generation: entities are drawn uniformly and at random from the annotated map and associated with randomly-selected entities of the same type in the model. Two pairs of corresponding entities are sufficient to uniquely specify a transform hypothesis. This data-driven method of generating hypotheses is much more efficient than uniformly sampling the space

of possible transforms or exhaustively searching a discretization of the transform space.

hypothesis testing: Given a transform hypothesis, we project all of the entities in the model to the coordinate frame of the map and assess the quality of the match based on both spatial similarity and type matching. This gives us the likelihood that the given hypothesis could have generated the observed data in the map.

For each spatial model, we use RANSAC to randomly generate and test a large number of plausible transforms and select those hypotheses (a combination of a model and a valid transform) with match quality better than a specified threshold.

Since our spatial transforms have four degrees of freedom, they can be fully specified by two pairs of point correspondences. First, we randomly select two entities from the model under consideration; then based on the types of the entities (e.g., civilians, hard cover, hazard) we randomly select candidate entities on the map with compatible object types. The positions of these entities is used as the minimal set to generate a transform hypothesis as follows.

Given the minimal set $\{(x_1, y_1), (x_2, y_2)\}$ from the model and the corresponding set of points $\{(X_1, Y_1), (X_2, Y_2)\}$ from the map, we generate a third virtual pair of correspondences $(x_3, y_3) \mapsto (X_3, Y_3)$ where

$$\begin{aligned} x_3 &= x_1 + y_2 - y_1 \\ y_3 &= y_1 + x_1 - x_2 \\ X_3 &= X_1 + Y_2 - Y_1 \\ Y_3 &= Y_1 + X_1 - X_2 \end{aligned}$$

From these three correspondences, we can directly recover $\mathbf{T}$ using matrix inversion.

$$\begin{bmatrix} t_{11} & t_{12} & t_{13} \\ t_{21} & t_{22} & t_{23} \\ t_{31} & t_{32} & t_{33} \end{bmatrix} = \begin{bmatrix} X_1 & X_2 & X_3 \\ Y_1 & Y_2 & Y_3 \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ 1 & 1 & 1 \end{bmatrix}^{-1}$$

This is a solution to a general affine transform [5] given three pairs of point correspondences, however $\mathbf{T}$ is guaranteed to be a valid, orientation-preserving similarity transform due to our construction of the third point.

To score a hypotheses, we transform the location of every entity in the model to the map using the transform $\mathbf{T}$. Each model entity contributes a positive vote for the given hypothesis if the distance from its predicted location to the closest map entity of compatible type falls below a specified threshold. The quality of a hypothesis is defined as the normalized sum of these individual votes.

Since RANSAC stochastically searches the space of possible transforms it is not guaranteed to find the best match. However the following formula can be used to determine how many iterations are necessary to achieve the best match with a specified probability of success [19]:

$$m = \left\lceil \frac{\log(1-P)}{\log[1-(1-\epsilon)^s]} \right\rceil$$

P is the target probability (e.g., $P = 0.99$ means the best match is found 99% of the time). s is the number of elements required to define the minimal set ($s = 2$ since a similarity transform requires 2 pairs of point correspondences). ϵ is the expected fraction of outliers in the data set. In traditional RANSAC applications ϵ is typically only about 0.1 (10% of the points are expected to be invalid). For our application, the fraction of outliers refers to the number of map annotations that do not match a single model; since each map actually contains multiple models in addition to entities that do not match any model the fraction of expected outliers is approximately 0.95. From the formula above, this indicates that the number of RANSAC iterations required to reliably find the best match is 1840. Note that executing the given number of iterations does not guarantee a particular level of classification accuracy; it merely ensures that there is only a 0.01% probability that a similarity transform exists that would achieve a higher score than the one returned by RANSAC. In Section 5.1, we present classification results for identifying team behaviors from 2D annotated maps of simulated urban layouts using our team template model and RANSAC.

4.3 Spatio-temporal Classification

There are some cases, particularly for smaller two-soldier subteams, in which static spatial configurations, by themselves, lack predictive power. To recognize these behaviors, our classifiers need to exploit the *temporal* information in behavior sequences in conjunction with spatial information on the position and velocities of team members. Since team behaviors can be executed in a variety of terrains, the classifiers must be robust to deviations in behavior execution caused by the team's response to local terrain features. However, arbitrarily introducing similarity transforms in the middle of a behavior sequence can destroy the spatio-temporal pattern created by the team's movements. To address the problem, we developed spatially-invariant classifiers, by transforming our position data into a canonical reference frame defined by the team's motion, and applying a set of Hidden Markov Model classifiers to recognize three statically similar team behaviors (bounding overwatch, buttonhook entry, stacked movement).

4.4 Human Data Collection

To evaluate our spatio-temporal classifiers, we collected data from a pair of human players using our modified Unreal Tournament game interface to manipulate "bots" through a small urban layout while performing a particular sequence of team behaviors (see Figure 1). Note that the subjects were not playing Unreal Tournament, but using Unreal Tournament to execute sequences of commonly used MOUT team maneuvers. To directly monitor the performance of human players, we customized Unreal Tournament (UT) using the game development language *Unrealscript*. Many of the original UT game classes were written in *Unrealscript* and thus can be directly subclassed to produce modified versions of the game (known as mods); for example, Gamebots [9] is an example of a mod that allows external programs to control game characters using network sockets.

We developed our own `TrainingBot` mod that allows us to save the state of all the bots in the scenario; currently we save each player's ID number, position $(x, y.z)$, and rotation (θ,ϕ) every 0.15 seconds. This information is useful for both offline behavior analysis and for a separate replay mode that allows us to create bots that follow the paths recorded by the original players.

4.5 Canonical Representation

Due to the continuous nature of the domain, automatically determining the exact transition points between team behaviors is a difficult problem. While approaching and entering buildings, the players continue moving their bots, changing team behaviors as appropriate for the physical layout. We address this issue by dividing the traces into short, overlapping time windows during which we assume that a single behavior is dominant; these windows are classified independently as described in Section 4.6. To recognize team behaviors performed in different physical layouts, it is important for our classifier to be rotationally- and translationally-invariant; we achieve this by transforming the data in each window into a canonical coordinate frame as described below.

More formally, we define:

- $a \in 1, \ldots, A$ is an index over A agents;
- j is an index over W overlapping windows;
- $t \in 1, \ldots, T$ is an index over the T frames in a given window;
- $\mathbf{x}_{a,j,t}$ is the vector containing the (x, y) position of agent a at frame t in window j.

The centroid of the positions of the agents in any given frame can be calculated as:

$$\mathbf{C}_{j,t} = \frac{1}{A} \sum_{\forall a} \mathbf{x}_{a,j,t}.$$

We describe the configuration of the agent team at any given time relative to this centroid to achieve translation invariance. However, rather than rotating each frame independently we define a shared canonical orientation for all of the frames in a window. This is important because it allows us to distinguish between similar formations moving in different directions (e.g., agents moving line abreast vs. single file). One standard technique for defining a canonical orientation is to use the principal axis of the data points for that window, which can be calculated using principal component analysis (PCA). However for efficiency we have empirically determined that we can achieve similar results by defining the canonical orientation as the displacement of the team centroid over the window: $\mathbf{d}_j = \mathbf{C}_{j,T} - \mathbf{C}_{j,1}$.

We rotate all of the data in each window so as to align its canonical orientation with the x-axis, using the rotation matrix $\mathbf{R}_j$. Thus the canonical coordinates, $\mathbf{x}'$, can be calculated as follows: $\mathbf{x}'_{a,j,t} \equiv \mathbf{R}_j \mathbf{x}_{a,j,t} - \mathbf{c}_{j,t}$. Our current recognition technique (described in Section 4.6) also relies on observations of agents' velocity as a feature which we locally compute as: $\mathbf{v}_{a,j,t} \equiv ||x'_{a,j,t+1} - x'_{a,j,t}||$.

4.6 HMM Classification

For each canonically-transformed window in our trace, our goal is to select the best behavior model. We perform this classification task by developing a set of hidden Markov models (HMMs), one for each behavior b, and selecting the model with the highest log-likelihood of generating the observed data. Our models ($\{\lambda_b\}$) are parameterized by the following:

- N, the number of hidden states for the behavior;
- $\mathbf{A} = \{a_{ij}\}$, the matrix of state transition probabilities, where $a_{ij} = Pr(q_{t+1} = j | q_t = i), \forall i, j$ and q_t denotes the state at frame t;
- $\mathbf{B} = \{b_i(o_t)\}$, where $b_i(o_t) = \mathcal{N}(\mu_i, \Sigma_i)$. The observation space is continuous and approximated by a single multivariate Gaussian distribution with mean, μ_i and a covariance matrix, Σ_i, for each state i;
- $\pi = \{\pi_i\}$, the initial state distribution.

For our problem, given A agents in a team, the observations at time t and window w are the tuple:

$$o_t = (\mathbf{x}'_{1,w,t}, v_{1,w,t}, \ldots, \mathbf{x}'_{A,w,t}, v_{A,w,t}).$$

We determine the structure for each behavior HMM based on our domain knowledge. For instance, the stacked behavior can be described using only two states ($N = 2$), whereas we represent the more complicated bounding overwatch behavior using six states connected in a ring. Each hidden state captures an idealized snapshot of the team formation at some point in time, where the observation tuple (in canonical coordinates) is well modeled by a single Gaussian. Rather than initializing the HMMs with random parameters, we use reasonable starting values. These can be polished using expectation-maximization (EM) [3] on labeled training data.

To determine the probability, $Pr(o_{1\ldots T}|\lambda_b)$, of generating the observed data with the model λ_b, we employ the forward algorithm [13] as implemented in the Hidden Markov Model toolbox [10]. We classify each window segment with the label of the model that generated the highest log-likelihood.

5. RESULTS

We evaluate our methods using two sets of experiments: 1) formation recognition in simulated 2-D overhead maps of urban areas annotated with the location of MOUT entities (see Section 4.1). 2) behavior identification from activity traces of two-person human teams performing sequences of MOUT behaviors (see Section 4.4). The former assesses the accuracy of the RANSAC-based method while the latter examines the performance of spatially-invariant HMMs. The two methods are complementary, and Section 6 discusses strategies for combining them to further improve recognition accuracy.

5.1 Team Template Matching

To test the robustness of our team template matching approach, we add clutter to the maps and distort formations by perturbing the positions of MOUT entities. Figure 5.1 reports the precision (fraction of correctly-classified results) and recall (fraction of formations that were detected) of our classifier under different conditions of clutter and location perturbation. Note that our approach independently matches each template against the data; thus, all matches that exceed the threshold score are reported as detections. The precision/recall curves are generated by varying this threshold parameter. There is no intrinsic restriction against assigning the same map entity to different templates — this enables us to create templates corresponding to a team and its component sub-teams, and to simultaneously recognize both.

In each experiment, we randomly place fifty MOUT formations on the urban map and report the precision and

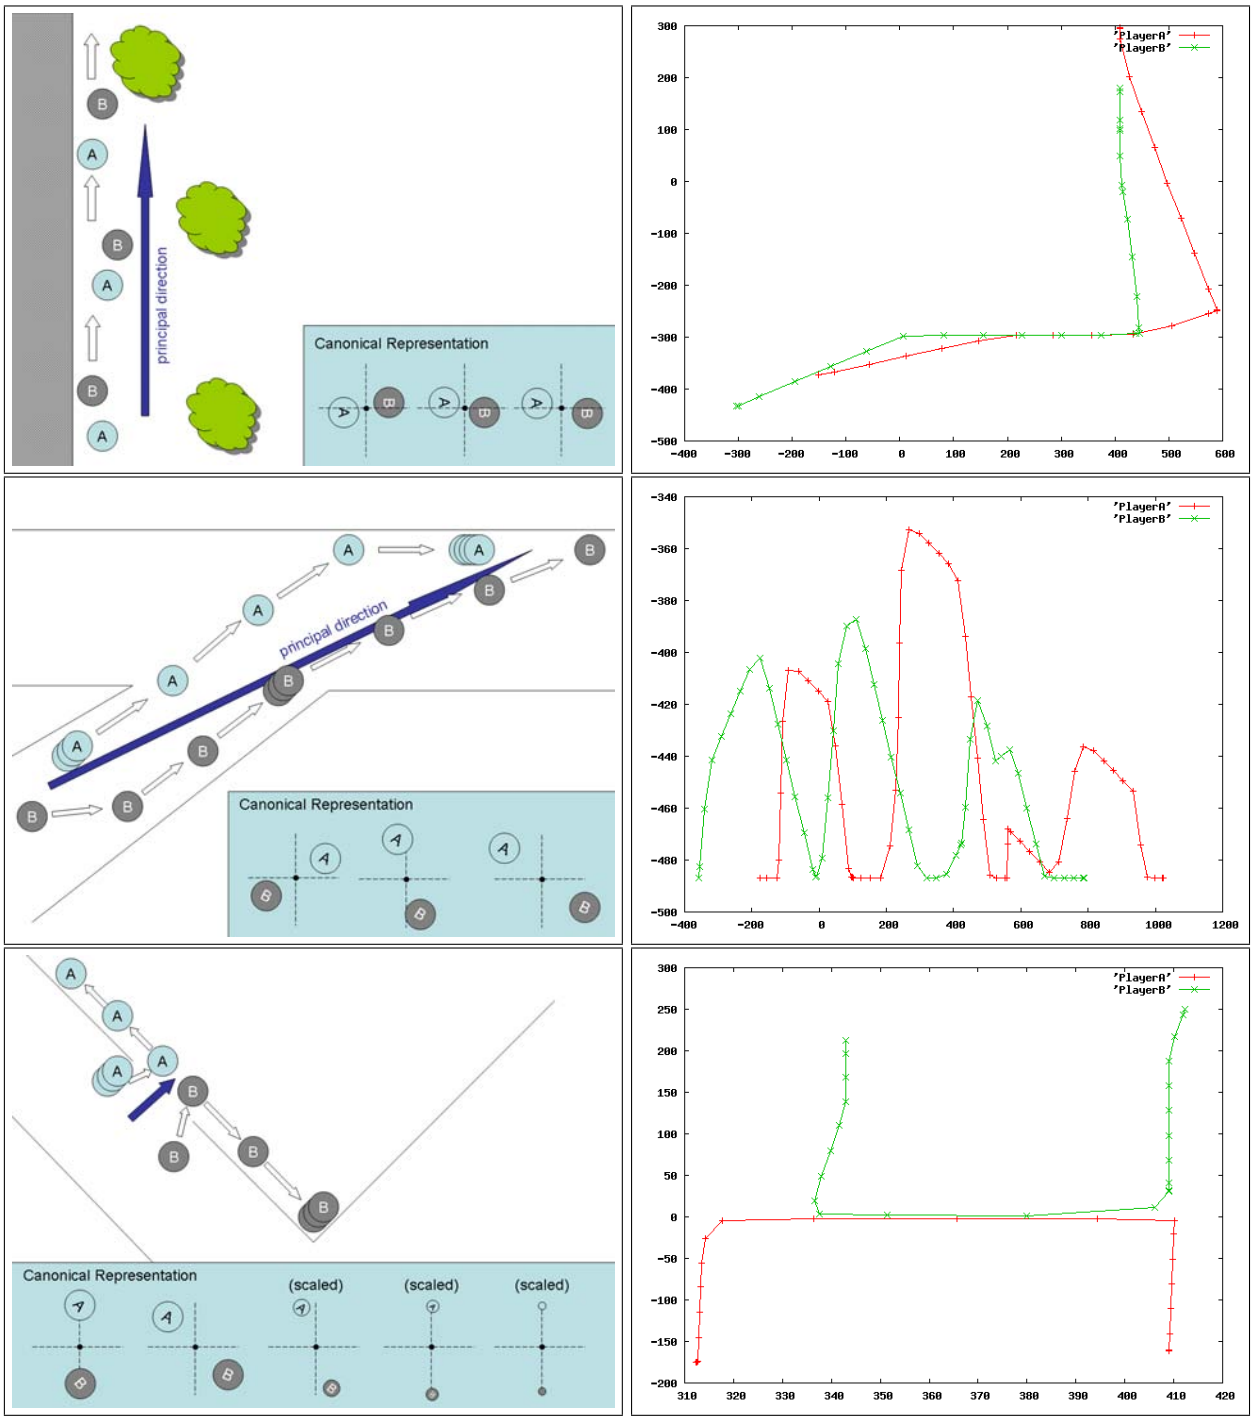

Figure 3: Team Behaviors: Stacked Formation (top), Bounding Overwatch (middle), Buttonhook Entry (bottom). Schematics for each behavior, along with the canonical representation for several frames, are depicted in the left column. A sample raw trace for each behavior is shown in the right column; the coordinates of the axes are in Unreal Tournament length units.

recall averaged over ten RANSAC searches. The left panel of Figure 5.1 shows the effects of adding clutter (spurious MOUT entities of the appropriate type) to the map, without increasing the number of RANSAC iterations. The percentage of clutter is measured against the total number of MOUT entities in the formations on the map (thus 100% clutter denotes a 1:1 ratio between spurious and desired MOUT entities). The results show that, as expected, the RANSAC-based approach is very resistant to the presence of spurious entities on the map, and that precision/recall are both very high even at the extreme clutter levels. The right panel of Figure 5.1 shows precision/recall results for experiments where the locations of each of the MOUT entities were perturbed with iid Gaussian noise. As expected, the performance degrades as noise is added since the spatial configuration of the formation ceases to resemble the formation represented by the idealized model. However, we note that the technique is successful at identifying an acceptable number (80%) of the formations under reasonable noise conditions.

5.2 Spatially-Invariant HMMs

To evaluate our spatio-temporal classification method, we developed HMM models for three behaviors typically employed by two-person firing teams during the building clearing task: stacked movement, bounding overwatch, and buttonhook entry (see Figure 3). Note that these three behaviors look very similar in static snapshots and can only be robustly recognized by observing spatio-temporal traces. Position data was simultaneously recorded from two subjects at 0.15 second intervals using our `TrainingBot` mod (see Section 4.4). Players executed team behaviors in predesignated sequences, transitioning smoothly from one behavior into the next, adapting each behavior as needed to the local physical layout (turning corridors, entering rooms). The traces were divided into overlapping 20 frame (3 second) windows, which were transformed into a canonical coordinate frame as described in Section 4.5 (illustrated in the inset of Figure 3). The window size was empirically selected base on the observed average speed of the MOUT soldiers.

By using real data collected from human players rather than simulated traces, we can evaluate the robustness of our approach to realistic deviations during behavior execution. Figure 3 (right) shows a raw trace for each behavior; note that consecutive executions of the same behavior exhibit significant variation, particularly noticeable in the bounding overwatch behavior. Each behavior was also performed in a variety of local physical layouts. Table 1 presents the classification results (confusion matrix) for the three modeled behaviors; the accuracy of the HMM approach is good, particularly for the stacked formation. Buttonhook entry is sometimes confused with bounding overwatch, as may be expected from similarities in the canonical representation shown in Figure 3.

Table 1: Confusion matrix for HMM behavior classification. The ground truth is given in the left column; the classification result is given in the top row. The spatially-invariant Hidden Markov Model approach achieves good accuracy. Buttonhook entry is often confused with bounding overwatch, as may be expected from similarities in the canonical representation as shown in Figure 3.

	stacked	bounding	buttonhook
stacked	90%	10%	0
bounding	14%	67%	19%
buttonhook	0%	33%	67%

6. DISCUSSION

The two approaches presented in this paper, team templates and spatially-invariant HMMs, are complementary. Team templates are easy to author and can be rapidly executed over large, cluttered maps. Spatially-invariant HMMs are more difficult to design, but are well-suited for classifying statically-indistinguishable behaviors. We believe that combining outputs from both models should lead to improved recognition accuracy. Team templates are effective at determining the spatial context of an observed behavior, enabling improved discrimination between behaviors that display a similar temporal structure. For instance, although a buttonhook entry and a bounding overwatch often appear similar to the spatially-invariant HMM, the presence of context can enable us to disambiguate them since the former behavior is typically performed to enter a door or window, while the latter is used to move the formation down a corridor or street.

We are interested in applying our algorithms to the recognition of large team formations [17]. The efficient team template matching strategy described in the first half of the paper scales well to larger team sizes. Introducing more points into the team template is actually beneficial for two reasons: 1) the minimal set required to calculate the transform is independent of team size; 2) including additional model entities improves the robustness of the matching since a greater number of entities can contribute votes in support of the best hypothesis, and it is less probable that a configuration of spurious entities will be a good match.

In principle, the spatially-invariant HMM approach can also be applied to larger teams; however constructing models for teams with more members can become difficult since having more team members creates many more possible configurations (even in our canonical representation). For our particular domain, separating larger teams (of 8 or 16) into two-person subteams which can be be analyzed separately is a feasible approach. We are investigating strategies for combining multiple classifiers to recognize team behaviors; using repeated executions of static template matching followed by the use of more specialized classifiers designed for detecting particular behaviors. Larger team behaviors would be detected by combining the outputs of specialized classifiers (e.g., detecting invariants) rather than using a single highly-complex classifier.

7. CONCLUSION AND FUTURE WORK

This paper presents two methods for recognizing physical team behaviors from spatio-temporal movement patterns. We demonstrate that our techniques are robust to the effects of local spatial variations, clutter, noise, and human variability during behavior execution. In future work, we are particularly interested in the following problems: 1) incorporating the outputs of our classifiers into a framework for symbolic team plan recognition; 2) evaluating our mod-

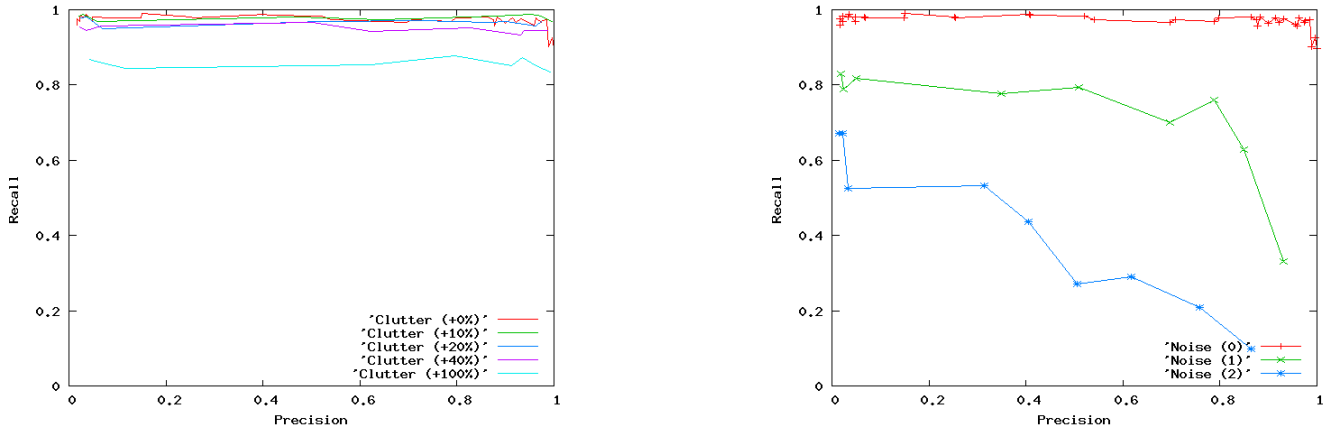

Figure 4: Precision and recall curves for matching team templates using the RANSAC-based method. Fifty formations were placed on an urban map using randomized similarity transforms. Each run employed 100,000 iterations and the precision/recall averaged over 10 trials is shown. The left panel shows the effect of adding spurious MOUT entities (clutter) while maintaining the same number of iterations. The right panel shows the results of distorting observed formations by perturbing the location of each MOUT entity on the map with iid Gaussian noise.

els on MOUT data from human domain experts; and 3) evaluating alternate temporal classifier formalisms.

ABSTRACT
The hard computational problems, such as the traveling salesman problem (TSP), are relevant to many tasks of practical interest, which normally can be well formalized but are difficult to solve. This paper presents an extended multiagent optimization system, called $MAOS_E$, for supporting cooperative problem solving on a virtual landscape and achieving high-quality solution(s) by the self-organization of autonomous entities. The realization of an optimization algorithm then can be described in three parts: a) encode the representation of the problem, which provides the virtual landscape and possible auxiliary knowledge; b) construct the memory elements at the initialization stage; and c) design the *generate-and-test* behavior guided by the law of *socially-biased individual learning*, through tailoring to the domain structure. The implementation is demonstrated on the TSP in details. The extensive experimental results on real-world instances in TSPLIB show its efficiency as comparing to other algorithms.

1. INTRODUCTION
The hard computational problems are ubiquitous in scientific and engineering fields [26], which often are conceptually simple and can be cast as a search through a space of alternatives [24][37].

The landscape paradigm originated in theoretical biology is used for search in general [25]. Suppose the *representation space* (S_R) contains all the potential solutions, where each is called a *state* $\vec{s}$, and the solution space (S_O) is a set of states with reasonable quality. Normally, the $|S_O|/|S_R|$ is quite small since that $|S_R|$, i.e. the cardinality of S_R, expands exponentially with the size of problems [24]. For the task to find $\vec{s} \in S_O$ with high probability, typical challenges include: a) little *a priori* knowledge is available; and b) total computational resource and time are bounded.

The traveling salesman problem (TSP) [40] is a classic NP-hard problem. Although the TSP is easily formulated, it exhibits various aspects of hard computational problems and has often served as a touchstone for new problem solving methods [29][54]. The researches [10][17][53] have indicated the phase transitions under certain order parameter(s), however, it seems most real-world instances are still located at the hard computational region.

Autonomy oriented computing (AOC)[31] addresses the modeling of autonomy in the entities of a complex system and the self-organization of them in achieving a specific goal. The complex behaviors can emerge from the interactions of autonomous entities following simple rules. Recently, the AOC based methods have been applied to solve various problems [30][47][51].

In this paper, the compact multiagent optimization system ($MAOS_C$) [51], which is originally proposed for handling with the numerical optimization problem (NOP) only, is extended for supporting the cooperative search on a virtual landscape by a society of compact agents with limited memory capacity and simple behavioral rules under ecological rationality [18]. Each agent only has moderate problem solving capability by comparing with two extremes: a) the reflex agent, such as *ant* [12], which has no declarative memory and can only produce reflex behaviors in the environment; b) the cognitive architecture, such as ACT-R [1], which is rather sophisticated under unbounded rationality. Besides, the cooperation [13] is necessary because no single agent has sufficient knowledge on the virtual landscape. Here the agents collaborate with the others by indirect interactions, which are implemented through the communication medium role of the environment [31], instead of by sophisticated negotiation [27].

The paper is organized as follows. In Section 2, the extended multiagent optimization system ($MAOS_E$) in two levels is introduced in details. In Section 3, the implementation is demonstrated on the TSP, which addresses exploiting the problem features in search. In Section 4, the extensive experimental results by $MOAS_E$, using real-world instances from the TSPLIB, are

compared with those of some existing algorithms [45][54]. In the last section, this paper is concluded.

2. THE MULTIAGENT SYSTEM

The extended multiagent optimization system is built in two levels: a) the symbolic level for supporting basic problem solving; and b) the multiagent framework for specifying the organization structure and operation mechanism based on the symbolic level.

2.1 The symbolic level

The general problem solving capability arises from the consequence of the interaction of declarative and procedural knowledge [1]. As in the information process system [37], the declarative knowledge is represented in *symbol structures*, called T_INFO elements, and the procedural knowledge is represented in *elementary information processes*, called behavioral rules.

Each T_INFO element is described by a tuple <I_RC, I_TYPE, I_CON>, where I_RC is the retrieve cue, I_TYPE indicates a certain search space, and I_CON is its state.

The memory [19][37] is used for storing T_INFO elements. Each element can be retrieved from a memory according to its I_RC.

The memory must be updated if it is to be useful [19]. But updating is not encoding a new T_INFO element. Instead, only the I_CON is subjected to change. Then a T_INFO element can be referred as a trajectory that comprise of many instances. For specified time t, a T_INFO instance is expressed as $\text{I\_TYPE}_{\text{I\_RC}}^{(t)}$.

Each behavioral rule is described by a tuple <I_NAME, I_KEY>, where I_KEY indicates a virtual interface for handling specific T_INFO elements, and I_NAME indicates the real operations, which can be controlled by specifying setting parameters within a rule-parameter space. A behavioral rule is expressed as $R_{\text{I\_KEY}}^{\boxed{\text{I\_NAME}}}$.

2.2 The multiagent framework

As an AOC-based model [31], the framework consists of a society of N agents where they cooperate in a sharing environment (E) to realize a common intention of finding high-quality solution for an optimization task. Since the optimization task can be well-defined, the sophisticated negotiation [27] among agents is not necessarily. Instead, an agent is communicated with the others by indirect interactions, which are implicit implemented through the communication medium role of the environment (E).

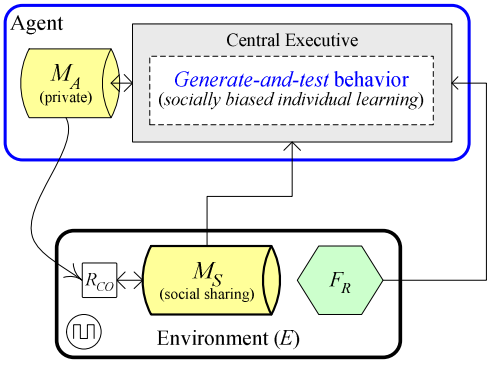

Figure 1. An agent and the environment (E) it roams

Without loss of generality, the agents are homogenous in the sense that they have the same organized structure. Figure 1 shows one of the agents and the environment it roams. All other agents are interacted with the environment in same way.

2.2.1 *Environment*

The environment serves as the domain in which agents roam [23].

Firstly, it contains an internal representation (F_R) [36][41] of the optimization task, which encapsulates accessible rudimental knowledge, includes a virtual landscape [25] and some auxiliary information associated with problem structure.

For the landscape, a quality evaluation rule (R_M) is used for measuring which one has better quality between any two states ($\vec{s}$) in the representation space (S_R). The quality evaluation implies the *intention* to attain the state that is better than another.

For normal problems, there is a cost function $f(\vec{s})$ for each state $\vec{s} \in S_R$. Then the evaluation is realized by a $R_M^{\boxed{O}}(\vec{s}_a, \vec{s}_b)$ rule: for $\forall\ \vec{s}_a, \vec{s}_b \in S_R$, if $f(\vec{s}_a) \le f(\vec{s}_b)$, then the $\vec{s}_a$ is better than the $\vec{s}_b$, and $R_M^{\boxed{O}}$ returns TRUE, else it returns FLASE.

Secondly, the environment holds a socially-shared memory (M_S), called *collective memory* [38], which serves as the blackboard for all agents by creating a shared past. The information flow from the agents to the M_S is supported by the *coordinating* behavior (R_{CO}) as in Fig. 1. In this sense, the environment also serves as an accumulation pool for the emergent collective behavior instead of a pure information provider as in cognitive architectures [1].

Thirdly, the environment keeps a central clock that helps synchronizing the behaviors of the total system, if necessary [31].

In fact, the environment can be seen as a pseudo autonomous entity for supporting the indirect cooperation of agents.

2.2.2 *Agent*

Each agent is a socially situated autonomous entity. Autonomy [31] is an attribute of a self-governed, self-directed entity with respect to its own status, free from the explicit control of another entity. The essence is that each entity is able to make decisions for itself, subject to the limitations of the available information.

The central executive (CE), the most important component of working memory model [3][43] in term of its general impact on cognition, is responsible for manipulating the local behavior and behavioral rules of an agent, which govern how it should act or react to the available information on the representation of problem while determine the next status to which the entity will transit.

The agent has two *belief* sources. Firstly, it possesses a private memory, called M_A, which has limited capacity and can only be modified by agent itself. The M_A is a fundamental mental component for supporting individual learning. Secondly, it can access to the M_S, which is socially available from the environment.

The law of behavior is *socially biased individual learning* (SBIL) as adopted by many species in real world [16], which is a mix of reinforced practice of own experience and socially available information. The SBIL is suggested to be a heuristic in ecological rationality [8][18], which a) gains most of the advantages of both individual and social learning; and b) facilitates the emergent and

collective properties by allowing learned knowledge to be accumulated from one generation to the next.

Due to lack of enough knowledge on the landscape to be searched, the essential behavioral rule is *generate-and-test* rule (R_{GT}). The essential components of an R_{GT} rule include a generating part (R_G), a solution-extracting part (R_S) and a testing part (R_T) [51]. The R_S part has no influence on the problem-solving process. It just exports potential solution(s) during a run. Without loss of generality, it can be supposed that only the R_G part can create new information that contains new potential solution(s), and the R_T part only produces simple reflex behavior, which may determine nontrivial properties for some T_INFO elements in memory.

2.2.3 Working process

The framework runs in two phases. The first phase is *memory initialization* phase, which initializes the T_INFO elements in M_S and in the M_A of all agents according to the F_R. The second phase is *generate-and-test* phase. For a run, the number of cycles is T. The behavior of system in the tth ($t \in [1,T]_{\mathbb{Z}}$) cycle only relies on the status of system in the (t-1)th cycle. By running as a Markov chain process, the system can be analyzed in each cycle.

Each cycle contains two clock steps: the C_PRE and the C_RUN.

At the C_PRE step, the coordinating behavior (R_{CO}) at the environmental level, which summarize the information submitted by all the agents into the M_S, is executed, i.e.

$$\{M_{A(i)}^{(t)} \mid i \in [1,N]_{\mathbb{Z}}\},\ M_S^{(t)} \xrightarrow{R_{CO}} M_S^{(t+1)} \tag{1}$$

For simplicity, here only the observational information is taken into account, i.e. the T_INFO elements in all agents with same I_RC are collected into a T_INFO element in M_S. It is significant since *observational learning* [5] can lead to cumulative evolution of knowledge that no single agent could invent on its own.

At the C_RUN step, if an agent is activated, where its *generate-and-test* rule is executed for generating new information by estimating the distribution of promising space according to available information in M_A and M_S and updating its M_A, i.e.,

$$M_A^{(t)},\ M_S^{(t)} \xrightarrow{R_{GT}} \begin{cases} \{\vec{s}^{(t)}\} \\ M_A^{(t+1)} \end{cases} \tag{2}$$

Naturally, there are two run modes: a) *full-run* mode, where all agents are activated; b) *partial-run* mode, where only N_{ACT} agents ($N_{ACT} \in [1,N]_{\mathbb{Z}}$), which are selected at random, are activated. Under same agent activated times, the system in *partial-run* mode often converges fast since it allows fast information diffusion.

3. IMPLEMENTATION FOR THE TSP

For solving the TSP, the implementation is realized in three steps: a) define the representation of the TSP (F_R); b) initialize the memory; and c) design suitable generate-and-test behavior. According to *no free lunch* theorem [50], the domain knowledge of the problem must be embedded at the implementation stage.

3.1 Representation of the TSP (F_R)

The representation (F_R) provides a basic interface for accessing the essential domain information of the TSP, which includes a TSP landscape and a candidate set for accelerating the local search (LS), the basis of many good heuristic methods.

3.1.1 The TSP landscape

The TSP landscape is quite straightforward. It is a weighted complete graph with V nodes (or called cities) and a cost matrix $D=(d_{ij})$, where d_{ij} represents the length of an edge that connects between cities i an j ($i, j \in [1, V]_{\mathbb{Z}}$). Here we only concern with the symmetric TSP, which have $d_{ij} = d_{ji}$ for every pair of nodes.

The TSP then is to find a minimal-cost Hamiltonian tour that passes through each node once. Each state $\vec{s}$ is a complete tour, which can be represented as a permutation (i_1, i_2, …, i_V) of the integer values from 1 through V, where the cost function is

$$f(\vec{s}) = d_{i_1 i_2} + d_{i_2 i_3} + ... + d_{i_V i_1} \tag{3}$$

The *distance* of two states is defined as the number of edges in which they differ [15][29][34].

In this paper, the original TSP landscape is used in order to allow a fair evaluation of the performance of algorithms. However, it should be mentioned that the transformation of the cost matrix always be an approach for improving the solving performance.

One kind of methods does not change the relative order of the states. As in Lagrangean relaxation [23][40], the length of every tour is increased by $2 \cdot \sum \pi_i$ as we associate with each node i a penalty value π_i and use the transformed cost matrix $D'=(d'_{ij})$, where $d'_{ij} = d_{ij} + \pi_i + \pi_j$. Of course, the order for the same segments of a tour may be changed under different cost matrix.

The other kind of methods indeed changes the global landscape. As in *search space smoothing* [21], the original landscape is transformed into a series of gradually smoother landscapes, which the smoothest one is solved at first and the solutions are used for guiding the following landscapes until the original one.

3.1.2 Candidate set ($\underline{E}_C$) for local search

Local search (LS), also known as neighborhood search, has been shown very effective for hard computational problems, including the TSP. A basic LS algorithm, under a predefined candidate set of neighborhood description, starts from an arbitrary complete tour and repeatedly improves the current tour till it is trapped into a local minimum. 2-Opt, 3-Opt and Lin-Kernighan (LK) algorithm [29] are representative LS methods.

The complete graph for a symmetric TSP has (V^2-V)/2 edges. However, it is intuitively that most of the possible edges will not occur in good tours because they are simply too long [40]. It is therefore reasonable to restrict major attention to promising edges, or called the candidate set, for accelerating local search (LS) methods. The examples of candidate sets include the k ($k \geq 1$) nearest neighbor subgraph, and the Delaunay graph, etc [40]. Of course, it is often expected the candidate set to be smaller so as not to result in a substantial increase in running time.

Helsgaun [23] estimates the chances of a given edge being a member of a good tour by using minimum 1-trees [40]. A 1-tree is a spanning tree with an additional edge combined two nodes with degree 1. The minimum 1-tree is often used for estimating the lower bound on the optimum since it is a relaxation of the TSP. The estimation, or called Held-Karp bound [22], can be improved

substantially on the 1-tree with Lagrangean relaxation [40] by applying *subgradient optimization* [22] for determining a certain transformation of the cost matrix with the suitable set of penalties, which each π_i is associated with each node *i*.

In *α-nearness measure* [23], each edge has a corresponding α-value, which is the minimum length when a 1-tree is required to contain the specified edge based on a transformed cost matrix. Intuitively, the more accurately Held-Karp bound achieved by the transformed cost matrix, the better estimation of α-values for the edges. Then the candidate edges of each node are sorted in ascending order of their *α*-values. Usually the minimum 1-tree shares many edges with an optimal tour. It is intuitive that the smaller *α* is for an edge, the more promising is this edge.

3.1.3 The features of the TSP landscape

The landscape is often studied in various ways. The first way is to understand the landscape in terms of simple parameters [44], in particular, to depict the phase transitions according to certain order parameters [10][17][24][53]. For the TSP, most researches are focused on the matrix *D*. Chessman et al. [10] investigated the standard deviation of the *D* as an order parameter by using a backtrack algorithm. Zhang [53] went deep into the precision of the elements in the *D* by using a branch-and-bound algorithm. The phase transitions in many hard computational problems have revealed interesting regularities across different problems and algorithms [24]. However, most real-world TSP instances are still classified as hard at the existing phase diagrams.

The second way is to understand the landscape based on the hints accumulated from the solving experience of existing algorithms.

Most modern LS variants [2][23][32][45] are essentially under the umbrella of iterated LS (ILS) [32], or called chained LS (CLS) [2], where the basic idea is to modify the current tour by applying a *kick-move* on a previous found tour instead of independently generated one. The intuition behind using chained starting tours is that the strong positive correlation between solution cost and the distance from the closest optimal tour, i.e., better local minima tend to have smaller distance to the closest global optimum by sharing many common partial structures [7][11][54]. The observations have led to the "big valley" hypothesis [7], which argues that the high-quality tours tend to concentrate on a very small subspace around the optimal tour(s) [46].

Moreover, the inherent features of a set of high-quality tours have been exploited in several ways. The first is reduction [29], which locks the edges in the intersection of the edge sets ($\underline{E}_I$) of the tours for speeding up the subsequent search. However, this method is brittle [54], especially as a locked edge is not part of good tour. The second is tour merging [11], which is to look for a high-quality tour in a restrict graph (G_R) consisting of the union of the edge sets ($\underline{E}_U$) of the tours through a "branch-width" algorithm. In fact, the number of edges in a G_R can be quite few due to the large number of shared edges among high-quality solutions. However, optimizing over a G_R can be hard as the original TSP instance. Besides, although a G_R may contain most of edges of an optimal tour, it may not ensure containing at least one optimal tour, then the tour merging may be failed to achieve optimum. The third is backbone guided search [54], which makes using of global information embedded in the pseudo-backbone frequencies for changing the landscape. However, the local search may be trapped into a local minimum unaffected by the changed landscape.

In this paper, the TSP landscape is exploited in the following ways: a) the LS method is applied at the initialization (or early) stage in order to reach the "big valley" as soon as possible [7]; b) The new tour(s) are generated based on the *kick-move* on a previous found tour as in the iterative LS [32]; c) an edge set ($\underline{E}_U$), which is represented in a set of high-quality tours, are used as the guiding information for the kick-move. The basic idea is that, for the edges to be introduced, most of them come from the $\underline{E}_U$ and a few of promising edges are safely introduced by greedy search. Moreover, to use a $\underline{E}_U$ with repeated edges instead of a restrict graph may utilize the pseudo-backbone frequencies implicitly; and d) the diversity among tours is maintained carefully: firstly, each starting tour is conserved in the private memory of each agent; secondly, the partial instead of the full information in $\underline{E}_U$, normally be a single tour, are used for guiding the kick-moves; and thirdly, the diffusion distance for each starting tour is restricted by an additional testing criterion on multiple trails.

3.2 Memory initialization

For simplicity, We use one T_INFO element in M_A, i.e. a tour called $\vec{s}_P^{(t)}$. Hence the element in M_S is $\underline{\vec{s}}_P^{(t)} = \{ \vec{s}_{P(i)}^{(t)} \mid i \in [1, N]_{\mathbb{Z}} \}$.

Following a random initialization, each tour is improved by a LS method, indicated as LS_{MI}. The default choice for LS_{MI} is a 3-Opt with k_{NNI}=20 neighborhood nodes in the candidate set.

3.3 The generate-and-test behavior

For solving the TSP, the generate-and-test behavior can be seen as a *kick-move* on $\vec{s}_a$, the starting tour to be improved, as in ILS [32].

To improve the chances for escaping from the local optimal tours, the double-bridge (DB) [29][32], a non-sequential *kick-move*, is normally used [2]. Helsgaun [23] has extended it into a *2-stage kick-move*, i.e., any infeasible 2- or 3-Opt move (producing an intermediate solution consisting sub-tours) followed by any 2- or 3-Opt move, which produces a valid tour (by merging the sub-tours). The infeasible intermediate solution is significant so as to alter the global shape of a tour [2]. However, the blind mutation should be avoided since it may be ineffective and inefficient.

The *kick-move* guided by a high-quality edge set ($\underline{E}_U$) has been exploited extensively. Many of them [15][28][34][42] can be classified as the *tour-guided 2-stage kick-move* (TG2KM): guided by a tour $\vec{s}_b$ in $\underline{E}_U$, the tour $\vec{s}_a$ is first modified into an infeasible intermediate solution, normally consist disjoint segments or sub-tours, which are then repaired by ingenious greedy mechanisms while considering available information, such as the $\underline{E}_C$.

Many edge-based recombination operators, such as Voronoi Quantized Crossover (VQX) [41], Natural Crossover (NX) [28], Distance Preserving Crossover (DPX) [15], Edge Assembly Crossover (EAX) [34][35], etc., can be taken as the examples.

Guiding by a tour instead of mutating blindly brings an implicit advantage by utilizing the distance between $\vec{s}_a$ and $\vec{s}_b$. Normally, the larger distance, the large perturbation on $\vec{s}_a$ is then allowed. It brings an adaptive control of the balance between exploration and exploitation along with the execution cycles.

Using a single tour instead of the whole information available is simply because the former has inherent mechanism for preventing premature convergence by locally diffusion of information in a

self-organized agent network while the latter needs sophisticated mechanism although it provides more complete information.

Normally, new promising edges can only be safely introduced when repairing the intermediate solution in greedy way. Hence the unexpected edges that are introduced into the intermediate solution, which are not existed in the $\vec{s}_b$ and the set $\underline{E}_C$, should be as less as possible. The following R_{GT} rule, called $R_{GT}^{\boxed{EA}}$, is extended from the EAX [34], because it meets the requirement.

3.3.1 The generating behavior

The generating part (R_G) is applied for generating new tour(s).

The preliminary operation is to build the mappings between the external and internal information sources, i.e., from the $\vec{s}_P^{(t)}$ and the $\$\vec{s}_P^{(t)}$ to the starting tour $\vec{s}_a$ and the guiding edge set $\underline{E}_U$. Here $\vec{s}_a = \vec{s}_P^{(t)}$ so as to preserve information naturally by using the private memory; and $\underline{E}_U = \$\vec{s}_P^{(t)}$ so as to make use of the cumulative pool. Moreover, the $\vec{s}_b$ is a tour selected from the $\$\vec{s}_P^{(t)}$ at random so as to utilize the pseudo-backbone frequencies implicitly.

By defining the G_{AB} as a graph constructed by merging $\vec{s}_a$ and $\vec{s}_b$, the edges on G_{AB} are then divided into AB-Cycles [35], where an AB-cycle is defined as an even-length sub-cycle on G_{AB} generated by tracing different edges of $\vec{s}_a$ and $\vec{s}_b$ alternately. As an AB-Cycle is identified, then the edges making up the AB-Cycle are removed from G_{AB} and the AB-Cycle is stored into the AB-Lib if it only contains the common edges of $\vec{s}_a$ and $\vec{s}_b$. The procedure is repeated till no AB-Cycle could be extracted.

Each AB-cycle in AB-Lib can be used as the guiding information for applying a *kick-move* on $\vec{s}_a$ in two steps [35][49].

The first step is to generate an intermediate solution, i.e., by removing edges of $\vec{s}_a$ in the AB-cycle from $\vec{s}_a$ and adding edges of $\vec{s}_b$ in the AB-cycle to $\vec{s}_a$. The result is a set of disjoint sub-tours. It is obviously that all the changed edges of $\vec{s}_a$ are selected from $\vec{s}_b$. Besides, the edges in $\vec{s}_a$ will be unchanged in the intermediate solution if the edges that connected to a node in $\vec{s}_b$ belong to the edges that connected to the same node in $\vec{s}_a$.

The second step is to modify the intermediate solution into a valid tour by merging its sub-tours. Of course, it is a choice to apply the 2-Opt for merging sub-tours [9]. For reducing the computational cost, a LS version, which can be seen as the first round of 2-Opt, is used: two sub-tours are greedy merged, by deleting a single edge from each sub-tour and adding two edges, where one of them is a node selected at random in the candidate set $\underline{E}_C$, to connect the nodes in both sub-tours with degree 1.

Of course, to find a good tour by simple one trail is not always easy. Fortunately, there already are many AB-cycles in the AB-Lib, which allows us to perform a multi-trail mechanism (MTM), or called iterative child generation (ICG) [35][49], i.e. to generate N_{MTM} candidate tours, where each is based on an AB-Cycle selected in AB-Lib at random. The idea was also exploited by the Fitness-Distance-Based Diversification (FDD) [45] and the brood selection mechanism [48]. The default value for N_{MTM} is set as 30.

3.3.2 The testing behavior

The testing part (R_T) is used for maintaining the M_A, which is similar as updating the starting solution in iterated LS, based on the competition among the generated candidate tours.

The smaller difference between two information sources for the R_G part, the higher probability for falling into one of the local minima associated with the guiding information [7][15]. Hence, it is critically to maintain the diversity of information intentionally since the high-quality solutions are already rather close.

For the competition of generated tours, it may easily get trapped in specific regions of the TSP landscape if we only consider the essential high-quality criterion [49]. The FDD mechanism [45] hence utilizes an additional criterion, i.e., high quality as well as rather distant from the starting tour.

If $\vec{s}_a$ is located at a local valley, then a tour better than $\vec{s}_a$ is located at another valley of the TSP landscape. Here if only such tours are allowing for competition, then it is no long necessarily to keep large distance from the current solution intentionally.

It is expected that the private information in M_A has strong influence on the generated states, so as to keep a local diffusion effect. Hence large adjustments are possible, but are much less probable than small adjustments [4]. For a generated tour $\vec{s}_c$ with better quality than $\vec{s}_a$, the cost function is transformed as follows:

$$f'(\vec{s}) = (f(\vec{s}_c) - f(\vec{s}_a))/(DIS(\vec{s}_a, \vec{s}_c))^{C_D} \qquad (4)$$

where $DIS(\vec{s}_a, \vec{s}_c)$ is a function to reflect the increasing of distance between $\vec{s}_a$ and $\vec{s}_c$, and C_D is called *diffusion coefficient*. As in [34], the $DIS(\vec{s}_a, \vec{s}_c)$ function is defined as half of the number of edges in the corresponding AB-cycle to reduce computational cost for calculating the exact distance.

If C_D=0, $f'(\vec{s})$ represents the high-quality criterion, as in EAX-1AB [34][35] or in brood selection mechanism [48]. If C_D=1, $f'(\vec{s})$ represents the criterion as in EAX-Dis [35]. If C_D is very large, the $\vec{s}_c$ will be selected from the tours with smallest *DIS* value. In fact, the C_D determines the diffusion velocity of information. The default setting is C_D=1.5.

The selected $\vec{s}_c$ is then used for replacing the $\vec{s}_P^{(t)}$ in M_A. Hence $\vec{x}_P$ is a steady-state solution satisfying the above testing criterion.

4. EXPERIMENTAL RESULTS

The experiments are carried out on a set of real-world instances with $1000 \le V < 3000$ nodes in TSPLIB [39].

The results are compared with the iterative LS (ILS-FDD) [45] and the iterated backbone guided LK algorithm (IBGLK) [54].

The ILS-FDD generates a new starting tour for ILS with Fitness-Distance-Based Diversification (FDD) [45]. Their 3-Opt uses some standard speed-up techniques under a candidate list of 40 nearest neighbors. The ILS version has achieved best performance while comparing to three other algorithms, i.e., the genetic algorithm (GA) using DPX-crossover (GA-DPX) [15], the repair-based GA [48], and the MAX-MIN ant system (MMAS) [46].

The IBGLK [54] combines pseudo-backbone utilization with the iterated LK algorithms by considering two issues: the first issue is to construct unbiased samples of local minima for constructing pseudo-backbone; and the second issue is to alternate between BGLK and regular LK once each of them fails. For LK algorithm, length-20 nearest nodes, *don't look bits* [6], and the *two-level tree* [14] tour representation, are used. The IBGLK version has outperformed than three versions of LK algorithms [54], i.e. the *ILK-1-run*, the *ILK-5-run*, and the *ILK-10-run*.

Table 1 gives the setting parameters for the standard case of $MAOS_E$, called #Std, where $\underline{E}_C$ indicate the candidate set. Table 2 gives five other cases by changing one parameter value based on the template of #Std. As same as in [45], 25 trails are run on pr1002, pc1173, d1291, and 10 trails are run on other instances.

Table 1. The parameter setting for the case #Std of $MAOS_E$

Parameter	N	N_{ACT}	$\underline{E}_C$	LS_{MI}	C_D	k_{NNI}	N_{MTM}
Value	300	300	α-measure	3-Opt	1.5	20	30

Table 2. The parameter changes for other cases (based on #Std)

Case	#NA100	#N400	#D1.0	#NN	#2Opt
Changes	N_{ACT}=100	N=400	C_D=1.0	$\underline{E}_C$ =*nearest*	LS_{MI}=2-Opt

Table 3 shows the results for average percentage deviation (Δavg) from the optimum by ILS-FDD [45], IBGLK [54], and the $MAOS_E$ cases. Besides, the average CPU-time (*sec*) for the ILS-FDD and the IBGLK, and the average cycles ($\overline{T}$) for the $MAOS_E$ cases, are listed. We also list the run-time (*sec*) for the case #Std and #400. The result for si1032 is just for reference and is not used in the following discusses since it is not tested by ILS-FDD. At the last row, the average values for all instances are calculated.

For the $MAOS_E$ cases, the calculation time mainly contains two parts: the first is N times of LS executions at the initialization stage; the second is $N_{ACT} \cdot \overline{T}$ times of R_{GT} executions by agents. The less R_{GT} executions is normally preferable, although there are great deviations for the costs between different R_{GT} executions.

Both the ILS-FDD and the IBGLK are coded in "C". The ILS is run on 450MHz P3 processor, and the IBGLK runtime is normalized for a 500MHz Alpha. The $MAOS_E$ is coded in JAVA, and is run on 2.8GHz and 3GHz P4 processors in a public cluster. In fact, to compare the computational cost is not so easy we can only count the run-time instead of CPU-time by JAVA. However, the average run-time of the case #Std is 16.2% of that of the IBGLK. Hence the case #Std can be at least comparable with the IBGLK even by only considering the speed difference of CPUs.

The case #Std can achieve the optimum of thirteen instances in all trails, which is better than both the ILS-FDD and the IBGLK. Besides, here we use *worse than/equal to/better than* (W/E/B) analysis. For #Std vs. the ILS-FDD, the W/E/B is 2/6/12, which means that for the results of #Std, 2 instances was worse than, 6 instances were equal to, and 12 instances were better than that of ILS-FDD. For #Std vs. the IBGLK, the W/E/B is 3/6/11.

The effects of parameters are also concerned. From the number of solved instances, the #Std is slightly better than #D1.0, #NN, and #2Opt. However, as the parameter C_D is increased from 1.0 to 1.5, the average $\overline{T}$ is increased by 14.1% due to the reduced diffusion velocity. Hence for the parameter C_D, the balance between the quality and the cost must be minded. As the α-measure instead of the *nearest* measure for the candidate set is used, the average $\overline{T}$ is reduced by 19.3%, which due to the better estimation of promising edges. Although 3-Opt itself is normally slower than the 2-Opt, the average $\overline{T}$ can be reduced by 42.4%. Hence for the LS_{MI}, the 3-Opt is normally preferable than 2-Opt as the $\overline{T}$ is large.

Then the *partial-run* mode is checked by two cases: #NA100 and #N400. For the #NA100 and the #Std, the time to be costed at the initialization stage is same. Although the average Δavg is slight worse, the R_{GT} execution times of #NA100 is 50.8% of that of #Std. For #N400, it can achieve quite good performance in reasonable run-time (*sec*), where the fails only occurs in five instances, which are mainly due to the enriched socially-shared information and preserved diversity among the larger society.

5. CONCLUSIONS

This paper has described an extended multiagent optimization system ($MAOS_E$) based on autonomy oriented computing, which consists of a society of agents under ecological rationality where they cooperate in a sharing environment to search on a virtual landscape, for solving hard computational problems. Although each agent only possesses limited memory and simple behavioral rules, the collective properties can emerged from their cooperation.

From the viewpoint of computation, each agent is a stochastic algorithm. Although the agents have same organized structure, they become heterogonous since their memories are initialized with different contents. If the agents do not utilize the information in M_S, then the system becomes a *portfolio of algorithms* [20][26]. The studies [20][26][33] have indicated the portfolios may have unequivocal advantage than any of its individual member algorithms running alone for dealing with hard computation problems. In $MAOS_E$, the agents are cooperated through the information located in M_S. Then the multiagent system becomes a *cooperative algorithm portfolio*. The cooperation between agents will introduce statistical correlations between their performance, which is capable of reducing both the expected time and the solving risk when manifested in negative correlations [26].

Under the $MAOS_E$, the realization of a problem solver then can be divided into three parts: a) encode the representation of the problem into the landscape and the possible auxiliary knowledge; b) construct the memory elements at the initialization stage; and c) design the *generate-and-test* behavior guided by the law of *socially-biased individual learning*. The implementation has been demonstrated on the TSP, where all three parts are realized by exploiting the problem features. The extensive experimental results on real-world instances in TSPLIB show its efficiency as comparing to the ILS-FDD and the IBGLK.

One possible extension of current work is to apply the agents for solving other well-studied hard computational problems, which are key components for many practical tasks, by utilizing inherent features. Another possible extension is to study rational strategies for agents to deploy multiple R_{GT} rules under certain knowledge.

The agents may also be adapted to the cooperative distribute problem solving (CDPS) [13][52] by requesting the guiding information from other agents. Of course, the negotiation mechanisms then may be required, especially as the agents use various virtual landscapes for involved task.

ABSTRACT

In the recent past, several different methods for coordinating behavior in multi-robot teams have been proposed. Common to most of them is the use of communication to coordinate behavior. For many practical applications, however, communication might not be an option (e.g., because of energy constraints of embedded platforms, limited communication range of wireless transmitters, security risks of potential interception of messages in hostile territory, etc.).

In this paper we examine low-complexity, low-cost strategies without communication for coordinated agent behavior. Specifically, we investigate the utility of a "social preference mechanism" and a "pairing mechanism" in territory exploration tasks, where agents have to explore their environment to find and visit k checkpoints, which only count as "visited" when n agents are present at them at the same time. Experimental results indicate that pairing is the better strategy, raising interesting questions about tradeoffs between agent complexity and group size (e.g., whether fewer, more expensive agents with the ability to visit checkpoints individually are a better choice than more less expensive agents).

1. INTRODUCTION

Efficient performance of multi-agent tasks often requires some form of coordination between agents. Even in seemingly simple tasks, where agents perform autonomously without the need for help from others, agents may work at odds with one another, leading to wasted effort and reduced efficiency. More complex tasks may even *require* coordination in order to perform them. Communication is often used to facilitate coordination in multi-robot tasks, yet it may not always be feasible to include communication. Other investigations use behavior coordination among robotics agents to study the utility of communication. Arkin and Hobbs [2, 9], for example, compare results with and without communication on robotic *retrieval tasks*. Communication was found to be beneficial if agents communicated their states, which could cause other agents to join in the task. Werger [11], on the other hand, found communication to be unnecessary to achieve task formation in a system which uses behavior-based mechanisms to generate cooperative behaviors, as did Quinn et al. ([6]). Ijspeert et al. [4, 5] found that signaling is helpful when the number of agents is small relative to the number of subtasks. While some of these results are in line with the conclusions of this paper, the tasks involved are very different from the one described below.

Clearly the benefits of communication are inconclusive. Factors in determining the feasibility of communication for multi-robot exploration teams include weight (communication will require additional equipment), communication range, the cost of transmitters, and the energy required to communicate and process communicated information (i.e., communication in itself is useless without some process that utilizes the extra information). In many cases, these additional factors eliminate communication as an option for coordination, so a low-cost, low-complexity strategy is needed for coordination instead. Such a strategy would avoid the high cost of communication, but must provide sufficient coordination to allow good task performance.

In this paper, we present two coordination mechanisms, a "social preference mechanism" and a "pairing mechanism" for multi-agent coordination. We test these new mechanisms in *multi-agent territory exploration* (MATE-n) tasks, which require a group of agents to visit all checkpoints in the environment. In order for a checkpoint to count as "visited," n agents must be present simultaneously (consider a task in which extraplanetary landers with heterogeneous equip-

ment must explore the terrain, but may not be able, individually, to accomplish scientific goals at interesting sites). When $n > 1$, the degree of coordination required to accomplish the task efficiently is substantial. Experimental results show that, while the social preference mechanism is able to improve performance, the pairing mechanism is the better choice for coordination in MATE-n tasks.

This paper proceeds as follows: first MATE-n is specified in detail. Then the methods used are described, including the agent model that serves as a base for the experiments, as well as the experimental setup used. Then experiments and results are presented for the base agent, social preference agents, and pairing agents.

2. THE MATE-N TASK

The *multi-agent territory exploration* (MATE-n) task is inspired by biological foraging tasks, but finds applications in other domains (e.g., mine-detecting robots or frogs searching for mating sites) [8, 7]. Agents explore their environment, looking for marks indicating the presence of a checkpoint. When enough agents (n) are present at a checkpoint, its mark is removed and the agents continue the task, exploring the environment until all checkpoints have been visited by n agents simultaneously (note that agents do not need to *arrive* at the checkpoint simultaneously, only to be present simultaneously). More formally:

Definition 1: A MATE-n task $T(C_n, A, R, D)$ requires a group of agents A, each with sensory range R, to visit a set of checkpoints C, each of which requires n agents present to remove its mark, in a 2D environment where agents and checkpoints are placed according to a probability distribution D.

Performance is defined as the time it takes to remove all checkpoint marks from the environment.[1] Thus, unlike many natural foraging tasks, agents in MATE-n tasks are working as a group. Individual performances are important insofar as they contribute to group performance, but individuals are not rewarded for good performance.

Typically, agents do not have *a priori* knowledge of the distribution D; both agents and checkpoints are distributed randomly in the environment, requiring agents to explore to locate checkpoints. If this information *is* available, it is possible to calculate an optimal offline solution by exhaustively searching the entire space of checkpoints assigned to each agent, along with the order in which each agent visits its assigned checkpoints. Such a solution, however, is computationally intractable.

MATE-n tasks are similar in some ways to Traveling Salesman Problems (TSP), and even more so to multi-Traveling Salesman Problems (MTSP), in which some member of a sales team is required to visit each city. The delivery scheduling problem is an instance of MTSP for which approximations exist [3, 10, 1]. However, because TSP variants require agents to return to their initial positions, no TSP approximation fits exactly the MATE-n task; the optimal visit order is affected by requiring a round trip.

3. METHODS

[1]Other measures of performance could be the total distance traveled by all agents in A, or the difference in length between all agents' paths (as in a load balancing goal)

We begin by investigating the performance of a base agent model in a MATE-n task, then add a new (coordinating) feature F to the architecture and compare the performance of the new agent kind with the performance of the old. The remainder of this section describes the base agent model used to obtain absolute performance, and the experimental setup employed.

3.1 Agent Model

The simplified sensor model employed by the agents ignores sensor modality, assuming that agents can sense all checkpoints in a full 360° radius within a sensory range of R. The agent's sensory input S is combined with its inner states I to produce behaviors according to the agent function F. F is a mapping $F : 2^S \times I \rightarrow D$, where 2^S is the power set of sensory data given as pairs $< d, \alpha >$ of distances $d \in [0, R]$ and angles $\alpha \in [0, 2\pi]$, I is a set of inner states (possibly empty), and $D \in [0, 2\pi]$ is the set of possible directions the agent will move in.

For MATE-1 tasks, a simple agent that targets for collection the closest checkpoint detected is sufficient for reasonably good performance. When $n > 1$, however, these simple agents are susceptible to 'deadlock' states in which each agent moves to the nearest checkpoint and waits for another agent to arrive; when all agents have found (distinct) checkpoints, the task cannot proceed. We therefore introduce the *timeout* agent, which incorporate a *wait timer* w that is started when the agent arrives at a checkpoint and expires after a fixed duration W. At that point, the checkpoint is added to the agent's *filter set*, which forces the agent to ignore the checkpoint. Effectively, the agent does not perceive a checkpoint that is in its filter set. After a fixed cycle count, the checkpoint is removed from the filter set, and the agent can once again perceive the checkpoint (if it is within sensory range).

The following ruleset comprises the agent model for timeout agents:

Rule 1: if no checkpoint is perceived ($S = \emptyset$), perform a random walk $RW(rwd, \beta)$ (i.e., move in the direction of the current heading θ for rwd cycles, then change heading randomly to some value in $[\theta - \beta, \theta + \beta]$)

Rule 2: if some checkpoint C is within visiting range (i.e., the agent is close enough to remove the mark) and there are n agents within visiting range of C, remove the checkpoint's mark and reset w to 0

Rule 3: if some checkpoint C is within visiting range, there are fewer than n agents within visiting range of C, and $w = W$, reset w to 0 and add C to the agent's filter set

Rule 4: if some checkpoint C is within visiting range, there are fewer than n agents within visiting range of C, and $w < W$, increment w

Rule 5: if no checkpoint is within visiting range but some checkpoints are perceived ($S \neq \emptyset$), go directly towards the closest checkpoint (the direction is given by α such that $\min_d [\langle d, \alpha \rangle | \langle d, \alpha \rangle \in S]$)

These simple agents employ a random walk mechanism that changes their heading after rwd cycles without perceiving a checkpoint. The value of rwd was determined for each combination of group size and sensory range employed

by systematically exploring the space of values and selecting those with the best performance. Additionally, the environment is bounded; agents "bounce" off of the edge of the environment with a small amount of random error. Agents will move directly to the nearest perceived checkpoint (when there is one) and wait there for a total of n agents to arrive. After waiting for W cycles, the checkpoint is added to the agent's filter set and the agent can then target other perceived checkpoints or begin foraging via the random walk mechanism. The value of W was determined similarly to *rwd*: a systematic exploration of the performance space of each group size/sensory range combination yielded the value of W with the best performance; this is the value of W for that combination. A counter is associated with each member of the filter set that is incremented at every cycle. When the counter reaches f (i.e., the filter set duration), the checkpoint is removed. The value of f is fixed at 200.

3.2 Experimental Setup

To begin exploring coordination in MATE-n we must choose a reasonable value for n. While there is some degree of coordination required when $n = 1$, for the most part it comes down to keeping out of each other's way; cooperation is not required in visiting individual checkpoints in MATE-1. MATE-2 provides a task in which agents must actively coordinate checkpoint visits if efficient performance is expected. The chances of two agents being at the same checkpoint simultaneously are small if there is no coordination effort. The challenge is similar in kind for $n = 3$, $n = 4$, etc., albeit with increasing difficulty. Hence, for this paper we select $n = 2$ for the number of agents that must be present at a checkpoint.

Each experiment reported in this paper consists of 40 experimental runs using different randomly generated initial conditions in a continuous 2D world, which is limited to an 800 by 800 square region. Sensory range is varied from 25 to 250 in steps of 25, and from 300 to 800 in steps of 50. Group size is varied from 2 (the minimum size required to successfully complete the MATE-2 task) to 10. The same set of 40 initial placements of checkpoints ($|C| = 10$) is used for all experiments. Moreover, the same 40 initial placements of agents is used for all experiments with identical group size (i.e., all experiments with $|A| = 2$ will use the same 40 initial conditions, regardless of sensory range or agent type, etc.). The results reported here are the average cycles to completion of each experiment set for each architectural configuration. Agents are allowed 10,000 cycles within which to complete the task; after that point, the experimental run is considered a failure, and its value is set at 10,000. Thus, 10,000 cycles is the ceiling for performance.

4. TIMEOUT AGENTS

The first set of experiments measures the performance of the base architecture, the timeout agent. Recall that this agent forages for checkpoints in the environment and goes to the nearest one it sees. If there is another agent at the checkpoint, the mark is removed and the agents move on. Otherwise, the agent waits at the checkpoint for W cycles, or until another agent arrives and the mark can be removed.

4.1 Results

The performance results for timeout agents are presented in Figure 1 (left). Overall, the trends are predictable: as sensory range increases, performance increases (i.e., average cycles to completion decreases), to a point. When sensory range is greater than 300, performance levels off, and there is little benefit to increased range. Similarly, performance increases with group size, but improvements diminish as size increases so that, for example, there is little difference in performance between $|A| = 9$ and $|A| = 10$.

A two-way 9x21 ANOVA with *group size* (2-10) and *sensory range* (25-800) as randomized variables and *average cycles to completion* as the dependent variable shows highly significant main effects for group size ($F(8, 7371) = 1983.8795, p < 0.001$) and range ($F(20, 7371) = 207.4370, p < 0.001$), confirming that increasing group size and sensory range improves performance. There is also a highly significant interaction between group size and sensory range ($F(160, 7371) = 5.8574, p < 0.001$); this confirms that larger groups increase performance faster as sensory range increases, reaching earlier the point at which added sensory range is of no benefit. These results are exactly what one would expect; essentially we are increasing the resources available, and should, therefore, expect performance to increase. Similarly, we should expect that a point at which more resources will be of little benefit.[2]

4.2 Analysis

As expected, two trends are evident in the results: larger groups outperform smaller groups, and higher sensory ranges outperform smaller sensory ranges. Several additional functional roles are displayed, each of which is a contributor to poor performance:

Jilted Groom: an agent at a checkpoint whose wait timer expires (the bride never arrives)

Jilted Bride: an agent that targets an occupied checkpoint, but the occupying agent's wait timer expires before the "bride" arrives

Lonely Bachelor: an agent that spends a prolonged period searching for a checkpoint

Unlucky Bachelor: an agent caught in a cycle of waiting for the full length of the wait timer and then foraging again for another checkpoint, only to have its wait timer expire again

Dedicated Bachelor: similar to the unlucky bachelor, except that there are other occupied checkpoints within sensory range, but the agent continues to target unoccupied checkpoints (seemingly preferring to remain a bachelor)

Bridesmaid: an agent that targets a checkpoint that is already targeted by two nearer agents, and so is destined to arrive late, after the checkpoint has been visited ("always a bridesmaid, never a bride")

With low sensory range, agents tend to spend a lot of time as lonely bachelors because of the difficulty of locating a checkpoint. Moreover, once they do locate a checkpoint, they tend to play the part of the jilted groom, because the other agents have the same difficulty locating the occupied checkpoint due to their own low sensory ranges. The wait

[2]These are independent of the type of agent tested, so this pattern will be repeated in subsequent results. Therefore, while we will continue to report the values for the randomized variables group size and sensory range, we will not discuss them specifically in subsequent results, except when they interact significantly with other variables tested.

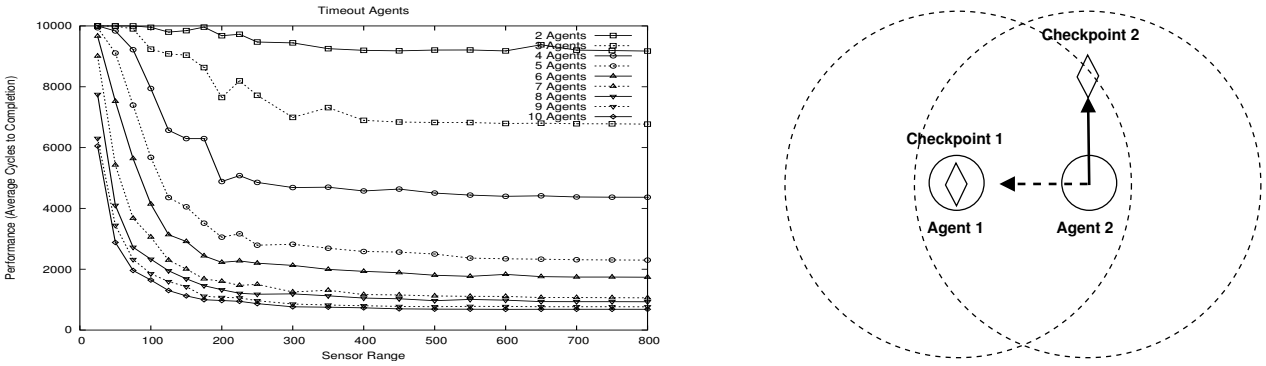

Figure 1: Left: Average performance of timeout agents for two to ten agents and sensory ranges from 25 to 800. Right: A difficult situation for timeout agents to handle: the default behavior of Agent 2 is to move to Checkpoint 2, as a result of Rule 2. However, with Agent 1 at Checkpoint 1, a better strategy would be to move to Checkpoint 1.

timer expires and the groom moves on, returning to the bachelor role. As sensory range increases it becomes easier to locate checkpoints, and the lonely bachelor is seen less often, while the frequency of the groom role increases.

When the number of agents is small, agents have similar difficulties: when they do locate a checkpoint, there is often no other agent in a position to play the role of bride. Instead, because they are unlikely to be placed near each other in the environment, they tend to assume the unlucky bachelor role. Increasing sensory range does not address this problem; agents target the closest checkpoint detected, and there will often be checkpoints between them, preventing potential brides from targeting a groom's checkpoint. Fortunate initial placement can mitigate this problem, and agents may drift toward one another, allowing them to eventually break out of the unlucky bachelor role. However, in the case of 2-agent groups, this seldom happens.

The simulations are limited to 10,000 cycles, as described above. The results for 2 agents in Figure 1 (left) show that they do not even approach 9,000 cycles. This is because they fail to complete in most cases, regardless of the sensory range. 3- and 4-agent groups improve, but still fail in many experimental runs. 5 agents appear to be sufficient to overcome the unlucky bachelor problem.

4.3 Discussion

The timeout mechanism works to break deadlocks by limiting the amount of time agents spend waiting at checkpoints for other agents to arrive. The mechanism is not perfect (e.g., there are times when an agent's wait timer will expire just before another agent arrives, giving rise to the jilted bride), but overall performance is improved. For timeout agents, some wait cycles are inevitable; the first agent arriving at a checkpoint must wait for another agent to arrive (unless we expect them to arrive simultaneously–highly unlikely!). However, some wait cycles are especially wasteful.

Figure 1 (right) presents a scenario in which Agent 1 is waiting at Checkpoint 1 but Agent 2 is closer to Checkpoint 2. In this situation, Agent 2 will move to Checkpoint 2 and wait W cycles. This is less efficient than moving to Checkpoint 1 in most cases, because Agent 1 will wait until its timer expires to leave Checkpoint 1. Furthermore, it is possible that Checkpoint 2 will be in Agent 1's filter set, in which case it will not move there to join Agent 2. Finally, it is possible (and, in our observations, frequently the case) that Agent 2's timer will expire before Agent 1 arrives, in which case they may enter a cycle of flipping between checkpoints without marking any visited. These are examples of the dedicated bachelor functional role, in which Agent 2 appears to intentionally avoid targeting a checkpoint with a waiting groom, although this behavior is really a result of the same control architecture that would require Agent 2 to move to Checkpoint 1 if it were nearer.

As a measure of how often agents make the dedicated bachelor mistake, we tracked *redundant wait cycles*. A redundant wait cycle is one spent by an agent waiting at a checkpoint while another agent is waiting at another checkpoint in sensory range. The average number of redundant wait cycles for all agents in a simulation is the measure of *Redundant Wait Cycles* (RWC) for the simulation:

$$RWC = \frac{\sum_{n=1}^{|A|} RedundantWaitCycles(a[n])}{|A|} \quad (1)$$

Figure 2 (upper left) shows the proportion of the total cycles in Figure 1 that timeout agents spent redundantly waiting. The proportion is substantial, particularly for smaller groups with higher sensory range. Agents in larger groups are not as susceptible to redundant wait cycles because there is more frequently another agent near enough to target the checkpoint at which an agent is waiting. Similarly, when sensory range is low, agents are not as likely to perceive other checkpoints, including other checkpoints with agents waiting. A direct coordination mechanism that targets redundant wait cycles for reduction should be particularly useful for increasing performance in MATE-2 tasks, particularly in small groups with high sensory range.

5. SOCIAL PREFERENCE AGENTS

One simple, and seemingly natural, architectural enhancement is to modify the timeout architecture so that the agent takes into account states of other agents, preferring occupied checkpoints over checkpoints with no agent. The agent model is modified by changing Rule 5:

Rule 5a: if no checkpoint is within visiting range, at least one checkpoint is perceived ($S \neq \emptyset$), and there is an-

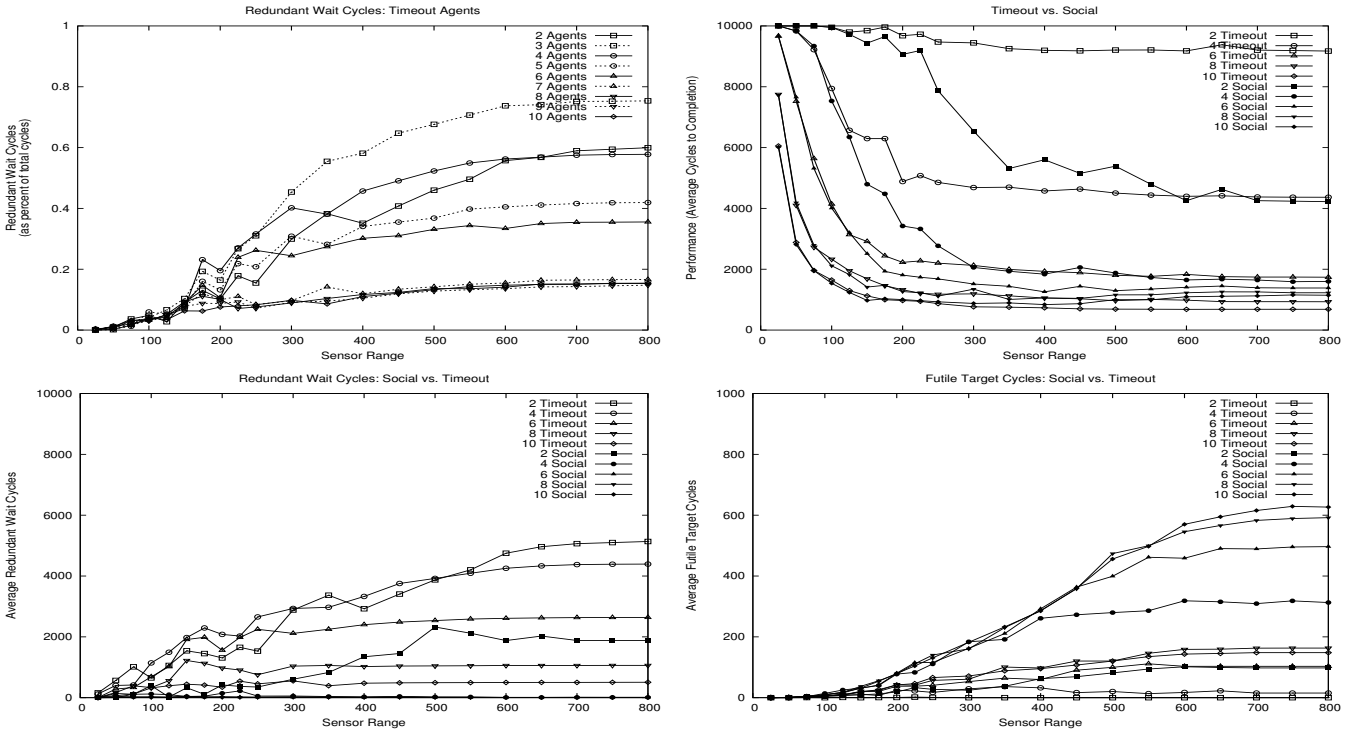

Figure 2: Upper left: Portion of total cycles spent in redundant wait. Upper right: Average performance of timeout agents and social agents. Lower left: Comparison of redundant wait cycles for timeout agents and social preference agents. Lower right: Futile target cycles for target-closest agents and social preference agents.

other agent waiting within visiting range of a perceived checkpoint, go directly towards the closest checkpoint with an agent (the direction is given by α such that $\min_d [\langle d, \alpha \rangle | \langle d, \alpha \rangle \in S]$)

Rule 5b: if no checkpoint is within visiting range, at least one checkpoint is perceived ($S \neq \emptyset$), and there is no other agent waiting within visiting range of a perceived checkpoint, go directly towards the closest checkpoint (the direction is given by α such that $\min_d [\langle d, \alpha \rangle | \langle d, \alpha \rangle \in S]$)

This modified ruleset constitutes the agent model for *social preference* agents. Social preference agents will ignore nearer checkpoints when there is an agent at another checkpoint within sensory range. This modification addresses the inefficiency in Figure 1 (right); social preference agents avoid the dedicated bachelor role in most cases, although they are more susceptible to becoming bridesmaids.

5.1 Results

Social preference agents prefer as targets checkpoints with another agent present. This simple modification leads to dramatically increased performance–in most cases. Figure 2 (upper right) is a comparison of timeout agents and social agents. In virtually all cases, social agents outperform timeout agents. A three-way 9x21x2 ANOVA for *group size* (2-10), *sensory range* (25-800), and *agent kind* (timeout and social preference) as randomized variables with the dependent variable *average cycles to completion* finds highly significant main effects for group size ($F(8, 14742) = 3433.6255, p < 0.001$), sensory range ($F(20, 14742) = 741.4416, p < 0.001$), and agent kind ($F(1, 14742) = 998.0511, p < 0.001$). This confirms that there is an absolute performance difference between groups. There are highly significant two-way interactions between group size and sensory range ($F(160, 14742) = 20.6668, p < 0.001$), between group size and agent kind ($F(8, 14742) = 211.8039, p < 0.001$), and between range and agent kind ($F(20, 14742) = 20.1746, p < 0.001$), and a highly significant three-way interaction between all three factors ($F(160, 14742) = 6.7453, p < 0.001$). The interactions confirm the prediction (based on Figure 2, upper left) that small groups with high sensory range would benefit most from the social preference mechanism. Interestingly, the performance of large groups with high sensory range is actually *harmed* by the social preference modification.

5.2 Analysis

Social preference agents outperform timeout agents overall, with the interaction between group size and agent kind confirming that the mechanism is more effective in small groups, and the interaction between sensory range and agent kind confirming that it is most effective for higher sensory ranges. Performance is nearly identical at small sensory ranges for all group sizes, because in those cases there is rarely an opportunity for Rule 5a to fire; few checkpoints are detected, with or without agents. As sensory range increases, social preference agents soon become better.

The performance advantage of social preference agents is explained by the coordinating effects of the preference modification. Figure 2 (lower left) compares redundant wait cy-

cles of social preference and timeout agents. In most cases, social agents experience fewer.

It may seem surprising that social preference agents experience *any* redundant wait cycles. If they ignore closer checkpoints when they perceive another agent at a checkpoint, the only situation in which two agents should be at different checkpoints within sensory range is when they arrive at their checkpoints simultaneously. This is true when agents perceive all checkpoints within sensory range. However, there is an interaction here between the timeout mechanism's filter set and the social preference mechanism. Consider a situation in which agent A_1 is at checkpoint C_1 and agent A_2 comes within sensory range. A_2 will move toward C_1, whether there are closer checkpoints or not. In the meantime, A_1's wait timer expires. A_1 leaves C_1, placing it in its filter set. While A_1 is traveling to C_2, A_2 arrives at C_1, but A_1 does not perceive C_1, so it does not turn around. When A_1 arrives at C_2, redundant wait cycles begin to accrue.

5.3 Discussion

Social agents see little benefit when sensory range is low, because agents are less likely to see two checkpoints at the same time and, therefore, less likely to be in a situation where their added capability is beneficial. When sensory range is high, agents have more information at any given time to which they can apply the preference. This suggests that the primary obstacle to agent performance is acquiring information; coordination is of little use in the absence of sufficient information about the environment. Once the information hurdle has been overcome, however, the benefit of coordination can be seen in small groups.

Similarly, there is little benefit when group size is high, because there are enough agents in the environment to minimize the need for coordination; agents are not as likely to be penalized by "wrong" decisions, because there is likely to be another agent nearby to visit the occupied checkpoint. Increasing group size is one way to increase the probability that two agents will target the same checkpoint. The value of $|A|$ at which increasing group size is no longer beneficial will depend on the size of the environment and the number of checkpoints that must be visited. In the environments studied, the benefit of introducing the social preference mechanism into groups of eight or more agents is probably not worthwhile. However, for $|A| < 8$, social agents significantly outperform their communicating timeout peers. When group size is small, it will often be the case that there is only one additional agent within sensory range of an occupied checkpoint. In such cases it is important for the second agent to make a good decision, because it is unlikely that another agent will happen along.

Social preference agents are more susceptible to becoming "bridesmaids" because, while they do take the state of the groom into account, they pay no attention to other potential brides. Hence, they spend time futilely targeting a checkpoint when they have no chance of being the bride. A cycle is considered *futile* if the agent targets a checkpoint but subsequently fails to visit it (i.e., because another pair of agents arrives first). More formally, the measure *Futile Target Cycles* (FTC_A^{cyc}) for a simulation run is the average number of futile target cycles for all agents in A in the simulation run (of *cyc* cycles):

$$FTC_A^{cyc} = \frac{\sum_{a \in A} FutileTargetCycles^{cyc}(a)}{|A|} \qquad (2)$$

where $FutileTargetCycles^{cyc}(a)$ is the total number of futile target cycles of agent a in the given simulation run of *cyc* cycles. The average of FTC_A^{cyc} for all simulation runs is taken as a measure of how susceptible the agents were to wasting cycles targeting ultimately unvisitable checkpoints.

As noted, social preference agent performance becomes worse than normal timeout agent performance in large groups with high sensory range. As Figure 2 (lower right) indicates, this is due to an increase in futile target cycles. When social preference agents perceive most or all checkpoints in the environment, any time an agent arrives at a checkpoint, every agent will target that checkpoint, even when it is remote and the agent has no chance of arriving before another agent. This distracts agents from foraging locally, requiring them to return in order to visit checkpoints left behind. Note that, while the difference in scale between the graphs for redundant wait cycles and futile target cycles makes then look similar, the impact of futile target cycles is much smaller. This inefficiency could be dealt with, at least in part, with the addition of mechanisms that observe and use the states of other brides when making control decisions. However, we decided to try a different approach, presented in the next section.

6. PAIRING AGENTS

As we mentioned before, MATE-n tasks for $n > 1$ require greater degrees of coordination than MATE-1 tasks, because when $n = 1$, there is no need to coordinate actual checkpoint visits. Any time an agent arrives at a checkpoint, it is visited. This suggests a different approach to improving performance on MATE-2: rather than adding increasingly more complex mechanisms to attempt to deal with coordination inefficiencies, we can design agents that change the character of the task itself, superimposing a different, simpler task on the original one. Specifically, MATE-2 can be reduced to MATE-1 by simply allowing the agents to "team up" and proceed in pairs. After the initial pairing off phase, agent pairs should be perfectly coordinated: there will never be a wait cycle if both agents always arrive simultaneously. We created *pairing* agents that do this, to see how effective explicitly teaming up can be. The following ruleset constitutes the agent model for the pairing agent A:

Rule S1: if A's $role = scout$ and no other agent is perceived, perform a random walk $RW(rwd, \beta)$
Rule S2: if A's $role = scout$, some other agent O is perceived, O's $role = scout$, and O's leadership characteristic L is greater than A's own, $role = follower$ and $leader = O$
Rule S3: if A's $role = scout$, some other agent O is perceived, O's $role = scout$, and A's own leadership characteristic L is greater than O's, $role = leader$
Rule F1: if A's $role = follower$, follow the leader
Rules L1–L5: if A's $role = leader$, proceed with rules 1–5 for timeout agents, given above, with $W = 10000$

A pairing agent can be in one of three states: scout, leader, and follower. The scouting phase is when the agent is looking for a partner. while scouting, the agent ignores checkpoints, searching only for other agents. Each agent has a "leadership characteristic" L, which is not specified for these agents, but can be any rankable characteristic (e.g., the size of an animal, or the serial number of an extraplanetary rover). When another (scout) agent is located, they

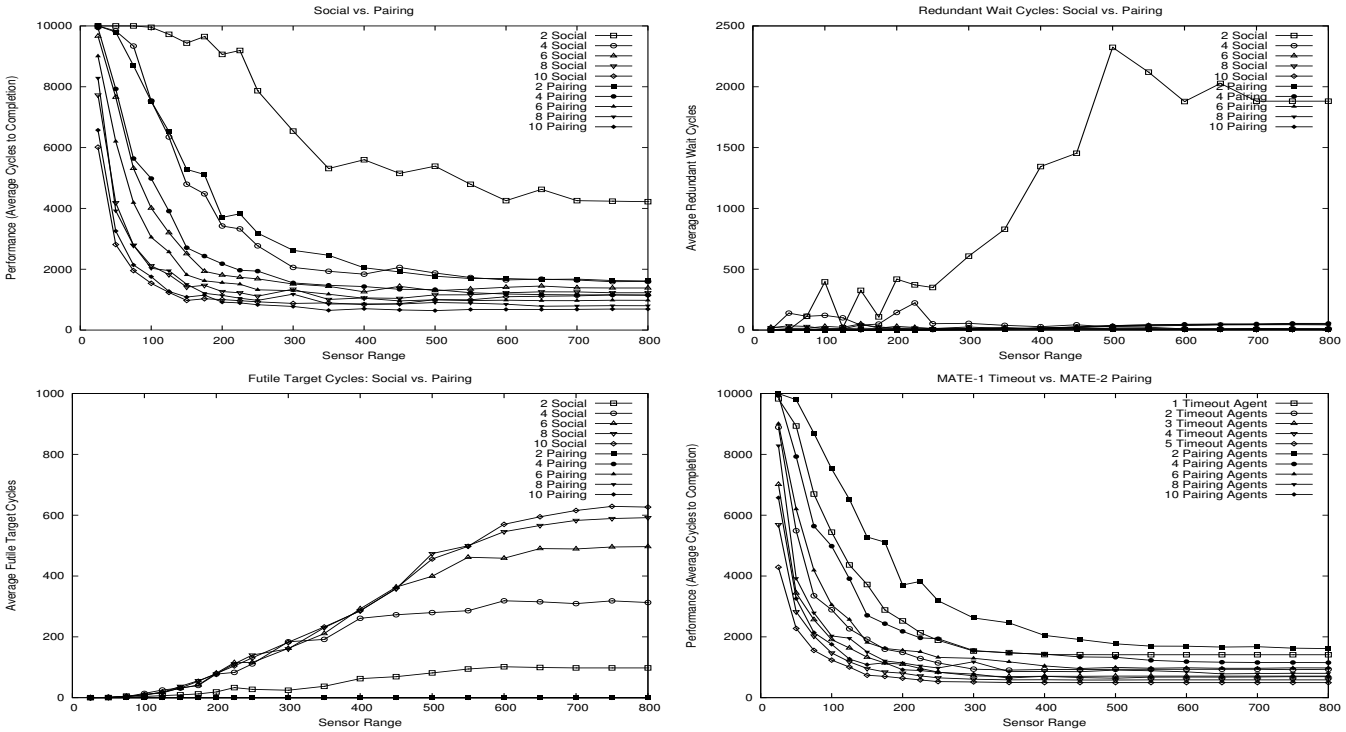

Figure 3: Upper left: Average performance of pairing and social agents. Upper right: Redundant wait cycles for pairing agents and social preference agents. Lower left: Futile target cycles for pairing agents and social preference agents. Lower right: Average performance of 1 to 5 timeout agents in MATE-1 and 2 to 10 pairing agents in MATE-2.

compare their leadership characteristics to determine the leader. If more than two agents are within sensory range, the top two pair off, then the next two, etc. Any odd agent is left out and continues to scout for a partner.

Once agents have formed a team, one enters the leading phase, while the other enters the following phase. In the leading phase, the agent effectively becomes a timeout agent. It explores the environment looking for checkpoints and moving to them when detected. In the following phase, the agent ignores all checkpoints, blindly following the leader wherever it decides to go.

6.1 Results

Figure 3 (upper left) compares pairing agents with non-communicating social agents. The performance improvements in small groups is quite good, although large groups of social agents perform as well as or better than pairing agents at low sensory range. A three-way 9x21x1 ANOVA was conducted with *group size* (2-10), *sensory range* (25-800), and *agent kind* (social and timeout) as the randomized variables and *cycles to completion* as the dependent variable. Group size ($F(8, 14742) = 2357.9752, p < 0.001$), sensory range ($F(20, 14742) = 2039.0519, p < 0.001$), and agent kind ($F(1, 14742) = 1692.0771, p < 0.001$) were all found to be highly significant main effects for cycles to completion, confirming that, overall, pairing agents outperform social preference agents. There is a highly significant two-way interaction between group size and agent kind ($F(160, 14742) = 47.7577, p < 0.001$), confirming that increases in sensory range are most effective in smaller groups, another highly significant two-way interaction between group size and agent kind ($F(8, 14742) = 276.9290, p < 0.001$), confirming that the greatest performance differences between social and pairing agents are to be found in smaller groups, and a final highly significant two-way interaction between sensory range and agent kind ($F(20, 14742) = 13.9703, p < 0.001$), confirming that the performance differences between social and pairing agents varies with sensory range. Finally, a highly significant three-way interaction ($F(160, 14742) = 8.1646, p < 0.001$) is a result of the social agents having greater performance in large groups with low sensory range, but worse performance in the remaining configurations.

6.2 Analysis

Pairing can almost be viewed as the ultimate in coordination for tasks like MATE-n. Once a pair has teamed up, the effect of the above coordination issues is minimal. Figures 3 (upper right) and 3 (lower left) confirm this. These demonstrate that the two sources of inefficiency are virtually eliminated by the pairing mechanism, thereby leading to improved performance. Note that they are not eliminated completely; it is still possible for two leaders to target the same checkpoint, leading to futile target cycles for the second pair. Similarly, leaders and followers do not always arrive at a checkpoint simultaneously,[3] so it is possible, particularly with high sensory range, for two leaders within sensory range to be waiting for their followers to arrive. Note,

[3] They can arrive separately at the first checkpoint they visit, because when they initially pair up, they are at a distance R from each other.

however, that these redundant wait cycles do not have any negative impact on performance.

7. DISCUSSION

The experimental results presented here show that the pairing mechanism is a good solution for coordination in MATE-n, without the need for communication. The degree of coordination achieved is high, after the initial pairing phase. The jilted groom role is eliminated, because agents do not target checkpoints until they have paired with another agent, which will arrive simultaneously, except possibly the first checkpoint visited (see Footnote 3). Similarly, the leader will not leave the checkpoint before the follower arrives, eliminating the jilted bride role. The lonely bachelor can still be a problem, in both the scout and leader/follower phases, when sensory range is low, but this is unavoidable and not a coordination issue. There are no dedicated bachelors, because, again, agents do not begin targeting checkpoints until they are paired with another agent. The final detrimental functional role, the bridesmaid, is the only one that still negatively affects pairing agents, in this case when one *pair* of agents arrives at a checkpoint before another pair. However, the magnitude of its impact is significantly decreased (especially at high sensory ranges) relative to social preference agents, which are particularly susceptible to playing the bridesmaid under these circumstances.

The bottom right graph in Figure 3 compares the performance of pairing agents in MATE-2 with the performance of timeout agents in MATE-1, for the same environmental conditions. The MATE-1 results are for 1–5 agents, whereas the MATE-2 results are for 2, 4, 6, 8, and 10 agents. If we compare the performance of a particular group size A in MATE-1 with the performance of $2 \cdot A$-agent groups in MATE-2, we can get a close approximation of the initial cost of teaming up for pairing agents. The figure shows that, while performance of pairing agents in MATE-2 is similar to the performance of timeout agents in MATE-1, there is a substantial penalty for the initial teaming up period. This suggests that, if it were possible to construct single agents that are capable of performing the task at a checkpoint individually at a reasonable cost, it would be beneficial to do so (thereby completing the reduction of the task to MATE-1). What is a "reasonable cost?" If the new agent kind were to cost less than or equal to twice what the old agent kind cost, this would clearly be a win. Moreover, given the cost of pairing shown in Figure 3, the cost of the enhanced agent could actually be somewhat more than twice that of the original MATE-2 pairing agents, and still achieve a better performance-cost ratio than the pairing agents.

8. CONCLUSION

In this paper we demonstrated that a simple mechanism like pairing can give rise to very high performance in MATE-n tasks. This is not only a good alternative to solutions with communication in situations in which communication is either not possible or is too expensive, but may actually be the better solution overall. Degenerate forms of leadership strategies like this one may in general provide good alternatives to communication for even more complex tasks than MATE-n. Future work will investigate this hypothesis for the $\bigcup_{k=1}^{n}$ MATE$-k$ tasks, in which checkpoints require from 1 to n agents, and there may be no way to predict the value of k for any particular checkpoint without being within sensory range of the checkpoint, where agents can perceive what kind of checkpoint it is (i.e., where they can figure out k). Also, MATE-n tasks in which heterogeneous agent groups are required to visit a checkpoint will be explored. Such heterogeneity requirements are likely to improve the utility of forming an appropriately composed group and proceeding in lockstep; the initial cost of grouping will be higher, however, the cost of breaking the group up due to the random walk mechanism is likely to be much greater.

ABSTRACT

Previous research about multi-agent coordination has concentrated at a high level, e.g. developing communication protocols for coordination, constructing special purpose agents to dictate the coordination behaviors of an entire system, or associating rules or coordination mechanisms with every agent to achieve cooperative behaviors. Much less research addresses multi-agent coordination at a low level: evaluating the effects of agents' task structures upon agents' coordination behaviors. This paper presents an Extended Hierarchical Task Network (EHTN) to represent precisely those structural features that affect coordination. Using this EHTN formalism, an extended set of Generalized Partial Global Planning (GPGP) coordination mechanisms has been developed for multi-agent coordination. Each coordination mechanism is defined in terms of EHTN rewriting rules and an associated set of pre-defined EHTN behaviors. This set of GPGP coordination mechanisms has been applied to a simulated emergency medical service (EMS) system. The experimental results reveal some of the performance relationships between specific mechanisms and external environmental characteristics.

Keywords

Multi-Agent Coordination

1. INTRODUCTION

Well coordinated behaviors can greatly improve agent performance, while inappropriate coordination results in reduced system efficiency, unfinished tasks, misuse of key resources, and even system crashes. It is critical to understand how to achieve well coordinated behaviors for involving intelligent software agents. While much research has focused on high-level coordination approaches, less attention has been focused on the use of task structure detail for coordination.

In order to make use of task structural information, it is key to find a suitable way to represent agents' task structures. STRIPS-style planning systems were developed almost thirty years ago. Most current practical planning systems within the past decade have been based on Hierarchical Task Network (HTN) decomposition. The analysis of the syntax and semantics of HTNs has been well studied [5, 11, 13]. However, the traditional HTNs do not represent what is happening in dynamically changing systems. Particularly, traditional HTNs are not expressive enough to represent certain problems concerning worth-oriented goals, contingencies, and the uncertainties that arise when task plans are in fact distributed over multiple agents. There has been no adequate representation method to capture the task features useful for coordination purposes.

We have developed a highly expressive representation method, Extended Hierarchical Task Networks (EHTNs), to accurately describe the features of agents' tasks, such as information flow and control flow of a complicated task network, the dependency relationship between the tasks of involving agents, and effects of task execution results. We believe that task structural information is helpful for multi-agent coordination, i.e., agents' task structures can be analyzed and manipulated for managing the interdependency relationships among agents.

This paper further articulates a domain-independent approach for specifying an extended set of seventeen GPGP (Generalized Partial Global Planning) coordination mechanisms, which are recast using the EHTN formalism.

We chose a simulated emergency medical service (EMS) system to demonstrate the effectiveness of the extended set of GPGP coordination mechanisms. Based on the experimental results, quantitative and qualitative analysis has been carried out and significant conclusions have been presented to guide agents in selecting the best mechanisms in various environments.

The EHTN task representation language will be presented in Section 2. Our extended set of GPGP coordination mechanisms will be explained in Section 3. A simulated emergency medical service system is briefly introduced in Section 4. The experimental results of the application of these coordination mechanisms in EMS is discussed in Section 5. Finally, we state our conclusion and future work.

2. EXTENDED HIERARCHICAL TASK NETWORKS (EHTNS)

Following the definition of coordination as "managing dependencies between activities"[9], interdependency relationships among multiple agents introduce the problem of con-

tingency, uncertainty, and worth-oriented goal tradeoffs. Traditional HTNs do not have the language constructs to model the quantitative features of task execution results and the information flow and control flow of the task networks in a distributed environment. For example, one prerequisite input of a task, named TaskA, of Agent A is the result value of a task, named TaskB, of another agent, Agent B; in the absence of any additional information it is unlikely that TaskA in Agent A could be listed as a valid candidate plan step at all. Several approaches have tried to address parts of this problem [7, 10], however, there is no formal representation that is able to quantitatively denote worth-oriented goals, contingencies, and uncertainties distributed across multiple agents. In discussing the Markov decision process (POMDP) approach Boutilier[1] observes that in practice standard AI representations and algorithms survive because real "problems commonly possess structure ... [therefore] specialized representations, and algorithms employing these representations, can achieve computational leverage by exploiting these various forms of structure." It is such a practical approach to extend the existing traditional hierarchical task networks with enriched syntax, semantics, and reasoning capabilities to tackle the aforementioned coordination problem, merging features from TÆMS[12]; the HTN-style agent languages used by RETSINA[**?**] and DECAF[6]; and Erol's formalization of HTNs[5].

It is important to explicitly represent non-local tasks with EHTNs. If one agent's action(s) depends on another agents' action(s), we call this kind of relationship a *coordination relationship* or *interdependency*[4, 12]. An interdependency is *a relationship between a local task (of one agent) and a non-local task (of another agent) where the execution of one changes some performance-related characteristics associated with the other*. A non-local task denotes a task network from a remote agent and is the key to understanding and managing task interdependencies. If non-local tasks can be properly represented, identified, and analyzed, it is possible to develop coordination mechanisms to manipulate non-local tasks based on the task features.

We will briefly present Extended Hierarchical Task Networks (EHTNs) based on the well known work of Erol, et al. [5] and focus primarily on the differences. Note that we only concentrate on an agent's (partially) *local* view—primitive or compound tasks at other agents are represented locally as *non-local tasks* (NLTs). The vocabulary of the language $\mathcal{L}$ is a tuple $\langle V, C, P, F, T, N, NLT, I, O, A, CAF\rangle$, where V, C, P, F, T, N have the same meanings as defined by Erol [5]: V is an infinite set of variable symbols; C is a finite set of constant symbols; P is a finite set of predicate symbols; F is a finite set of *primitive* task symbols, T is a finite set of *compound* task symbols, and N is an infinite set of symbols used for labeling tasks. Our new language constructs are introduced as follows: NLT is a finite set of *non-local task* symbols; I is a finite set of input provision symbols; O is a finite set of outcome symbols including "OK" and "FAIL"; and A is a finite vector of domain-dependent task/action characteristics represented by text values, $\langle A_1, A_2, ..., A_n\rangle$, where A_i is the ith attribute of a task/action (quality, duration, cost, completeness, reputation, etc.). An instance of attribute A_i is shown as a_i. For example, the duration of an information searching task using a specialized database search engine is one minute, the cost is $1.00, and the quality, or satisfaction rate, is 10; while using a free search engine, the corresponding characteristics are two minutes, $0 cost, and the satisfaction rate of 5. CAF is a finite set of characteristic accumulation functions (CAF); a CAF specifies how the value of an attribute A_i of a parent task is derived from the cumulative values of its direct child tasks. Typically functions are *MAX, MIN, SUM*, etc. For example, the cost of a task could be the *sum* of the costs of all its children; the duration of a task is the maximum (*max*) child duration in parallel execution and *sum* in serial execution; and those tasks that only need one child to be completed ("OR" tasks, or "OR" nodes) may have *max* as a quality-CAF, i.e. characteristic accumulation function on quality, etc. We modify Erol's HTN representation to include explicitly named input provisions and outcomes (representing possible contingencies). The information flow and control flow represented with EHTNs can be managed for coordination. Details about the syntax, semantics, and algorithms based on ETHNs are explained in [2]. In Figure 1,

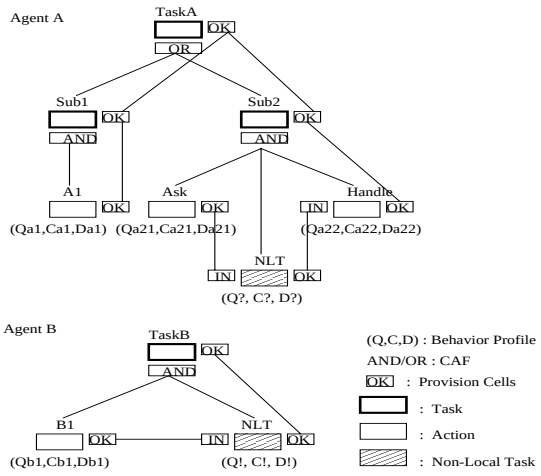

Figure 1: Example Agent Task Structure.

the task networks, TaskA and TaskB, belong to Agent A and Agent B respectively. The new language construct, NLT, of EHTNs means the set of non-local tasks; the task labeled "NLT" within the task network, TaskA, is an example of a non-local task. The cell labeled "IN" associated with the action, "Handle", is a provision, which indicates that the action can not be executed until a value is filled for this provision. The cell labeled "OK" is an output of the action, Handle, which refers to the execution result of this action. The information flow and control flow are indicated by the lines connecting the provisions and outcomes. For example, the outcome "OK" of the action, "Ask", connects to the provision cell, "IN", of the non-local task, "NLT"; the outcome "OK" of "NLT" connects to the provision "IN" of "Handle". The connections indicates that "NLT" will not be executed until "Ask" is finished; and "Handle" will not be executed until a value has been transported from outcome "OK" of "NLT" to "IN" of "Handle". The cell labeled "AND" associated with the sub-task, Sub2, dictates that all child tasks (Ask, NLT, and Handle) should be finished to reach the achievement of their parent task "Sub2". The vector, (Q,C,D), below each action specifies the quantitative features of that action. Notably, the quantitative features of a non-local task are uncertain, which results in the failure of

proper scheduling for Agent A. The existence of uncertainty is because the NLT actually represents the execution of a requested remote task, TaskB of Agent B in this case; Agent A has limited view about other agents and has no knowledge about TaskB. Certain coordination activities may be carried out so that the uncertainty can be removed, as explained in Section 3.

Our proposed coordination process has two steps: (1) locating the interdependencies in the task structure, and (2) applying the coordination mechanisms at those dependencies. We will introduce the application of mechanisms in Section 3. Here we explain the rules for locating interdependencies within agents' tasks.

Given that tasks are represented by our EHTNs, it is easy to detect interdependencies within agents' tasks structures. Any non-local tasks that meet the following conditions are interdependencies, or called *coordination points*, and require the application of a suitable coordination mechanism:[1]

- A non-local task, "NLT", exists within a task network;
- A provision of "NLT" is connected with an outcome of one child action, which shares the same parent task;
- An outcome of "NLT" connects to a provision of another child action of the same parent task.
- There is no other non-local tasks for the parent task.

With the explicit EHTN representation of coordination and the rules for detecting interdependencies among agents' tasks by analyzing structural features, algorithms have been developed for our agents to find out the needs for coordination.

3. AN EXTENDED SET OF GPGP COORDINATION MECHANISMS

Previously, we have introduced the detection of interdependencies by analyzing characteristics of agents' task structures. In this section, we will introduce an extended set of GPGP (Generalized Partial Global Planning) coordination mechanisms and the actual operations for these mechanisms.

Each coordination mechanism consists of (1) a set of coordination communication protocols and (2) a pattern-directed re-writing of our extended hierarchical task networks, EHTNs [2]. Figure 1 shows a general example, Agent A's action, Handle, can not be executed until action B1, is finished by Agent B, (B1 of Agent B enables Handle of Agent A). Thus, Agent B is an *enabler* (enabling the task of a remote agent) and also called a *predecessor*; Agent A is an *enablee* and called a *successor* as well. There are many potential coordination mechanisms for this situation. The coordination component in Agent A detects the interdependency relationships between these two agents (as explained in Section 2), and the task NLT with uncertain characteristics in Agent A is replaced (the task tree is rewritten) by a selected coordination mechanism which may include information communicated about *TaskB* from Agent B.

Our extended set of seventeen GPGP coordination mechanisms are briefly listed and explained as below. *Avoidance* and *sacrificial avoidance*: Agent A removes the branch containing the NLT if the CAF of TaskA is OR (with or without some sacrifice of system quality); *reservation*: Agent A reserves the execution of B1 by Agent B at a future time, so that Agent A is able to schedule its own activities in the mean time; predecessor-side commitments (Agent B): Agent B commits to do task B1 at sometime in the future (*predecessor notice at start*), to do it by a deadline (*predecessor deadline commitment*), to an earliest-start-time (*predecessor EST commitment*), or to notify when complete (*predecessor sending result*); simple successor-side commitments (Agent A): Agent A commits to do the action, Handle, with or without a specific Earliest Start Time (EST) (*successor EST commitment*); Agent A commits to do the action by specifying a deadline (*successor deadline commitment*); polling approach: Agent A consistently queries about the execution of the enabling tasks, B1, (*polling for result*) or the schedule of Agent B (*polling for schedule*); *constant headway / timetabling*: Agent A schedules its tasks according to a constant pattern, e.g., either in a fixed periodic manner (every ten minutes) or following a timetable, e.g, catching a bus based on a published bus schedule; shifting task dependencies: either Agent A sends its task structure (Sub2) to Agent B (*promotion shift*), or Agent B sends B1 to Agent A (*demotion shift*), by learning or mobile code (promotion or demotion); third-party mechanisms: a third agent, Agent C schedules the tasks for both Agent A and Agent B (*third party coordinator*), or Agent C executes B1 for Agent B if Agent B is busy (*third party execution*); *bidding*: Agent A broadcasts a coordination request to all available agents for the engagement of coordination process; or other complex multi-stage negotiation strategies. Details about these coordination mechanisms will be explained in the simulated EMS system shown in Section 4.

Let us explain the operation of *reservation* mechanism as an example. This mechanism is named after the real world activity of reservations. For example, if you want to have dinner in a restaurant, before you go there you had better make a reservation so that at some agreed future time, you will be there and the people there will be ready to serve you to avoid the potential waiting time. Imagine Figure 2 with task $Sub1$ removed so that Agent A has no alternative choice. The reservation mechanism includes a new protocol, instantiated as new task structures (called "GPGP_ReservationR" at Agent B and "GPGP_ReservationE" at Agent A) that processes a message from Agent A indicating a request to do a task (B1 of Agent B) sometime in the future. The reply is a message from Agent B indicating whether the request is agreed or refused; and if agreed, when (if ever) the task will occur. The reservation mechanism rewrites the task structure for Agent A so that a new subtask ("GPGP_ReservationE") is executed and invokes the "GPGP_ReservationR" at Agent B and then processes the return message. The result is an annotation on the non-local task that allows Agent A to predictively schedule task $Sub2$ and execute other potential tasks locally at a time before the enabling task (B1) has been completed.

This mechanism includes both a rewriting of the local task structure and some external communication protocol depicted in Figure 3. Only three rounds of message transfer are needed for the basic reservation process. We assume that there is no need to introduce a confirmation phase in this process. After the re-writing process, the new task structure for Agent A is very similar to that shown in Figure 2,

[1]Formalization of of interdependency detection is presented in [2] together with the full introduction of the EHTNs.

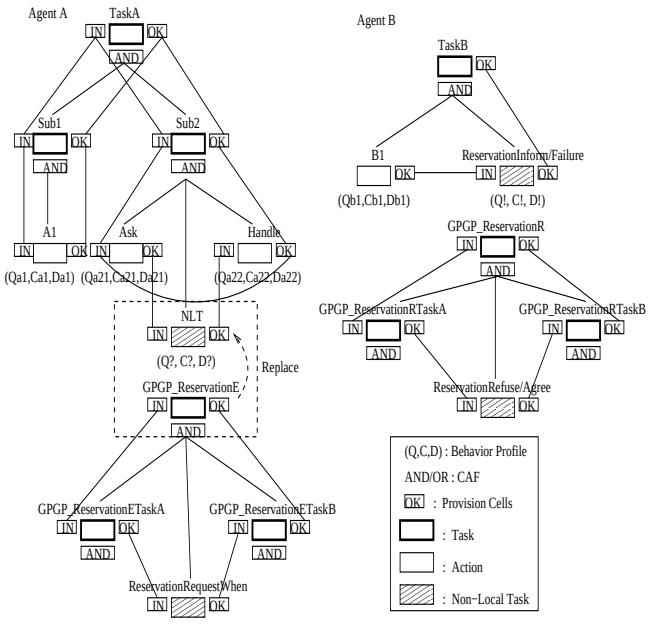

Figure 2: The domain tasks and the inserted GPGP mechanism – coordination by reservation.

except that the task NLT is replaced with the task network GPGP_ReservationE in the dashed box with links is altered. Details about the other mechanisms are in [2].

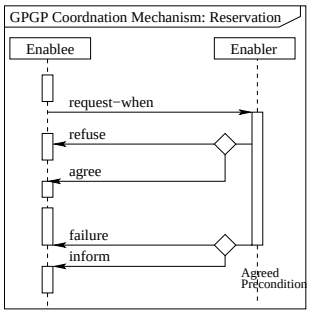

Figure 3: Sequence diagram of GPGP coordination mechanism protocol: Reservation.

4. A SIMULATED EMERGENCY MEDICAL SERVICE (EMS) SYSTEM

Emergency Medical Service, EMS, is defined as a comprehensive, coordinated arrangement of health and safety resources designed to provide expedient care to victims of sudden illness and injury. This paper focuses on *prehospital EMS*, which is generally defined as the response process from the start of an incident to the hospitalization of victims. In EMS systems events happen rapidly and unexpectedly; decision making is highly time-critical based on involving response organizations, institutions, and even geographical sites; doctors, nurses, and paramedics are constantly on the move. Such high-velocity environments pose special computing and communication needs. Information flow among the related entities needs to be highly effective; however, communication channels could be radically impaired based on certain environmental changes, such as traffic jams and power failures. Thus, effective dynamic coordination is key to EMS systems.

A typical EMS process is briefly explained as shown in Figure 4: when an emergency happens, an incident call is reported to the EMS system dispatcher; based on the nature of the incident, e.g. the type of the incident, whether there is any victim at the incident, the dispatcher contacts an appropriate response agency or multiple agencies and sends appropriate vehicles to the incident location; the response vehicle finds its way to the incident location; then proper management of the incident is provided until the incident is considered finished; if any victim needs further medical care, an ambulance will be called to the incident location and the victim will be transported to a proper medical facility by the ambulance; if the incident still requires additional care, other appropriate response vehicles will be dispatched to the incident location as well; after the incident is finished, all participating response vehicles find their ways back to their base stations or move on in response to other incident calls. Further description about the simulated EMS system can be found in [3, 2]. In this paper, we will concentrate on explaining the task structures of response agents within EMS and the application of our extended GPGP mechanisms in this environment.

The first interdependency is named *EMS coordination point one*. The coordination points are also shown as dashed boxes in Figure 4. When an incident happens, the dispatcher needs to deliver the incident message to certain response agents; response agents will send a message back to the dispatcher indicating whether they are available to manage this incident; based on response agents' replies, the dispatcher decides which agent should be selected in response to this incident. That is, the dispatcher can not decide which agent to dispatch for an incident until reply messages arrive; furthermore, the task of a response agent can not start until the notification of the the selection of certain agents. Clearly the dependency is between the message-sending task of the dispatcher and the task of a response agent.

The second interdependency is named *EMS coordination point two* and the task structures of the involving agents are shown in Figure 5[2]. If a police agent has been selected to respond to a police incident, after it arrives at the incident location, it finds that the incident develops and is not simply a police call any more—a victim of the incident needs immediate medical care and potentially needs to be transported to a hospital for treatment; thus the police agent sends a message to a local ambulance agent about the victim; the police agent needs to wait for the arrival of an ambulance; in the meantime the police agent can not carry out other tasks, e.g. to respond to another incident, until the arrival of the ambulance at the incident location; it is easy to figure out that the dependency is between the police agent's tasks and the arrival of the ambulance for immediate medical treatment for victims.

The third interdependency is named *EMS coordination point three*: When an ambulance arrives at the incident location, it finds out that a victim needs to be transported to a local hospital for further treatment; however, open beds

[2]Due to the paper length constraint, the figures for the other two interdependencies are not shown. See [2] for details.

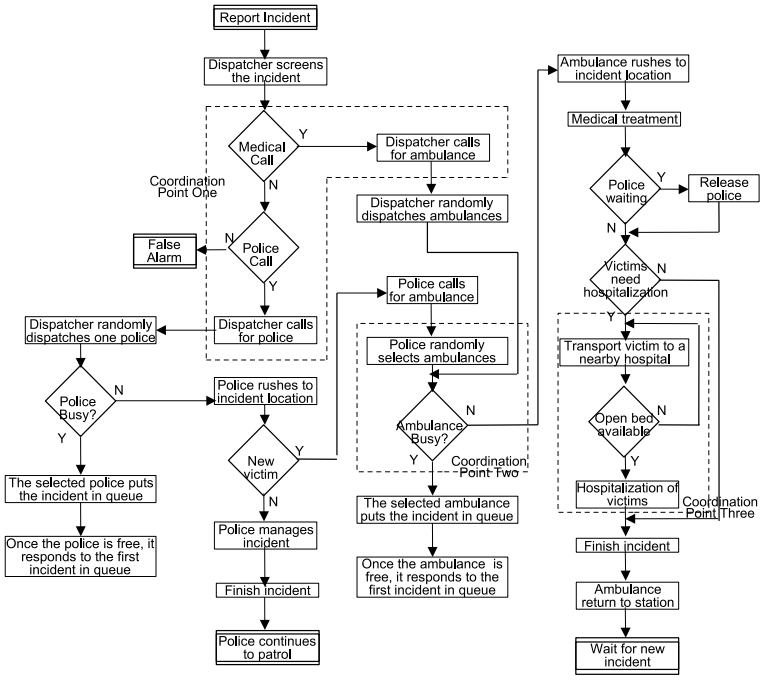

Figure 4: Diagram of EMS operation

may not be always available at hospitals; the hospitalization of a victim for further medical treatment depends on the availability of open beds in the hospital at the time of the victim's arrival; if an ambulance containing the victim arrives at the hospital and there are no any open beds available, the victim has to be transported to another hospital, which is a major delay for further treatment for the victim. In this case the dependency is between further medical treatment for victims by hospitals and the acknowledgment of available open beds from a hospital.

5. EXPERIMENTAL RESULTS

The EMS experimental environment is simplified to include two classes of agents: three police cars and two ambulances move around in local area map in response to incident calls and travel from their base stations (for ambulances) or their current patrol locations (for police agents) to incident locations. There are many other dependencies in an EMS environment. However, we will apply our extended set of GPGP coordination mechanisms to these three coordination points.

Different types of agents have different tasks; tasks for the same type of agents share the same structures. Initial task structures for ambulance, police car, and hospital are shown in Figure 5. These tree-style structures represent tasks for response agents. Top-level root nodes indicate agents' goal tasks. Leaf nodes represent the actions each agent has to execute. The cloud-shape nodes are communication interfaces for an agent to receive and send messages to remote agents. For coordination processes, these communication interfaces could represent non-local tasks as well. The task structures depicts the decomposition of corresponding root tasks into low level tasks until executable actions. The symbols, Input and OK, are the input and output of a task or an action. The links connecting the input and output represent information flow. The meanings of various types of nodes, the task structural information, and task decomposition are further discussed in [6]. Figure 5 only shows main tasks and actions of response agents as a simplified version. The

17	Bidding	Y	Y	Y

seventeen GPGP coordination mechanisms can be suitably applied to the aforementioned corresponding coordination points as shown in table 5. P1 means Coordination Point One. A "Y" cell in the table shows that the mechanism (to the left of the row) can be applied to the correspond-

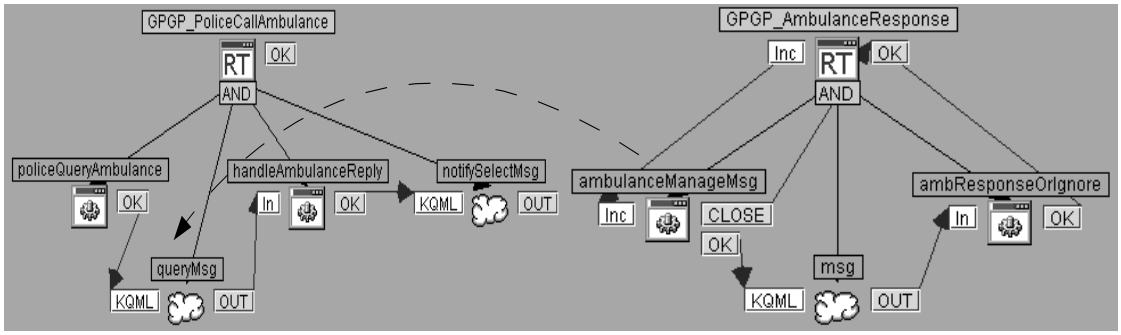

Figure 5: EMS coordination point two: between police and ambulance.

ing coordination point (indicated by the coordination point number to the above of the column); a blank cell indicates the mechanism is not applicable to the corresponding coordination points. For example, the first mechanism, *avoidance*, can be suitably applied to coordination point two, but not to coordination point one and three, simply because there is no alternative local task available; the second mechanism, *reservation*, can not be suitably applied to coordination point one, but can be applied to point two and three; the seventeenth mechanism, *bidding*, can be applied to all three coordination points safely; while *promotion* can not be applied to any of the coordination points.

We define an event, or an accident, that causes a 911 emergency call as an *incident*. There are various types of incidents requiring different response organizations. Coordination during response processes may involve all types of participating agents. An incident is represented as *incident(time, type, severity, location, duration, number, victims[number].(life, life_function))*.

Time means the start time of an EMS process. There are three types of incidents in the model: *medical calls*, *police calls*, and *mixed calls*. A medical call requires ambulances to provide incident victims with primitive treatment and potential transportation to a nearby hospital if needed. A police call requires police agents; it is modeled as a traffic accident or a criminal accident and requires the police to manage the situations, e.g. clearing road or catching criminals. A mixed call starts as a police call and requires police agents at the beginning; upon the arrival of a police agent, the police agent finds out that there are new victims associated with the police call; thus, the police agent calls for ambulances to take care of the victims, as if it was an a medical call. *Severity* indicates whether there are any injured victims associated with the incident and the level of the injury: $(severity = 0)$ means low severity injury and an ambulance is needed for primitive treatment, e.g., CPR or other first aid assistance; $(severity = 1)$ means high severity and an ambulance is not only needed to provide the above basic treatment, but also to transport the victims to a nearby hospital for further medical treatment. An *incident location* means the spot where the incident happens; it is represented with coordinate $Incident.Location(x, y)$; *Duration* indicates how long an incident lasts, e.g how long a response agent is kept on the incident location; in other words, duration indicates the working time for a response agent to manage the incident; an actual duration in experiments follows exponential distribution and will be described later. *Number* represents the number of the victims of an incident; candidate values are (0, 1, 2); if the number is greater than a single ambulance's capacity, multiple ambulances may be dispatched. Notably, the capacity of an ambulance is one, i.e. each ambulance is able to transport one victim at a time. The compound variable, *victim*, is one of the major resources in the EMS framework. *Victim[number].life* represents the victim's initial life value immediately following the incident and this value drops according to the victim's *life function*. A life function indicates how a victim's life value drops as time goes on after an incident. If *life* of a victim drops to zero before entering an appropriate medical facility, it indicates the death of this victim. There are two kinds of life functions defined: sharp linear reduction and flat linear reduction according to time change:(1) $f_1 = (\text{Initial Value} - a_{sharp} * t)$ and (2) $f_2 = (\text{Initial Value} - a_{flat} * t)$, where a_{sharp} and a_{flat} are coefficients indicating sharp and less sharp life value reductions. Based on different values of an incident, different response agents will participate and different operations will be carried out.

In EMS systems, the occurrence of incidents follows a Poisson distribution; and the distribution of time intervals between successive incidents follows an exponential distribution. The time interval, t, from the occurrence of a current incident until the occurrence of a next incident is calculated as the following equation shows.

$$t = \frac{\log(1 - rand())}{-\lambda},$$

where rand() is a uniformly generated random number within the range of $[0, 1)$, $\lambda = \frac{1}{\text{mean}}$, mean is the average value of a series of expected time intervals for next incidents.

There are three main evaluation factors for EMS at a system level: *response time* for quality control, *survival rate* for effectiveness control, and *coordination cost* for efficiency control. In our EMS model, the start of a response time is *when an emergency call is received*; and the end time is *when any appropriate response agent first arrives at the incident location*. Survival rate evaluates the effectiveness of EMS and reflects the overall system performance; survival rate is defined as the rate of victims surviving from an incident reported by a particular EMS system. Coordination cost is another important factor, which reflects system resource consumption by coordination processes, e.g. extra communication for coordination purpose, extra computation for coordination mechanism execution.

The experiments was carried out in a local area network,

agents may reside in different Sun workstations. Each round of experiment consists of one hundred incidents, which have been generated randomly following an exponential distribution at locations in a local area map.

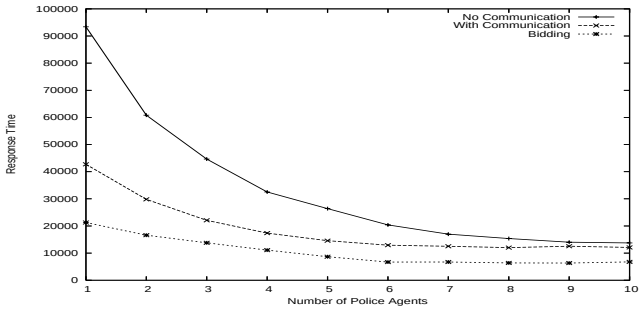

Figure 6: Response time based on changing number of agents (mean=20s).

The first experiment is to estimate the response time of three selected mechanisms, No Communication, With Communication, and Bidding, based on changing number of agents. Different numbers (from one to ten) of agents have been used in each round of experiment. Each response time is an average value of the one hundred response times according to the one hundred incidents for each run. The experimental result is shown in Figure 6. The result indicates that when the number of response agents is limited, e.g., below four, *Bidding* mechanism achieves the shortest response time; coordination without communication has the worse response time; the availability of communication improves response time significantly. As the number of agents increases, the agents are distributed across a local area and the response times approximates with each other when the number is above eight. This experiment leads us to the most suitable number of limited resources (agents) for a certain EMS environment.

Now let us introduce the experiments on the performance of various coordination mechanisms applied to different coordination points in our EMS system. The selection of each kind of response agents is: three police agents, two ambulance agents, two hospitals, one dispatcher. These facts are randomly generated and follow an exponential distribution: next incident arrival time (average arrival time is ten seconds), service time for response agents (average time for a police or an ambulance agent to work at an incident location is two seconds), hospital service schedule time (the average schedule cycle, the arrival of a next victim not from this EMS framework, occupying the open beds, is ten seconds; the service time for a victim is four seconds.). Initial life value of a victim is twenty seconds. The coefficient of life function with sharp reduction is simply one; the coefficient of life function for less sharp reduction (life value decrease slowly.) is 0.5. The EMS evaluation factors of GPGP coordination mechanisms applied to coordination points based on Table 5 will be presented in detail.

As the tasks from Figure 5, Figure 7 shows the sorted average EMS response time of the selected thirteen mechanisms. The *base case* is the situation where there is no GPGP coordination mechanism deployed. If there is an alternative local task, the coordination task can be removed;

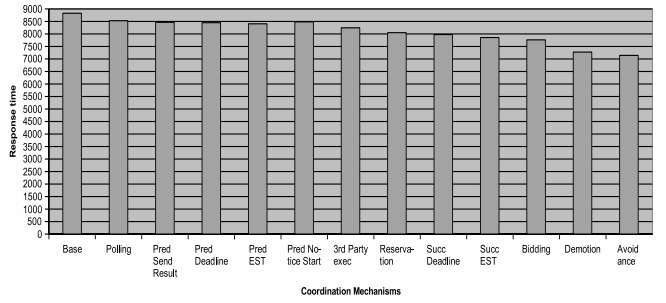

Figure 7: Average response time of selected GPGP Coordination Mechanisms on EMS Coordination Point Two.

thus the *Avoidance* mechanism has the shortest response time. When there is no alternative tasks, *Demotion* mechanism is the best, while *Polling* takes the longest time. Other mechanisms have difference performance in between.

In response to the performance of the selected coordination mechanisms, the shortest response time results in the highest victim survival rate, because a response agent may reach the incident location and provide treatment to the victim immediately. The survival rates of different coordination mechanisms maintain the sequence as in Figure 7 and are shown in Figure 8. The survival rate is affected by the response time: *Avoidance* produces the highest survival rate; *Demotion* is the best if coordination cannot be avoided; *Polling* has the lowest survival rate; other mechanisms fall in between.

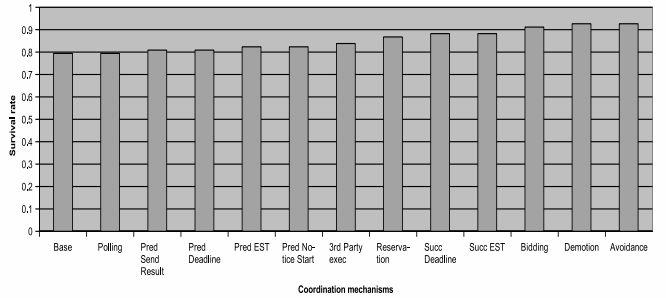

Figure 8: Average survival rate of selected GPGP Coordination Mechanisms on EMS Coordination Point Two.

Figure 9 shows EMS coordination cost versus selected coordination mechanisms applied to coordination point two. Given that *Polling* is carrying out persistent queries, it does results in the highest coordination cost. *Avoidance* has little coordination cost (the only cost is the detection of interdependency and its local alternative task). Other coordination costs by the rest of the mechanisms are as shown.

Due to the distinctive structural features of the three coordination points described earlier, different coordination mechanisms generate different results for the three EMS evaluation factors. We have shown coordination point two in detail as an example. The figures of the experimental results of the mechanisms applied to coordination point one

and three are omitted here. But, the most important factor, EMS response time, of the selected mechanisms for coordination point one and three will be listed as follows. Seven coordination mechanisms have been applied to coordination point one, the order from the longest response time to the shortest is: Base Case, Polling, Successor Deadline Commitment, Success EST Commitment, Third-Party Execution, Bidding, and Third-Party Coordinator. Similarly, eight coordination mechanisms have been applied to point three, and the order from the longest response time to the shortest is: Base Case, Polling, Third-Party Execution, Success EST Commitment, Successor Deadline Commitment, Constant Headway, Bidding, and Reservation.

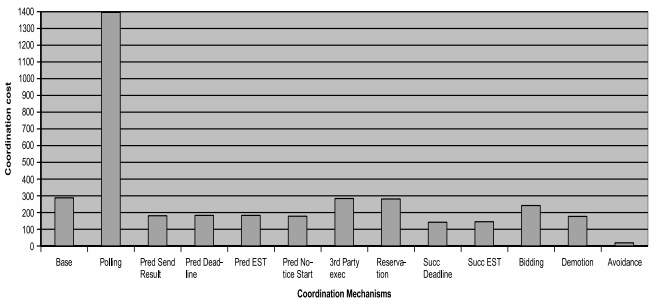

Figure 9: Average coordination cost of selected GPGP Coordination Mechanisms on EMS Coordination Point Two.

The above experiments have shown that different coordination mechanisms may perform best at different coordination points. It is important to see how the overall system performances be improved by a combination of the best mechanisms. In this experiment, we select a *combination* environment: *bidding* mechanism applied to coordination point one, *demotion* applied to point two, *reservation* applied to point three. The base case is that there is no any coordination mechanism applied to any coordination point. The next table shows the result and concludes that a careful

Table 2: System performances caused by a combination of the best mechanisms applied to the corresponding three coordination points .

Environments	ResponseTime	SurvivalRate	TotalCost
Base Case	9523	80%	1010 msec
Combination	3598	100%	624 msec
Improvement	37.8%	125%	61.8%

selection of our extended set of GPGP coordination mechanisms at different coordination points significantly improves the overall system performances.

6. CONCLUSIONS AND FUTURE WORK

We have briefly introduced a highly expressive representation, EHTNs, to explicitly denote the characteristics of agents' task structures. Given EHTNs, interdependencies can be detected and analyzed. An extended set of domain-independent GPGP coordination mechanisms has been developed to address the coordination problem. We also introduced a simulated EMS system for demonstrating the performance of various mechanisms applied to selected interdependencies. We have experimentally demonstrated that the application of our mechanisms improves system performance and different mechanisms may outperform others in different environments (or coordination points within an environment). We have demonstrated that the development of coordination mechanisms based on the analysis and alteration of agents' task structures is a promising approach.

The final experiment about overall system performance is a greedy approach, meaning that selecting the best mechanism for each coordination point without considering potential relationships among these coordination points, i.e. it is not determined whether the result shown in table 5 is the best possible improvement, since other combinations of mechanisms may be better. The experiments about other potential combinations of mechanisms, and of course learning appropriate sets of mechanisms, are part of future work.

ABSTRACT

Norms constitute a powerful coordination mechanism among heterogeneous agents. We propose means to specify and explicitly manage the normative positions of agents (permissions, prohibitions and obligations), with which distinct deontic notions and their relationships can be captured. Our rule-based formalism includes constraints for more expressiveness and precision and allows the norm-oriented programming of electronic institutions: normative aspects are given a precise computational interpretation. Our formalism has been conceived as a machine language to which other higher-level normative languages can be mapped, allowing their execution.

1. INTRODUCTION

A major challenge in multi-agent system (MAS) research is the design and implementation of *open* multi-agent systems in which coordination must be achieved among self-interested agents defined with different languages by several designers. Norms can be used for this purpose as a means to regulate the observable behaviour of agents as they interact in pursuit of their goals [13, 2, 3, 8]. There is a wealth of socio-philosophical and logic-theoretical literature on the subject of norms (*e.g.*, [11, 12]), and, more recently, much attention is being paid to more pragmatic and implementational aspects of norms, that is, how norms can be given a computational interpretation and how norms can be factored in in the design and execution of MASs (e.g. [1, 6, 7]).

A normative position [11] is the "social burden" associated with individual agents, namely, their obligations, permissions and prohibitions. Depending on what agents do, their normative positions may change – for instance, permissions/prohibitions can be revoked, or obligations, once fulfilled, may be removed. Ideally, norms, once captured via some suitable formalism, should be directly executed, thus realising a computational, normative environment wherein agents interact. This is what we mean by *norm-oriented programming*. We try to make headway along this direction by introducing an executable language to specify agents' *normative positions* and manage their changes as agents interact via speech acts [10].

In this paper we present a language that acts as a "machine language" for norms on top of which higher-level normative languages can be accommodated. This language can represent distinct flavours of deontic notions and relationships. Although our language is rule-based, we achieve greater flexibility, expressiveness and precision than production systems by allowing constraints to be part of our rules and states of affairs. In this way, normative positions can be further refined. Hence, constraints are considered as first-class citizens in our language.

Although in this paper we restrict to a particular class of MASs, namely electronic institutions [4], our work sets the foundations to specify and implement open regulated MASs via norms.

Our main goal is to produce a language that supports the specification of coordination mechanisms in multi-agent systems by means of norms. For this purpose, we identify below the desirable features we expect in candidate languages.

Explicit management of normative positions. As a result of agents' observable, social interactions, their normative positions [11] change. Hence, the first requirement of our language is to support the *explicit management* of agents' normative positions.

General purpose. We require that our language captures different deontic notions along with their relationships. In other words, the language must be of *general purpose* so that it helps MAS designers to encode any axiomatisation, and thus specify the widest range of normative systems as possible.

Pragmatic. We pursue a "machine language" for norms on top of which higher-level languages can be accommodated. Along this direction, and from a language designer's point of view, it is fundamental to identify the *norm patterns* (*e.g.*, conditional obligation, time-based permissions and prohibitions, continuous obligation, and so on) in the literature to ensure that the language supports

their encoding[1]. In this way, we shall guarantee the expressiveness of our language, and also address pragmatic concerns by providing *design patterns* to guide and ease MAS design.

Declarative. In order to ease MAS programming, we shall also require our language to be *declarative*, with an implicit execution mechanism to reduce the number of issues designers ought to concentrate on. As an additional benefit, we expect its declarative nature to facilitate verification of properties of the specifications.

2. A RULE LANGUAGE FOR NORMS

The building blocks of our language are first-order terms (denoted as τ) and implicitly, universally quantified atomic formulae (denoted as α) without free variables . We shall make use of numbers and arithmetic functions to build terms; arithmetic functions may appear infix, following their usual conventions[2]. We also employ arithmetic relations (*e.g.*, $=, \neq$, and so on) as predicate symbols, and these will appear in their usual infix notation with their usual meaning. Atomic formulae with arithmetic relations represent *constraints* on their variables and have a special status, as we explain below. We give a definition of our constraints, a subset of atomic formulae: a constraint γ is an atomic formula of the form $\tau \lhd \tau'$, where $\lhd \in \{=, \neq, >, \geq, <, \leq\}$. We need to differentiate ordinary atomic formula from constraints. We shall use α' to denote atomic formulae that are *not* constraints.

Intuitively, a state of affairs is a set of atomic formulae. As we will show below, they can store the state of the environment[3], observable agent attributes and the normative positions of agents: a state of affairs $\Delta = \{\alpha_0, \ldots, \alpha_n\}$ is a a finite and possibly empty set of implicitly, universally quantified atomic formulae.

Our rules are constructs of the form *LHS* $\rightsquigarrow$ *RHS*, where *LHS* contains a representation of parts of the current state of affairs which, if they hold, will cause the rule to be triggered. *RHS* depicts the updates to the current state of affairs, yielding the next state of affairs. The grammar in Fig. 1 defines our rules, where x is a variable name and *LHS** is a *LHS* without set constructors (see below). The Us represent the updates: they add (via operator $\oplus$) or remove (via operator $\ominus$) atomic formulae αs. Furthermore, we make use of a special kind of term, called a *set constructor*, represented as $\{\alpha' \mid LHS^*\}$. This construct is useful when we need to refer to all α's for which *LHS** holds,e.g., $\{p(A,B) \mid A > 20 \wedge B < 100\}$ is the set of atomic formulae $p(A,B)$ such that $A > 20$ and $B < 100$.

R	::=	*LHS* $\rightsquigarrow$ *RHS*
LHS	::=	*LHS* $\wedge$ *LHS* $\mid \neg$(*LHS* $\wedge$ *LHS*) $\mid$ Lit
RHS	::=	U $\wedge$ *RHS* $\mid$ U
Lit	::=	$\alpha \mid \neg\alpha \mid x = \{\alpha' \mid LHS^*\}$
U	::=	$\oplus\alpha \mid \ominus\alpha$

Figure 1: Grammar for Rules

We need to refer to the set of constraints that belongs to a state of affairs. We call $\Gamma = \{\gamma_0, \ldots, \gamma_n\}$ the set of all constraints in Δ. Given a state of affairs Δ, relationship $constrs(\Delta, \Gamma)$ holds iff Γ is the smallest set such that for every $\gamma \in \Delta$ then $\gamma \in \Gamma$. In the definitions below we rely on the concept of *substitution*, that is, the set of values for variables in a computation, as well as the concept of its application to a term [5].

We now define the semantics of our rules as relationships between states of affairs: rules map an existing state of affairs to a new state of affairs. We adopt the usual semantics of production rules, that is, we exhaustively apply each rule by matching its *LHS* against the current state of affairs and use the values of variables obtained in this match to instantiate the *RHS* via $\mathbf{s}^*$: $\mathbf{s}^*(\Delta, LHS \rightsquigarrow RHS, \Delta')$ holds iff $\mathbf{s}_l^*(\Delta, LHS, \{\sigma_1, \ldots, \sigma_n\})$ and $\mathbf{s}_r(\Delta, RHS \cdot \sigma_i, \Delta'), 1 \leq i \leq n, n \in I\!N$, hold. That is, two states of affairs Δ and Δ' are related by a rule *LHS* $\rightsquigarrow$ *RHS* iff we obtain all different substitutions $\{\sigma_1, \ldots, \sigma_n\}$ that make the left-hand side match Δ and apply these substitutions to *RHS* (that is, $RHS \cdot \sigma_i$) in order to build Δ'.

Our rules are *exhaustively* applied on the state of affairs thus considering all matching atomic formulae. We thus need relationship $\mathbf{s}_l^*(\Delta, LHS, \Sigma)$ which obtains in $\Sigma = \{\sigma_0, \ldots, \sigma_n\}$ *all* possible matches of the left-hand side of a rule: $\mathbf{s}_l^*(\Delta, LHS, \Sigma)$ holds, iff $\Sigma = \{\sigma_1, \ldots, \sigma_n\}$ is the largest non-empty set such that $\mathbf{s}_l(\Delta, LHS, \sigma_i), 1 \leq i \leq n, n \in I\!N$, holds. We now define the semantics of the *LHS* of a rule: $\mathbf{s}_l(\Delta, LHS, \sigma)$ holds between state Δ, the left-hand side of a rule *LHS* and a substitution σ depending on the format of *LHS*:

1. $\mathbf{s}_l(\Delta, LHS \wedge LHS', \sigma)$ holds iff $\mathbf{s}_l(\Delta, LHS, \sigma')$ and $\mathbf{s}_l(\Delta, LHS', \sigma'')$ hold and $\sigma = \sigma' \cup \sigma''$.
2. $\mathbf{s}_l(\Delta, \neg\, LHS, \sigma)$ holds iff $\mathbf{s}_l(\Delta, LHS, \sigma)$ does not hold.
3. $\mathbf{s}_l(\Delta, \alpha', \sigma)$ holds iff $\alpha' \cdot \sigma \in \Delta$ and $constrs(\Delta, \Gamma)$ and $satisfiable(\Gamma \cdot \sigma)$ hold.
4. $\mathbf{s}_l(\Delta, \gamma, \sigma)$ holds iff $constrs(\Delta, \Gamma)$ and $satisfiable((\Gamma \cup \{\gamma\}) \cdot \sigma)$ hold.
5. $\mathbf{s}_l(\Delta, x = \{\alpha' \mid LHS^*\}, \sigma)$ holds iff $\sigma = \{x/\{\alpha' \cdot \sigma_1, \ldots, \alpha' \cdot \sigma_n\}\}$ for the largest $n \in I\!N$ such that $\mathbf{s}_l(\Delta, \alpha' \wedge LHS^*, \sigma_i), 1 \leq i \leq n$

Cases 1-3 depict the semantics of atomic formulae and how their individual substitutions are combined to provide the semantics for a conjunction. Case 4 formalises the semantics of our constraints when they appear on the left-hand side of a rule: we apply the substitution σ to them (thus reflecting any values of variables given by the matchings of atomic formula), then check satisfiability of constraints.[4] Case 5 specifies the semantics for *set constructors*: x is the set of atomic formulae that satisfy the conditions of the set constructor.

We now define the semantics of the *RHS* of a rule: Relation $\mathbf{s}_r(\Delta, RHS, \Delta')$ mapping a state Δ, the right-hand side of a rule *RHS* and a new state Δ' is defined as:

1. $\mathbf{s}_r(\Delta, (\mathsf{U} \wedge RHS), \Delta')$ holds iff both $\mathbf{s}_r(\Delta, \mathsf{U}, \Delta_1)$ and $\mathbf{s}_r(\Delta_1, RHS, \Delta')$ hold.
2. $\mathbf{s}_r(\Delta, \oplus\alpha', \Delta')$ holds iff $\Delta' = \Delta \cup \{\alpha'\}$.
3. $\mathbf{s}_r(\Delta, \oplus\gamma, \Delta') = \mathbf{true}$ iff $constrs(\Delta, \Gamma)$ and $satisfiable(\Gamma \cup \{\gamma\})$ hold and $\Delta' = \Delta \cup \{\gamma\}$.
4. $\mathbf{s}_r(\Delta, \ominus\alpha, \Delta')$ holds iff $\Delta' = \Delta \setminus \{\alpha\}$

Case 1 decomposes a conjunction and builds the new state by merging the partial states of each update. Case 2 caters for the insertion of atomic formulae α' which do not conform to the syntax of constraints. Case 3 defines how a constraint is added to a state Δ: the new constraint is checked whether it can be satisfied with constraints Γ and then it is added to Δ'. Case 4 caters for the removal of atomic formulae.

We extend $\mathbf{s}^*$ to handle sets of rules: $\mathbf{s}^*(\Delta_0, \{\mathsf{R}_1, \ldots, \mathsf{R}_n\}, \Delta_n)$ holds iff $\mathbf{s}^*(\Delta_{i-1}, \mathsf{R}_i, \Delta_i), 1 \leq i \leq n$ hold.

The semantics above define an infinite sequence of states $\langle\Delta_0, \Delta_1, \ldots\rangle$ if $\mathbf{s}^*(\Delta_i, \{\mathsf{R}_1, \ldots, \mathsf{R}_n\}, \Delta_{i+1})$, that is, Δ_{i+1} (obtained by applying the rules to Δ_i) is used to obtain Δ_{i+2} and so on. Fig. 2 illustrates how this sequence can accommodate the intervention of agents sending/receiving messages. The diagram shows an initial state Δ_0 (possibly empty) that is offered (represented by "$\Rrightarrow$") to a set of agents $\{ag_1, \ldots, ag_n\}$. These agents exchange messages, adding a record

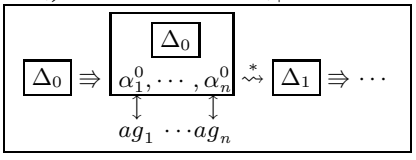

Figure 2: Semantics as a Sequence of Δ's

[1] Work available in `http://www.iiia.csic.es/~andres/NOPLforEIs.pdf`

[2] We adopt Prolog's convention using strings starting with a capital letter to represent variables and strings starting with a small letter to represent constants.

[3] We refer to the *state of the environment* as the set of atomic formulae that represent aspects of the environment in a given point in time.

[4] Our work builds on standard technologies for constraint solving – in particular, we have been experimenting with SICStus Prolog constraint satisfaction libraries.

(via "$\updownarrow$") $\{\alpha_1^0, \ldots, \alpha_n^0\}$ of these messages to Δ_0. After the agents add their utterances, then the rules are exhaustively applied (represented by "$\overset{*}{\rightsquigarrow}$") to $\Delta_0 \cup \{\alpha_1^0, \ldots, \alpha_n^0\}$. The resulting state Δ_1 is, on its turn, offered to agents, and so on.

Our work extends *electronic institutions* (EIs) [4], providing them with an explicit normative layer. There are two major features in EIs : the *states* and *illocutions* (*i.e.*, messages) uttered (*i.e.*, sent) by those agents taking part in the EI. Illocutions I are terms $p(ag, r, ag', r', \tau, t)$ where p is an illocutionary particle (*e.g., inform,ask*); ag, ag' are agent identifiers; r, r' are role labels; τ is a term with the actual content of the message and $t \in I\!N$ is a time stamp. We shall refer to illocutions that may have uninstantiated (free) variables as *illocution schemes*, denoted by $\bar{\mathsf{I}}$. Another important concept in EIs that we employ here is that of a *scene*. Scenes offer means to break down larger protocols into smaller ones with specific purposes.

We differentiate seven kinds of atomic formulae in our state of affairs Δ, with the following intuitive meanings:

1. $oav(o, a, v)$ – object (or agent) o has an attribute a with value v.
2. $att(s, w, \mathsf{I})$ – an agent attempted to get illocution I accepted at state w of scene s.
3. $utt(s, w, \mathsf{I})$ – I was accepted as a legal utterance at w of s.
4. $ctr(s, w, t_s)$ – the execution of scene s reached state w at time t_s.
5. $obl(s, w, \bar{\mathsf{I}})$ – $\bar{\mathsf{I}}$ ought to be uttered at w of s.
6. $per(s, w, \bar{\mathsf{I}})$ – $\bar{\mathsf{I}}$ is *permitted* to be uttered at w of s.
7. $prh(s, w, \bar{\mathsf{I}})$ – $\bar{\mathsf{I}}$ is *prohibited* at w of s.

We only allow fully ground attributes, illocutions and state control formulae (cases 1-4 above) to be present[5]; however, in formulae 5-7 s and w may be variables and $\bar{\mathsf{I}}$ may contain variables. We shall use formulae 4 to represent state change in a scene in relationship with global time passing. We shall use formulae 5–7 above to represent normative positions of agents within EIs.

Thus, we can write rules for prohibiting (or permitting) actions by default, for permitting (or prohibiting) certain actions and for choosing which actions will be prevented or only sanctioned. For example, in the context of a Dutch auction [9], agents can be prevented from making unsupported bids or only sanctioned:

$$\left(\alpha_0 \wedge \neg\,(\alpha_1 \wedge T2 > T) \wedge oav(Ag, credit, C) \wedge C < P \right) \rightsquigarrow \oplus\alpha_2$$

where

$$\begin{cases} \alpha_0 = utt(dutch, w_3, inform(Au, auct, A, buyer, offer(It, P), T)) \\ \alpha_1 = utt(dutch, w_3, inform(Au, auct, A, buyer, offer(It, P), T_2)) \\ \alpha_2 = prh(dutch, w_4, inform(A, buyer, Au, auct, bid(It, P_2), T_3)) \end{cases}$$

The rule above prevents agents from issuing bids in a Dutch auction they cannot afford (their credit is insufficient). It states that if agent Ag's credit is less than P (the last offer the auctioneer called for item It, at state w_3 of scene $dutch$), then agent Ag is prohibited to bid.

$$\left(X = \{\ \alpha_0 \mid \alpha_1 \wedge \neg\,(\alpha_2 \wedge T_2 > T_1) \wedge T_0 > T_1\ \} \wedge \begin{array}{c} \\ |\,X\,| = 1 \wedge oav(A_1, credit, C) \wedge C < P \end{array} \right) \rightsquigarrow$$

$$\left(\begin{array}{c} \ominus oav(A_1, credit, C) \wedge \\ \oplus oav(A_1, credit, C_2) \wedge \oplus\alpha_3 \wedge \\ \oplus(C_2 = C - P * 0.1) \wedge \oplus(P_2 = P * 1.2) \end{array} \right)$$

where

$$\begin{cases} \alpha_0 = utt(dutch, w_4, inform(A_1, buyer, Au, auct, bid(It, P), T_0)) \\ \alpha_1 = utt(dutch, w_3, inform(Au, auct, all, buyer, offer(It, P), T_1)), \\ \alpha_2 = utt(dutch, w_3, inform(Au, auct, all, buyer, offer(It, P), T_2)) \\ \alpha_3 = obl(dutch, w_5, inform(Au, auct, all, buyer, offer(It, P_2), T_3)) \end{cases}$$

The previous rule punishes agents when issuing a winning bid they cannot pay for. More precisely, the rule punishes agent A_1 by decreasing his credit a 10% of the value of the good being auctioned. The oav predicate on the *LHS* of the rule represents the current credit of the offending agent. The rule also adds an obligation for the auctioneer to restart the bidding round along with the constraint that the new offer should be greater than 120% the old price.

These examples illustrate how our language addresses the explicit management of normative positions and the pragmatic concerns raised in the desiderata.

[5] We allow agents to utter whatever they want (via att formulae). However, the illegal utterances may be discarded and/or may cause sanctions, depending on the semantics of the specified deontic notions. The utt formulae are thus *confirmations* of the att formulae that turn illocutions into legal.

3. CONCLUSIONS AND FUTURE WORK

In this paper we have introduced a formalism for the explicit management of the normative position of agents in electronic institutions. Ours is a rule language in which constraints can be specified and changed at run-time, conferring expressiveness and precision on our constructs. The semantics of our formalism defines a kind of production system in which rules are exhaustively applied to a state of affairs, leading to the next state of affairs. The normative positions are updated via rules, depending on the messages agents send. Our formalism addresses the points of a desiderata for normative languages introduced above.

We would like to generalise our language to cope with arbitrary actions, rather than just speech acts among agents – this would allow our work to address any type of open multi-agent system. We would also like to improve the semantics of the language in order to support the use of temporal operators for the management of time along the lines of [6].

Learning to Identify Winning Coalitions in the PAC Model

Ariel D. Procaccia Jeffrey S. Rosenschein

{arielpro, jeff}@cs.huji.ac.il

ABSTRACT

We consider PAC learning of *simple* cooperative games, in which the coalitions are partitioned into "winning" and "losing" coalitions. We analyze the complexity of learning a suitable concept class via its Vapnik-Chervonenkis (VC) dimension, and provide an algorithm that learns this class. Furthermore, we study constrained simple games; we demonstrate that the VC dimension can be dramatically reduced when one allows only a single minimum winning coalition (even more so when this coalition has cardinality 1), whereas other interesting constraints do not significantly lower the dimension.

PAC Learning, Coalition Formation

1. INTRODUCTION

A significant portion of recent research in multiagent systems has focused on learning. Nevertheless, very few investigations have been devoted to learning in coalition formation, an area of game theory that is exceedingly relevant to multiagent systems. Classical models of coalition formation assume that the values of all coalitions are known *a priori*, but this assumption is unreasonable in many (indeed, almost all) multiagent settings. Surprisingly, even fewer researchers have attempted to apply PAC[1] (Probably Approximately Correct) learning theory to multiagent settings, although this model has been extensively studied by researchers in computational learning theory (readers who are not familiar with this model are urged to consult [4]).

In this paper, we endeavor to remedy these shortcomings by studying PAC learning of *simple* cooperative games, in which each coalition is either "winning" or "losing". A basic structure is induced by the assumption that if a coalition is winning, any coalition that contains it is also winning. Simple games are a suitable model for numerous n-person conflict situations.

The Vapnik-Chervonenkis (VC) dimension is a combinatorial measure of the "richness" of a concept class[2], and is proportional to the difficulty of learning the class. We define several concept classes, which characterize settings of learning simple games with different restrictions, and identify the complexity of learning these classes by calculating their VC dimensions.

2. THE MODEL

A *cooperative n-person game in characteristic form with side payments* is a pair $(N; v)$, where $N = \{1, 2, \ldots, n\}$ is a set of players, and v is the *characteristic function*, which assigns a real number $v(C)$ to each *coalition* $C \subseteq N$. $v(C)$ is the *value* of C.

Simple games are games where each coalition has a value of either 1 or 0. A coalition C is said to be *winning* if $v(C) = 1$, and *losing* if $v(C) = 0$. 2^N, the powerset of N, is partitioned into $\mathscr{W}$, the set of winning coalitions, and $\mathscr{L}$, the set of losing coalitions. A standard assumption is that this partition satisfies:

$$[C_1 \in \mathscr{W} \wedge C_1 \subseteq C_2] \Rightarrow C_2 \in \mathscr{W}. \quad (1)$$

We wish to find a way to identify winning coalitions. In other words, given a coalition, we would like to label it by "winning" or "losing", or equivalently, by 1 or 0, respectively. Essentially, we would like to learn a function from coalitions to $\{0, 1\}$.

The assumption given in Equation (1) allows us to easily represent such functions. Indeed, we say that $C \subseteq N$ is a minimum winning coalition if and only if

$$C \in \mathscr{W} \wedge \forall i \in C,\ (C \setminus \{i\}) \in \mathscr{L}.$$

[1]The PAC model is also known as the *formal* model.
[2]A concept class is a binary function whose domain is the set of possible samples.

A simple game can be concisely represented by a set of minimum winning coalitions. Furthermore, a set of minimum winning coalitions may be regarded as a function from the set of coalitions to $\{0,1\}$: a coalition is winning (labeled by 1) if and only if it is a superset (in the weak sense) of one of the minimum winning coalitions.

REMARK 1. Surprisingly, learning to identify minimum winning coalitions (with the above formalization in mind) is equivalent to learning monotone[3] DNF formulas. Indeed, one can associate players with variables, and coalitions with terms. A hypothesis consisting of a set of minimum winning coalitions is essentially a disjunction of terms. When learning minimum winning coalitions, the sample space is the space of all coalitions; these can be identified with assignments to variables, where a coalition C induces an assignment of 1 to the variables associated with the players in C, and 0 to all other players. This equivalence allows us to leverage some of the research on monotone DNF in order to prove certain results.

For the sake of completeness, we give a swift description of the VC dimension; more details can be found in [4].

DEFINITION 1. Let $\mathcal{C} : X \to \{0,1\}$ be a concept class, $S = \{x_1, x_2, \ldots, x_m\} \subseteq X$, and let

$$\Pi_{\mathcal{C}}(S) = \{\langle h(x_1), h(x_2), \ldots, h(x_m)\rangle : h \in \mathcal{C}\}.$$

If $|\Pi_{\mathcal{C}}(S)| = 2^m$, then S is considered *shattered* by $\mathcal{C}$.

In other words, if S is shattered by $\mathcal{C}$, then $\mathcal{C}$ realizes all possible dichotomies on S.

DEFINITION 2. The *Vapnik-Chervonenkis (VC) dimension* of a concept class $\mathcal{C}$, denoted VC-dim($\mathcal{C}$), is the size of the largest set S that is shattered by $\mathcal{C}$. If $\mathcal{C}$ shatters arbitrarily large sets, then VC-dim($\mathcal{C}$) $= \infty$.

It is known that the VC dimension of a concept class almost completely characterizes the complexity of learning it in the PAC model. Therefore, we focus on calculating the VC dimension of several concept classes of interest.

3. LEARNING UNCONSTRAINED GAMES

In order to calculate the VC dimension of the concept class of minimum winning coalitions, when no restrictions are imposed on the game, we first need to address a natural combinatorial problem.

Given the numbers $\{1, 2, \ldots, n\}$, we would like to find a maximal antichain of subsets, i.e., a family of subsets such that for any two subsets, neither one is contained in the other. Finding an antichain of size $\binom{n}{\lfloor n/2 \rfloor}$ is easy: we simply choose all the subsets of size $\lfloor n/2 \rfloor$ (see Table 1). But can one do better? The theorem gives a negative answer.

THEOREM 1 (SPERNER'S THEOREM). *Let $\mathcal{F}$ be a family of subsets of $\{1, 2, \ldots, n\}$, such that for all $A, B \in \mathcal{F}$: $A \not\subseteq B$. Then $|\mathcal{F}| \leq \binom{n}{\lfloor n/2 \rfloor}$.*

Now we can straightforwardly prove the main theorem.

[3]DNF formulas in which all the literals are positive.

		$\emptyset$			
	$\{1\}$	$\{2\}$	$\{3\}$	$\{4\}$	
{1,2}	**{1,3}**	**{1,4}**	**{2,3}**	**{2,4}**	**{3,4}**
	$\{1,2,3\}$	$\{1,2,4\}$	$\{1,3,4\}$	$\{2,3,4\}$	
		$\{1,2,3,4\}$			

Table 1: Subsets of {1,2,3,4}, sorted by size. A maximal antichain is constructed by choosing all subsets of size 2; Sperner's Theorem states that one cannot construct a larger antichain.

THEOREM 2. *Let $\mathcal{C}^*$ be a concept class, in which each concept is a set of minimum winning coalitions. Then:*

$$\textit{VC-dim}(\mathcal{C}^*) = \binom{n}{\lfloor n/2 \rfloor}.$$

PROOF. We first show that the VC-dimension is at least $\binom{n}{\lfloor n/2 \rfloor}$, by producing a set of size $\binom{n}{\lfloor n/2 \rfloor}$ which is shattered by $\mathcal{C}^*$. Consider the set S of all coalitions of size $\lfloor n/2 \rfloor$. Clearly, any dichotomy on S can be realized by the concept that contains as minimum winning coalitions exactly the coalitions in S that are labeled by 1.

On the other hand, the VC-dimension is at most $\binom{n}{\lfloor n/2 \rfloor}$. Indeed, consider a set S of more than $\binom{n}{\lfloor n/2 \rfloor}$ coalitions. By Theorem 1, there are two coalitions $C_1, C_2 \in S$ such that $C_1 \subseteq C_2$. The dichotomy in which C_1 is labeled by 1 and C_2 is labeled by 0 cannot be realized. □

CONTRACT, given as Algorithm 1, is a learning algorithm for $\mathcal{C}^*$: it returns a set of minimum winning coalitions which is consistent with the given samples (assuming one exists).

Algorithm 1

```
1: procedure CONTRACT({(C_i, y_i)}_{i=1}^m)    ▷ y_i ∈ {0,1} is the label of coalition C_i
2:     W^m ← ∅                                  ▷ Set of minimum winning coalitions
3:     for i = 1 to m do                        ▷ All sample coalitions
4:         if y_i = 1 ∧ ∀R ∈ W^m, R ⊈ C_i then
5:             W^m ← W^m \ {R ⊆ N : C_i ⊆ R}
6:             W^m ← W^m ∪ {C_i}
7:         end if
8:     end for
9:     return W^m
10: end procedure
```

4. LEARNING CONSTRAINED GAMES

Veto games are cooperative games where any coalition with nonzero value contains a distinguished player, called the *veto* player. In some veto games, the inclusion of the veto player in a coalition is also a sufficient condition for the coalition to be winning, not just a necessary one; in this case, we say the veto player is a *dictator*. Some real-world n-person conflict situations are simple games with a dictator.

That being the case, in order to identify winning coalitions in a simple game with a dictator, it is enough to pinpoint this distinguished player. The set of minimum coalitions contains exactly one coalition of cardinality 1: the dictator.

The following proposition follows from [1].

PROPOSITION 3. *Let $\mathcal{C}_1$ be a concept class, in which each concept is a single minimum winning coalition of cardinality 1. Then:*

$$VC\text{-}dim(\mathcal{C}_1) = \lfloor logn \rfloor.$$

It is worthwhile to generalize our requirement of a single dictator player; we now assume there is a coalition W such that for all coalitions C, C is winning if and only if $W \subseteq C$. Since W is the only minimum winning coalition, the goal of the learning process in such games is to recognize W.

By the equivalence between minimum winning coalitions and monotone DNF, it is possible to derive the following proposition from [2].

PROPOSITION 4. *Let $\mathcal{C}_1^*$ be a concept class, in which each concept is a single minimum winning coalition. Then:*

$$VC\text{-}dim(\mathcal{C}_1^*) = n.$$

REMARK 2. Another possible generalization is having at most k minimum winning coalitions; denote this concept class by $\mathcal{C}_k^*$. An upper bound for this case is given by Schmitt [3]. In particular, if $k = O(1)$, then VC-dim$(\mathcal{C}_k^*) = O(n)$.

Proper simple games are another type of common constrained games. In such games it holds that

$$\forall S \subseteq N,\ S \in \mathscr{W} \Rightarrow N \setminus S \in \mathscr{L}. \quad (2)$$

However, this constraint does little to reduce the VC dimension, compared with unconstrained simple games.

PROPOSITION 5. *Let $\mathcal{C}_p^*$ be a concept class, in which each concept is a set of minimum winning coalitions in a proper simple game. Then:*

$$VC\text{-}dim(\mathcal{C}_p^*) \geq \binom{n-1}{\lfloor \frac{n-1}{2} \rfloor}.$$

PROOF. We must exhibit a set S of size $\binom{n-1}{\lfloor \frac{n-1}{2} \rfloor}$ which is shattered by $\mathcal{C}_p^*$. Let

$$S = \left\{ C \subseteq N :\ 1 \in C \wedge |C| = \left\lfloor \frac{n-1}{2} \right\rfloor + 1 \right\}.$$

It holds that the cardinality of S is as desired. Moreover, for any dichotomy on S, one may choose exactly the subsets labeled by 1 as the minimum winning coalitions: since the intersection of all subsets in S is not empty, the constraint (2) is not violated. □

Another popular constraint is the elimination of *dummy* players.

$$\forall i \in N \exists C \subseteq N \ s.t.\ i \in C \wedge C \in \mathscr{W} \wedge (C \setminus \{i\}) \in \mathscr{L}. \quad (3)$$

Informally, for every player there is a winning coalition which cannot do without it. The elimination of dummy players also does not substantially reduce the VC dimension.

PROPOSITION 6. *Let $\mathcal{C}_d^*$ be a concept class, in which each concept is a set of minimum winning coalitions in a simple game with no dummy players. Then:*

$$VC\text{-}dim(\mathcal{C}_d^*) \geq \binom{n-1}{\lfloor \frac{n-1}{2} \rfloor}.$$

PROOF. We must exhibit a set S of size $\binom{n-1}{\lfloor \frac{n-1}{2} \rfloor}$ which is shattered by $\mathcal{C}_d^*$. Let

$$S = \left\{ C \subseteq N :\ 1 \notin C \wedge |C| = \left\lfloor \frac{n-1}{2} \right\rfloor \right\}.$$

It holds that the cardinality of S is as desired. Given a dichotomy on S, let S^+ be the set of coalitions in S that are labeled by 1, and let B be the set of players that are not members of any of the coalitions in S^+. The set of minimum winning coalitions is $S^+ \cup \{B\}$; the purpose of including B is to ensure that constraint (3) is not violated. It remains to show that this is a legitimate set of minimum coalitions in a proper simple game, which realizes the dichotomy. Since $1 \in B$, B is not a subset of any of the coalitions in S, and in particular is not a subset of any of the coalitions in $S \setminus S^+$ — so it is not the case that the addition of B to the set of minimum winning coalitions mistakenly labels a coalition in $S \setminus S^+$ by 1. Clearly, neither is B a superset of any of the coalitions in S^+; thus it is not the case that there are two winning coalitions such that one is a superset of the other. Since the coalitions in S^+ are included in the set of minimum winning coalitions, the dichotomy is realized. Moreover, constraint (3) is satisfied: every $i \in N$ is contained in one of the coalitions in S^+, or in B, and these are all *minimum* winning coalitions. □

5. CONCLUSIONS

Simple games have natural interpretations in multiagent systems. Such games can be concisely represented by the set of minimum winning coalitions; this set may be regarded as a function from the set of coalitions to $\{0, 1\}$.

We have shown that the VC-dimension of the concept class which contains sets of minimum winning coalitions is $\binom{n}{\lfloor n/2 \rfloor}$; this implies that in general, it is very difficult to learn to identify winning coalitions in the PAC model.

We have also discussed constrained simple games, and have proven that restricting the set of minimum winning coalitions to a single coalition, or a dictator player, greatly reduces the VC-dimension. These constrained games are thus efficiently learnable. Nevertheless, other popular constrained games, such as proper simple games and games with no dummy players, are almost as hard to learn as unconstrained games.

ABSTRACT
In this paper, we describe the adaptation of an open-source multi-agent platform for distributed energy applications and the trial deployment of resource-controller agents. The platform provides real-time, two-way communication and decision making between distributed energy resources – loads and generators – in electricity distribution networks. Such a decentralized architecture improves grid reliability, allows consumers to play a more active role in their energy usage, benefits the network by alleviating the effects of peak wholesale prices and network constraints, and creates new business opportunities in a deregulated market. Agents have been deployed to control hardware at trial locations in Australia, providing a realistic test environment for the platform, and medium-scale trials are anticipated in the near future.

Applications of autonomous agents and multi-agent systems; collective and emergent agent behavior; frameworks, infrastructures and environments for agent systems.

1. INTRODUCTION
The GridAgents Framework is being developed by Infotility, under contract with the U.S. Department of Energy, and CSIRO. It consists of an adaptive, intelligent agent-based software system which can provide real-time, two-way communication and decision making between distributed DER system nodes. Distributed Energy Resources (DER) have the potential to provide significant benefits to the electric grid infrastructure and to society as a whole. DERs are typically smaller-scale energy and storage technologies sited close to electrical and thermal loads. DER technologies are increasingly being considered to augment the existing power delivery infrastructure as part of grid reliability programs (emergency response, price response, ancillary services, etc.). They also offer a solution to electricity market participants exposed to peak wholesale prices and constrained network infrastructure. DER has the potential to provide reactive power (generated close to loads) which is highly beneficial for maintaining grid voltage stability. DER combined with next-generation sensing, communication, and control technologies will enable a "path change" by providing the ability to intelligently respond to grid reliability and market signals in a cost-effective manner. The traditional site-specific benefits of DER (efficiency, environmental, local reliability, etc.) can be enhanced by the use of next-generation distributed computing technologies such as those used in this work. Another important aspect of the proposed agent-based software is that it enables the ability to create on-the-fly "aggregate" blocks of capacity for presentation to the energy markets. This functionality along with intelligent islanding and other control concepts has been proposed as various forms of the "microgrid" concept by several research organizations including the DOE. The design is based on a distributed, bottom-up approach to responding to grid contingencies and is intended to supplement the existing power distribution network communication infrastructure.

2. SELECTING A PLATFORM
Agent-based software applications require a foundation to manage basic operations. Various agent toolkits, platforms, toolkits, and methodologies, both proprietary and open-source, were reviewed in order to select a platform to build upon for the GridAgents Framework under development. An agent platform acts as a middleware layer, providing services such as lifecycle management, resource management, messaging, security, directory services, and behaviors. By using such a platform, a programmer is not required to re-invent (and debug) the wheel for each agent project.

The available platforms offer a wide range of programming models and assumptions about locality, communications and agent sophistication. The GridAgents Framework is expected to operate over a large range of hardware platforms and sites. In particular, the CSIRO trial deployments use personal digital assistants (PDAs) as computing resources attached to various loads and generators. The use of PDAs requires an agent platform capable of operating on limited devices, a requirement that quickly eliminates most platforms from consideration. Three agent platforms capable of being deployed on PDAs were evaluated: Cougaar [5], Cybele [6], and JADE [7]. In addition, the general-purpose .NET platform [8] was also evaluated as a sanity-check, to ensure that using an agent platform really did result in a reduction in effort.

A set of detailed criteria were developed in order to choose the agent platform as part of the requirements assessment process. The evaluation methodology used was an informal version of the i-Mate process [3]. Although .NET and Cybele were quickly eliminated from consideration, Cougaar and JADE provided similar facilities, different implementation models and contrasting strengths and weaknesses. Eventually, JADE was chosen on the grounds of a cleaner design and implementation, better documentation and the ease with which agents could be deployed on limited devices. JADE is by no means perfect; a considerable amount of effort has since gone into architectural issues, such as publish/subscribe notification, agent discovery and deployment. However, JADE has stood up as the "least-worst" choice.

3. ARCHITECTURE AND MESSAGING

DER agents appear to each other to fulfill certain functions which we have termed "roles". In this system, a role is the ability to send and receive a certain fixed set of message types. The means by which an agent determines its message content is invisible to other agents, and other agents know only the allowed message types. The roles include buyer, seller, bulletin board, physical device, and others. An agent which fulfills the seller role will respond to a request for a price function or a request to conclude a transaction. An agent which fulfills the physical device role will respond to requests for status information or a request to set the device state. As other agents see only these functions, the DER agent system is a "plug and play" system, in which an agent enjoys broad latitude within which it can implement the role functions in various ways, so long as all functions for a given role are implemented.

An agent may fulfill more than one role. As agents interact only through the role interfaces, a new type of agent can coexist happily with others so long as the role interfaces are implemented appropriately. There is no need to restart the whole agent system when a new agent type comes on-line. This is an especially important consideration in systems comprising multiple hosts, as it may be impractical to coordinate the operations of different hosts. It is feasible, though perhaps somewhat involved, to create agents which are not JADE agents, by constructing FIPA messages of appropriate types and contents. At this time we have no plan to implement non-JADE agents, but we see no need to rule out the possibility.

Data persistence is accomplished in the DER agent system through the bulletin board role. A bulletin board is just a repository of messages organized according to a label, which is called the topic. Agents can query the bulletin board by topic, receiving the messages under that topic in response. Aside from messages exchanged through role interfaces, public information in the DER agent system is published via a bulletin board. The types of information available may include prices, parameters, notices, and measurements. It is anticipated that the contents of a bulletin board may be stored in a conventional database, or published in a format accessible outside the DER agent system, such as an XML-based syndication format.

4. APPLICATIONS AND ALGORITHMS

Whether the application is grid security or services for electricity market participants, the fundamental algorithmic requirement of a DER multi-agent network is the provision of aggregated capacity through load shifting, load shedding, or distributed generation by a multiplicity of resources. Aggregated capacity is characterized by a quantity of kW or MW and also time and timeliness, reliability or "firmness", and traceability to a known set of customers. Note that reliability may be represented as a profile rather than a single value: 20 MW at 99.99% firmness, 40 MW at 99% firmness, and 70 MW at 90% firmness would be an example. This is enough information for a user to make an informed risk calculation. At the resource agent level the ability to shift or curtail load or dispatch local generation requires planning ahead, with a planning horizon long enough to account for time constants inherent in the loads and generators.

Each agent in the DER agent system attempts to choose among available alternatives according to the criterion of minimum operating cost and subject to constraints. This local optimization may lead to a solution with identifiable global properties, such as a Nash equilibrium, although we have not proved any such properties yet. We assume that each agent has a planning and execution cycle, which may be regular or irregular, and coordinated or uncoordinated with other agents. The result of the planning phase is a series of actions to be carried out in the future. In the execution phase, the agent carries out the plan by executing commands to a physical device, or perhaps issuing commands to subordinate agents which result in a command to a device.

The planning problem is generically phrased as a constrained optimization problem. The appropriate method for solving such problems varies according to the form of the cost function, and thus agents may employ various techniques for planning. Agents which aggregate or broker the output of other agents may employ integer linear programming to solve their planning problems, as their costs are the sum of the prices stated by their subordinate agents and their resources are the sum of the resources supplied by their subordinates. Aggregating agents may also employ genetic optimization [1] to optimize subsidiary agents for soft-real-time application.

As an exact solution to an optimization problem may be very time-consuming, we are also developing methods which provide "any-time" solutions based on selfish agents seeking to optimize local cost functions. Although the resulting global solution may be suboptimal, this may be a worthwhile sacrifice it the net result of the selfish agents' actions – their emergent behavior – converges to a useful solution in a short time.

Planning algorithms present a scalability problem: there are many free parameters for each resource, combinatorial optimisation of any kind tests computational resources quite severely, and our aim

is to coordinate many thousands of agents. Decentralised algorithms are therefore of great interest because they use the multi-agent network as a parallel computer and thereby promise better scaling properties provided that messaging overheads do not defeat this purpose. A decentralised algorithm does not yet exist for planning as we've defined it, although a candidate with many of the capabilities we require is the market-based algorithm of Kok et al. [2], and other algorithms under development will be reported in the near future. All candidate planning algorithms presume a defined group of agents that should plan together and a defined connectivity between agents in the group.

The approach we are taking is to construct a meta-algorithm that governs the groups of agents within which planning is used. Decentralised clustering is an example of a multi-agent algorithm that creates groups, and it has been shown to scale better than an equivalent centralised algorithm [4]. We are developing an adaptation of decentralised clustering to govern the formation of planning groups of energy agents and the topology of messaging connections within each group. The crucial requirement is to interleave the two levels of algorithm so that time scales are compatible and sufficiently short for the system responses desired.

5. DEPLOYMENT

To test the behavior of various multi-agent system approaches and showcase our technology, we have established a comprehensive experimentation and testing hardware platform. The platform is made up of a variety of loads and generators, configured for agent control, and subject to real-world constraints:

- Two cool rooms typical of a small business setting.
- An heating, ventilation and air-conditioning (HVAC) system in an office building.
- A 30 kW gas turbine or "microturbine".
- A large photovoltaic (PV) system.
- A small wind turbine and solar-tracking PV array, 1 kW each, combined with battery storage.

The interacting set of loads and generators are electrically connected to form a microgrid, their controlling agents being designed to coordinate demand and supply while reacting intelligently to national electricity market price signals. Agents controlling loads and generators are run on personal digital assistants (PDAs) while personal computers (PCs) are used for implementing more computationally intensive agent roles:

- A web scavenging agent which obtains current and forecast electricity market prices and weather data.
- A snapshot agent which monitors various real-time parameters of the agent system.
- An aggregation agent which offers a price schedule for resources from subordinate agents.
- A manager agent which directs the operation of a number of loads and sources.

The hardware platform has a comprehensive Internet Protocol (IP) based infrastructure for inter-agent communications. This infrastructure uses a variety of physical layer technologies, including Ethernet and Wireless LAN mechanisms, with Bluetooth and cable based connections used for serial communications to distributed energy devices.

Throughout this implementation work, and the subsequent experimental phase, a number of challenges and their solutions have been encountered. We believe many of these challenges would exist in *any* geographically distributed multi-agent system implemented in common computing and communications hardware. Space does not allow detail here, but the authors are happy to be contacted about such issues as agent communication, firewalls, network addressing, processing overheads, unique and diverse hardware installations, reliable and fail-safe behavior, and message content encoding.

6. CONCLUSIONS

We have developed the GridAgents Framework for managing distributed energy resources – customer loads and generators – by adapting the JADE multi-agent platform. Several aspects peculiar to our application are described in this paper, many of them based on experience of deployment on distributed processors controlling typical small-business loads and generators. We have developed algorithms to aggregate capacity and provide a distributed energy service to meet network and market goals. This work continues.

Future work will include advanced demonstrations of the GridAgents Framework for Microgrid applications, automated demand response applications, and electric distribution network control applications. A "smart grid" project is planned for 2006 with a large U.S. utility for embedded intelligence and control for compact networks. In Australia our next goal, in collaboration with utility, hardware, and telecommunications partners, is a moderate-scale deployment of the order of 1,000 agents.

Behaviosites: A Novel Paradigm for Affecting Distributed Behavior

ABSTRACT

We present the Behaviosite paradigm, a new approach to affecting the behavior of distributed agents in a multiagent system, which is inspired by biological parasites with behavior manipulation properties. Behaviosites are special kinds of agents that "infect" a system composed of agents operating in that environment. The behaviosites facilitate behavioral changes in agents to achieve altered, potentially improved, performance of the overall system. Behaviosites need to be designed so that they are intimately familiar with the internal workings of the environment and of the agents operating within it, and behaviosites apply this knowledge for their manipulation, using various infection and manipulation strategies. To demonstrate and test this paradigm, we implemented a version of the El Farol problem, using behaviosites.

Categories and Subject Descriptors

I.2.11 [**Artificial Intelligence**]: Distributed AI—*Intelligent Agents, Multiagent Systems*

1. INTRODUCTION

Parasites have been examined in biomimetics, but one of the most interesting abilities of biological parasites has received little attention in technological contexts — their ability to manipulate and alter their host's behavior. In rare cases, biological parasites can actually benefit the host or the host's society.

In this paper, we present a novel paradigm that employs a special kind of agent (called a *behaviosite*) that manipulates the behavior of other agents so as to achieve altered, possibly improved, performance of the entire system. The behaviosite (by definition) is not itself necessary for the normal conduct of the system; thus, it is termed a kind of "parasite".

Within the field of MultiAgent Systems (MAS), the behaviosite is closely related to the idea of adjustable autonomy (AA) [6]. In the context of the Behaviosite paradigm, an agent usually transfers some of its autonomy to the behaviosite unwittingly, and in any case the agent is better described as *ceding autonomy*.

Introducing behaviosites to a system may be either planned as part of the overall system design, or added (after the fact) to an already working system. When planned as part of the overall system, it is possible to choose between applying *internal behaviosites* (design hooks inside agents, so that behaviosites can attach to the agent and manipulate them) or *external behaviosites* (which manipulate only the input/output of the agent, vis-à-vis the environment). When applied to an already working system, external behaviosites are usually the only option.

Section 2 presents a formalization of the Behaviosite paradigm. Section 3 discusses the El Farol problem, and how behaviosites could be employed in its solution. Section 4 concludes with a discussion of our approach and of future work.

2. THE BEHAVIOSITE MODEL

2.1 Overall Structure

The Behaviosite paradigm is composed of three parts: the environment, agents (also referred to as hosts), and behaviosites. Environment, agents, and behaviosites will be referred to collectively as "the system" (as in ecosystem).

Environment: encapsulates all of the external factors, conditions, and influences that affect a community of agents and behaviosites.

Agent society: A society of agents is a system composed of multiple, interacting, possibly cooperating agents.

Behaviosite: Most basically, a specialized type of agent. A behaviosite is an additional property/information added to a system with a society of agents, and is not (and should not be) a property of the agent or the environment. The behaviosite is not required for the system, but should be beneficial in some sense; too many behaviosites can degrade some aspects of the system.

2.2 Required Traits

Benefiting the system: Behaviosites must prove beneficial to the system in some respect, since they come with costs. Behaviosites may influence a system in two desired ways: they may increase social utility, or they may create new features in a working system. Both are accomplished by altering the behavior of some of the agents.

System knowledge: A behaviosite must be designed with deep understanding of how the system works: agent-agent interactions, agent-environment interactions, and also internal workings of the agents in some cases. One type of system in which behaviosites can be beneficial is a system that works in a suboptimal equilibrium. The internet is one example of a system in suboptimal equilibrium, with regard to the congestion problem caused by packet routing. The El Farol problem presents another, similar example.

Not a property of the agent nor of the environment: Behaviosites exist in the middle ground between agents and the environment, and should not be a property of either of them.

2.3 Optional Traits

Hidden or apparent infection: We usually will not want agents to know who is infected by the behaviosite, since such knowledge might help individual agents exploit the situation. However, there are some settings in which such knowledge can benefit the system (as also occurs in nature).

Finding the host: A behaviosite designer may endow the environment with the responsibility of infecting agents in the system using some strategy (like in the parasitized El Farol problem), or it may leave the task of infection to the behaviosites themselves, thus making the behaviosites more autonomous.

Behaviosite communication: Behaviosites may communicate with one another within a host (the host may be infected with more than one behaviosite), or across hosts. This may enable the behaviosites to be a catalyst for the creation of norms or social laws.

2.4 Placing the Behaviosite

To alter host behavior, the behaviosite should be placed somewhere along the flow of the system, as can be seen in Figure 1.

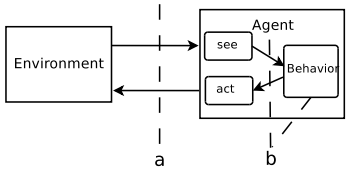

Figure 1: (a) marks where external behaviosite can alter host's behavior, by altering its input/output. (b) marks where internal behaviosite can alter host's behavior, by altering internal data or by partial or full replacement of behavior modules.

Behaviosites can be divided into two groups, external behaviosites, and internal behaviosites. External behaviosites can alter the input or output of the agent vis-à-vis the environment (Figure 1a). In this way, the host designer(s) need not know of the possible existence of a behaviosite now or in the future. Moreover, the behaviosite designer may introduce them into an existing system.[1] On the other hand, internal behaviosites usually require the system to be designed "plug and play" for the behaviosite (Figure 1b).

Internal behaviosites can have two main manipulation methods: changing the host's internal data (Figure 1b, interaction between see-behavior-act modules) or replacing some or all of its behavioral modules (Figure 1b, behavior module). The hook for the second manipulation method is very easy to program, by using the behavioral design patterns suggested by the "gang of four" [3].

2.5 Cost of Manipulation

In different scenarios, behaviosites have different types of costs. The first cost that should be considered is the cost to the system designer, for there is the immediate issue of designing behaviosites and testing them. Other costs of behaviosites are system specific, such as balancing behaviosite complexity and number with the benefit they give to the system, cost of possibly increased variation in the society, oscillations, run-time costs, and so forth.

3. PARASITIZED EL FAROL PROBLEM

3.1 The El Farol Problem

In the El Farol problem [1], N (e.g., 100) agents decide independently each week whether to go to the El Farol bar or not. Comfortable capacity is limited, and the evening is enjoyable only if the bar is not overcrowded (specifically, fewer than 60 agents out of the possible 100 attend). No communication or collusion is possible, and the only information available to the agents is the number of attendees in the past. An agent will go if it predicts less than 60 agents will go, and will stay home otherwise. Arthur's [1] utility function was:

$$Util(ag[i]) = \begin{cases} x & attended\ and\ undercrowded \\ 0 & did\ not\ attend \\ -y & attended\ and\ overcrowded \end{cases}$$

where $x = y = 0.5$. A set of personal deterministic strategies combined with a simple learning algorithm facilitated system convergence to the capacity after some initial learning time. Moreover, membership kept changing, and some degree of fairness was maintained. However, the system fluctuated chaotically around the capacity, resulting in low personal and social utility.

The learning algorithm used in the parasitized El Farol simulation was the additive updating learning algorithm, introduced in [5]. Basically, each agent has a pool of simple, personal deterministic strategies. Each such behavior has a weight, initially distributed uniformly, and updated each round.

3.2 Applying Behaviosites

The El Farol bar problem presents a distributed system with suboptimal social and personal utility. The main idea of the parasitized El Farol problem is to increase social utility with as few side effects as possible, using behaviosites. The main problem was that agents learn and adapt themselves to new situations — behaviosites' effects can vanish, or in each round behaviosites will need to make a stronger impact to achieve the same effect.

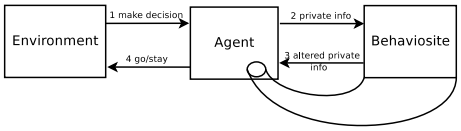

Figure 2: The environment/agent/behaviosite relationship

The system is composed of environment, agents (hosts) and behaviosites (Figure 2). Each agent has an internal behaviosite field that is always occupied, usually with the null behaviosite (see [3]) who has no effect over his host's behavior. Each round, the environment infects some of the agents according to an infection strategy, and infection lasts only one round. Agents are asked to provide a decision and if the behaviosite is not the null behaviosite, it alters the relevant host's data (the behaviosite is placed between "see" and "behavior" of Figure 1).

Environment infection strategies: The environment had three strategies of infection. In the first, all agents were candidates for infection (*infect all*). In the second, only the agents attending in the given round were candidates for infection (*infect attending*). In the third, all the agents attending in the given round were candidates for infection, but only when the bar was overcrowded (*infect overcrowded*). In each strategy, only a percentage of the candidates for infection actually got infected (responsibility of the behaviosite design), depending on the infection rate (0%-100%).[2]

Behaviosite manipulation strategies: The behaviosite replaced the parasitized agents' belief regarding the current capacity with a

[1]Of course, these external behaviosites affect inter-agent communication only if it, too, travels via the environment.

[2]Another possible design is that the entire infection strategy is a property of the behaviosite, but this was not implemented.

lower one, common to all behaviosites. Since capacity information was kept as the private history of the agent, this decrease was also considered in future rounds by the agent. This was intended to enforce a strict approach; agents were affected by the world according to their personal beliefs, not according to global truth.

3.3 Parasitized El Farol Simulation Results

The parasitized El Farol problem was simulated for 2000 rounds, with 100 agents in the system. 3 different capacities were tested: 50, 60, and 80, where the behaviosite manipulation strategy was to decrease capacity for parasitized agents (50 decreased to 40, 60 also decreased to 40, and 80 decreased to 60). For each capacity, 3 different environment infection strategies were tested, as mentioned above: *infect all*, *infect attending*, and *infect overcrowded*, giving a total of 9 different simulations. For each of the 9 simulations, a different percentage of the agents who were candidates for infection were actually infected, with infection rates ranging from 0% to 100% with jumps of 10% (11 different simulations for each). Each of these 99 different simulations was repeated 50 times.

3.3.1 Mean Attendance

In the parasitized El Farol problem, we would like to increase the social utility, without lowering by too much the mean attendance. As would be expected, the *infect all* strategy decreased the mean attendance severely, while the *infect overcrowded* strategy resulted in a relatively low effect on the mean attendance. The outcome of the *infect attending* strategy depended on the bar's capacity. For capacity of 80, the *infect all* and *infect attending* strategies yielded very similar results and for capacities of 50 and 60, *infect attending* strategy's effect resembles the *infect overcrowded* strategy.

3.3.2 Mean Utility

The main objective in the parasitized El Farol problem simulation was to show that it is possible to increase social utility using behaviosites. The *Infect all* strategy for capacities of 60 and 80 showed improvement of 7–9 times that which was achieved in a system without behaviosites, and was relatively close to the optimal. For capacity of 50, improvement was 27 times the minimal, though still near zero (0.065 out of possible 0.25).

Infect overcrowded resulted in a moderate utility increase, with respect to other strategies. For capacities of 60 and 80, the maximal mean utility was about 2.5–3.5 times that which was achieved in a system without behaviosites. For the capacity of 50, the maximal mean utility was 22 times better, but still near zero (0.034).

The *Infect attending* outcome depended heavily on the level of the used capacity. For high capacities (specifically 80), the strategy's behavior was very much like *infect all*, and for low capacities (specifically 50), the strategy's outcome was very much like *infect overcrowded*. In between (specifically 60), the behavior of this strategy combined features of both.

3.3.3 Forced Justice

Two previous attempts to increase social utility in the El Farol problem resulted in two proposed solutions, both with undesirable features in certain settings. One feature was the need to charge utility from attending agents [4], which basically kept the social utility within the system. Another led to the creation of bullies [2] — regulars and casuals. In the original El Farol problem, the membership of the agents kept changing, thus keeping some level of social fairness. Social fairness was calculated by the following formula:

$$1 - \frac{1}{\#trials} \sum_{t \in trials} \frac{Personal\ \ Attendance\ \ SD[t]}{Mean\ \ Attendance[t]}$$

For capacities of 50 and 60, *infect attending* and *infect overcrowded* strategies increase social fairness as a function of infection rate. For capacity of 80, they improved social fairness only a small amount, since the vast majority of agents already go to the bar. However, the *infect all* strategy increased social fairness as a function of infection rate until a certain maximum was reached, and then decreased again. For capacity of 80, it reached exactly the level of social fairness of capacity 60, as would be expected.

4. DISCUSSION AND FUTURE WORK

We presented the Behaviosite paradigm in the spirit of biomimetics — parasites manipulating their hosts' behavior. We specified the behaviosite concept, which in essence is a special type of agent, which infects and manipulates other agents to achieve altered performance of the system. We described the parasitized El Farol problem, and showed that social and personal utilities and social fairness can be increased using behaviosites; in some cases, mean attendance deviates from the capacity by only a small amount.

The parasitized El Farol problem simulated self-interested agents with external behaviosites. However, behaviosites could also be integrated into a cooperative society to form new norms or social laws, or to eliminate ill-functioning agents.

Behaviosites are not just a way of propagating false information within a system. The intimacy of the agent-behaviosite relationship induces far more powerful effects. Lies can be disregarded or overcome by agents. However, when a host is parasitized, the behaviosite is considered an almost integral part of the agent. Agents can doubt external information, but do rely on their internal beliefs.

In the future, we would like to further strengthen the Behaviosite paradigm by showing it is applicable and desirable in other scenarios. An appealing application is the automatic generation of stories; it is a rapidly growing field, with high potential in the gamers community. Behaviosites are an excellent solution for altering stories by changing some of the characters' behavior and adding new, unpredictable system behavior in a distributed manner.

ABSTRACT

In the multi-agent systems, even if each agent behaves selfish or cooperative, its behavior influences the other agents' behaviors and their behaviors influence its behavior cyclically. Thereore a certain information about the relative position of each agent among all the agents may be able to be extracted only from its behavior. If this information can be extracted, each agent has the possibility to improve its efficiency only by seeing its own behavior without knowing about the information of the other agents. In this paper, we verified this hypothesis by using the competitive multi-agent simulation environment named Minority Game, and confirmed that each agent's performance gain was actually possible. This analytical technique may be especially useful for massively multi-agent systems.

1. INTRODUCTION

Generally, in the multi-agent systems, each agent only has local view and cannot obtain the global information of the agents as a whole. In this case, for the each agent to be able to do is to infer the global view or its relative position by getting information from the other agents. But, there is no confirmation that the correct information can be obtained. At this point, in the multi-agent system, even if each agent behaves selfish or cooperative, its behavior influences the other agents' behaviors, in other words, its behavior changes the state of the environment formed by the agents. Then, the changed environment also influences each agent's behavior, and this cycle continues. Hence, it can be thought that the behavior of each agent may include some certain information about its relative position in the agents as a whole. If these information actually exist and each agent can extract one of these information, it can know its position by only checking its own behavior and may be able to improve its behavior efficiently. The purpose of this paper is to verify the possibility of this assumption by using the Minority Game (MG)[**?**]. In MG, a lot of agents play a simple game and even though they have quite local view and behave quite selfish, certain cooperative behaviors are emerged. So, some information about each agent's performance must be included in the behavior of each agent in MG.

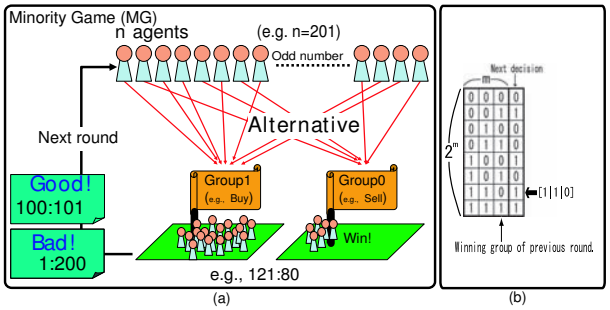

Figure 1: Rules and strategy table

2. MINORITY GAME

Firstly, we review the rules of MG (see Fig. **??**(a)). There are n (odd number) autonomous agents, each of which independently chooses between two alternatives (*group-0* or *group-1*) according to its own behavioral rules, that is, it does not see other agents' behaviors. After all of the agents choose one alternative or the other, and the agents that finish in the minority group are considered to be winners. This is one round of the game. Each winner agent is awarded one point, and the total numbers of winner agents is the profit in this round of the game. The each agent makes its selection by using one of multiple strategy tables that it holds. The entities in the table contain all combinations of m past history of the minority group choices and next decisions that corresponds to each of the combinations for the next round (see Fig. **??**(b)). At the beginning of the game, each agent prepares s ($s \geq 2$) strategy tables, and the next decision entries of each strategy table is stored randomly by 0 or 1. After the game starts, the entries of each table cannot be modified. In the first round of the game a *m-past-winner-group-history* is randomly set, for example, to [1|1|0], and each agent randomly choises one of its holding s strategy tables and sees the next decision entry corresponding to [1|1|0] (see Fig. **??**(b)). And if the next decision entry is *group-1*, the agent selects *group-1*. Then if the agent becomes winner, one point is assigned to the agent and also to the selected strategy table. And if the agent loses, one point is deducted from the selected tables. After the score of the strategy

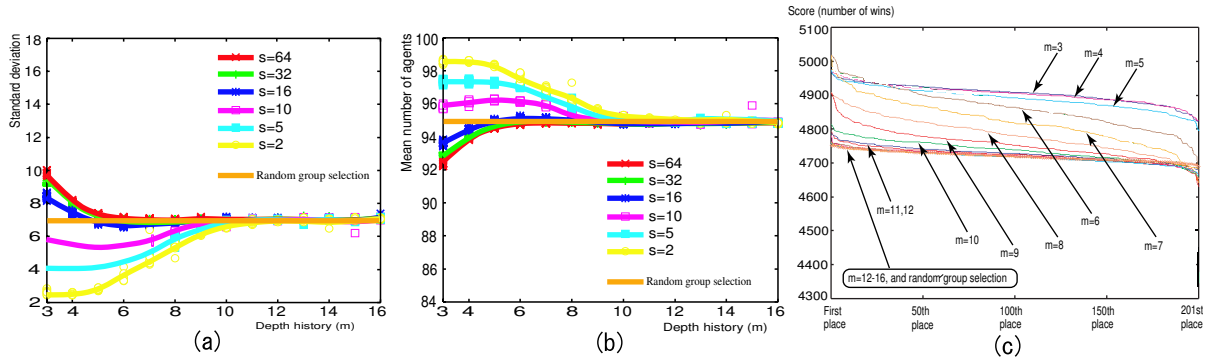

Figure 2: (a) Standard deviations of the number of winning agents. (b) Mean numbers of winning agents

tables of all the agents are updated, then the *m-past-winning-group-history* is updated from [1|1|0] to [1|0|1] because *group-1* becomes winner-group in this round of the game. In the second and subsequent rounds, each agent selects the strategy table that has the highest score. The round is repeated a predetermined number of times, and the final result of the game is the total number of points acquired by winner-agents.

2.1 Coordinated behaviors

Then, the following overall order is emerged through such the simple rules. The game was played for the number of rounds described below; One trial for each parameter pair, (s, m), $\{s|2, 5, 10, 16, 32, 64\}$, $\{m|3\ to\ 16\}$, is 10,000 rounds of the game by 201 agents; ten trials were conducted for each pair. Fig. **??**(a) shows the standard deviation of the number of winning agents, and Fig. **??**(b) shows the mean numbers of winning agents. The horizontal lines in Fig. **??**(a) and (b) represent the standard deviation and mean value when all of the agents choice *group-0* or *group-1* randomly for each round. These graphs show that, for the lower values of s, especially for s = 2, the standard deviation became lowest and the mean number of winning agents became highest when m was from about three to five. Fig. 2(c) shows the rankings of the 201 agents by average score after 10,000 rounds ($s = 2$). In the case where each agent randomly selected *group-0* or *group-1*, all of the agents were able to get approximately 4750 points. In contrast to this, the mean score was high for small m (m = 3 to 5), and although some few differences between agents can be seen in the scores, all or almost all of the agents were able to achieve stable high scores. These simulation results mean that some kind of cooperative behavior among the agents was driving the winning-group ratio closer to 100:101 in small s, especially in s = 2, and m. Especially, the most interesting characteristic is that, although we would expect behavior based on longer histories to be more efficient, m larger than 10 produce results that are the same as those of random behavior. In this paper, we mainly ran the game by several number of agents like n = 101, 201, and 301, and since our interesting is in the cooperative behavior of agents, we ran the game by s=2 (each agent has two strategy tables).

3. AGENT BEHAVIOR AND POWER-LAW

For each agent, its holding strategy tables are very important to decide its behavior, so, in [**?**], we investigated how the strategy tables are used by each agent to analyze each agent detail behavior. Then, up to now, we have discovered the following curious fact, While the high winning ratio agents used both strategy tables, there was no typical fixed period for the continuous use of one strategy table. That is , a self-similarity was visible in these results. Fig. **??** shows, on log-log scales, per-agent histograms of the periods over which either of the strategy tables was continuously used. Results for m=3, 7, and 14 are given for (a) n = 101, and (b) n = 301. Power-law can be seen in both cases of m=3 (graphs were nearly straight lines) and this also reflects the presence of a self-similarity. To the contrary, when m=14 power-law is not seen. Interestingly, the histograms for agents with m=7 show a mix of the two types of results; some agents are similar to the graphs for m=3, while others are similar to those for m=14. It can be thought that the straight lines are for *cooperative agents*, while the curves are for *non-cooperative agents*. So, we calculated the all slopes of the histograms in Fig. 3 (see Fig. **??**). As you can see, the consistent relation can be seen that is the slope of high winning-ratio agent is more horizontal (nearer to 0) than that in low winning-ratio agent. That is, it can be thought that each agent can know its rough position among the group by seeing whether the way of its own strategy table selection obeys the power-law or not.

4. IMPROVEMENT OF WINNING-RATIO USING POWER-LAW FEATURE

The easiest way to change the agent's behavior is to renew its holding strategy tables. So, the following experiments in which each agent renews its strategy tables by three rules were done. As for the experiment, we ran the game by 101 agents (n = 101, s=2). After the game is repeated 10,000 times (10,000 times is one turn), each agent's efficiency is evaluated by the following three kinds of criteria, and each agent which is identified as inefficient renews its strategy tables, then next 10,000 times is started cyclically. In the experiment we repeated the renewing process 10 times that is we ran the game total 100,000 times. We prepared these three evaluation-rules:

(evaluation-1) Since the agent with its power-law slope being nearly 0 has high winning-ratio, we randomly select u pieces of agents whose power-law slope become lower than the previous turn, and selected u pieces of agents renew their strategy tables. In this evaluation, since the calculation of each agent's power-law is computable only from its behavior, each agent need not know the total of agents in the game. However since this evaluation uses only the change of slope even the high winning-ratio agent may renew its strategy tables.
(evaluation-2) We randomly select u pieces of agents whose power-law slope become lower than the certain value (0.75), and selected agents renew their strategy tables. In this evaluation, we use the following knowledge that is, there are consistent relation between the

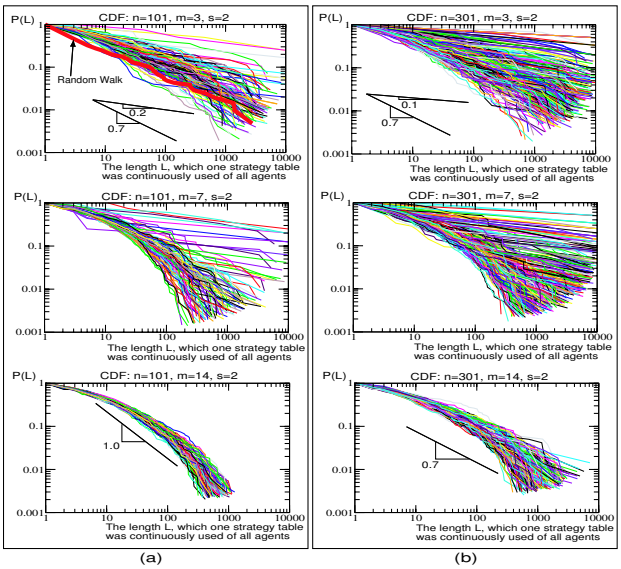

Figure 3: No. of steps L over which either strategy table was in continuous use for (a) n=101 and (b) n=301 with (upper) For m=3 (all 101 agents and 301 agents), (middle) For m=7 (all 101 agents and 301 agents) (lower) For m=14.

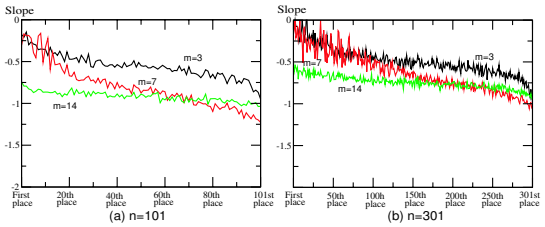

Figure 4: Slopes of the histograms in Fig. 5.

power-law slope and the winning-ration in each agent and this consistent relation does not depend on the total of participating agents in the game. In this evaluation, each agent can know its approximate position without knowing the total of participating agents, and agents only having low winning-ratio can renew their strategy tables.

(evaluation-3) We select u pieces of agents having low score, and selectedagents renew their strategy tables. In this evaluation, it is necessary for each agent to know the following global information, each agent's score and the number of total of participating agent. This evaluation can be thought as the best way to select the agent to renew its strategy table. We prepared this evaluation for the comparison to above evaluation-1 and -2.

Fig. **??** shows the score of 101 agents of nine kinds of evaluation settings. We ran the three kinds of games (u=5, u=10, and u=20) for each evaluation. And as mentioned above, in each situation, strategy table renewing process was repeated 10 times and score of agents after the each renewing process was plotted to the graph of each evaluation setting. As a result, in all settings it can be confirmed that the winning-ratio has improved in all almost agents. First of all, u = 5 was the best in all three kinds of evaluation. The reason can be thought as follows; if we select too many agents, many renewed strategy tables may destroy the current good strategy table's combination of high winning-ratio agents and thus the effect of renewing may be lost. As for the evaluation-1 and -2,

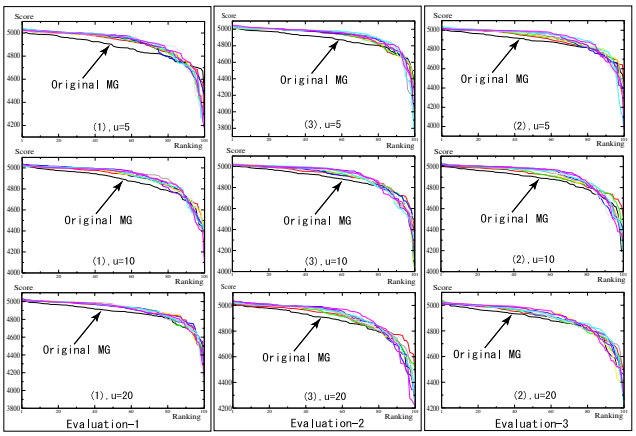

Figure 5: Score of 9 kinds of evaluation settings

evaluation-2 was better than evaluation-1 as we expected because in evaluation-2, only the agents having low winning-ratio are able to renew their strategy tables. Consequentially, evaluation-2 was the most effective though it had been expected that evaluation-3 was at first most effective. While the evaluation-3 uses the several global information, it pays attention only to the score transition of agent. On the other hand, the evaluation-1 and -2 pay attention to the agent behavior. So, in the following two situations, "the score is good by chance even if the evaluation of behavior is bad" and "the score is bad by chance even if the evaluation of behavior is good", agent should not renew its strategy tables in the former situation, and should renew them in the latter situation, thus this experiment result shows paying attention to agent behavior is effective as the evaluation methodology.

5. CONCLUSION

In this paper, we verified whether the efficiency of each agent behavior was able to be improved only by seeing its behavior in MG. In MG, important information for the agent to know the efficiency of its behavior was power-law. Power-law is most typical factor of scal-free network. For example, in the Internet it is known that power-law can be seen in the flow of packets when the number of packets of flowing is the maximum in the traffic [**?**]. This means if the flow of traffic can be controlled to follow of power-law when the flow of traffic becomes an inefficiency situation due to some troubles, the flow of traffic may be corrected to an efficient situation. In the future work, we also plan to apply this coordination methodology to an actual system like the ubiquitous information communication systems and to verify whether an efficient performance improvement is possible.

ABSTRACT

Preferences of a single agent are often partially ordered. For example, it may be hard to compare a novel with a biography. In such a situation, the agent may want the novel and the biography to be considered incomparable. We consider here how to aggregate the partially ordered preferences of multiple agents in order to return a set of most preferred outcomes. We define the notion of strategy-proofness for such a scenario. This is when preference aggregation cannot be manipulated. We prove that if there is no dictator, agents can manipulate the result by voting strategically to determine the most preferred outcomes. This extends the well-known theorem by Gibbard and Satterthwaite for total orders.

1. INTRODUCTION

Many problems require us to combine the preferences of different agents. For example, when planning a wedding, we must combine the preferences of the bride, the groom and possibly some or all of the in-laws. Typically such preferences are partial orders over the outcomes. We can view many different mechanisms for preference aggregation in terms of voting. Each agent is voting for their preferred outcomes. When aggregating preference orders, one may be interested in obtaining a combined ordering among the outcomes, or just the set of most preferred outcomes (also called the winners). The first choice, in which the aggregation function is called a *social welfare* function, provides more information about the combined preference ordering since it tells us the ordering between any pair of outcomes. The second scenario, in which the aggregation function, called a *social choice* function, returns a set, is less informative but often enough when we are just interested in choosing one of the most preferred outcomes.

In this paper we will consider social choice functions. Thus the result of aggregating preferences will be just a set of outcomes. A very desirable property of preference aggregation is non-manipulability (also called strategy proofness). It should not be possible for agents to manipulate the election by voting strategically. Strategic voting is when agents express preferences which are different from their real ones, to get the result they want. If this is possible, then the preference aggregation rule is said to be manipulable. For social choice rules on *totally* ordered preferences, the Gibbard Satterthwaite theorem [3] proves that it is not possible to be at same time non-manipulable and have no dictators. Either there is a dictator (that is, an agent who gets what he wants by voting sincerely) or a manipulator (that is, an agent who gets what he wants by lying). In either case, there is an agent who gets what he wants no matter what the other agents say. In this paper we extend this result to *partially* ordered preferences. Even in this more general case, we prove that it is impossible for a social choice function to have no dictator and be non-manipulable at the same time. As with total orders, we conjecture that there will be ways around this negative result. For example, it may be that certain social choice functions on partial orders are computationally hard to manipulate. As another example, it may be that certain restrictions on the way agents vote (like single-peaked preferences for total orders) guarantee strategy-proofness.

2. SOCIAL CHOICE ON PARTIAL ORDERS

In some situations, the result of aggregating the preferences of a number of agents might not need to be an order over outcomes. It might be enough to know the "most preferred" outcomes. Social choice functions identify such most preferred outcomes.

A **profile** p is a sequence of n orderings $p_1, \ldots, p_n$ over outcomes, one for each agent $i \in \{1, \ldots, n\}$. A social choice function on total orders is a mapping from a profile to the optimal outcome, or winner. With partial orders, (i.e. binary relation which are reflexive, transitive, antisymmetric

and not always complete), there can be several outcomes which are incomparable and optimal. We can therefore consider a generalization in which a social choice function is a mapping from a profile to a non-empty set of outcomes, called the optimal outcomes, or the winners.

Let us now consider some properties of such social choice functions. Our definition of these properties is a generalization of the corresponding definition for social choice function on totally ordered profiles [1]. We say that a social choice function f is **unanimous** iff

- for any profile p with $a \in top(p_i)$ for every agent i, then $a \in f(p)$;
- for any profile p with $\{a\} = top(p_i)$ for every agent i, then $f(p) = \{a\}$.

It is instead **monotonic** iff, given two profiles p and p',

- if $a \in f(p)$ and, for any other alternative b, $a >_{p_i} b$ implies $a >_{p'_i} b$, $a \bowtie_{p_i} b$ implies $a \bowtie_{p_i} b$ or $a >_{p'_i} b$, for all agents i, then $a \in f(p')$;
- if $f(p) = A$ and for all $a \in A$, for all b, $a >_{p_i} b$ implies $a >_{p'_i} b$ and $a \bowtie_{p_i} b$ implies $a \bowtie_{p'_i} b$ or $a >_{p'_i} b$, for all agents i, then $f(p') = A$.

We define three notions of dictators for social choice functions: a **strong dictator** is an agent i such that, for all profiles p, $f(p) = top(p_i)$; a **dictator** is an agent i such that, for all profiles p, $f(p) \subseteq top(p_i)$; a **weak dictator** is an agent i such that, for all profiles p, $f(p) \cap top(p_i) \neq \emptyset$. Notice that, in any profile p, if a is the unique top of a weak dictator i, then $a \in f(p)$. However, this is not true if a is not the unique top of i.

We say a social choice function is **strongly fair**, **fair** or **weakly fair** if it is unanimous, monotonic, and does not have a strong dictator, dictator or weak dictator, respectively. Since a strong dictator is a dictator, and a dictator is a weak dictator, weak fairness implies fairness which itself implies strong fairness. In [6], we generalize the Muller-Satterthwaite theorem [5] to social choice functions over partial orders without ties, for weak dictators. That is, weak dictators are inevitable if we have two or more agents, three or more outcomes and the social choices function is unanimous and monotonic. We rewrite here this theorem formally since it will be used in the rest of the paper.

Theorem 1 ([6]) *If we have at least two agents and at least three outcomes, and a social choice function on partial order without ties is unanimous and monotonic, then there is at least one weak dictator.*

3. STRATEGY PROOFNESS

The Gibbard Satterthwaite theorem on totally ordered preferences [3, 7] proves that either we have a dictator or the social choice function can be manipulated. That is, agents can manipulate the result using tactical voting. We may now wonder if a similar relationship holds between weak dictators and non-manipulability. To answer this question, we must generalize the notion of non-manipulability (also called strategy proofness) to social choice functions on partially ordered preferences, and then consider the Gibbard Satterthwaite theorem [3, 7] in this more general context.

We will show that weak dictators are inevitable if we have at least two agents and three outcomes, and the social choice function is strategy proof and onto. These conditions are identical to those in the Gibbard Satterthwaite theorem for total orders. A social choice function is strategy-proof if it is best for each agent to order outcomes as she really prefers and not to try to order them tactically, with the hope of getting a better result. More precisely, the social choice function must never allow an agent to get a preferred outcome among the winners by ordering outcomes in a way that contradicts his or her true preferences [1].

Formally, a social choice function is **strategy proof** if, for every agent i, for every pair of profiles p and p', which differ only for the agent i's ranking, that is, p_i, we have that

- $\forall a \in f(p) - f(p')$, $\forall b \in f(p')$, if $a \bowtie_{p_i} b$, then $a \bowtie_{p'_i} b$ or $a <_{p'_i} b$; if $a <_{p_i} b$, then $a <_{p'_i} b$;
- $\forall a \in f(p) - f(p')$, $\exists b \in f(p')$ such that, if $a >_{p_i} b$, then $a \bowtie_{p'_i} b$ or $a <_{p'_i} b$; if $a \bowtie_{p_i} b$, then $a <_{p'_i} b$.

In other words, a social choice function is strategy proof if an agent can remove an element a from the set of winners only by worsening its rank with respect to at least one the new winners b, and not improving it with respect to any other new winner. This means that it is not possible for an agent to make a disappear from the set of winners by improving its ranking in her preference ordering. In fact, this would be tactical voting.

In general, even in the totally ordered case, most voting procedures involving three or more alternatives are not strategy proof [1]. This is true also in the partially ordered case. Let us consider the following two social choice functions: f_1 is such that $f_1(p) = \bigcup_i top(p_i)$, that is, this function returns the union of the sets of optimal elements of each agent and f_2 is the Pareto function, which returns the optimal elements of the ordering returned by the Pareto social welfare function (where $a > b$ if all agents say $a > b$, otherwise $a \bowtie b$).

Let us now consider two profiles p and p' on three alternatives a, b and c such that $p = (p_1 = (c > a \wedge c \bowtie b \wedge a \bowtie b)$, $p_2 = (c \bowtie a \wedge c \bowtie b \wedge a \bowtie b)$, $p_3 = p_1)$ and $p' = (p'_1 = p_1$, $p'_2 = (c > a > b)$, $p'_3 = p_3)$. Then, for both such social choice functions, the set of winners in profile p is $\{a, b, c\}$, while in profile p' is $\{b, c\}$. Thus a has disappeared by passing from p to p' but its ranking has improved with respect to b in agent 2. Thus both social choice functions are not strategy-proof.

In order to prove the generalization of the Gibbard Satterthwaite theorem to the partial order case we first prove the following result, which relates strategy proofness to unanimity and monotonicity.

Theorem 2 *If a social choice function is strategy proof and onto, then it is unanimous and monotonic.*

PROOF. The proof is composed by two parts. Part 1 shows that if a social choice function f is strategy proof then it is monotonic, while part 2 shows that if f is onto and monotonic then it is unanimous.

Part 1. Consider two profiles p and p', which differ only for the ranking of *agent* i.

Assume that $a \in f(p)$ and that for any other alternative b, $a >_{p_i} b$ implies $a >_{p'_i} b$ and $a \bowtie_{p_i} b$ implies $a \bowtie_{p_i} b$ or $a >_{p'_i} b$. We want to show that $a \in f(p')$. For the sake of

contradiction, assume that $a \notin f(p')$. Since f is strategy proof, then $\exists c \in f(p')$ such that one of the following holds: (i) if $a >_{p_i} c$, then $a \bowtie_{p'_i} c$ or $a <_{p'_i} c$, (ii) if $a \bowtie_{p_i} c$, then $a <_{p'_i} c$. If the first holds then there is an element c which is worse than a in p_i and that becomes strictly better than or incomparable to a in p'_i. This contradicts the fact that for any other alternative b, $a >_{p_i} b$ implies $a >_{p'_i} b$. If the second holds then there is an element c which is incomparable with a in p_i and becomes strictly better then a in p'_i. This contradicts the fact that for any other alternative b, $a \bowtie_{p_i} b$ implies $a \bowtie_{p'_i} b$ or $a >_{p'_i} b$.

Assume now that $\forall a \in f(p)$, for any other alternative b, $a >_{p_i} b$ implies $a >_{p'_i} b$ and $a \bowtie_{p_i} b$ implies $a \bowtie_{p_i} b$ or $a >_{p'_i} b$. We want to show that $f(p) = f(p')$. For the sake of contradiction, we can assume that $\exists a$ such that $a \in f(p)$ and $a \notin f(p')$ or that $\exists a$ such that $a \in f(p')$ and $a \notin f(p)$. If $\exists a$ such that $a \in f(p)$ and $a \notin f(p')$ then, since f is strategy proof, the same reasoning above leads to the same contradictions. If instead $\exists a$ such that $a \in f(p')$ and $a \notin f(p)$, then since f is strategy proof, then $\exists c \in f(p)$ such that one of the following holds: (i) if $a >_{p'_i} c$, then $a \bowtie_{p_i} c$ or $a <_{p_i} c$, (ii) if $a \bowtie_{p'_i} c$, then $a <_{p_i} c$. In the first case there is an element a which is stricly smaller than or incomparable to c in p_i that becomes strictly greater than c in p'_i. This is in contradiction either with the fact that for any other alternative b, $c \bowtie_{p_i} b$ implies $c \bowtie_{p'_i} b$ or $c >_{p'_i} b$ or with the fact that $c >_{p_i} b$ implies $c >_{p'_i} b$. If the second case holds then there is an element a that is smaller than c in p_i and that becomes incomparable with c in p'_i. This contradicts the assumption that for any other alternative b, $c >_{p_i} b$ implies $c >_{p'_i} b$.

Consider two profiles q such that $f(q)$ $\{a\}$ and a profile q' such that *for every agents* i and for every alternative b, $a >_{q_i} b$ implies $a >_{q'_i} b$. We want prove that $f(q')$ $\{a\}$, that is the first part of the definition of the monotonicity for social choice functions. Since we can move from $q = (q_1, ...q_n)$ to $q' = (q'_1, ...q'_n)$, passing from $q = (q_1, q_2..., q_n)$ to $(q'_1, q_2..., q_n)$, and $(q'_1 q'_2, ..., q_n)$ to $(q'_1, q'_2, ..., q_n)$ and so on, and we have shown above that at each step a remains in the set of winners, $a \in f(q')$. The same reasoning holds for profiles q such that $f(q) = A$ and q' such that for every agent i, for $\forall a \in A$, for every other alternative b, such that $a >_{q_i} b$ implies $a >_{q'_i} b$. In this case we conclude that $f(q') = A$. This is the second part of the definition of monotonicity for social choice function. We have thus shown that f is monotonic.

Part 2. Since f is onto, then for every subset S of alternatives there is a profile p such that $f(p) = S$. If $S = \{a\}$, where is a is an alternative, since f is onto, there is a profile p such that $f(p) = \{a\}$. If we consider the profile p', obtained from profile p bringing a to the very top of every agent, then for strict monotonicity on profiles p and p', that we have just proved, $f(p') = a$. Therefore, whenever a is the unique top of every agent's ranking in a profile $\bar{p}$, then $f(\bar{p}) = \{a\}$. Because a is arbitrary then f satisfies Pareto efficiency in the case of unique top for every agent.

If $S \supset \{a\}$, since f is onto, then there is a profile p_1 such that $f(p_1) = S \supset \{a\}$. If we consider a profile p'_1 where a is at the top (not unique) for every agent, then, for monotonicity on profiles p_1 and p'_1, $f(p'_1)$ must contain a. Therefore, whenever a is one of the tops of every agent's ranking in a profile $\bar{p}$, then $f(\bar{p})$ $\{a\}$. Because a is arbitrary, then f satisfies Pareto efficiency in the case of not unique top for every agent. Q.E.D.

We now use this result, together with the extension of the Muller-Satterwaithe result (Theorem 1), to prove the main theorem stating that it is not possible for a social choice function to be at the same time strategy proof and onto, and have no weak dictators.

Theorem 3 *If there are at least two agents and at least three outcomes and the social choice function is strategy-proof and ontothen there is at least one weak dictator.*

PROOF. By Theorem 2, if f is onto and strategy proof then it is monotonic and unanimous. Moreover, Theorem 1 states that if f is monotonic and unanimous then there is at least one weak dictator. Q.E.D.

4. RELATED WORK

Efforts have been made to weaken the conditions of the Gibbard Satterthwaite theorem. For example, in [2], the domain of the social choice function has been generalized to preferences over sets of outcomes and an impossibility result proved. The Gibbard Satterthwaite theorem has been shown to be robust to several other restrictions of the domain of the social choice function. Here we have shown that this theorem is robust also to including incomparability in the preference ordering.
