In this paper we illustrate how a role-based semantics for agent communication languages can embed the two main existing models of agent communication languages, respectively based on 'mental attitudes' and 'social commitments' semantics. These two models have been presented as incompatible approaches, but recently we illustrated for persuasion dialogues and using our normative multi-agent systems framework, that they can be seen also as complimentary ones. Independently from our own multi-agent model, in this paper we illustrate for the speech act 'inform' how the role based semantics embeds the other two semantics.

1. SYNTHESIS

In [1] we argue that a *role metaphor* can be used to bridge the gap between the mental attitudes approach [4] and the social commitments approach [8] to the semantics of agent communication languages. We show how dialogues can be modelled as games in normative systems and how mental attitudes can be attributed not only to agents, but also, in a public manner, to the roles of the game. The dialogue moves allow an agent playing a role to modify the roles' mental states, as specified by so-called counts-as conditionals or constitutive norms defining the game. The player of a role is expected to act as if he has the mental attitudes attributed to his role and to prevent his role's mental attitudes from becoming incoherent, just as he does for his own private mental attitudes.

Thus, we embed the mentalistic approach by showing how mental attitudes can be attributed to public roles instead of agents. The motivation of maintaining a mentalistic semantics, albeit referred to roles, is to be able to reuse the extensive FIPA work on the agent communication semantics. It is sufficient to refocus the model from the agents' beliefs and goals to the roles' beliefs and goals. However, though the mentalistic approach is embedded, the following drawbacks of the FIPA approach are not inherited.

- Communication is intersubjective and public, while beliefs and goals are private and, thus, not accessible by the receiver.
- An independent observer cannot verify whether agents conform to the agent communication semantics [11].
- The sincerity assumption that is necessary to reason with mentalistic semantics does not apply to non-fully cooperative dialogue contexts, like argumentation and negotiation.

Moreover, we embed the social approach by showing how roles as descriptions of expected behavior maintain the normative character of social semantics. Roles are useful because mental attitudes attributed to roles of a dialogue game capture the public character of meaning which is offered by commitment approaches. The following limitations of the social commitments approach are not inherited by our role-based semantics:

- Commitment interpreted as an obligation is too strong in cooperative dialogues, where the notion of expectation is sufficient. Moreover obligations are associated with sanctions, which are specific only in some kinds of dialogues.
- Commitment is related to the notion of obligation, while the notion of permission is not considered even if it is necessary to explain the notion of concession. Walton and Krabbe [10] argue that after an 'inform' the receiver can make a concession explicitly, or implicitly by not challenging or failing to challenge the 'inform'. In case of concessions the receiver becomes weakly committed to the proposition: he can no longer make the speaker committed to defending the proposition by challenging him, albeit the receiver does not have to defend the proposition himself if challenged. This situation cannot be expressed in social semantics.
- Propositional commitment is not clearly distinguished from action commitment. Thus it has the same conditions of fulfillment as action commitment, while propositional commitment for Walton and Krabbe is fulfilled when the receiver concedes, instead of when the commitment is true in the world.
- The action of informing is not related with any effect on the hearer, only the attitude of the speaker is considered. A precondition that the speaker does not believes that the receiver knows what is communicated is not expressible.

Our approach in [1] discusses persuasion dialogues and assertive speech acts, and uses our normative multi-agent systems framework describing roles via the agent metaphor and formalizing mental attitudes of the agents in Input/Output logic [7]. In this paper we consider the general problem of embedding mentalistic and social semantics in a role based semantics, independently from the dialogue type or agent model. In the following section we use visualizations of the communicative act 'inform' to illustrate how the role-based semantics can be seen as a natural combination of the 'mental attitudes' and 'social commitments' semantics. In the final section we sketch some formal aspects.

2. EMBEDDING IN ROLE SEMANTICS

Figure 1 visualizes the communicative act 'inform' in a mental attitudes approach like the one provided by FIPA [4]. This figure should be read as follows. The two ovals represent the two agents x and y. Within the ovals the mental state of the agent is represented. The top half of the oval contains the beliefs (B) of the agent, and the lower half his goals (G). Agent x thus has the belief p and the goal that agent y believes p; in a modal language, these may be represented by $B_x p$ and $G_x B_y p$. Note that the outer modalities are not represented in the figure. Agent y believes p too if he trusts x. The arrow between the agents visualizes a communication channel.

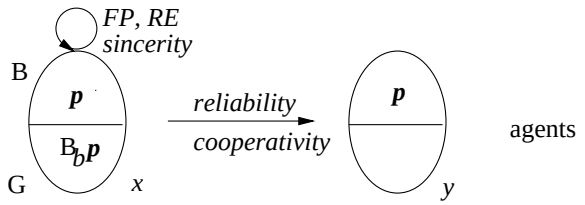

Figure 1: Mental attitudes semantics

In the mental attitudes semantics, communicative acts are defined in terms of the mental state of the BDI agent who issues them. The bridge between the communicative acts and the behavior of agents is provided by the notions of rational effect and feasibility preconditions. The rational effect (RE in Figure 1) is the mental state that the speaker has the goal to bring about in the receiver by issuing a communicative act; the feasibility preconditions (FP) encode the appropriate mental states for issuing a communicative act. From the execution of a communicative acts it can be inferred that the speaker believes the feasibility preconditions and has the goal to achieve the rational effects. This kind of inference can be compared to presupposition accommodation [9]. However, this inference does not guarantee that the speaker actually has these attitudes nor that he would agree that these are the effects of a communicative act. Moreover, RE and FP are concerned only with the speaker, since they do not say anything about the receiver. Thus, assumptions about the reliability and sincerity of the speaker and about the cooperativity of the receiver are necessary to infer that the receiver believes what has been communicated, or wants to comply with a request.

Figure 2 visualizes the same communicative act 'inform' in the social commitment approach. This figure should be read as follows. Again there are a speaker x and a hearer y with their beliefs and goals. Moreover, there are also two commitment stores, represented by the two squares, but not distinguished between propositional and action commitment. The arrows represent that due to agent x informing p, and to avoid a sanction, he may believe it. In this way, agent communication languages based on social commitment constitute an attempt to overcome the mentalistic assumption of FIPA by restricting the analysis to the public level of communication.

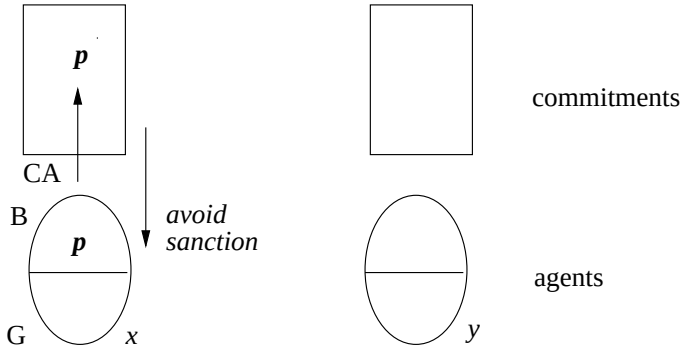

Figure 2: Social commitment semantics

In the social commitments approach, communicative acts are defined in terms of the social commitments they publicly determine for the speaker and the hearer (see Figure 2). However, there are many ways in which this has been made more precise, and the term of commitment has been used in different ways. For example, Walton and Krabbe focus on propositional commitments: "to assert a proposition may amount to becoming committed to subsequently defending the proposition, if one is challenged to do so by another speaker" [10]. However, this kind of propositional commitment is biased towards argumentation dialogue, thus failing to be general enough for other kinds of dialogue. By contrast, Singh is interested in negotiation, and he investigates action commitments, that typically result from commissives and directives. According to Fornara and Colombetti [5], commitment is "a social relationship between the speaker and the hearer".

In Figure 3 we visualize the role-based semantics of 'inform'. The ovals x and y represent two agents playing respectively the roles a and b in the dialogue game. The constitutive rules of the game operate on the mental states of both roles. Only external assumptions like sincerity attribute beliefs to the agents, but they are not part of the game. The basic idea is that communicative acts can be modelled as plan operators with preconditions and effects which can refer to beliefs, goals and intentions, but the mental attitudes they refer to are not the private inaccessible ones of the agents. Rather, the beliefs, goals and intentions to which speech acts refer are attributed to a public image of the participants in the dialogue representing the role they play.

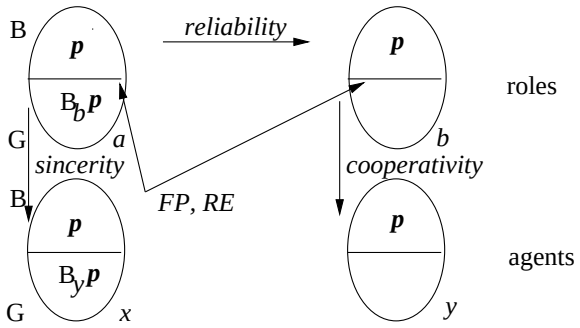

Figure 3: Role-based semantics

Of course, communication among agents is often associated with the roles played in the social structure of the systems, and role names like 'speaker' and 'addressee' or 'buyer' and 'seller' are often mentioned in the definition of agent communications languages. However, usually these terms only serve the function to bind individual agents to the speech acts in the protocol, whereas in our role semantics they are associated with a state which changes during the conversation as a result of the performed speech acts. Technically, attitudes are attributed to agents enacting a role; we just abstract over the agent. So what we are modelling, is similar to the public mental states associated with role enacting agents (REAs) in the model of Dastani *et al.* [3]. A similar solution is also proposed by Gaudou *et al.* [6], where beliefs (but not goals) can be publicly attributed to agents by means of a grounding operator.

3. TOWARDS FORMALIZATION

In the following, we sketch how a role-based semantics can be defined for FIPA and social semantics. With some adjustments of notation, the FIPA definition of the *inform* communicative act is as follows.

inform(a, b, p)
FP: $B(a, p) \wedge \neg B(a, B(b, p) \vee B(b, \neg p))$
RE: $B(b, p)$

We assume that a, b are variables that range over roles, whose attitudes are maintained in public. The inference that can be based on the *feasibility preconditions* (FP) of a speech act, is modeled in the following way:

$$\textit{inform}(a, b, p) \rightarrow B(a, p)$$
$$\textit{inform}(a, b, p) \rightarrow \neg B(a, B(b, p) \vee B(b, \neg p))$$

Because roles' beliefs are maintained in public, these preconditions can indeed be verified.

The inference that is based on the *rational effect* (RE) is as follows. This inference is based on a kind of abduction. Uttering a speech act only makes sense when the rational effect is a goal of the speaker.

$$\textit{inform}(a, b, p) \rightarrow G(a, B(b, p))$$

In the social commitments model, speech acts introduce commitments in the dialogue state or manipulate them. A commitment has a *debtor* and a *creditor*, i.e., respectively, the agent who has the commitment, and the agent to which the commitment is made. A commitment can have different states: unset (i.e., to be confirmed), active (i.e., confirmed), fulfilled, *etc*.

In our translation, a commitment state corresponds to a specific configuration of roles' beliefs and goals. So the commitment to defend a proposition (c.f. [10]), is treated as equivalent to a public belief: the agent must not contradict himself by means of conflicting speech acts or by failing to defend his beliefs.

We focus here on propositional commitment and concessions. Consider a dispute between debtor and creditor about a propositional variable p. A propositional commitment PC is *active* whenever the debtor publicly believes the proposition, while nothing is required for the creditor:

$$PC(\text{active}, a, b, p) \equiv B(a, p)$$

A propositional commitment PC is *fulfilled* when the creditor concedes the proposition:

$$PC(\text{fulfilled}, a, b, p) \equiv \neg B(b, \neg p)$$

Regarding the effect of speech acts in such a dispute, we can say that a *concession*, means that the debtor does not publicly believe (and defend) the opposite:

$$\text{concede}(a, b, p) \rightarrow \neg B(a, \neg p)$$

An 'inform' introduces an active propositional commitment of the speaker and, if it is not challenged, also a concession of the receiver:

$$\text{inform}(a, b, p) \rightarrow B(a, p)$$
$$\text{inform}(a, b, p) \wedge \neg\text{challenge}(b, a, q \rightarrow \neg p, q) \rightarrow \neg B(b, \neg p)$$

The second part of the rule prevents the player of role b from asserting the opposite proposition $\neg p$ in the subsequent dialogue, since this would lead to a contradiction: $\neg B(b, \neg p) \wedge B(b, \neg p)$.

Please note the similarity between the inferences that can be made based on FIPA-style FP and RE, and the inferences that can be made on the basis of propositional commitments. For both the $\text{inform}(a, b, p)$, we get $B(a, p)$ and $\neg B(b, \neg p)$: the difference rests in the effect of challenging or failing to defend beliefs.

Thus, in our framework we are able to model both the mental attitudes and social commitment approaches, but avoiding their major limitations. First, with respect to FIPA, mental attitudes are public, because they are attributed to roles; second, the semantics of speech acts is public too since it consists in public constitutive rules; third, the model is not restricted to cooperative situations, since sanctions can be added to the expectations represented by roles [2].

With respect to social commitment, first, we can consider also cooperative situations were expectations are sufficient; second, as in Walton and Krabbe we can model the notion of concession, but, with respect to them, we can also distinguish between propositional and action commitment by means of the distinction between roles' beliefs and goals. Finally, we can refer to beliefs and goals of roles to express more complex preconditions on speech acts.

ABSTRACT

Knowledge transfer between expert and novice agents is a challenging problem given that the knowledge representation and learning algorithms used by the novice learner can be fundamentally different from and inaccessible to the expert trainer. We are particularly interested in team tasks, robotic or otherwise, where new teammates need to replace currently indisposed team member(s). We are interested in a general knowledge transfer framework where existing team members or experts can train a new agent to follow its role in team coordination by using exemplars of desirable behavior. Each such exemplar presents a team situation and a preferred action. We envisage an iterative training process where the trainer selects more exemplars in the next iteration based on the errors made by the learner in action choices for test exemplars presented in the current iteration. Such an iterative, exemplar based generic knowledge transfer scheme can be used by agents using arbitrary knowledge representation and learning methods. We evaluate the success of training new teammates in the well-known pursuit problem, where some of the current set of expert predators is being replaced by new ones with no *a priori* hunting knowledge. Experimental results demonstrate the robustness of our knowledge transfer scheme with a graceful performance degradation.

1. INTRODUCTION

We have proposed an Agent Teaching Agent (ATA) framework to address the problem of transfer of concept description knowledge between a trainer and a trainee agent. A concept description is a boolean-valued function that classifies input examples into various discrete classifications of the target concept [5]. We assumed that the trainer agent does not have access to the internal knowledge representation of the trainee agent, but can evaluate the latter's concept recognition abilities by asking it to categorize selected exemplars and non-exemplars of the target concept. We focused on the incremental selection of training exemplars by the trainer to expedite the learning of the trainee agent. The ATA framework involves several iterations of training and test set presentations to the trainee, where the trainer chooses the training set of one iteration based on the mistakes made by the trainee on the test set in the previous iterations.

The goal of this paper is to show that the ATA framework can be used to transfer coordination knowledge to other agents, without information about the other agent's internal knowledge representation and learning algorithms. Such coordination knowledge transfer allows teams to recover from failure of some team members as well as deploy "clone" teams in the environment to reduce load on the current team of trainers. We assume that the trainer itself is a learner (a member of the current team), who learns its coordination knowledge from training instances provided by a domain expert, e.g., a coach. We further assume that this training set provided by the expert is no longer available, and the trainer must generate new exemplars from introspection to train new teammates.

To support our claims for the effectiveness of the iterative training process used in ATA, we also compare the performance of ATA-trained trainees with the performance of other trainee agents taught by the teacher agent in one iteration by presenting a single training set. Our results clearly show that the concept description generated by the trainee agent in the latter case is less effective in comparison to the concept description formed by the trainee agent trained using the ATA framework.

2. ATA FRAMEWORK

The trainer agent uses its learning module to acquire the target concept from its interaction with an environment, which may include an expert providing feedback. This learning process produces a target concept description in the knowledge representation used by the trainer agent. The

Train-Agent(Trainer,Trainee,Trainer-knowledge){

  $M_i \subset T_i$, examples misclassified by trainee after training on N_i
  $T_{i+1} \leftarrow T_i \cup newTestInstances(M_i)$
  $N_{i+1} \leftarrow N_i \cup newTrainingInstances(M_i)$
  $i \leftarrow i + 1$
until $|M_i| < threshold$

Figure 1: Algorithm for incremental training.

trainer agent also has a training module which interacts with the trainee and provides successive training and testing sets to train and evaluate the progress in learning of the trainee agent. The trainee learns its own concept description from the set of classified training examples provided by the trainer. It also classifies each of the unclassified test examples provided by the trainer and returns these classified instances to the trainer for evaluation.

We envisage an iterative training procedure in which alternatively the trainer selects a set of training and testing exemplars, the trainee trains using the training set and then classifies the testing set, the trainer observes errors made by the trainee in classifying the instances in the last testing set and accordingly generates the next training and testing sets. This iterative process converges when the error of the trainee falls below a given threshold. We present these iterative training steps in an algorithmic form in Figure 1.

3. DOMAIN AND TRAINING DATA

The domain used for our experimentation is the predator-prey pursuit problem [3] in a continuous world. This problem requires effective coordination by a group of agents to achieve a goal. The goal of the predator in this paper is to capture a prey which is moving in a straight line with half the speed of the predator. The predators who move simultaneously can see each other and the prey, but cannot communicate explicitly to coordinate their moves. To capture the prey, predators must surround it from four sides and be within a threshold distance of the prey. However if they come in close proximity of each other, a collision occurs and each of the colliding parties move a significant number of steps away from the collision point. To avoid such collisions, an expert predator moves a few steps orthogonal to the direction of the prey when it senses another predator in close proximity. The predators must capture the prey within a maximum number of steps, after which the game stops.

For our experimental setup, we have considered C4.5, a decision tree based algorithm [7] as the learning mechanism for the trainer and an instance based learning algorithm, IB2, as the learning mechanism for the trainee. IB2 uses an incremental learning algorithm that stores a subset of the training examples as its classification knowledge [1].

The experts provide the trainers with 17500 instances from various configurations to learn from. The large size of training is required to capture the complexities of coordinating four teammates in continuous space. To derive a rich set of training instances, the experts calculated all possible orientations of the four predators in the four quadrants centered at the prey. A configuration is a vector $< n1, n2, n3, n4 >$ where $n_i \in \{0, 4\}$ and $\sum_{i=1}^{4} n_i = 4$ and n_i is the number of predators in quadrant i with respect to the prey. Several initial predator-prey situations were generated for each such configuration, and the move of the experts from each such situation was noted. A training instance is created for each situation-move pairs by noting polar coordinates of the other predators and the prey, assuming this expert's positions as origin, were the classification of the instance is the move(right, left or ahead) selected by this expert at this situation. A typical training set data is a tuple $(r1,\ 1, r2,\ 2, r3,\ 3, rp,\ \mathrm{p}, M)$, where the different r and values signify the polar quadrants of the other three experts and the prey with respect to the expert who is teaching the trainer. M signifies the move that would be taken by the teacher expert under such an orientation. Once the trainers learn their coordination knowledge, they use the ATA framework to teach a new team member, the trainee.

4. RESULTS

Now we present the results from our experiments. The game is played on a 20×20 grid. We denote the various participants in our experiments by the following notations.

- Expert, E ,
- Trainer agent C: a decision tree based [7] learner,
- Trainee agent I: an instance based learner taught by a C agent in one iteration,
- Trainee agent A: an instance based learner taught by a C agent iteratively using the ATA framework.

Table 1 shows the performance of the different mixes of predators in the predator-prey pursuit game averaged over 1750 games. The first notable observation from Table 1 is the relative performances of the homogeneous groups of trainees who are taught either through the ATA framework or in one iteration. The relevant rows from Table 1 in this case are those with configurations AAAA and IIII. Clearly the AAAA configuration shows a higher capture rate and a faster capture to signify that the trainees who have undergone the learning process through the ATA framework have developed better coordination knowledge than those who have been taught in one iteration. Also the percentage capture rate for the AAAA configuration is fairly close to that of the CCCC configuration, consisting of all trainers, which shows that ATA framework has done a good job in teaching coordination knowledge to the new agents.

Now we shift our attention to heterogeneous predator team compositions. Interestingly, heterogeneous groups have smaller standard deviation compared to homogeneous groups, except for the group of experts. One reason for heterogeneous groups performing better than homogeneous groups can be that the differences in the knowledge of C and A agents can present useful complementarity that actually facilitate coordination. We also ran the Wilcoxon Matched-Pair Signed-Ranks test for pairs of groups where the team compositions differ by one trainee. The results show that the difference in step sizes to capture the prey is statistically significant for all such head-to-head comparisons.

Configurations	%*Capture*	Steps	
		Mean	*STD*
EEEE	100	14.77	6.63
CCCC	86.74	45.49	32.53
CCCA	100	17.85	8.19
CCAA	95.77	24.12	11.39
CAAA	89.54	32.69	18.59
AAAA	81.54	43.34	29.90
IIII	67.42	62.18	50.32

5. RELATED WORK

Multiagent learning has been an active area of research in the late 90s [8, 9]. The most relevant work involves one learner telling another agent what portions of the search space to ignore [6], a learner sharing experience [2], problem-solving traces or even learned policies [10] with another concurrent learner. A recent paper discusses a method for two agent to mutually define a concept [11]. Though emphasis is placed on instance selection, in contrast to the current work, there is no pre-existing concept, and hence the learners are peers rather than a trainer-trainee pair. Tan's work [10] of an expert sharing effective problem solving traces with a novice agent and Clouse's work of a trainer suggesting actions to take [4] are perhaps the closest in motivation to the current work, but the iterative nature of teaching, at the heart of the ATA framework, is not addressed by them.

6. CONCLUSIONS

We developed a generic approach for knowledge transfer between experts and novice agents where the knowledge representation and learning algorithms of the experts and the trainees are fundamentally different. We present arguments for the generality of our approach for learning coordination knowledge and evaluate its effectiveness in the pursuit problem with a decision tree learner used as the learning module of the trainer and an instance based learner used as the learning module of the trainee. Initial results are encouraging and demonstrates effective transfer of coordination. The learners trained through the ATA framework exhibit consistently higher performance compared to the learners trained with a single presentation of training data. A team composed entirely of new trainees perform close to the team of trainers. More importantly, heterogeneous teams of trainers and trainees outperform homogeneous teams of either the trainers or the trainees. The results show effective transfer of coordination knowledge to new teammates by existing players using the ATA framework.

We plan to run experiments on a wider set of problem instances with variants of the pursuit problem. We plan to use a support-vector machine based agent as trainer and trainee agents in conjunction with the current instance-based agent and decision-tree based agents. We also plan to explore possible combinations of active learning and ATA approaches to train new teammates. In the future, we would like to run our ATA framework on predators that collude between themselves to evolve a strategy for capturing the prey in optimal number of steps as well as for transferring coordination knowledge in other challenging multiagent problems.

Efficient Agents for Cliff-Edge Environments with a Large Set of Decision Options

Ron Katz, Sarit Kraus
Department of Computer Science and The Gonda Brain Research Center
Bar-Ilan University, Ramat-Gan 52900, Israel, sarit@cs.biu.ac.il

ABSTRACT

This paper proposes an efficient agent for competing in Cliff Edge (CE) environments, such as sealed-bid auctions, dynamic pricing and the ultimatum game. The agent competes in one-shot CE interactions repeatedly, each time against a different human opponent, and its performance is evaluated based on all the interactions in which it participates. The agent, which learns the general pattern of the population's behavior, does not apply any examples of previous interactions in the environment, neither of other competitors nor its own. We propose a generic approach which competes in different CE environments under the same configuration, with no knowledge about the specific rules of each environment. The underlying mechanism of the proposed agent is a new meta-algorithm, Deviated Virtual Learning (DVL), which extends existing methods to efficiently cope with environments comprising a large number of optional decisions at each decision point. Experiments comparing the performance of the proposed algorithm with algorithms taken from the literature, as well as another intuitive meta-algorithm, reveal a significant superiority of the former in average payoff and stability. In addition, the agent performed better than human competitors executing the same task.

1. INTRODUCTION

In many games and economic interactions agents are challenged by the strive of maximizing their profits while preventing the entire deal from falling through. Consider, for example, an agent in an online Web-store that needs to determine the price of a good: Increasing the price would increase its profits as long as the price it charges is not higher than the price the consumer would be willing to pay. A little greedier price would make it lose the whole deal [11]. Similarly, a bidder in a sealed-bid first-price auction [3] attempts to bid the exact amount that is slightly higher than others' biddings. The same goes for the proposer in the ultimatum game (UG) [9], who tries to offer the exact amount equal to the acceptance threshold of his opponent. Higher offers would decrease self profits, while lower offers would yield no profits at all. This situation is somewhat similar to a person standing on the edge of a cliff, trying to see the panoramic view. The closer he gets to edge, the better he can see the view. However, one step too many may cause him to fall off the cliff. Hence, this set of interactions and games are referred to as Cliff-Edge (CE) interactions.

We focus on one-shot CE interactions which are repeatedly competed with different opponents. Such repeated interactions occur, for example in the important application of dynamic pricing, i.e. periodically changing prices according to the reactions of consumers that change over time. This task becomes even more common in the E-commerce world, where communication with the consumers is restricted [11, 4]. Sealed-bid auctions repeated periodically with the same goods are very popular, especially via the internet (see [3, 5]). Similarly, the sequential version of UG with different opponents is under thorough investigation [13, 2, 1]. Thus, designing efficient agents for repeated CE environments is very important for the everyday commercial world.

Moreover, our research deals mainly with interactions between humans and automated agents. This differs from conventional environments of pure computerized agents, where most competitors have large amounts of computational power and act as rational negotiators. In particular, when interacting with humans, the theoretical equilibrium strategy is not necessarily the optimal strategy since human subjects, inherently rationally bounded as well as computationally restricted, commonly do not behave according to perfect equilibrium. Thus, this study joins the important growing research field of interactions between humans and agents (e.g. [6, 12]).

Previous studies of automated agents interacting with humans have been concerned mainly with agents who interact repeatedly with a single human opponent (e.g. [12]). The general approach for such a problem is to model the opponent's behavior, and to adjust a strategy which optimally reacts to the opponent's predicted reaction. In the current study, however, a specific opponent modeling is not relevant, since the agent interacts with each opponent only once. Alternatively, agents who interact with a series of different people, should learn the general pattern of the opponent population.

A possible approach to efficiently adjust to an unknown opponent population, is to simply observe previous samples of interac-

tions within this population. Several studies have successfully used this approach in order to develop automated agents that can successfully compete with human opponents (e.g. [6]). This approach however, requires a large number of historical examples of human behavior. Moreover, the option of using a historical database is not always possible. For example, in a sealed-bid auction, a bidder usually cannot obtain information about the bids which were offered in previous similar auctions. Therefore, we propose a mechanism to develop an agent which does not depend on examples of previous interactions. Our agent learns while interacting with others, and its performance is evaluated from the first interaction.

Moreover, this study focuses on settings where in each interaction the agent is required to choose an action from a large set of possible options. Most of the previous studies on CE environments focus on settings in which an agent has to choose from at most 10 options during each interaction [13, 11, 1]. A large scale of option settings reflects commercial environments more realistically, where the number of decision options is commonly much higher than 10 (e.g. [4, 5]). Unfortunately, as we show in this study, the performance of existing algorithms choosing from a large set of options such as 100 options is insufficient. The existence of a large set of options demands a construction of a fast and efficient screening procedure. Furthermore, the importance of quickness is emphasized, since we examine short term interactions with only several dozens of opponents.

In this paper we propose a meta-algorithm which extends existing algorithms to efficiently compete in multi-interaction CE environments that consist of a large set of decision options. The general idea of the proposed algorithm is to reinforce options which are slightly greedier than the optimal option currently considered. Thus, in the conflict between exploration and exploitation of current information, we compromise by a small deviation from the current optimal option. A broad description of this method, named Deviated Virtual Learning (DVL), is presented below.

Several approaches for automatically competing in CE environments have been previously proposed [17, 15, 11]. Those approaches are broadly described below. In this paper, we experimentally show that the extension of the DVL meta-algorithm over the basic Reinforcement Learning (RL) algorithm [14], performs significantly better than previous algorithms when competing against human opponents in various CE environments. Moreover, the DVL extension of the RL algorithm (DVRL) is shown to perform better than another intuitive meta-algorithm named Segment-Based, which appears here for the first time. We also found that the DVRL algorithm performs better than human competitors who face the same task.

It is noteworthy that the algorithms discussed here are all generic and suitable for various CE environments, without knowing the specific rules of each environment. Thus, the agent is not aware of whether it is competing in an auction or in the UG. Moreover, in all the simulations presented hereinafter, each algorithm was run with a fixed configuration setting that was not changed from environment to environment.

In the next section, we formally describe the CE environment. In section 3 we present the proposed DVL meta-algorithm. In section 4 we survey other relevant algorithms which appear in previous studies, and present the Segment-based meta-algorithm. We then compare the performance of the DVRL algorithm with the performance of other relevant algorithms, and analyze the results. We conclude and present directions for future work in section 5.

2. THE CE ENVIRONMENTS

The general pattern of one-shot CE interactions considers an agent required to choose an offer *i*, which is an integer $0 \leq i \leq N$, where *N* is the maximal optional choice. Then a positive reward *r* corresponding to the offer *i* is determined, depending on whether the offer passed a certain acceptance threshold set by the opponent (in auctions we refer to the acceptance threshold of the auctioneer, which is the second highest bid proposed). Since the CE set includes various environments, we detail the model of each of the three environments mentioned above: auction, UG and pricing. Other CE environments can be similarly modeled.

- In the sealed-bid first-price auction model an amount *N* is auctioned [1]. The agent is required to choose its bid which is an integer $i, 0 \leq i \leq N$. Given the bid, a reward *r* is determined according to the highest bid τ, among all the bidders (two or more) in the current auction. If $\tau \leq i, r = N - i$ (the amount gained subtracted by the bid amount), otherwise r=0 [2]. In the all-pay version, where all the bidders must pay their bids, even if they have not won the auction [10]: if $\tau \leq i, r = N - i$ otherwise $r = -i$.

- In the UG, the agent should divide an amount of *N* between itself and its opponent. It is required to choose an integer $i, 0 \leq i \leq N$, which is the amount proposed to the opponent. The reward *r* is determined by the opponent's acceptance threshold τ . If $\tau \leq i, r = N - i$ otherwise *r*=0.

- In the pricing task, an agent is required to select a price *i* for an item being sold to a certain consumer (*i* actually represents the profit of the seller, beyond the cost price). In our model, *i* is an integer $0 \leq i \leq N$, where *N* is the maximal reasonable price of the item. After the decision about the price, a reward, *r*, is determined according to the current consumer's acceptance threshold τ. If $\tau \geq i, r = i$ otherwise *r*=0.

In this paper, which considers environments with a large set of decision options, we set *N* to be 100.

To demonstrate the challenge of a competitor in CE environments, let *S(i)* be the corresponding reward of offer *i* if the move succeeds (if the offer is accepted by the consumer in the price setting task, higher than the other bids in the case of an auction, or accepted by the responder in the UG), let *F(i)* be the corresponding reward of offer *i* if the move fails, and let *P(i)* be the probability that an offer *i* will succeed. An efficient agent interacting in multi-interaction CE environments with different opponents must find the optimal offer *i* for the opponent population that maximizes the accumulative utility function:

$$U(i) = S(i)*P(i) + F(i)*(1-P(i))$$

Obviously, there is a trade-off between *S* and *P*: choosing an offer which increases the expected reward, *S*, decreases the probability of success, *P*, and vice versa. Similarly, in the all-pay auction, which is the only case where *F(i)* values are negative and are not equal to zero, choosing an offer which decreases the expected loss, *F*, increases the probability of failure, *(1-P)*.

The naive approach for such problems would be to apply the Monte-Carlo (MC) method (see [14] chapter 5). According to this method each optional proposal or bid amount is examined many times, in a serial or random order, and finally (the later the better) a model for success probabilities (P) distribution of the opponent

[1] In order to evade considerations of value estimations [5] the item auctioned is an amount of money.

[2] For reasons of compatibility with other environment models, equal bid amounts yield a gain for the learning agent.

population is constructed. However, the learning process in this approach is extremely time consuming. Moreover, a large number of actions made by the MC method are totally irrational. An efficient agent should quickly realize, for example, that most responders in the UG would accept a share of 50 percent, and thus a proposal of more than 50 percent, is not advised. Therefore, we would rather use a less naive attitude, in which directed exploration is conducted.

Nevertheless, for a very large number of interactions, the MC method may provide a more precise model of the real success probabilities distribution in the population, than algorithms which use directed exploration. However, in this study we are more concerned with finding fast and efficient approaches for the first several dozens of opponents. Handling the initial interactions, when almost nothing is known about the environment is obviously the most difficult stage. Moreover, considering a larger number of interactions, the severity of the accuracy problem caused by directed exploration, could be reduced by combining a sophisticated algorithm with a naive one. A method such as MC, may replace a more sophisticated algorithm in the progressive interactions, based on previous interactions conducted by the latter.

3. THE PROPOSED APPROACH

In this section we present a detailed description of the proposed meta-algorithm for competing in CE environments. As a meta-algorithm, it extends basic algorithms and improves their performance. We assume that the basic algorithms select their actions according to an evaluation of the expected utility that each decision option would yield, provided it is chosen. The evaluation of the expected utilities is determined according to the results of previous interactions. Hereinafter, we will refer to the database which stores the evaluations of each decision option as the Q-vector [3]. Each algorithm includes its own UPDATE procedure, which determines how to update the Q-vector after observing the successfulness of the latest action. It should be noted that the Q-values stored in those Q-vectors, do not necessarily express the real evaluations of the expected utility, but rather the relative profitability of choosing each option. In addition, we assume each algorithm includes its own SELECT procedure, which determines how to select the next action (apparently according to the current Q-vector). The SELECT procedure moves between exploiting the evaluations stored in the current Q-vector and exploring options with lower current Q-values, in order to improve the correctness of the Q-vector's evaluations. The first action is chosen randomly in all the algorithms presented in this paper.

A reasonable approach for the UPDATE procedure in CE environments is *Virtual Learning* (VL) [16]. According to the VL principle, the agent in UG, for example, treats all the offers (not actually proposed) higher than a successful offer as if they were (virtually) successfully proposed as well. Similarly, it considers all the offers lower than an unsuccessful offer as unsuccessfully proposed. The rationale behind this principle is that the higher the amount proposed to the opponent - the higher the probability of the proposal being accepted [4]. Thus, we should reinforce the Q-values of all the offers higher than the actual offer, provided it was successful, and we should reduce the Q-values of all the offers lower than the actual offer, provided it was unsuccessful. A crucial problem with this approach is an *information asymmetry*[16], which causes an intensified reinforcement of Q-values higher than the optimal option's Q-value. The reason for this phenomenon, as demonstrated in [16], is that whenever the optimal offer is successfully chosen, offers which are higher than the optimal offer are reinforced as well. However, when the optimal offer fails it is punished, while the offers just above suffer no penalty, giving them the appearance of having a much higher probability of success.

In order to overcome this information asymmetry problem, we propose the *Deviated Virtual Learning* principle. This principle can be implemented in various basic algorithms, thus producing a general meta-algorithm, as presented in **Algorithm 1**. According to the DVL principle, we should deviate from the strict rationale underlying the VL principle, and extend the range of offers updated after each interaction. Thus, after a successful interaction, we would raise the Q-values of all the offers higher than the actual offer, as well as a few offers under the actual offer, as described in line 8 in **Algorithm 1**. Similarly, after an offer has failed, we would reduce the Q-values of all the offers lower than the actual offer, as well as a few offers above the actual offer, as described in line 6 [5].

Algorithm 1 THE DVL META-ALGORITHM

Notation: α, β are two integers $0 \leq \alpha < \beta \ll$ N, (where N is the upper bound of possible offers), which denote the deviation rate. The values α and β gradually decrease during the learning process.

```
1: For j=0 to N, Do Q(j)=1
2: For each interaction, Do
3:    Select offer i according to a SELECT procedure
4:    Observing opponent's move, calculate reward
5:    if offer i has failed then
6:       For j=0 to (i + α), Do
            reduce Q(j) according to an UPDATE procedure
7:    else
8:       For j=(i - β) to N, Do raise Q(j) according to an UPDATE procedure
```

As mentioned above, the DVL meta-algorithm can extend any basic algorithm, according to its SELECT and UPDATE procedures. However, we claim that the best algorithm for human environments, as we will demonstrate, is the DVL extension of the Reinforcement Learning [14] algorithm (DVRL), as presented in **Algorithm 2**. The SELECT procedure of the RL version we have used, was to select the offer with the current maximal Q-value (line 3). The UPDATE procedure was to divide the accumulated reward of each offer by the number of previous interactions where offer i was actually or virtually (according to the DVL principle) proposed (lines 6 and 8).

It is important to note that in this study DVRL was run in all the environments with the same configuration of α and β as detailed in **Algorithm 2** (lines 1 and 10).

There are two additional motivations for the deviation principle underlying the DVL approach. First, from the statistical aspect it is not necessarily a mistake to consider an offer which is slightly lower than a successful offer, as successful as well. Using UG terminology, it is quite reasonable to assume that if proposal *i* was accepted (rejected) by an opponent, she would have also accepted (rejected) a slightly lower (higher) proposal. The chance that the proposal would exactly hit the acceptance threshold of the opponent is low, especially for a large set of options. Second, and even

[3] It is noteworthy that despite the name, this paper does not concern the Q-learning algorithm, which handles situations in which the state may be changed at each interaction (see [14] chapter 6.5).

[4] The same rationale stands behind the auctions environment. However, in the pricing environment the opposite is true: all the offers lower than a successful offer are considered successful, since the lower the price of an item the higher the probability of it being purchased by the consumer.

[5] It is worth noting that all the VL-based algorithms in this paper are presented in a version suitable for auctions and for the UG. In the pricing environment, where increasing the price decreases the acceptance probability, the update ranges in lines 6 and 8 should be swapped.

Algorithm 2 THE DVRL ALGORITHM

Notation: n(j) denotes the number of previous interactions where offer j was actually or virtually proposed, s(j) is the corresponding reward for a successful offer j and f(j) is the corresponding reward for offer j when it fails. α, β denote the deviation rate.
We present the configuration used in our environment. However, the initial values of parameters N, α and β (line 1) as well as the update function of α and β (line 10) can be adjusted to other environments as well.

1: N=100, α=10, β=15, t=0 For j=0 to N, **Do** Q(j)=1, n(j)=0
2: For each interaction t, **Do**
3: offer i=$\arg\max_j Q(j)$
4: Observing opponent's move, calculate reward
5: **if** offer i has failed **then**
6: For j=0 to (i + α), **Do** n(j)=n(j)+1, $Q(j) = \frac{Q(j)(n(j)-1)+f(j)}{n(j)}$
7: **else**
8: For j=(i - β) to N, **Do** n(j)=n(j)+1, $Q(j) = \frac{Q(j)(n(j)-1)+s(j)}{n(j)}$
9: t = t+1
10: $\alpha = \frac{10}{\lfloor t/10 \rfloor + 1}$ $\beta = \frac{15}{\lfloor t/10 \rfloor + 1}$

more important, the deviation principle actually outlines a direction of the optimal solution searching, rather than the random trial-and-error approach that underlies conventional methods, such as RL. A DVRL agent that offered 70% of the cake (N) to his UG opponent in the first interaction, and his offer was accepted, would offer 55% (according to our configuration of β) in the next interaction. The agent continues to decrease the offer until it is rejected. A similar pattern of this directed searching was observed in human learning, and is compatible with the directional learning theory (see [8]). According to this theory, if an offer *i* is rejected at interaction *t*, then at interaction *t+1* the proposer will offer his opponent a higher offer, while if offer *i* is accepted at interaction *t*, then at interaction *t+1* the offer will be decreased. This simple method, which was simulated by [2] without yielding any impressive performance, lacks all the data experienced before the previous interaction.[6] In our algorithm, on the other hand, all the previous interactions are taken into account, and the model comes closer to the real distribution of the opponents' population during the learning process. This is the reason for the gradual decrease of α and β values. Another advantage of our approach over the naive directional learning is achieved by setting $\alpha < \beta$, asymmetrically. This property enables fast converging to the optimal solution, by speedily decreasing the proposal amount, and slowly increasing it to the optimal amount.

4. EXPERIMENTAL DESIGN AND ANALYSIS

In this section we examine the performance of the proposed DVRL algorithm competing in various CE environments with human opponents, and compare it to other algorithms' performance. A broad survey of the algorithms examined is presented, followed by a description of the experiment process and the results. After analyzing the results, we compare the performance of DVRL to human negotiators' performance. At the end of this section, we briefly discuss the situation of a small set of decision options' environments.

4.1 Comparative Algorithms description

[6]Simulations of the directional learning method in our environment also does not yield an impressive performance. A similar approach, namely the Derivative-Following strategy, was proposed for the dynamic pricing problem [4]. However, each round (one commerce day) was considered as a set of several interactions with a number of opponents, which is totally summed up by thousands of interactions.

In this section we survey several algorithms which can be used in repeated CE environments. Subsections 4.1.1-4.1.4 describe previously published algorithms, while in 4.1.5 we present a new intuitive meta-algorithm for a large set of options environments.

4.1.1 Roth and Erev's Algorithm (R&E)

Concerning the UG, Roth and Erev [13] designed a human proposer model based upon basic RL [14]. The general idea of the RL method is that each offer is chosen with a probability according to its current Q-value - the larger an offer's Q-value, the higher the probability it will be chosen. After each interaction, provided that the latest offer succeeded, its probability to be chosen again is increased by increasing its Q-value by the reward this offer yields. Roth and Erev showed that despite the fact that UG is characterized by having a significant gap between empirical human behavior and subgame perfect equilibrium predictions, the RL algorithm with a few additional modifications can successfully model typical human empirical behavior in UG. The most noticeable modification, based on the Persistent Local Environment principle, uses a "generalization" parameter which prevents the probability of an option from going to zero if it is adjacent to a successful option. The criterion of adjacency was configured in [13] to be +-1, and thus, if an offer of 4 out of 10 is accepted by the opponent, the agent would reinforce the Q-values of offers 3,4 and 5. Their assumption, which is valid in all of the CE environments, was that an adjacent option of an optimal solution cannot be an extremely bad solution. The detailed algorithm can be found in [13].

4.1.2 Modified version of Zhong, Wu and Kimbrough's (ZWK) RL algorithm

Zhong et al.[17] developed an agent which played UG against various simulated opponents, using a version of RL which is different from R&E's. The UG agent designed by these authors used an ϵ-greedy selection procedure, in which the agent selects, with a probability of (1-ϵ), the offer with the current maximal Q-value, and with a probability of ϵ it uniformly selects an offer for exploration purposes. The advantage of this selection procedure over a selection according to the Q-value's distribution as in R&E, is that it mainly chooses the best option. The disadvantage is that the exploration is not weighted by the estimation of expected utility considerations, as in R&E, but is rather completely random. In order to decrease the effect of this disadvantage, we have modified the selection procedure in our experiment, to take into account the generalization principle of R&E. Thus, when not selecting the offer with the current maximal Q-value, our ZWK algorithm selects an offer giving higher priority to offers which are adjacent to the offer with the current maximal Q-value (**Algorithm 3**, state 4), rather than selecting them uniformly. In addition, since the exploration is much more important in the initial interactions, we decreased the probability for random selection gradually during the learning process. These two modifications were examined and were found to be significantly efficient in our environment. The UPDATE procedure in ZWK's algorithm was also different from that of R&E, by taking into account the previous failures of offer *i*, rather than merely the positive previous rewards (line 6).

4.1.3 Virtual Reinforcement learning (VRL)

Despite the information asymmetry in VL found by [16], Todd and Borgers [15], have shown that the addition of a virtual learning mechanism to the RL algorithm when playing UG, may be very efficient. However, the efficiency is dependent on several configurations of the learning procedure, such as the selection procedure (R&E's or ZWK's) and the Q-values update procedure (reinforce-

Algorithm 3 THE ZWK ALGORITHM

Notation: ϵ denotes the probability for random selection, γ is the probability for selecting an offer which is adjacent to the offer with the current maximal Q-value ($\epsilon + \gamma < 1$), and δ determines the adjacency range ($\delta \ll$ N). The values ϵ and γ are gradually decreased during the learning process.

1: For j=0 to N, **Do** Q(j)=1, n(j)=0
2: For each interaction, **Do**
3: m = $\arg\max_j Q(j)$
4: With a probability of (1- ϵ- γ), offer i = m
With a probability of γ, select offer i uniformly, for i's such that max(0, m - δ) $\leq$ i $\leq$ min(N, m + δ)
With a probability of ϵ, select offer i uniformly, for i's such that 0 $\leq$ i $\leq$ N
5: Observing opponent's move, calculate reward r
6: n(i)=n(i)+1, Q(i) = $\frac{Q(i)(n(i)-1)+r}{n(i)}$

ment of a successful offer by a unit payoff, or by the real amount gained, or rather by the virtual amounts the agent would keep if he hypothetically offered different proposals).

After examining the performance of VRL with all the optional configurations suggested by Todd and Borgers, in **Algorithm 4** we present the version that yields the best performance in our environment. This algorithm includes the same SELECT procedure as in ZWK.

Algorithm 4 THE VRL ALGORITHM

Notation: s(j) denotes the corresponding reward for a successful offer j and f(j) is the corresponding reward for offer j when it fails.

1-5: As in **Algorithm 3**
6: **if** offer i has failed **then**
7: For j=0 to i, **Do** n(j)=n(j)+1, $Q(j) = \frac{Q(j)(n(j)-1)+f(j)}{n(j)}$
8: **else**
9: For j=i to N, **Do** n(j)=n(j)+1, $Q(j) = \frac{Q(j)(n(j)-1)+s(j)}{n(j)}$

4.1.4 Gittins' index strategy

Some researchers have observed CE environments as a special case of the multi-armed bandit problem [11, 1]. In this problem every period a decision maker has to decide on which one of *n* slot machines he wants to play, given each machine has different gain probabilities (unknown a priori). These researchers used Gittins' index strategy [7], an optimal strategy for the multi-armed bandit problem, to model the behavior of proposers in UG and of sellers in the pricing problem, considering each optional proposal or price as an arm. The Gittins' strategy was applied to CE environments by multiplying the Bernoulli reward process index value of each option (see [7] p. 222) by its reward. However, these CE problems are different from the classical multi-armed bandit problem since the arms are independent, while in CE environments the success probability of an offer is gradually influenced by the size of the offer. This difference may become more critical when there is a large number of options rather than the 10 optional arms problems considered in these papers. Thus, Brenner and Vriend [2] tried to adjust to the interdependent arms in UG by adding the VL mechanism to the Gittins' strategy. In the following section we present the performance of both the basic Gittins' strategy (GS) (as in [11, 1]) and the virtual Gittins' strategy (VG) (as in [2]) in our environment.

4.1.5 Segment-based meta-algorithm

This algorithm, suggested here for the first time is an intuitive meta-algorithm which can extend any of the former basic methods. This algorithm is specifically designed for environments with a large number of decision options. The idea of the segment-based approach is to divide all the options into segments, and to activate the learning method in the initial interactions on these segments, rather than on specific discrete options (**Algorithm 5**, state 3). After several interactions the resolution can be increased by focusing on smaller segments. This process continues gradually towards the last segmentation hierarchy with the smallest segments, i.e. specific discrete options, where final fine tuning is performed (end of state 3). This algorithm is based on the assumption of locality, i.e. adjacent options yield similar average profits. The advantage of this approach is the gradual filtering of the optimal solution. A common problem in conventional RL, for instance, is that an option might have a high Q-value in a progressive stage of the learning process, although it is far from the optimal option. With the proposed meta-algorithm, this situation is prevented already in the preliminary stages of learning, by weakening the Q-value of the entire range surrounding this non-beneficial solution.

Algorithm 5 THE SEGMENT-BASED META-ALGORITHM

Notation: H denotes the number of segmentation hierarchies configured by the user according to the size of the options set (setting this parameter, the order of magnitude of the expected number of interactions must be considered), S_h is the size of each segment in the hth segmentation hierarchy, Q_h are the Q-values vectors corresponding to the hth segmentation hierarchy, and T_h is the serial number of the last interaction of the hth segmentation hierarchy.

1: For h=1 to H, **Do** For j=0 to $\lceil \frac{N}{S_h} \rceil$, **Do** Q_h(j)=1,
2: For each interaction, **Do**
3: For interactions $0 - T_1$: c = 1
Select segment j from the 1st segmentation hierarchy according to a SELECT procedure, using vector Q_1
Select offer i uniformly from segment j
For interactions $T_{x-1} - T_x$: c = x
Select segment j from the xth segmentation hierarchy according to a SELECT procedure, using vector Q_x
Select offer i uniformly from segment j
...
For interactions $T_{H-1} - T_H$: c = H
Select offer i according to a SELECT procedure, using vector Q_H
4: Observing opponent's move, calculate reward
5: For h=c to H, **Do** update Q_h according to an UPDATE procedure

4.2 Experiment Description

In order to evaluate the performance of the proposed algorithm, and to compare it with other algorithms, we experimentally examined agents interacting with human opponents in 4 different CE environments, as follows:
1. UG, where the players had to divide 100 new Israeli Shekels (NIS, where 1 U.S. \$ $\approx$ 4.5 NIS), i.e. N=100.
2. A variant of UG in which the responder determines only whether the proposer gets his share. The responder himself always receives his own allocation [9]. In this version the responder's decision is influenced by fairness and vindictiveness considerations, rather than profitability as in the original UG version. Here also N=100.
3. Sealed-bid 2-bidders auction. The auction was for 100 NIS.
4. All-pay sealed-bid auction for 100 NIS, where all the bidders must pay their biddings[10]. In this version risk taking considerations is added to the bidder's decision.

The examination of different environments which activate different personality characteristics of human opponents, guarantees generality of the results. Dynamic pricing was not experimentally examined, since no specific item can be unquestionably desired by

all of the participants. The following algorithms were examined:
1. R&E, as described in section 4.1.1.
2. ZWK, as specified in section 4.1.2.
3. Virtual RL (VRL), as specified in section 4.1.3.
4. Basic Gittins' index strategy (GS), as described in section 4.1.4.
5. Virtual Gittins' index strategy (VG), as described in 4.1.4.
6. Segment-based extension of the ZWK version of RL (SZWK).
7. Segment-based extension of VRL. (SVRL).
8. DVRL, as specified in section 3.
9. Segment-based extension of VG (SVG).
10. Deviated virtual extension of GS (DVG).

The first five algorithms were suggested by others and adapted to our environment as detailed above, while the last five algorithms are based on the two meta-algorithms we developed [7].

It is important to mention that each algorithm was run with fixed parameter configurations (such as the ϵ value's decreasing rate, and deviation rates α, β in the DVL algorithms) for all the different environments. Though specific configurations for each environment could yield better performance, we preferred the generality of the algorithms over a variety of CE environments, ensuring that no environment specific characterization would be used.

In the first experiment human participants were used as responders in the UG games, and as bidders in the auctions. Each person participated once in each of the 4 environments. The automated agents, on the other hand, interacted serially against different human opponents. Evaluating agents that were designed for human involved environments by examining their performance with real human data is necessary. As mentioned above, human competitors do not obey subgame perfect equilibrium, and thus their behavior cannot be a priori simulated. Additionally, human behavior cannot be accurately statistically modeled, especially in small populations as in this case. Another benefit from empirical experiments is the ability to provide a concrete algorithm, namely DVRL (with a concrete configuration of parameters), which successfully competed against human opponents. Thus, this agent can be immediately applied in real applications, at least as a starting point.

In the first stage of the experiment we surveyed 34 students (17 males and 17 females) participating in four CE environments. The participants were students at Bar Ilan University, aged 20-28 (average 23.75), who were not experts in negotiation strategies nor in economic theories directly relevant to the experiment (e.g. game theory, decision theory). Each of the participants, who sat in an isolated room at a computer work-station, interacted in the 4 CE environments, one after the other.

In the auctions the participants were required to propose a bid, which could be any integer from 0 to 100 NIS. The winner gained a virtual 100 NIS. In the ultimatum games, where 100 NIS was the full amount to be shared, the participants were required to respond to various proposals, which were artificially provided in order to determine the minimal acceptance amount of the players [8](though the participants were told that the proposals were provided by other people). Data from a few participants who were inconsistent in their decisions were excluded. At the end of the experiment, each participant was paid between 15 to 30 NIS, proportionally to her earnings in the interactions in which she participated.

After extracting the bids from people in the auctions, as well as their acceptance thresholds in the ultimatum games, we constructed sets of opponents' reactions for each environment. The sizes of the sets were 34 for the auctions, 28 for the UG and 27 for the UG variant, due to the exclusion of inconsistent players. At this stage we examined the performance of each of the ten algorithms detailed above, which were run serially against the sets of opponents' thresholds. Thus, each algorithm had one interaction with each of the human opponents in each of the four environments, without knowing in advance the number of interactions. Since there is importance to the order of the opponents, we constructed 200 random permutations of the human decisions series, for each environment, and compared the average payoffs of the different algorithms for each permutation. In addition, these algorithms were run against an artificial series of 50 auction opponents, constructed randomly according to a normal distribution N(71,10). In this manner, we wanted to examine the performance of the algorithms with a theoretical population which distributes normally, though there is no evidence of such a distribution in any CE environment.

4.3 Experimental results

Table 1 presents the average payoffs for each algorithm. The average payoffs integrate the data of all the 200 permutations. Due to the fact that the algorithms' random factors cause variation in the results we ran each algorithm repeatedly for 50 times for each permutation,. The standard deviations of the 50 results of each algorithm with each permutation are also presented in order to measure the stability and self-consistence of each algorithm.

4.3.1 Payoff analysis

The results show that the DVRL algorithm was almost always the most profitable algorithm. A non-parametric Friedman test revealed significant differences in the ranking of the algorithms ($p < 0.001$). Further pairwise Wilcoxon tests showed that the most efficient algorithm was significantly the DVRL algorithm, except for the auction, where DVG was significantly better though only slightly, and for the normal distribution auction, where no significant difference was found between DVRL and SVG.

Moreover, the extension of both DVL and Segment-based meta-algorithms almost always improved the payoff. Pairwise Wilcoxon tests revealed that the algorithms SVRL, DVRL, SVG and DVG always achieved higher payoffs than the first five algorithms ($p < 0.001$). The SVRL method always achieved the lowest payoff of the leading quartet (SVRL, DVRL, SVG and DVG) ($p < 0.001$), except for the UG, where no significant difference was found between SVRL and DVG. The internal ranking of SVG and DVG was inconsistent, with no significant differences in the all-pay auction and the UG variant. As for the SZWK algorithm, we found that its performance was always significantly higher ($p < 0.001$) than the basic ZWK's algorithm, except for the all-pay auction, where no significant difference was found between these methods.

Virtual learning was revealed as an efficient method, as can be concluded by the general superiority of VRL over ZWK (except for the UG variant), of VG over GS (except for the UG variant, and for UG, where no difference was found) and of SVRL over SZWK (except for the auction). A non-virtual version of SVG (a segment based extension of GS), which is not presented because of space considerations, was similarly overpowered by SVG.

4.3.2 Results explanations

In order to understand the origin of the advantage of DVRL over DVG, SVRL and over SVG, we should observe **Figure 1**. This plot describes the average payoff of each algorithm - SVRL, DVRL, DVG and SVG - (the y-axis), during the interactions (the x-axis).

[7] A combination of the 2 meta-algorithms is not presented in this paper since its performance was experimentally worse than DVRL's. Moreover, the implementation of the combined agent is much more complicated than DVRL's, since it includes a large number of configurational parameters.

[8] This method of responders' behavior examination is widely accepted in UG literature [1].

Environment		R&E	ZWK	VRL	GS	VG	SZWK	SVRL	DVRL	SVG	DVG
UG	payoff	35.55	39	41.3	37.43	37.44	40.13	41.59	**43.28**	42.35	41.79
	SD	5.56	4.2	4.03	4.02	3.90	3.86	3.47	2.3	2.17	2.12
UG variant	payoff	28.93	33.99	32.41	31.88	30.44	35.23	36.37	**39.24**	37.42	37.23

Table 1: Average payoff and standard deviation of various algorithms against human opponents

The plot, which enables easier tracking of the learning process, presents only the data of the all-pay auction. However, the data of the other environments were quite similar, thus we can refer to the all-pay auction as a representative case. The left side of the plot shows a noticeable preliminary advantage of the DVRL method. Particularly, the payoff of DVRL is higher than the others until the 12th round, where it becomes proximately equal to DVG. This preliminary advantage can be attributed to the low extent of reinforcement in the RL's Q-values update procedure, compared to the extensive reinforcement conducted by Gittins' indices. For example, the Q-value of an offer which succeeded 2 out of 3 interactions, would be reinforced in the RL method by 66% of its reward, while using Gittins' method it would be reinforced by 91%. An offer which was successful only once out of 5 interactions, would be reinforced in the RL approach by 20% of its reward, whereas while using Gittins' method it would be reinforced by 47%. Thus, offers which are extremely far from the optimal will be filtered more quickly with the pedant RL methods.

The pedantry of RL is also the reason for the relative success of the SVRL in the first learning stages. However, in SVRL this pedantry becomes an obstacle in the progressive learning stages: Optimal segments, where the probability of success is usually not 100%, were sometimes rejected after a few interactions, and were hardly focused in later stages[9]. However, this problem in the progressive learning stages, was much less harmful in the DVRL method. The reason for this is that, in contrast to SVRL, (optimal) options with currently low Q-values will not necessarily be abandoned for long. In addition, according to the DVL update protocol, (optimal) options are also reinforced by the success of options which are less risky. Thus, the DVRL becomes less sensitive to over filtering of the pedant RL method.

This difference in sensitivity between the segment-based and the DVL approaches underlies the superiority of DVG over the VSBG algorithm, in the progressive learning stages, as noticeable on the right side of **Figure 1** (from the 16th round on). However, the difference is much less significant than the difference between the RL-based algorithms, since the Gittins approach is much less pedant. Therefore, the SVG is not critically harmed by the abandonment of low valued options. Moreover, the fast convergence to an optimal (large) segment which usually occurred in SVG, provided a superiority over the DVG algorithm, in the initial interactions.

Another finding in our experiment was the general improvement caused by virtual learning. This could be explained by the fast

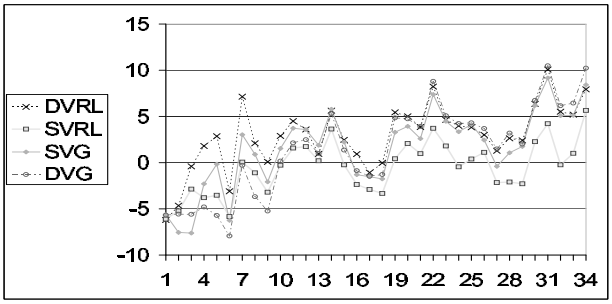

Figure 1: Average payoff during the all-pay auction

updating of a large set of offers after every interaction, with the VL method. Thus, offers which are significantly irrelevant are filtered within a few interactions, while it is easy to find a non virtual learner that proposes 90% in UG after the 20th interaction, for example. This significant advantage offsets the disadvantage in accuracy, caused by the information asymmetry in the virtual updating process mentioned above.

In order to measure the stability and self-consistence of each algorithm we compared the standard deviations of the payoff results of 50 runs with each permutation of the ten algorithms. Observing the standard deviations in **Table 1**, it can be concluded that the standard deviation of DVRL was always the least ($p < 0.001$), except for the UG, where both DVG and SVG were lower than DVRL. Since low values of standard deviation guarantee more certain and stable results, using the proposed DVRL algorithm is preferable from this aspect as well. This property may be attributed to the fact that the DVL meta-algorithm includes no random decision, except for the first interaction. In addition, the fast screening in the DVRL as well as the lower sensitivity to over-filtering of the optimal solution discussed earlier, provide a stable and consistent pattern of solution search. For similar reasons, the relative ranking of other algorithms in the deviations measures were compatible with the relative ranking in the payoffs measures.

4.3.3 Comparison with human performance

In this section we compare the performance of the DVRL algorithm with the performance of human competitors. For this purpose we asked our participants to compete iteratively against a series of other human opponents, exactly in the same manner the automated agents had been competing. In this manner we wanted to reveal whether the DVRL agent can outperform human natural intuitions and life experience in this context. Note that the automated agent was run with the same parameters for all the environments, and no domain specific knowledge had been applied to the agents.

We began our examination after collecting a series of acceptance thresholds in the ultimatum games from the first 21 participants, as

[9]Extending the duration of the first stages, where a few number of large segments are observed, would have reduced this problem. However, since we considered environments with a total number of 50 interactions at most, the average total payoff would not have risen by extending the duration of the first stages, since it would often harm the later interactions, where the fine tuning is managed. The final stage of fine tuning is critically important, especially in the context of CE environments.

Environment (# of human participants)	**Human**	**DVRL**
UG (13)	49.56 (3.41)	52.59
UG variant (13)	40.8 (7.45)	44.36
Auction (13)	15.74 (4.02)	19.01
All-pay Auction (13)	-0.18 (3.53)	1.4
Normal distribution auction (15)	11.79 (2.78)	14.35

Table 2: Average payoff (SD) of humans and of a DVRL agent competing with human opponents.

well as their biddings in the auctions (whereas in previous sections the series included all the 34 participants). In order to enlarge the size of the series we inserted each opponent twice, creating a 42-round auction, a 34-round UG and a 36-round UG variant (when using the original series without the enlargement, the results were not qualitatively different). Similarly, we constructed an artificial series of 40 biddings in an auction normally distributed, as before. The consequent participants were asked to interact with those series, functioning as proposers in the ultimatum games and as bidders in the auctions. After each decision, the participants were informed of the success of their offer by the "current" opponent. Actually, these proposers were expected to learn the acceptance thresholds distribution of the responders' population, exactly as the agents learn. All the learners, including the automated learner, competed with the same series of opponents.

The average payoffs of the human learners, as well as the payoffs of the DVRL agent, in the exact same scenarios, are presented in **Table 2**. The results show a clear advantage of the DVRL agent over the human learners in all the environments. Although this statement cannot be proved statistically, since we ran only one permutation from each environment, the results show that the DVRL average payoff was usually about one standard deviation above the human's average payoff.

4.3.4 A small set of decision options environments

In order to check the performance of our meta-algorithms in a small set of options, we performed the exact same simulations with merely 10 decision options. The agents could choose an integer from 0 to 10 in each interaction, and the original values of the opponents' vectors were divided by 10 and then rounded to the closest integer. The results, not presented here due to space restrictions, showed a significant advantage of the DVRL over the other algorithms, both in payoffs and in standard deviations, almost in all cases. Moreover, the internal hierarchy among the algorithms was similar to the 100-options version, and we found a general significant advantage of both meta-algorithms over the basic algorithms. Nonetheless, the gap between the performance of the basic algorithms and their extensions was smaller in the 10-options version.

5. CONCLUSION AND FUTURE WORK

We presented a new meta-algorithm, namely DVL, which extends existing methods for efficiently competing in multi-interaction one-shot CE environments with different human opponents. Our experimental findings show that the DVL extension of an RL basic algorithm performs significantly better than humans and other algorithms surveyed in this paper, especially in environments which contain a large set of optional decisions at each decision point. Moreover, our results show that both DVL and the segment-based meta algorithm, also presented here for the first time, almost always significantly improve the performance of the basic algorithms they extend.

In future work we intend to design agents which efficiently compete in CE environments for a high number of interactions. As mentioned above, in this study we were principally concerned with adaptable agents, which compete in no more than several dozens of repeated interactions. However, the DVRL algorithm does not necessarily grant efficiency for environments which last for hundreds of interactions. The reason is mainly due to the fact that the directed search for an optimal option, partially neglects the exploration of other options. Thus, we would like to explore the "damage" DVRL and other algorithms cause in the long run, and to suggest efficient approaches for interacting in CE environments for long durations.

In addition, we intend to extend the approaches discussed in this paper to more sophisticated classes of interactions. Particularly, we would like to examine the repeated version of CE interactions, in which several negotiation rounds can be conducted against each opponent. When competing repeatedly against the same opponent, a specific modeling of the current opponent must be done, in addition to the generic modeling of the population. Moreover, in contrast to the one-shot version, a current move may influence the future behavior of the opponent, a fact that must be taken into account. Therefore, we intend to design an agent that develops several optional models of typical opponents in the population, and matches the appropriate model to each opponent with which it interacts.

ABSTRACT

We present a novel method for automatically acquiring strategies for the double auction by combining evolutionary optimization together with a principled game-theoretic analysis. Previous studies in this domain have used standard co-evolutionary algorithms, often with the goal of searching for the "best" trading strategy. However, we argue that such algorithms are often ineffective for this type of game because they fail to embody an appropriate game-theoretic *solution-concept*, and it is unclear, what, if anything, they are optimizing. In this paper, we adopt a more appropriate criterion for success from evolutionary game-theory based on the likely adoption-rate of a given strategy in a large population of traders, and accordingly we are able to demonstrate that our evolved strategy performs well.

auctions and electronic markets, multi-agent evolution, adaptation and learning, game theoretic foundations of agent systems

1. INTRODUCTION

The automatic discovery of game-playing strategies has long been considered a central problem in Artificial Intelligence. The standard technique in evolutionary computing for discovering new strategies is *co*-evolution, in which the fitness of each individual in an evolving population of strategies is assessed relative to other individuals in that population by computing the payoffs obtained when the selected individuals interact. Co-evolution can sometimes result in *arms-races*, in which the complexity and robustness of strategies in the population increases as they counter-adapt to adaptations in their opponents.

Often, however, co-evolutionary learning can fail to converge on robust strategies. In this paper we explore some of the limitations of current co-evolutionary algorithms, and we introduce a novel method for automated strategy-acquisition by combining a game-theoretic analysis together with an evolutionary search involving a single non-coevolving population. The novel aspect of our method is that rather than using payoffs to individual strategies as our fitness function, we instead use the size of their basin of attraction under an evolutionary game-theoretic analysis. We apply our method to the double auction market [5]: a domain which has long served as a benchmark problem in understanding strategic-interactions in multi-agent systems.

The outline of this paper is as follows. In Sections 2 and 3 we give a brief introduction to game theory and evolutionary game theory within the context of automated strategy-acquisition. In Section 4 we review some of the weaknesses of standard co-evolutionary algorithms from the perspective of game-theory. In Section 5 we give a brief overview of a technique called heuristic-strategy approximation, also known as empirical game theory, on which our method is based, and discuss how it is able to overcome some of the limitations of co-evolutionary algorithms when analysing strategic interactions amongst *existing* well-known strategies for a given game. In Section 6 we perform a heuristic-strategy analysis on a variant of the double auction market called a clearing-house. In Section 7 we describe our novel contribution to this domain; viz, how we are able to combine heuristic-strategy analysis and evolutionary search in order to automatically acquire *new* strategies for the double auction game, and finally in sections 8 and 9 we discuss our results.

2. NASH EQUILIBRIUM

The failure of certain types of co-evolutionary algorithms to converge on robust strategies in certain scenarios is well known, and has many possible causes; for example, the population may enter a limit cycle if strategies learnt in earlier generations are able to exploit current opponents and current opponents have "forgotten" how to beat the revived living fossil. Whilst many effective techniques have been developed to overcome these problems, there remains, however, a deeper problem which is only beginning to be addressed successfully. In some games, such as Chess, we can safely bet that if player A consistently beats player B, and player B consistently beats player C, then player A is likely to beat

player C. Since the dominance relationship is transitive, we can build meaningful *rating systems* for objectively ranking players in terms of ability, and the use of such ranking systems can be used to assess the "external" fitness of strategies evolved using a co-evolutionary process and ensure that the population is evolving toward better and better strategies. In many other games, however, the dominance graph is highly intransitive, making it impossible to rank strategies on a single scale. In such games, it makes little sense to talk about "best", or even "good", strategies since even if a given strategy beats a large number of opponent strategies there will always be many opponents that are able to beat it. The best strategy to play in such a game is always dependent on the strategies adopted by one's opponents.

Game theory provides us with a powerful concept for reasoning about the best strategy to adopt in such circumstances: the notion of a *Nash equilibrium*. A set of strategies for a given game is a Nash equilibrium if, and only if, no player can improve their payoff by unilaterally switching to an alternative strategy.

If there is no dominant strategy[1] for the game, then we should play the strategy that gives us the best payoff based on what we believe our opponents will play. If we assume our opponents are payoff maximisers, then we know that they will play a Nash strategy set by *reductio ad absurdum*; if they did not play Nash then by definition at least one of them could do better by changing their strategy, and hence they would not be maximising their payoff. This is very powerful concept, since although not every game has a dominant strategy, every finite game posseses at least one *equilibrium* solution. Additionally, if we know the entire set of strategies and payoffs, we can deterministically compute the Nash strategies. If only a single equilibrium exists for a given game, this means that, in theory at least, we can always compute the "appropriate" strategy for a given game.

Note, however, that the Nash strategy is not always the *best* strategy to play in all circumstances. For 2-player zero-sum games, one can show that the Nash strategy is not exploitable. However, if our opponents do not play their Nash strategy, then there may be other non-Nash strategies that are better at exploiting off-equilibrium players. Additionally, many equilibria may exist and in n-player non-constant-sum games it may be necessary for agents to *coordinate* on the same equilibrium if their strategy is to remain secure against exploitation; if we were to play a Nash strategy from one equilibrium whilst our opponents play a strategy from an alternative equilibrium we may well find that our payoff is significantly lower than if we had coordinated on the same equilibrium as our opponents.

3. BEYOND NASH EQUILIBRIUM

Standard game theory does not tell us which of the many possible Nash strategies our opponents are likely to play. *Evolutionary* game theory [10] and its variants attack this problem by positing that, rather than computing the Nash strategies for a game using brute-force and then selecting one of these to play, our opponents are more likely to gradually adjust their strategy over time in response to to repeated observations of their own and others' payoffs. One approach to evolutionary game-theory uses the *replicator dynamics* equation to specify the frequency with which different pure strategies should be played depending on our opponent's strategy:

$$\dot{m}_j = [u(e_j, \vec{m}) - u(\vec{m}, \vec{m})]\, m_j \tag{1}$$

where $\vec{m}$ is a mixed-strategy vector, $u(\vec{m}, \vec{m})$ is the mean payoff when all players play $\vec{m}$, and $u(e_j, \vec{m})$ is the average payoff to pure strategy j when all players play $\vec{m}$, and $\dot{m}_j$ is the first derivative of m_j with respect to time. Strategies that gain above-average payoff become more likely to be played, and this equation models a simple *co-evolutionary* process of mimicry learning, in which agents switch to strategies that appear to be more successful.

For any initial mixed-strategy we can find the eventual outcome from this co-evolutionary process by solving $\dot{m}_j = 0$ for all j to find the final mixed-strategy of the converged population. This model has the attractive properties that: (i) all Nash equilibria of the game are stationary points under the replicator dynamics; and (ii) all focal points of the replicator dynamics are Nash equilibria of the evolutionary game.

Thus the Nash equilibrium solutions are embedded in the stationary points of the direction field of the dynamics specified by equation 1. Although not all stationary points are Nash equilibria, by overlaying a dynamic model of learning on the equilibria we can see which solutions are more likely to be discovered by *boundedly-rational* agents. Those Nash equilibria that are stationary points at which a larger range of initial states will end up, are equilibria that are more likely to be reached (assuming an initial distribution that is uniform).

This is all well and good in theory, but the model is of limited practical use since many interesting real-world games are *multi-state*[2]. Such games can be transformed into normal-form games, but only by introducing an intractably large number of pure strategies, making the payoff matrix impossible to compute.

4. CO-EVOLUTION

But what if we were to approximate the replicator dynamics by using an evolutionary search over the strategy space? Rather than considering an infinite population consisting of a mixture of all possible pure strategies, we use a small finite population of randomly sampled strategies to approximate the game. By introducing mutation and cross-over, we can search hitherto unexplored regions of the strategy space. Might such a process converge to some kind of approximation of a true Nash equilibrium? Indeed, this is one way of interpreting existing co-evolutionary algorithms; fitness-proportionate selection plays a similar role to the replicator dynamics equation in ensuring that successful strategies propagate, and genetic operators allow them to search over novel sets of strategies. There are a number of problems with such approaches from a game-theoretic perspective, however, which we shall discuss in turn.

Firstly, the proportion of the population playing different strategies serves a dual role in a co-evolutionary algorithm [3]. On the one hand, the proportion of the population playing a given strategy represents the probability of playing

[1]A strategy which is always the best one to adopt no matter what any opponent does.

[2]The payoff for a given move at any stage of the game depends on the history of play.

that pure strategy in a mixed-strategy Nash equilibrium. On the other hand, evolutionary search requires diversity in the population in order to be effective. This suggests that if we are searching for Nash equilibria involving mixed-strategies where one of the pure strategy components has a high frequency, corresponding to a co-evolutionary search where a high percentage of the population is adopting the same strategy, then we may be in danger of over-constraining our search as we approach a solution.

Secondly and relatedly, although the final set of strategies in the converged population may be best responses to each other, there is no guarantee that the final mix of strategies cannot be invaded by other yet-to-be-countered strategies in the search space, or strategies that became extinct in earlier generations because they performed poorly against an earlier strategy mix that differed from the final converged strategy mix. Genetic operators such as mutation or crossover will be poor at searching for novel strategies that could potentially invade the newly established equilibrium because of the above problem. If these conditions hold, then the final mix of strategies is implausible as a true Nash equilibrium or ESS, since there will be unsearched strategies that could potentially break the equilibrium by obtaining better payoffs for certain players. We might, nevertheless, be satisfied with the final mix of strategies as an approximation to a true Nash equilibrium on the grounds that if our co-evolutionary algorithm is unable to find equilibrium-breaking strategies, then no other algorithm will be able to do so. However, as discussed above, we expect *a priori* that co-evolutionary algorithms will be particularly *poor* at searching for novel strategies once they have discovered a (partial) equilibrium.

Finally, co-evolutionary algorithms employ a number of different selection methods, not all of which yield population dynamics that converge on game-theoretic equilibria [4].

These problems have led researchers in co-evolutionary computing to design new algorithms employing game theoretic solution concepts [2]. In particular, [3] describe a game-theoretic search technique for acquiring approximations of Nash strategies in large symmetric 2-player constant-sum games with type-independent payoffs. In this paper, we address n-player non-constant-sum multi-state games with type-dependent payoffs. In such games, playing our Nash strategy (or an approximation thereof) does not guarantee us security against exploitation, thus if there are multiple equilibria, it may be more appropriate to play a *best-response* to the strategies that we infer are in play.

5. EMPIRICAL GAME-THEORY

Reeves et al. [9] and Walsh et al. [11] obviate many of the problems of standard co-evolutionary algorithms by restricting attention to small representative sample of "heuristic" strategies that are known to be commonly played in a given multi-state game. For many games, unsurprisingly none of the strategies commonly in use is dominant over the others. Given the lack of a dominant strategy, it is then natural to ask if there are mixtures of these "pure" strategies that constitute game-theoretic equilibria.

For small numbers of players and heuristic strategies, we can construct a relatively small normal-form payoff matrix which is amenable to game-theoretic analysis. This *heuristic* payoff matrix is calibrated by running many iterations of the game; variations in payoffs due to different player-types (eg black or white, buyer or seller) or stochastic environmental factors (eg PRNG seed) are averaged over many samples of type information resulting in a single mean payoff to each player for each entry in the payoff matrix. Players' types are assumed to be drawn independently from the same distribution, and an agent's choice of strategy is assumed to be independent of its type, which allows the payoff matrix to be further compressed, since we simply need to specify the number of agents playing each strategy to determine the expected payoff to each agent. Thus for a game with k strategies, we represent entries in the heuristic payoff matrix as vectors of the form

$$\vec{p} = (p_1, \ldots p_k)$$

where p_i specifies the number of agents who are playing the ith strategy. Each entry $p \in P$ is mapped onto an outcome vector $q \in Q$ of the form

$$\vec{q} = (q_1, \ldots q_k)$$

where q_i specifies the expected payoff to the ith strategy. For a game with n agents, the number of entries in the payoff matrix is given by

$$s = \frac{(n+k-1)!}{n!(k-1)!} \tag{2}$$

For small n and small k this results in payoff matrices of manageable size; for $k = 3$ and $n = 6$, 8, and 10 we have $s = 28$, 45, and 66 respectively.

Once the payoff matrix has been computed we can subject it to a rigorous game-theoretic analysis, search for Nash equilibria solutions and apply different models of learning and evolution, such as the replicator dynamics model, in order to analyse the dynamics of adjustment to equilibrium.

The equilibria solutions that are thus obtained are not rigorous Nash equilibria for the full multi-state game; there is always the possibility that an unconsidered strategy could invade the equilibrium. Nevertheless, heuristic strategy equilibria are more plausible as models of real world game playing than those obtained using a standard co-evolutionary search precisely because they *restrict* attention to strategies that are commonly known and are in common use. We can therefore be confident that no commonly known strategy for the game at hand will break our equilibrium, and thus the equilibrium stands at least some chance of persisting in the short term future.

Of course, once an equilibrium is established, the designers of a particular strategy may not be satisfied with their strategy's adoption-rate in the game-playing population at large. As [11] suggest, the designers of, for example, a particular trading strategy in a market game may have financial incentives such as patent rights to increase their "market-share" – that is, the proportion of players using their strategy, or, in game-theoretic terms, the probability of their pure strategy being played in a mixed-strategy equilibrium with a large basin of attraction. They go on to propose a simple methodology for performing such optimization using manual design methods. A promising-looking candidate strategy is chosen for perturbation analysis; a new, perturbed, version of the original heuristic payoff matrix is computed in which the payoffs of the candidate strategy are increased by a small fixed percentage, thus modelling a hypothetical tweak to the strategy that yields in a small increase in payoffs. The replicator-dynamics direction field is then replotted to establish whether the hypothetically-optimized strategy is able to

to achieve a high adoption rate in the population. Strategy designers can then concentrate their efforts on improving those strategies that become strong attractors with a small increase in payoffs.

In this paper, we extend this technique by using a genetic-algorithm (GA) to *automatically* optimize candidate strategies by searching for a hitherto-unknown best-response — or, to use more appropriate nomenclature, a *better-response* — to an existing mix of heuristic strategies. Rather than using a standard co-evolutionary algorithm to perform the optimization, we use a single-population GA where the fitness of an individual strategy is computed from the heuristic-strategy payoff matrix according to the basin size it yields under the replicator dynamics.

6. THE DOUBLE-AUCTION

We apply our method to the acquisition of strategies for the *double auction* [5]. The double auction is a generalisation of more commonly-known single-sided auctions, such as the English ascending auction, which involve a single seller trading with multiple buyers. In a double auction, we allow multiple traders on both sides of the market; as well as soliciting offers to buy a good from buyers, that is bids, we also solicit offers to sell a good from sellers, so called *asks*. Variants of the double auction are commonly used in many real-world market places such as stock exchanges in scenarios where supply and demand are highly dynamic. Whilst single-sided auctions are well-understood from a game theoretic perspective, double-sided auctions remain intractable to a full game-theoretic analysis especially when there are relatively few traders on each side of the market. Thus much analysis of this game has focused on using heuristic methods to explore viable bidding strategies.

In previous work [8], we used a heuristic-strategy analysis to analyse two variants of the double auction market mechanism populated with a mix of heuristic strategies, and were able to find approximate game-theoretic equilibrium solutions. In this paper, we use the same basic framework, but we focus on the *clearing-house* double auction (CH) [5] with uniform pricing, in which all agents are polled for their offers before transactions take place, and all transactions are then executed at the same market-clearing price. In this paper, we consider only the following three heuristic-strategies. Future work will use a more representative (and larger) set of heuristic-strategies to optimize against.

- The truth-telling strategy (TT), whereby agents submit offers equal to their valuation for the resource being traded (in a strategy-proof market, TT will be a dominant strategy);
- The Roth-Erev strategy (RE) – a strategy based on reinforcement learning, described in [1] and calibrated with the parameters specified in [7]; and
- The Gjerstad-Dickhaut strategy (GD) [6], whereby agents estimate the probability of any bid being accepted based on historical market data and then bid to maximize expected profit.

Since all mixed-strategy vectors lie in the unit-simplex, for $k = 3$ strategies we can project the unit-simplex onto a two dimensional space and then plot the switching between strategies that occurs under the dynamics of equation 2. Figure 1 shows the direction-field of the replicator-dynamics equation for these three heuristic strategies, showing that we have two equilibrium solutions. Firstly, we see that GD is a best-response to itself, and hence is a pure-strategy equilibrium. We also see it has a very large *basin of attraction*; for any randomly-sampled initial configuration of the population most of the flows end up in the bottom-right-hand-corner. Additionally, there is a second mixed-strategy equilibria at the coordinates (0.88, 0.12, 0) in the simplex corresponding to an 88% mix of TT and a 12% mix of RE, however the attractor for this equilibrium is much smaller than the pure-strategy GD equilibrium; only 6% of random starts terminate here vs 94% for pure GD. Hence, according to this analysis, we expect most of the population of traders to adopt the GD strategy.

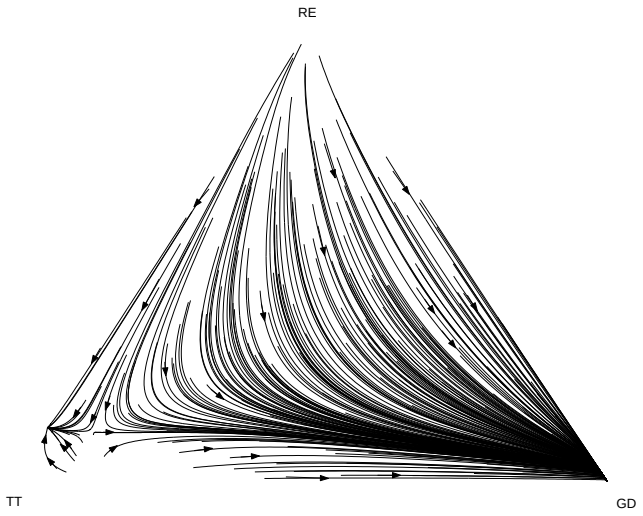

Figure 1: The original replicator dynamics direction field for a 12-agent clearing-house auction with the original unoptimized Roth-Erev strategy (labelled RE).

How much confidence can we give to this analysis given that the payoffs used to construct the direction-field plot were estimated based on only 2×10^3 samples of each game? One approach to answering this question is to conduct a sensitivity analysis; we perturb the mean payoffs for each strategy in the matrix by a small percentage to see if our equilibria analysis is robust to errors in the payoff estimates. Figure 2 shows the direction-field plot after we perform a perturbation where we remove 2.5% of the payoffs from the TT and GD strategies and assign +5% payoffs to the RE strategy. This results in a qualitatively different set of equilibria; the RE strategy becomes a best-response to itself with a large basin of attraction (61%), and thus we conclude that our equilibrium analysis is sensitive to small errors in payoff estimates, and that our original prediction of widespread adoption of GD may not occur if we have underestimated the payoffs to RE.

If we observe a mixture of all three strategies in actual play, however, the perturbation analysis also suggests that we could bring about widespread defection to RE if were able to tweak the strategy by improving its payoff slightly; *the perturbation analysis points to RE as a candidate for potential optimization.*

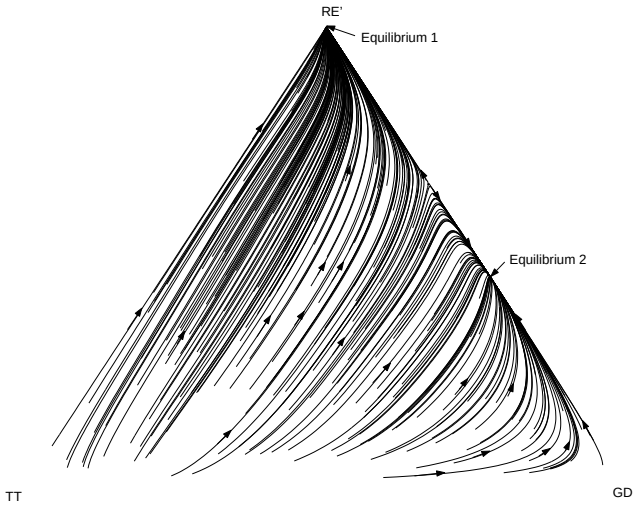

Figure 2: Replicator dynamics direction field for a 12-agent clearing-house auction perturbed with +5% payoffs to the Roth-Erev strategy (labeled RE')

7. STRATEGY ACQUISITION

In the previous section we described how we used heuristic-strategy approximation to identify a candidate strategy for optimization. We also introduced an intriguing metric for ranking strategies on a single fully-ordered scale: viz, the size of the strategy's basin of attraction under the replicator dynamics. In this section we use this metric to perform a heuristic search of a space of strategies closely related to the RE strategy. In the following we define the space of strategies that we search, and the details of the search algorithm.

The RE strategy uses re-inforcement learning (RL) to choose from n possible markups over the agent's limit price based on a reward signal computed as a function of profits earned in the previous round of bidding. Agents bid or ask at price p

$$p = l \pm mo \tag{3}$$

where l is the agent's limit price, o is the output from the learning algorithm and m is a scaling parameter. Additionally, the Roth-Erev learning algorithm itself has several free parameters: the recency parameter r, the experimentation parameter x, and an initialisation parameter $s1$. In addition to the original Roth-Erev (RE) algorithm, there are several other learning-algorithms that that have successfully been used for RL strategies in ACE. We search over three additional possibilities: stateless Q-learning (SQ), modifications to RE used by [7] (NPT) and a control algorithm which selects a uniformly random action regardless of reward signal (DR). SQ has free parameters: the discount-rate g, experimentation ϵ, and a learning-rate p.

Individuals in this search space were represented as a 50-bit string, where:

- bits 1-8 coded for parameter m in the range $(1, 10)$;
- bits 9-16 coded for the parameters ϵ or x in the range $(0, 1)$;
- bits 17-24 coded for parameter n in the range $(2, 258)$;
- bits 25-32 coded for parameters g or r in the range $(0, 1)$;
- bits 33-40 coded for parameter $s1$ in the range $(1, 1.5 \times 10^4)$;
- bits 41-42 coded for the choice of learning algorithm amongst RE, NPT, SQ or DR; and
- Bits 43-50 coded for parameter p in the range $(0, 1)$.

We used a genetic-algorithm (GA) to search this space of strategies, where the fitness of each individual strategy in the search space was computed by estimating its basin size under the replicator dynamics under interaction with our existing three strategies: GD, TT and RE. Basin size was estimated using the same brute-force methods described in Section 5, but since we recompute all entries in the heuristic-payoff matrix in support of each candidate strategy, we used lower sample sizes in order to facilitate evaluation of many strategies; the sample size for the number of games played for each entry in the heuristic payoff matrix was increased as a function of the generation number: $10 + int(100 \ln(g + 1))$ allowing the search-algorithm to quickly find high-fitness regions of the search-space in earlier generations and reducing noise and allowing more refinement of solutions in later generations. We used a constant number of replicator-dynamics trajectories — 50 — in order to estimate the basin size from the payoff matrix once it had been recomputed for our candidate strategy.

We chose a GA as our search algorithm principally because of its ability to cope with the additional noise that the lower sample size introduced into the objective function Our GA was configured with a population size of 100, with single-point cross-over, a cross-over rate of 1, a mutation-rate of 10^{-4} and fitness-proportionate selection. The GA was run for 32 generations, which took approximately 1800 CPU hours.

8. RESULTS

Figure 5 shows the mean fitness of the GA population for each generation. As can be seen, there is still a large amount of variance in fitness values in later generations. However, inspection of a random sample of strategies from each generation revealed a partial convergence of phenotype, but with significant fluctuations in fitness values due to small sample sizes (see above). Most notably, the fittest individual at generation 32 had also appeared intermittently as the fittest individual five times in the previous 10 generations, and thus we took this as the output from the search.

Our optimised strategy uses the stateless Q-learning algorithm with the following parameters:

$$\begin{aligned} m &= 1.210937 \\ n &= 6 \\ \epsilon &= 0.18359375 \\ g &= 0.4140625 \\ p &= 0.1875 \end{aligned}$$

The notable feature of this strategy is the small number of possible markups (n), and the narrow range of the markups

$[1, nm]$ as compared with the distribution of valuation distribution widths. This feature was shared by all of the top five strategies in the last ten generations, and is another factor that indicated convergence of the search.

We proceeded to analyze our specimen strategy under a full heuristic-strategy analysis using 10^4 samples of the game for each of the 455 entries in the payoff matrix. With the current version of our simulator[3], we are able to complete this analysis in less than twenty four hours using a dual-processor 3.6Ghz Xeon workstation.

Figure 6 shows twenty trajectories of the replicator dynamics plotted as a time series for each strategy, and shows the interaction between the new, optimised strategy, OS, together with the existing strategies: GD, TT and RE.

Taking 10^3 randomly sampled initial mixed-strategies, we calculate that there are two attractors:

$$\begin{aligned} A &= (0.0, 0.0, 1.0, 0.0) \\ B &= (0.67, 0.32, 0.0, 0.0) \end{aligned}$$

over (OS, TT, GD, RE). Attractor A captures only 3% of trajectories, whereas attractor B captures virtually the entire four-dimensional simplex (97%). Although this basin is very large, our optimized strategy shares this equilibrium with the truth-telling strategy (TT), giving us a final total market share to $0.67 \times 0.97 = 65\%$. This compares favourably with a market-share of 32% for truth-telling and 3% for GD. The original RE strategy is dominated by our optimised strategy. Figures 3 and 4 show the direction field for two of the 3-strategy combinations involving our optimised strategy: (OS, TT, GD) and (OS, GD, RE) respectively.

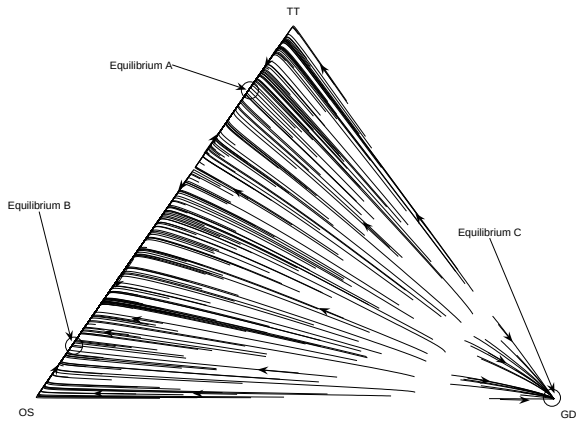

Figure 3: Replicator dynamics direction field for a 12-agent clearing-house auction showing interaction between optimised strategy (OS) verses TT and GD

9. DISCUSSION

It is somewhat remarkable that our somewhat simplistic optimised strategy is able to gain defectors from a highly sophisticated strategy like GD, whilst at the same time truth-telling is able to retain a share of followers in a population predominated by *OS*ers (TT appears to be *parasitic* on OS). What accounts for the ability of small OS mixes to invade high-probability mixes of a sophisticated adaptive strategy (GD), whilst remaining vulnerable to invasion by a low-probability mix of a non-adaptive strategy (TT)?

Our current hypothesis is that OS is able to exploit a flaw in the way that we construct valuation distributions. As discussed earlier, we use the same method of assigning valuations as in [11]; that is, for each run of the game, the lower-bound, b, of the valuation distribution is selected uniformly at random from the range $[61, 160]$ and the upper-bound b' is similarly drawn from $[b + 60, b + 209]$. For that run of the game, each agent's valuation is then drawn uniformly from $[b, b']$. However, we hypothesise that this results in a statistical correlation between the meta-bounds and the average slope of truthful supply and demand schedules— that is, given these distribution parameters there is insufficient variance in the difference between valuations of traders who are neighbours on the supply or demand curve. Since we are using a uniform-price k=0.5 clearing rule, the mechanism is vulnerable to price-manipulation from the least efficient trades; the buyer with the lowest matched bid, and the seller with the highest matched ask can potential manipulate the final clearing price - *provided that they do not overstate their value claim to the extent that it impinges on the 2nd-lowest matched bid, or the 2nd-highest matched ask.* Given sufficient variance in valuations between the lowest and the 2nd-lowest matched offers (call this random variable the "match delta"), this vulnerability is not easily exploited. However, in a market with a small number of traders and a narrow distribution for the match delta there is an opportunity to trade at small margin above truth if you find yourself with a valuation close to the equilibrium price. This is precisely the behaviour of the strategies that we observe to be predominant in the later generations of our GA- they all use a small number of possible markups, each of them small in comparison to the possible valuation bounds. The reinforcement-learning component of the strategy is then able to fine-tune the markup depending on where the trader finds themselves on the supply or demand curve after valuations are drawn. If it is far away from the equilibrium-price it can adjust its margin close to zero, whilst if it is near the equilibrium-price it can find a small margin that does not impinge on its nearest-neighbour. This hypothesis is also consistent with parasitic truth-telling; it is easy to see that truth-telling is a best-response for a 2nd-lowest matched bidder to a lowest matched bidder playing OS. Further work needs to be carried out to verify this hypothesis, but early indications are that the efficacy of our optimised strategy is highly sensitive to changes in the valuation meta-bounds.

Thus it appears that our evolved strategy over-fits to what is potentially an artifact. Does this invalidate our approach? On the contrary, we believe that it demonstrates that highly sophisticated strategies can possess an Achilles heel in certain situations, and that our method for strategy acquisition can find and exploit these vulnerabilities. GD performs robustly given a large variance in match delta, but given some partial prior knowledge about valuation distributions in a small market, then there may exist a more effective, and simpler strategy. In the particular case that valuation distributions are constructed as above, then the strategy OS will perform remarkably well.

10. SUMMARY

[3] `http://freshmeat.net/projects/jasa`

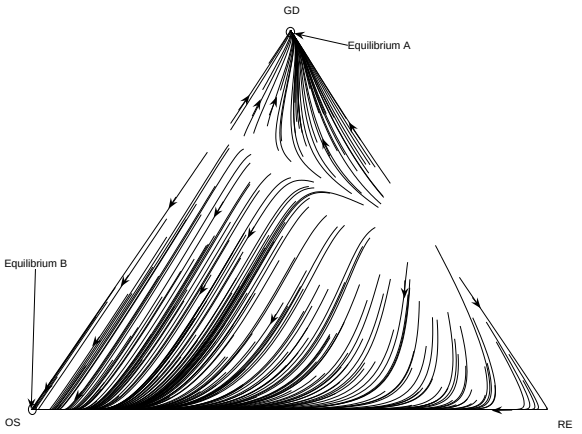

Figure 4: Replicator dynamics direction field for a 12-agent clearing-house auction showing interaction between optimised strategy (OS) verses GD and the original Roth-Erev strategy (RE)

In this paper we have described a novel method for strategy acquisition for n-player non-zero-sum games, and we have successfully applied our method to the acquisition of a trading strategy for the double-auction market; a recognised benchmark problem for this domain. Our method combines two existing methodologies in a very simple way: empirical game-theory and heuristic search (in this case, using a genetic-algorithm). Our key contribution to this domain is the use of the basin-size metric to rank strategies. Although we have not provided a thorough analytical verification of our method, we believe that at this stage its novel features over and above those of empirical game-theory are simple enough that a successful application of our method to well-known benchmark problem suffices to demonstrate the potential for future research.

11. FURTHER WORK

The main weaknesses of our current approach stem from: a) potential weaknesses in the underlying empirical game-theory methodology, and b) the lack of a customised search algorithm tailored specifically for this domain.

As regards a), we recognise that empirical game-theory is an emerging field. As such, advances and refinements are continually being made to address some of its earlier weaknesses. For example, Walsh et al. [12] describe a refinement to the method which allows for a more principled approach for determining optimal sample size, and [13] describe a further approximation technique that allows for a greatly reduced number of strategy profiles to be considered. These and other refinements will be incorporated into our approach in future work. One of the key acknowledged weaknesses of empirical game-theory is the somewhat arbitrary selection of initial heuristic-strategies. However, it is our hope that the search method outlined in this paper will become the basis of an iterative approach to extending an initial set of manually chosen heuristic-strategies by populating the mix with additional heuristic-strategies that are discovered through heuristic-search.

As regards b), designing such a search algorithm is future work. But note that *despite* the lack of a custom-designed search algorithm, we are still able to use a general-purpose heuristic-search method to successfully acquire an interesting novel strategy for our benchmark problem.

ABSTRACT

A standard assumption of search in two-player games is that the opponent has the same evaluation function or utility for possible game outcomes. While some work has been done to try to better exploit weak opponents, it has only been a minor component of high-performance game playing programs such as Chinook or Deep Blue. However, we demonstrate that in games with more than two players, opponent modeling is a necessary component for ensuring high-quality play against unknown opponents. Thus, we propose a new algorithm, soft-max^n, which can help accommodate differences in opponent styles. Finally, we show an inference mechanism that can be used with soft-max^n to infer the playing style of our opponents.

1. INTRODUCTION AND BACKGROUND

The minimax decision rule is well-known for its performance guarantees in perfect-information game trees. If we have a perfect evaluation function, minimax gives a lower-bound guarantee on our score, regardless of our opponent. This is different than being maximally exploitive, however, because minimax will not necessarily take maximal advantage of a weak opponent.

In two-player zero-sum games, different algorithms have been suggested with the intent of using opponent modeling to take better advantage of opponent weaknesses [2, 3, 7]. While these algorithms work in theory, they require an *a priori* model of the opponent, and the improvement does not offset the loss of deeper search afforded by alpha-beta pruning in two-player games.

In games with more than two players or teams of players we face a different situation. Game theory does not provide tight lower-bounds on performance in multi-player[1] games as in two-player zero-sum games, and existing algorithms for play demonstrate great weaknesses when playing new or unmodeled opponents. And, while better pruning techniques have recently been developed [14, 15], they are still not as effective as alpha-beta in two-player games.

This paper examines the role of opponent models for search in large multi-player perfect-information game trees. We make two novel contributions: a more robust algorithm for playing n-player games and a representation and method of inferring opponent preferences in these games.

This paper proceeds as follows: we will first discuss previous algorithms for opponent modeling in more detail, as well as the max^n algorithm [10] for playing multi-player games. We will then introduce a sample domain, the card game Spades, and demonstrate that an incorrect opponent model, such as assuming the opponent is using the same evaluation function, can be quite harmful. We introduce a new algorithm, soft-max^n, which can better accommodate differences in opponent styles. Finally, given this algorithm, we show how we can infer models of our opponents through observations of their play.

1.1 Related Work

Opponent modeling has been studied in the context of two-player, zero-sum, deterministic, perfect-information games for many years. Some of the earliest work on opponent modeling [8, 6] began with the recursive problem of opponent modeling. If I do not assume that my opponent is identical to me, I must have a model of my opponent. Similarly, if my opponent is also trying to model me, I will also need a model of my opponent's model of me, and so on. At first glance this seems to be a recursive nightmare. But, algorithms like M* [2] are capable of handling a number of opponent models and using them recursively. PrOM [3] expanded on these ideas, but still did not find measurably large success, even given a perfect opponent model to begin with.

In some sense, because most of this work is in the context of two-player, zero-sum games, it is not surprising that it has met with limited success in practice. This is the domain with the strongest theoretical algorithm, minimax, and thus has the least need for opponent modeling. We demonstrate here that in multi-player games there is a need for good opponent modeling. This same observation has been made in the context of poker [1, 13], although the approach in that game has been to model the opponent's strategy

[1]We use the phrase *multi-player* to specifically refer to situations with three or more players, as distinguished from the phrase *two-player*, although most of our statements with regard to multi-player games also apply to two-player non-zero-sum games.

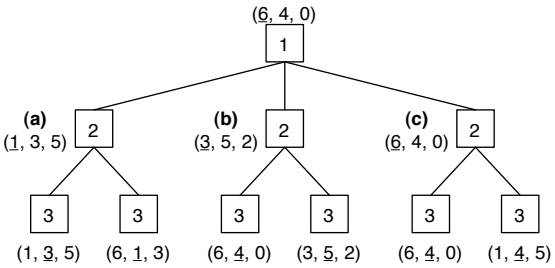

Figure 1: Example max^n tree.

rather than their evaluation function. In many cases the number of outcomes to be ordered is small compared to the domain's state space, making modeling of preferences more tractable.

1.2 Max^n

The max^n algorithm is used for calculating plays in perfect information game trees. In a max^n tree with n players, the leaves of the tree are n-tuples, where the ith element in the tuple is the ith player's score or utility for that position. At the interior nodes in the game tree, the max^n value of a node where player i is to move is the max^n value of the child of that node for which the ith component is maximum. Ties are traditionally broken toward the left, to maximize pruning. At the leaves of a game tree an exact or heuristic evaluation function can be applied to calculate the n-tuples that are backed up in the game tree.

We demonstrate this in Figure 1. In this tree there are three players. The player to move is labeled inside each node. At node (a), Player 2 is to move. Player 2 can get a score of 3 by moving to the left, and a score of 1 by moving to the right. So, Player 2 will choose the left branch, and the max^n value of node (a) is (1, 3, 5). Player 2 acts similarly at node (b) selecting the right branch, and at node (c) breaks the tie to the left, selecting the left branch. At node the root of the tree, Player 1 chooses the move at node (c), because 6 is greater than the 1 or 3 available at nodes (a) and (b).

1.3 Max^n Theoretical Properties

In order to better motivate the theoretical reasoning for our work, we briefly touch on one aspect of the game theory behind the minimax and max^n algorithms. The minimax algorithm works by computing the best response to any strategy a perfect opponent could play. The value of this strategy is called the minimax value or an equilibrium value. While there may be many strategies that allow a player to achieve this value in a two-player zero-sum game, each of these strategies has the same value.

Max^n calculates equilibrium values and strategies similar to minimax. It is simple to see that max^n returns a line of play which is an equilibrium, because at each point in the game tree players are always taking the move with the maximum score possible. Thus, no player can get a better result by unilaterally changing their strategy. See [10] for a full proof.

In a multi-player game there can be many different equilibrium strategies, but unlike in two-player zero-sum games, they are not guaranteed to all have the same value. Even more importantly, if your opponent is playing a different equilibrium strategy than you are, there is no guarantee that you will be in equilibrium, or that you will even receive the minimum equilibrium value that you expected to receive.[2]

[2]We could get a guaranteed lower bound on our score by reducing the n-player game to a two-player game, assuming all of our opponents are seeking to minimize our score. This approach is overly pessimistic, assuming that not only will opponents arbitrarily sacrifice their own score to reduce ours, but are also entirely coordinated in doing so.

Even in two-player games there are cases where there is a need to distinguish between different strategies with the same equilibrium value. Perhaps the biggest example is from the game of Checkers. In one situation the program CHINOOK was able to prove that a line of play was a draw, when humans mistakenly thought it was a win for the computer. Thus, it appeared to be a bug when CHINOOK made a move that led to a clear draw. In practice CHINOOK just lacked the ability to select between different equilibrium strategies to choose the one that was most likely to lead to an opponent mistake [12].

In the case of Checkers, the result of playing the minimax strategy without attention to an opponent model simply means that the program isn't maximally exploiting a weak opponent. Against a perfect opponent such differences don't matter. However, the concept of a perfect opponent in a multi-player game is ill-defined. In the next section we demonstrate the effects of playing a multi-player game when we have incorrect assumptions or models about our opponents' strategies.

2. SPADES

Most of the work in this paper is not specific to any particular game. But, because the game of Spades is well-known, and it is easy to create small, concrete examples from this game, we will use it as the primary domain for examples and experiments. There are many games similar to Spades which have similar properties, which we will not cover here, including Oh Hell! and Sergeant Major. The complete rules of Spades is found in [4], but many more games are described in detail at http://www.pagat.com/.

Spades is a card game for two or more players. In the 4-player version players play in teams, while in the 3-player version each player is on their own, which is what we focus on. We will only cover a subset of the rules of Spades here. A game is split into many hands. Within each hand the basic unit of play is a trick. At the beginning of a hand, players must bid how many tricks they think they can take in that hand. At the end of each hand they receive a score based on how many tricks they actually took. The goal of the game is to be the first player to reach a pre-determined cumulative score, often 300.

If players make their bid exactly, they receive a score of $10 \times bid$. Any tricks taken over their bid are called overtricks. If a player takes any overtricks they count for 1 point each, but each time a player accumulate 10 overtricks, they lose 100 points. Finally, if a player misses their bid, they lose $10 \times bid$. So, if a player bids 3 and takes 3, they get 30 points. If they bid 3 and take 5, they get 32 points. If they bid 3 and take 2, they get -30 points. Thus, the goal of the game is to make your bid without taking too many overtricks. In this work we consider the perfect-information version of Spades where we can see our opponents cards.

The perfect-information version of Spades is a complex and challenging problem in itself. If we wish to play the imperfect-information version of Spades, Monte-Carlo sampling can be used to turn a perfect-information player into a imperfect-information player, such as was done in Bridge [5].

To demonstrate the effect opponent modeling has on quality of play, we consider two player types, one player who tries to maximize the number of tricks they take in a hand (ignoring the bid), which we call MT. The other player type we consider attempts to minimize the number of overtricks they take, which we call mOT. Then, we varied these players by either giving them a model of

Table 1: The six ways to arrange two player types, A and B, in a three-player game.

	Seat 1	Seat 2	Seat 3
1	A	A	B
2	A	B	A
3	A	B	B
4	B	A	A
5	B	A	B
6	B	B	A

Table 2: The effect of opponent models on play.

	Players A v. B	Player A Score	Player A %Win	Player B Score	Player B %Win
(a)	mOT_{MT} v. MT_{mOT}	248.6	74.7	163.8	25.3
(b)	mOT_{MT} v. MT_{MT}	235.4	59.0	199.2	41.0
(c)	mOT_{mOT} v. MT_{mOT}	198.2	53.5	191.4	46.5
(d)	mOT_{mOT} v. MT_{MT}	178.2	44.0	207.3	56.0
(e)	mOT_{MT} v. mOT_{mOT}	212.4	37.2	250.8	62.8
(f)	MT_{mOT} v. MT_{MT}	157.3	36.0	218.4	64.0

their opponent, which we designate in the subscript. So MT_{MT} is a player who is attempting to maximize tricks, and assumes the same about all opponents. MT_{mOT} is also trying to maximize tricks, but assumes that all opponents are trying to minimize their overtricks. Players do not do any further recursive opponent modeling.

We arranged the experiments as follows. For each combination of the two player types and opponent models we played 100 games, each of which ended after any player reached 300 points. In each hand players were dealt seven cards from a standard 52 card deck and searched the game trees in their entirety. A rule-based system was used to determine player bids, and all players used the same system. Because there are three players in each game, each game was repeated with the same cards six times to account for different arrangements of players at the table (See Table 2). Although the specific results will vary based on the number of cards, the score limit for ending games, and the rule-system used for bidding, similar trends are found in the data regardless of these parameters.

We report the results of play in Table 2. Each row shows the average score and percentage of wins for the two listed player types averaged over the 600 games played[3] (100 games for each of the six combinations of player types). In each game two of the players will be of the same type and thus that type will have an increased chance of winning the game. This is offset by the fact that in the other half of the games that type will only be one of the three players and so have a lower chance of winning. In summary, if the player types were equal, they would be expected to win half of the games. Similarly, even if a player type wins 100% of the games, its average score would likely be less than 300 because in half of the games one of the losing players must be of the same type as the winner and presumably have a score less than 300.

By the rules of the game, we would expect the player who is minimizing overtricks to do best, and in general they do. This is particularly noticeable when they have a correct model of their opponent as shown in rows (a) and (b).[4] When both players have

[3]All results reported in this paper have 95% confidence of being within 7.2 points or less, which is sufficient to support our claims.

[4]Due to the nature of our experimental setup, one-third of a players' opponents will actually be of their own type. Hence, when we say player A has a correct model of its opponent, such as in row (a), we mean that at least two-thirds of its opponents are correctly modeled.

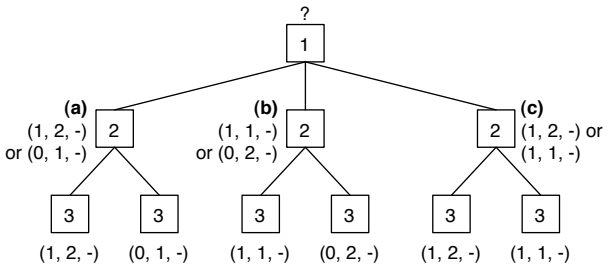

Figure 2: Example search tree in Spades.

correct models of each other (a), the mOT player wins 74.7% of the games. If the MT player does not have a correct model of the mOT player (b), the win rate drops to 59.0%. However, if the mOT player also has an incorrect model, the win rate drops to 44.0% and the preferred evaluation strategy can actually lose. This is a high price to pay for an incorrect opponent model. Furthermore, we cannot just assume our opponent is trying to maximize tricks, because we will do quite poorly against another player who is trying to minimize his overtricks as shown in row (e).

Lastly, row (f) shows the same results of the importance of correct modeling when both players try to maximize their tricks. In this case the average scores are much lower than in other games. This occurs because both players are using poor strategies, which increases the variance and thus lowers the average score. Similar results, not reported here, have been seen in other card games.

Note that because we are only doing one level of opponent modeling, it is important that we both have a correct model of our opponent and that our opponent has a correct model of us. Otherwise our predictions of our opponents' behavior will be incorrect. This explains why the results from row (a) are different from row (b). In row (b), the MT_{MT} player will behave differently than the mOT_{MT} player predicted since it expects to be facing an MT opponent. These results indicate that errors in second-level modeling effects (i.e., my model of my opponent's model of me) are important, but of a smaller magnitude than first-level modeling errors.

3. Soft-Max^n

We propose a new algorithm, soft-max^n, which is more robust to unknown opponents. We first present the algorithm intuition in the context of our results in Spades, followed by a more formal presentation of the algorithm.

First let us briefly return to Figure 1. At node (c) there is a tie for Player 2, so either move can be chosen, resulting in a score of 6 or a score of 1 for Player 1. Because max^n only backs a single value up the tree, there is no way for Player 1 at the root to know the risk of taking move (c). Because a value that is a tie for one player is not necessarily a tie for the others, there is a risk any time we encounter a tie in the game tree. The first inclination may be to remove all ties in the game tree. If all players have a publicly known total ordering on possible outcomes in a game (i.e., there are no ties), the max^n algorithm will work "perfectly", in that this problem will never arise. In practice, however, players themselves may only have a partial ordering on outcomes. When there is a tie in the partial ordering, there may be no way to predict how the opponent will break that tie.

Even worse, consider Player 2's decisions in Figure 2, where there are no ties. In this example, both Player 1 and 2 have bid 1

The only situation where a player has a correct model for all of its opponents is player B in rows (e) and (f).

Table 3: Dominance relations in max^n sets.

(a)	(3, 4, 3)
(b)	(2, 1, 7), (4, 2, 4)
(c)	(4, 1, 5), (3, 2, 5)
(d)	(10, 0, 0), (0, 10, 0), (0, 0, 10)

trick, and we will ignore Player 3 for the time being. Consider the possible strategies for Player 2. If Player 2 is trying to maximize tricks, at nodes (a) and (c) the outcome (1, 2, -) is chosen, which allows Player 1 to make their bid, and at node (b) (0, 2, -) is chosen. If Player 2 is trying to minimize overtricks, (1, 1, -) will be chosen at nodes (b) and (c), allowing Player 1 to make their bid, but at node (a), Player 2 will choose (0, 1, -).

If we think Player 2 is trying to maximize tricks, move (a) and (c) will have the same value. Barring additional information in the tie-breaking rules, there is the possibility we will make the wrong move to (a), missing our bid where moving to (c) would have guaranteed our bid. We get similar results if we model Player 2 as trying to minimize overtricks.

It should be clear that there is a tension between two issues. We want to avoid ties in our game trees, because they introduce extra uncertainty in whether we are backing up the correct max^n value. However, avoiding ties requires detailed knowledge of our opponent's preferences, i.e., very specific opponent models. We've already shown, though, that overly specific models can result in poor performance when the opponent's play does not correspond to the chosen model. For example, in Spades it is safe to assume the opponent prefers making their bid to missing it, but it is not safe to assume an opponent will necessarily avoid taking overtricks. Our solution, then, is to use generic, less presumptuous, opponent models, but more intelligently handle the resulting increase in the number of ties. We will first describe the soft-max^n algorithm and its alternate tie-breaking mechanism. In the next section we will describe our formalization of generic opponent models.

3.1 Max^n Sets

Instead of passing a single max^n value up the game tree, the soft-max^n algorithm backs up sets of max^n values. A max^n set s contains max^n values $v_1, \ldots, v_k$ where each value v_i is a standard max^n tuple. We combine multiple max^n sets with the *union* operation. The union of two sets is a new set containing all max^n values that appear in each individual set.

We compare sets using a dominance relationship. A max^n set s_1 strictly dominates another max^n set s_2 with respect to some player i if and only if,

$$\forall v_1 \in s_1 \; \forall v_2 \in s_2 \quad v_1[i] > v_2[i].$$

Similarly the max^n set s_1 weakly dominates s_2 relative to Player i if and only if,

$$\begin{aligned} &\forall v_1 \in s_1 \; \forall v_2 \in s_2 \qquad v_1[i] \geq v_2[i] \quad \text{and} \\ &\exists v_1 \in s_1 \; \exists v_2 \in s_2 \qquad v_1[i] > v_2[i]. \end{aligned}$$

We demonstrate these concepts with the values in Table 3. From the perspective of Player 1, (c) weakly dominates (a), because Player 1's scores in (c), 4 and 3, are at least as large as the score of 3 in (a). From the perspective of Player 2, (a) strictly dominates both (b) and (c), while from Player 3's perspective (b) strictly dominates (a), but does not dominate (c). If each player has a minimum score of 0 and a maximum score of 10, the set (d) can neither dominate another set or be strictly dominated by another set.

3.2 The Soft-Max^n Algorithm

Given the definition of a max^n set and dominance relation, we define soft-max^n as played by player i as follows:

1. At a leaf node, the max^n set is a heuristic or exact evaluation function.
2. At an internal node in the tree, the max^n set of values for that node is the union of all sets from its children that are not strictly dominated with respect to player j.
3. At the root of the tree, player i can use any decision rule to select the best set from among the non-dominated moves.

At the root of the tree, there are any number of ways to decide which move to make. For instance, depending on the game state, we may prefer to maximize potential score, minimize risk, or play to receive a guaranteed outcome. For all examples in this paper, we take the move which has the max^n set with the highest average value. There are obvious arguments why this may be the incorrect approach as there's no reason to assume all elements of the set are equally likely, but it is a simple approach that works in practice, as we demonstrate in the next section. We are currently exploring more principled options for making decisions.

We can illustrate soft-max^n using the tree in Figure 2. Recall that we now use only a generic opponent model for each player, which means that we will only distinguish between outcomes where our opponent are choosing to miss or make their bid. Player 1 and 2 each bid one trick. Since Player 2 always takes at least one trick, instead of returning one or the other result at (a), (b), and (c), we return a max^n set containing both child values at these nodes. At the root, Player 1 can, for instance, calculate the worst-case (or average-case) score on each path. Player 1 is guaranteed to take one trick on branch (c), so unlike (a) and (b), this move can be made safely. Thus, under soft-max^n Player 1 can make a more informed decision about which move to make.

The max^n algorithm has been shown to calculate one of many possible equilibria in a game. By comparison, Soft-max^n calculates all equilibria in the game.

LEMMA 1. *Soft-max^n calculates a superset of all pure-strategy equilibria values at every node in a game tree.*

Proof. We provide a proof by induction. First consider the leaves of a game tree. There are only single values in the leaves, so they must be equilibria for those sub-trees. Next, assume that at the kth level in the tree we have a max^n set containing a superset of all equilibria for that subtree. We show by contradiction that at the $(k+1)$th level of the tree we still have a superset of equilibria in our max^n set.

Assume there is a node, n, at the $(k+1)$th level for which soft-max^n does not return a max^n set which contains a superset of all equilibria. This means there is some child c whose max^n set contains an equilibrium not backed up into the parent. But, this can only happen if all values in the max^n set of c are strictly dominated by another child of n. If this is the case, then any individual value in c will always be dominated, and thus no value in c can be part of any equilibrium strategy. This is a contradiction, concluding the proof. □

We can be certain that all equilibria of the game are included in the soft-max^n sets. We cannot guarantee however that additional values will not be included. Informally, the extra values calculated by soft-max^n will be possible outcomes in the game, if we allow players to change their strategies at nodes in the middle of a game where they are indifferent to the possible outcomes.

3.3 Effect on Quality of Play

To demonstrate the effectiveness of soft-max^n, we repeated the experiments reported in Table 2, but this time the player trying to minimize overtricks uses soft-max^n and a generic opponent model. That is, the opponents are only assumed to be trying to make their bid. We employed the same methodology as in the previous experiments, except that now mOT$_g$ refers to the fact that the mOT player has this generic opponent model. The new results are in Table 3.3.

The new "% Gain" column is the increase in win percentage by using a generic model instead of an incorrect model. The generic model results in a substantial increase in the worst-case performance of playing an unknown opponent. In every case except against another mOT player that has modeled it, it is now winning at least half the games. Thus, if we are playing a game where we are unsure of the strategies that our opponents are using, we are better off using a generic model than making the wrong assumption about how our opponents play. The new "% Loss" column shows the further increase in win percentage that could be attained by using a *correct* opponent model rather than the general one. This demonstrates there is still room for improvement if the player can learn a model of its unknown opponent through play. In the next section we present a formalization of opponent models and then show how a specific opponent model can be inferred from opponent decisions.

4. OPPONENT MODELING

In the previous section we showed the improvement gained by using a generic model of the opponent. In this section we formalize a notion of an opponent model and how generic models can be constructed. A simple way to distinguish between two players is based on their evaluation function they use at the leaves of a search tree, that is, their relative utility of the different possible outcomes in the game. If an opponent has a total ordering for the possible outcomes in a game, we can use this information to simulate the decisions they would make in a game. In practice, a player may be ambivalent between two similar states. Thus, we model an opponent with a partial ordering defining their preferences over the possible outcomes in the game.

Formally, an *opponent model*, is a directed graph where the vertices are possible outcomes of the game. Edges are then used to encode the preference relationship. We define an opponent model, O, only by its edge set. In particular, $(u, v) \in O$ (*i.e.*, is an edge in the graph) if and only if u is preferred to v by the player being modeled. The graph thus provides a partial ordering over game outcomes. We assume the graph is closed under transitivity. In other words, if $(u, v) \in O$ and $(v, w) \in O$ then $(u, w) \in O$. Since preferences are necessarily transitive, we can always add edges into any model to form its transitive closure.

Two example opponent models are shown for two-trick Spades in Figure 3. There are six possible ways the two tricks can be taken in the game, which are shown on the left side of the figure. If Player 1 bids one, the models for maximizing tricks and minimizing overtricks are shown on the right. If the first player is trying to maximize tricks, they will prefer outcome 6 where they get two tricks, to all other outcomes. Outcomes 4 and 5 where they get one trick, would be preferred to outcomes 1, 2 and 3, where they get none. If Player 1 instead wants to minimize overtricks, they will have a slightly different model. Player 1 would prefer outcomes 4 and 5 to all other outcomes, and outcome 6 to outcomes 1, 2, and 3. For many domains, like Spades, the number of possible outcomes is relatively small and can be enumerated in a graph. In domains where this is not possible, the graph can be represented and reasoned over implicitly.

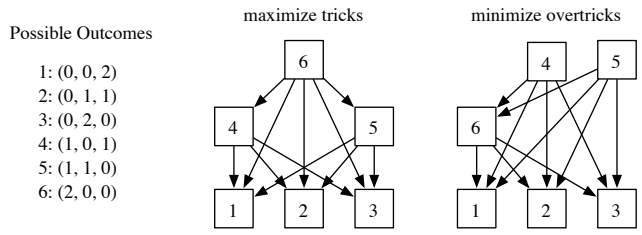

Figure 3: Two example opponent models for a tiny version of Spades.

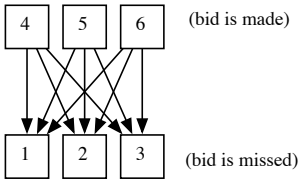

Figure 4: The *generalization* of the models from Figure 3.

It is likely that a player will not have a specific model of his opponent. The player, though, may have a set of candidate models, $O_1, \ldots, O_k$, believing that one of these models accurately captures the opponent's preferences. We saw in Table 2 that an incorrect model can have devastating effects on the quality of play. We also saw that soft-max^n with very generic assumptions about the opponents' preferences can greatly improve play. This suggests that given a set of candidate models we want to construct the *generalization* of these models. This generalization should (i) be as specific as possible, and (ii) be consistent with all of the candidate models. We can achieve this generalization by simple intersection:

$$G(O_1, \ldots, O_k) = \bigcap_{i=1}^{k} O_i.$$

Hence, $(u, v) \in G(O_1, \ldots, O_k)$ if and only if $\forall i\, (u, v) \in O_i$. In other words, u is preferred to v in the generalization if and only if u is preferred to v in all of the candidate models.

In Figure 4 we demonstrate the generalization of the models from Figure 3. In this case, the generalization of the two candidate models results in a model where the opponent prefers outcomes in which they make their bid, but it does not tell us anything beyond that.

4.1 Opponent Modeling and Soft-Max^n

Given an opponent model, it is easy to make use of it in soft-max^n by simply defining a dominance rule on max^n sets. Let s_1 and s_2 be max^n sets. We say s_1 strictly dominates s_2 under opponent model O, if and only if,

$$\forall u_1 \in s_1\ \forall u_2 \in s_2 \quad (u_1, u_2) \in O,$$

and weakly dominates, if and only if,

$$\begin{aligned} &\forall u_1 \in s_1\ \forall u_2 \in s_2 \qquad (u_2, u_1) \notin O \quad \text{and} \\ &\exists u_1 \in s_1\ \exists u_2 \in s_2 \qquad (u_1, u_2) \in O. \end{aligned}$$

These definitions of domination can now be used in the soft-max^n search for any given opponent model. Given a set of candidate opponent models, we can also construct the generalization of these models and use that model with soft-max^n.

Table 4: The effect of generalized opponent models on play.

	Players	Player A				Player B	
	A v. B	Score	%Win	%Gain	%Loss	Score	%Win
(a)	mOT_g v. MT_{mOT}	241.7	68.5	15.0	6.8	178.2	31.5
(b)	mOT_g v. MT_{MT}	218.2	53.5	9.5	5.5	206.1	46.5
(c)	mOT_g v. mOT_{MT}	242.2	54.8	4.8	8.0	228.7	45.2
(d)	mOT_g v. mOT_{mOT}	230.6	46.0	8.8	4.0	243.8	54.0

In domains where we cannot explicitly enumerate all possible outcomes in a game, we can instead use a functional model to provide the same information that we are getting from our explicit models in Spades.

4.2 Inferring Opponent Models

Without a specific opponent model we have shown that effective play can be obtained by generalizing a set of candidate models. During the course of a game, though, we actually observe our opponents' decisions. This opens up the possibility of inferring models of our opponents' preferences from observations of their choices. This is no easy task, as it is not generally possible from observations to distinguish between a player's preference over outcomes and simple indifference. Any decision of the opponent can always be explained as some tie-breaking mechanism on outcomes over which the player has no preference. Inference *ex nihilo* may be ill-defined, but inference based on a set of candidate models can still be done.

Given a set of candidate opponent models and a game with decisions by the opponents, we can identify which models are consistent with their actual decisions, and more importantly which are not. This will not identify which model best captures their preferences, but it can be used to eliminate models which certainly do not capture their preferences.[5] Eliminating these models will make the generalization of the remaining candidates more specific to the actual opponent. For example, near the end of a hand of Spades one may observe the opponent play their final cards so as to avoid taking a second overtrick, which they could have guaranteed taking. From this one can infer that the maximizing tricks model is inconsistent and eliminate it from the candidates. If maximizing tricks and minimizing overtricks were the only two candidates, one would then be certain the opponent minimizes overtricks. In later hands, this more specific model of the opponent can be used.

In order to perform this consistency check we need to reconstruct the actual decisions an opponent faced during the game. We can do this by running soft-max^n with generalized models for all of the players, including ourselves. Hence for any opponent decision we will have max^n sets, which we know contain the possible outcomes the opponent was deciding between. Let s_1 and s_2 be two sets the opponent decided between, where the actual decision was the action associated with s_1. This decision is definitely inconsistent with opponent model O if,

$$\forall u_1 \in s_1 \; \forall u_2 \in s_2 \quad (u_2, u_1) \in O.$$

We can perform this consistency check for every candidate model, for every opponent, for every decision that they made. For each opponent, we eliminate inconsistent models and recompute the generalization of the remaining models to be used in future soft-max^n searches against this opponent.

[5]This is essentially version-space learning [11] where the hypotheses are partial orderings and the training data are decisions the agent has made.

LEMMA 2. *If our opponent is described by some opponent model O_i and it is common knowledge that all players' preferences are consistent with the generalized model $G(O_1, \ldots, O_k)$, then our inference is sound, i.e., we will not eliminate O_i.*

Proof. By Lemma 1 we know that soft-max^n's values for each node in the tree is a superset of all equilibria consistent with the generalized opponent model. Let the opponent's decision for some node in the tree be between set s_1' and s_2', where s_1' was the set that was chosen. Let s_1 and s_2 be the soft-max^n sets for this node. Due to the common knowledge assumption, the soft-max^n sets must be supersets, i.e., $s_1' \subseteq s_1$ and $s_2' \subseteq s_2$. For purposes of contradiction, let s_2 strictly dominate s_1 under O_i, thus making the opponent's decision inconsistent with the model. By the definition of strict domination and the superset relation, since s_2 strictly dominates s_1 under O_i, then s_2' must strictly dominate s_1 and therefore s_2' must strictly dominate s_1'. Thus all outcomes in s_2' are preferred to s_1', and the opponent could not make this decision. □

4.3 Inference Experiments

To show the effectiveness of inference in Spades, we created 3 player types, which we refer to as MT, mOT and ML. As before, the MT player prefers outcomes where more tricks are taken. The mOT player tries to avoid overtricks. The ML player first tries to make their bid. But, among the set of hands where the bid is made or lost, the ML player tries to maximize the number of opponents that miss their bid.

In these games, one player was trying to infer the types of the other players only by observing their decisions. There are 9 ways to combine the 3 opponent types for the two opponents not doing inference, so we played 100 hands for each of these combinations for a total of 900 hands. Over these hands we were able to make 423 inferences about opponent types, although several times we made the same inference about player types multiple times in the same hand.

Because ML can look like both MT and mOT at times, it was the hardest to distinguish. We were only able to rule it out for a player in 51 of the overall hands. We were able to rule out mOT and MT, though, 106 and 103 times respectively. Combined, we successfully made an inference about an opponent in about one in six hands. Correct opponent inferences allow us to use a more specific model in soft-max^n resulting in 4–8% improvements in win percentage based on the results in Tables 2 and 3.3. The average number of hands per game in these results was 15, so this simple notion of consistency is fast enough to allow us to make game-altering inferences about our initially unknown opponents.

4.4 Generalizing Domains

Given that we have based so much of our discussion and experimentation on the game of Spades, it may not be immediately obvious how these results can be generalized. Spades makes a good example because we can easily divide the space of outcomes into two parts – those outcomes in which a player makes their bid, and

those outcomes in which they don't. Additionally, it is easy to enumerate all outcomes that can ever occur in a Spades game, and then reason over those outcomes.

But, consider the general case where each player has a utility in the range $\{0...1\}$. In this case there are, in theory, an infinite number of possible outcomes which we would like to reason over. In practice, however, we can reduce the number of possible outcomes using a clustering algorithm, or even more simply, just by dividing the space of possible utilities into discrete divisions. We can then assume that opponents are indifferent between outcomes within each cluster or division.

This is the opposite approach from what is normally taken in two-player zero-sum games. In these games more accurate utilities, often from increased depth of search, have been directly correlated with better play. But, in multi-player games we are seeing the opposite effect. That is, the more accurately we try to model our opponent's utilities, the more likely we are to make a mistake in our modeling. Thus, we want more generic models of our opponent that can tolerate small errors.

Thus, the benefits of soft-max^n may be even more apparent in domains where the number of possible outcomes is larger. Recent work in 4-player chess [9] suggests that max^n does not perform well in this domain because it does not consider minor collaborations which could lead to the max^n player losing the game very quickly. It would be interesting to see if soft-max^n with a generic opponent model could overcome these shortcomings.

5. CONCLUSIONS AND FUTURE WORK

In this paper we have proposed a new algorithm, soft-max^n, for playing multi-player games. Soft-max^n avoids many of the drawbacks of the max^n algorithm, particularly in the face of unknown opponents. Additionally, we have shown how we can use soft-max^n to make inferences about the types of opponents we are playing.

This work forms a very promising foundation for future work in multi-player game-playing. There are still two outstanding issues that must be addressed before soft-max^n can result in human competitive play. The first is to develop less brittle inference. Although we prove the soundness of our technique, human play will not likely correspond to any of our preselected opponent models. In fact, it may not be consistent with *any* opponent model, as it may depend upon external, unobserved circumstances. Hence, our inference could actually eliminate all candidate models in the course of a few hands, leaving no opponent model available for use with soft-max^n. We are currently exploring the replacement of our symbolic reasoning with a more probabilistic approach to mitigate this problem. The second issue is the extension of soft-max^n to imperfect information, which is a common feature of multi-player games. Although Monte-Carlo sampling will allow us to handle the uncertainty during play, the effect of imperfect information on inference still needs to be addressed.

Finally, we are also working to understand the trade-off between the deeper search allowed by max^n pruning algorithms, and the more informed search performed by soft-max^n. It appears that both approaches have their strengths, depending on the situation at hand. Future work is still needed to better understand and classify the relative strengths of each approach.

ABSTRACT

We contribute Policy Reuse as a technique to improve a reinforcement learning agent with guidance from past learned similar policies. Our method relies on using the past policies as a probabilistic bias where the learning agent faces three choices: the exploitation of the ongoing learned policy, the exploration of random unexplored actions, and the exploitation of past policies. We introduce the algorithm and its major components: an exploration strategy to include the new reuse bias, and a similarity function to estimate the similarity of past policies with respect to a new one. We provide empirical results demonstrating that Policy Reuse improves the learning performance over different strategies that learn without reuse. Interestingly and almost as a side effect, Policy Reuse also identifies classes of similar policies revealing a basis of *core* policies of the domain. We demonstrate that such a basis can be built incrementally, contributing the learning of the structure of a domain.

1. INTRODUCTION

We introduce Policy Reuse as a technique for reinforcement learning guided by past policies. Policy Reuse balances among exploitation of the ongoing learned policy, exploration of random actions, and exploration of the past policies. The exploration versus exploitation tradeoff defines whether to explore unseen parts of the space or to exploit the knowledge already acquired during the learning process. Several strategies, such as ϵ-greedy, Boltzmann or directed exploration [16], have been developed to balance this tradeoff. However these strategies only exploit knowledge obtained in the current learning process.

Several methods aim at improving learning by introducing additional knowledge into the exploration choices. Advice rules [7] define the actions to be preferred in different sets of states. The user provides the advice rules. Different knowledge sources can be used, for example through learning policies by imitation [10]. Other algorithms introduce previous knowledge through macro-actions or sub-policies. Macro-actions can be used to learn new action policies in Semi-Markov Decision Processes (SMDPs) [18]. Options can also be used in SMDPs by learning their behavior on line [13].

Hierarchical RL uses different abstraction levels to organize subtasks [3], and some approaches are able to learn such a hierarchy [6]. The methods for learning hierarchies or options capture the structure of the domain. Some related algorithms are SKILL [17], which discovers partially defined policies that arise in the context of multiple tasks in the same domain, and L-Cut, which discovers subgoals and corresponding sub-policies [12]. Sub-policies can suboptimally solve a task with computable bounds [1].

Transfer learning, as knowledge reuse across different learning task, can be performed by initializing the Q-values of a new episode with previously learned Q-values [2, 8]. However if the source and target tasks are very different, transfer learning requires expert knowledge to decide on the feasibility of the transfer, and on the mapping between actions and states from the source and target tasks [14, 15]. Value function transfer is an alternative but it is restricted to previous learning processes performed also through a value function.

In this paper we contribute Policy Reuse, a reinforcement learning method in which learned policies are saved and reused for similar tasks. The main algorithm of Policy Reuse is the PRQ-Learning algorithm, a method to probabilistically reuse a set of past policies that solve different tasks within the same domain. The PRQ-Learning algorithm has two main ideas. First, we introduce the π-reuse exploration strategy, which is able to probabilistically bias the exploration to include a given predefined past policy; and second, we introduce the similarity function that allows the estimation of the usefulness of past policies with respect to learning a new task.

We further present the PLPR algorithm, an incremental method to build a library of policies. When solving a new problem by policy reuse, the PLPR algorithm determines how different the learned policy is from the past policies as a function of the effectiveness of the reuse. If the past and new policies are "sufficiently" different, PLPR decides to add the new policy to the library of policies. Otherwise, it does not. PLPR is therefore capable of identifying a set of "core" policies that need to be saved to solve any new task in the domain within a threshold of similarity, δ. Given δ, our algorithm identifies a set of "δ-core-policies," as the basis or learned structure of the domain. Thus our method

to build the Policy Library has a novel "side-effect" in terms of learning the structure of the domain, i.e., the basis or the core policies of the domain.

In summary, Policy Reuse contributes to the overall goal of a lifelong reinforcement learning agent, as (i) it provides a mechanism to reuse past policies; (ii) it incrementally builds a policy library; and (iii) it learns an abstract domain structure in terms of core policies of the domain.

The paper is organized as follows. Section 2 introduces Policy Reuse for a reinforcement learning agent. Section 3 defines the π-reuse exploration strategy and presents experiment results in a large robot navigation domain. Section 4 formalizes the similarity metric among policies and introduces the PRQ-Learning algorithm. Section 5 presents the PLPR algorithm. Lastly, Section 6 draws conclusions.

2. POLICY REUSE IN REINFORCEMENT LEARNING

Reinforcement Learning problems are typically formalized using Markov Decision Processes (MDPs). An MDP is a tuple $< \mathcal{S}, \mathcal{A}, \mathcal{T}, \mathcal{R} >$, where $\mathcal{S}$ is the set of states, $\mathcal{A}$ is the set of actions, $\mathcal{T}$ is a stochastic state transition function, $\mathcal{T} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \Re$, and $\mathcal{R}$ is a stochastic reward function, $\mathcal{R} : \mathcal{S} \times \mathcal{A} \rightarrow \Re$. RL assumes that $\mathcal{T}$ and $\mathcal{R}$ are unknown.

We focus in RL domains where different *tasks* can be solved. The MDP's formalism is not expressive enough to represent all the concepts involved in knowledge transfer [11], so we define domain and task separately to handle different tasks executed in the same domain. We introduce a task as a specific reward function, while the other concepts, $\mathcal{S}$, $\mathcal{A}$ and $\mathcal{T}$ stay constant for all the tasks in the same domain. We characterize a domain, $\mathcal{D}$, as a tuple $< \mathcal{S}, \mathcal{A}, \mathcal{T} >$. We define a task, Ω, as a tuple $< \mathcal{D}, \mathcal{R}_\Omega >$, where $\mathcal{D}$ is a domain as previously defined, and $\mathcal{R}_\Omega$ is the stochastic and unknown reward function.

Definition 1. *A Domain $\mathcal{D}$ is a tuple $< \mathcal{S}, \mathcal{A}, \mathcal{T} >$, where $\mathcal{S}$ is the set of all states; $\mathcal{A}$ is the set of all actions; and $\mathcal{T}$ is a state transition function, $\mathcal{T} : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \rightarrow \Re$.*

Definition 2. *A task Ω is a tuple $< \mathcal{D}, \mathcal{R}_\Omega >$, where $\mathcal{D}$ is a domain; and $\mathcal{R}_\Omega$ is the reward function, $\mathcal{R} : \mathcal{S} \times \mathcal{A} \rightarrow \Re$.*

We assume that we are solving episodic tasks with absorbing goal states. Thus if s_i is a goal state, the probability of transitioning to the same state is 1 ($\mathcal{T}(s_i, a, s_i) = 1$), hence the transition probability to a different state is 0 ($\mathcal{T}(s_i, a, s_j) = 0$ for $s_i \neq s_j$), and the immediate reward is 0 ($\mathcal{R}(s_i, a) = 0$, for all $a \in \mathcal{A}$).

A trial or episode starts by locating the learning agent in a random position in the environment. Each episode finishes when the agent reaches a goal state or when it executes a maximum number of steps, H. The agent's goal is to maximize the expected average reinforcement per episode, W, as defined in equation 1:

$$W = \frac{1}{K} \sum_{k=0}^{K} \sum_{h=0}^{H} \gamma^h r_{k,h} \quad (1)$$

where γ ($0 \leq \gamma \leq 1$) reduces the importance of future rewards, and $r_{k,h}$ defines the immediate reward obtained in the step h of the episode k, in a total of K episodes.

An action policy, Π, is a function $\Pi : \mathcal{S} \rightarrow \mathcal{A}$ that defines how the agent behaves. If the action policy was created to solve a defined task, Ω, we call that action policy Π_Ω. The gain, or average expected reward, received when executing an action policy Π in the task Ω is called W_Ω^Π. Lastly, an optimal action policy for solving the task Ω is called Π_Ω^*. The action policy Π_Ω^* is optimal if $W_\Omega^{\Pi_\Omega^*} \geq W_\Omega^\Pi$, for all policy Π in the space of all possible policies when $K \rightarrow \infty$. Action policies can be represented using the action-value function, $Q^\Pi(s, a)$, which defines for each state $s \in \mathcal{S}$, $a \in \mathcal{A}$, the expected reward that will be obtained if the agent starts to act from s, executing a, and after it follows the policy Π. So, the RL problem is mapped to learning the function $Q^\Pi(s, a)$ that maximizes the expected gain. The learning can be performed using different algorithms, such as Q-Learning [19].

The goal of Policy Reuse is to use different policies, which solve different tasks, to bias the exploration process of the learning of the action policy of another similar task in the same domain. We call Policy Library to the set of past policies, as defined next.

Definition 3. *A Policy Library, L, is a set of n policies $\{\Pi_1, \ldots, \Pi_n\}$. Each policy $\Pi_i \in L$ solves a task $\Omega_i =< \mathcal{D}, \mathcal{R}_{\Omega_i} >$, i.e., each policy solves a task in the same domain.*

The previous definition does not restrict the characteristics of the tasks (they may be repeated), nor the characteristics of the policies (they may be sub-optimal). The scope of Policy Reuse is summarized as: we want to solve the task Ω, i.e., learn Π_Ω^*; we have previously solved the set of tasks $\{\Omega_1, \ldots, \Omega_n\}$ with n policies stored as a Policy Library, $L = \{\Pi_1, \ldots, \Pi_n\}$; how can we use the policy library, L, to learn the new policy, Π_Ω^*?

Policy Reuse answers this question by adding the past policies into a learning episode as an probabilistic exploration bias. We define an exploration strategy able to bias the exploration process towards the policies of the Policy Library, and a method to estimate the utility of reusing each of them and to decide whether to reuse them or not. Furthermore, Policy Reuse provides an efficient method to construct the Policy Library. We now detail the Policy Reuse approach.

3. REUSING A PAST POLICY

We now describe how one policy that solves a particular task can be used to bias the learning of an action policy for a similar task. Formally, we want to solve a new task Ω, i.e., learn Π_Ω^*. We assume that we are given a Policy Library, say $L = \{\Pi_1, \ldots, \Pi_n\}$ and that there is an oracle that returns Π_{past} as the most similar past policy to Π_Ω^*. We present how our algorithm reuses the policy Π_{past}.

Section 4 later defines a similarity metric between policies for different tasks, and introduces how to automatically estimate the policy to reuse.

3.1 The π-reuse Exploration Strategy

The π-reuse strategy is an exploration strategy able to bias a new learning process with a past policy. Let Π_{past} be the past policy to reuse and Π_{new} the new policy to be learned. We assume that we are using a direct RL method to learn the action policy, so we are learning the related Q function. Any RL algorithm can be used to learn the Q function, with the only requirement that it can learn off-policy, i.e., it can learn a policy while executing a different one, as Q-Learning does [19].

The goal of π-reuse is to balance random exploration, exploitation of the past policy, and exploitation of the new policy, as represented in Equation 2.

$$a = \begin{cases} \Pi_{past}(s) & \text{w/prob. } \psi \\ \epsilon - greedy(\Pi_{new}(s)) & \text{w/prob. } (1-\psi) \end{cases} \quad (2)$$

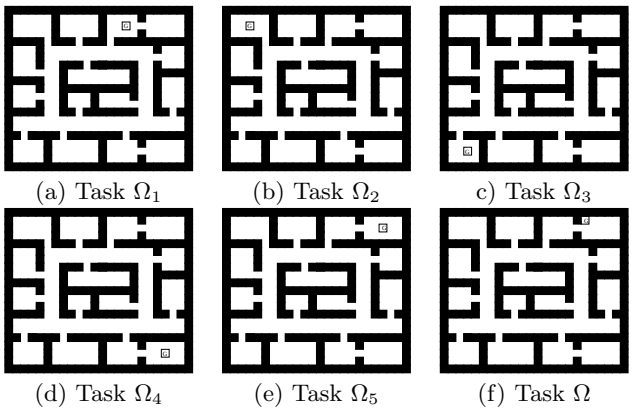
The π-reuse strategy follows the past policy with probability ψ, and it exploits the new policy with probability of $1-\psi$. As random exploration is always required, it exploits the new policy with an ϵ-greedy strategy.

Table 1 shows a procedure describing the π-reuse strategy integrated with the Q-Learning algorithm. The procedure gets as an input the past policy Π_{past}, the number of episodes K, the maximum number of steps per episode H, and the ψ parameter. An additional υ parameter is added to decay the value of ψ in each step of the learning episode. The procedure outputs the Q function, the policy, and the average gain obtained in the execution, W, which will play an important role in similarity assessment, as the next sections present. The variable ψ_h keeps the value of $\upsilon^h\psi$ in each step of each episode.

π-reuse ($\Pi_{past}, K, H, \psi, \upsilon$).
Initialize $Q^{\Pi_{new}}(s,a) = 0$, $\forall s \in \mathcal{S}, a \in \mathcal{A}$
For $k = 0$ to $K-1$
Set the initial state, s, randomly.
Set $\psi_1 \leftarrow \psi$
for $h = 1$ to H
With a probability of ψ_h, $a = \Pi_{past}(s)$
With a probability of $1-\psi_h$, $a = \epsilon$-greedy$(\Pi_{new}(s))$
Receive the next state s', and reward, $r_{k,h}$
Update $Q^{\Pi_{new}}(s,a)$, and therefore, Π_{new}:
$Q^{\Pi_{new}}(s,a) \leftarrow (1-\alpha)Q(s,a)^{\Pi_{new}} +$
$\alpha[r + \gamma \max_{a'} Q^{\Pi_{new}}(s',a')]$
Set $\psi_{h+1} \leftarrow \psi_h \upsilon$
Set $s \leftarrow s'$
$W = \frac{1}{K}\sum_{k=0}^{K}\sum_{h=0}^{H}\gamma^h r_{k,h}$
Return W, $Q^{\Pi_{new}}(s,a)$ and Π_{new}

Table 1: π-reuse Exploration Strategy.

3.2 Experiments



We describe the experiments performed to demonstrate the usefulness of the π-reuse exploration strategy. We first describe the experimental domain used.

3.2.1 Robot Navigation Domain

We use a grid-based robot navigational domain (see Figure 1) with multiple rooms. The environment is represented by walls, free positions and goal areas, all of them of size 1×1. The whole domain is $N \times M$ (24×21 in our case). The actions that the robot can execute are "North," "East," "South," and "West", all of size one. The final position after executing an action is noised by adding to the new position a random value that follows a uniform distribution in the range $(-0.20, 0.20)$.

Walls block the robot's motion, i.e., when the robot tries to execute an action that would crash it into a wall, the action keeps the robot in its original position.

The robot knows its location in the space through continuous coordinates (x, y). We assume that we have the optimal uniform discretization of the state space (which consists of 24×21 regions) [1]. The goal in this domain is to reach the area marked with 'G', in a maximum of H actions. When the robot reaches it, it is considered a successful episode, and it receives a reward of 1. Otherwise, it receives a reward of 0.

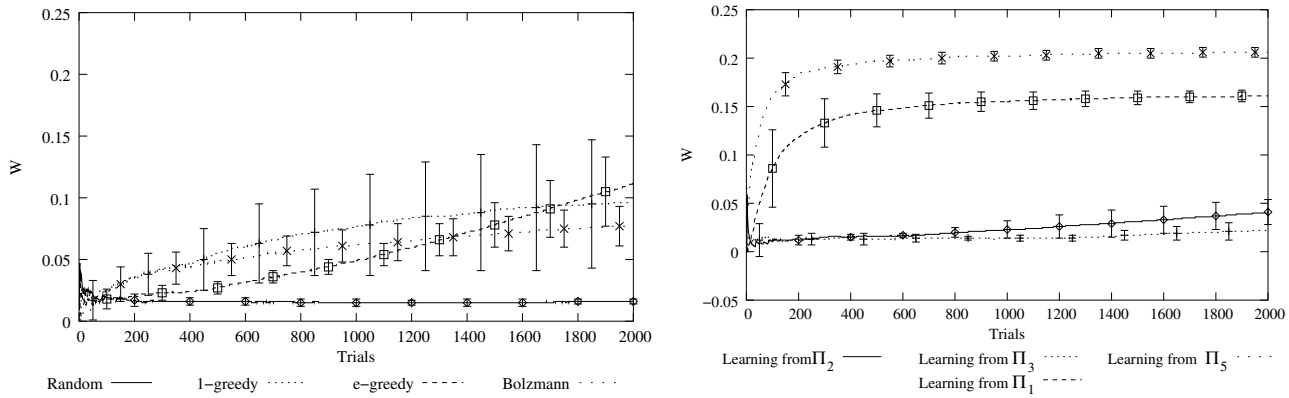
(a) Task Ω_1 (b) Task Ω_2 c) Task Ω_3

(d) Task Ω_4 (e) Task Ω_5 (f) Task Ω

Figure 1: Grid-based Office Domain

Figure 1 shows 6 different tasks, Ω_1, Ω_2, Ω_3, Ω_4, Ω_5 and Ω, given that the goal states, and therefore, the reward functions, are different. All these tasks are used in the experiments described in the next sections.

We choose the robot navigation domain for experimentation because it has been widely used in transfer learning papers (e.g., [17, 8, 11]). Transfer learning in more complex domains, as the Keepaway task in robot soccer, requires a mapping between tasks that use different state and action spaces [15, 14]. Such mapping requires a considerable amount of expert knowledge. Our ongoing research line includes the study of how our policy reuse algorithm can be extended to include transfer learning knowledge.



3.2.2 Results

We describe the experimental results of applying different exploration strategies for learning the task Ω, shown in Figure 1(f). Learning has been performed using the Q-Learning algorithm, for fixed parameters of $\gamma = 0.95$ and $\alpha = 0.05$, which empirically have demonstrated to be accurate for learning in this domain.

We analyze the learning performance in executing $K = 2000$ episodes. Each episode consists of following the defined strategy until the goal is achieved or until the maximum number of steps ($H = 100$) is reached. The x axis and the y axis show the episode or trial number and the average gain obtained respectively. A value of 0.2 for the episode 200 means that the average gain obtained in the first 200 episodes is 0.2. The results provided are the average of ten executions. Error bars provide the standard deviation in the ten executions.

The learning process has been first executed following different exploration strategies that do not use any past policy. Specifically, we have used four different strategies: (i) random; (ii) completely greedy; (iii) an ϵ-greedy (i.e., with probability ϵ follows the greedy strategy, and with probability $(1-\epsilon)$ acts randomly), with an initial value of $\epsilon = 0$, which is incremented by 0.0005 in each episode; (iv) the

[1] Different methods for function approximation have been successfully applied on this domain [4]. We have simplified the state space representation to a uniform discretization to focus on the study of Policy Reuse.

(a) Learning from Scratch (b) Learning with π-Reuse

Figure 2: Results of the learning process for different exploration strategies.

Boltzmann strategy ($P(a_j) = \frac{e^{\tau Q(s,a_j)}}{\sum_{p=1}^{n} e^{\tau Q(s,a_p)}}$), initializing $\tau = 0$, and increasing it by 5 in each learning episode.

Figure 2(a) shows the results. When acting randomly, the average gain in learning is almost 0, given that acting randomly is a very poor strategy. However when a greedy behavior is introduced, (strategy 1-greedy), the curve shows a slow increment, achieving values of almost 0.1. The curve obtained by the Boltzmann strategy does not offer significant improvements. The ϵ-greedy strategy seems to compute an accurate policy in the initial episodes, and it corresponds to the highest average gain at the end of the learning.

We then execute the learning with policy reuse. Figure 2(b) shows the learning curves of different learning processes performed with the π-reuse exploration strategy. In each of them, a different policy has been reused. In the first one, the policy reused is Π_5 ($\Pi_{past} = \Pi_5$), which is optimal to solve the task Ω_5. Such task has its goal into the same room as the goal of Ω. In the second case, $\Pi_{past} = \Pi_1$, which solved Ω_1. In the last two cases, $\Pi_{past} = \Pi_2$ and Π_3 respectively, whose associated tasks (Ω_2 and Ω_3) are very different when compared with Ω. All the reused policies are optimal for their respective tasks.

The parameters used in the Q-Learning update equation are the same as above ($\gamma = 0.95$ and $\alpha = 0.05$). The parameter setting for the π-reuse exploration strategy are $\psi = 1$, $\upsilon = 0.95$, and $\epsilon = 1 - \psi_h$. [2]

Figure 2(b) shows how, when biasing the exploration process for learning the task Ω with the policies Π_1 and Π_5, the obtained gain significantly increases within the first few episodes of the execution. For instance, when reusing Π_5, in only 100 iterations the average gain is higher than 0.15, and after 400 iterations the value stays around 0.2. When reusing Π_1, the gain is higher than 0.1 after only 200 episodes, and after 500 episodes it stays around 0.15. In both cases, the standard deviation is high in the initial episodes, but it approaches 0 in subsequent episodes.

However when the learning is biased with a very different policy, as Π_2 and Π_3, the average gain shown in Figure 2(a) is below 0.05, so the learning process is even worse than when learning from scratch.

The results show that reusing a past policy provides a bias in the exploration process which can speed up the learning when compared with learning from scratch. The improvement depends on whether the reused policy solves a task similar to the one we are currently learning. A similarity metric between tasks is hard to define even for a well structured domain.

Interestingly, we introduce a similarity metric between policies based on the usefuness of reuse. For instance, the results in Figure 2(b) show that the learning curves provide us information on the similarity between policies. In that figure, the gain obtained for each of the past policies can be understood as: (i) an estimation of how similar the policy reused is to the one we are currently learning; and (ii) an estimation of how useful the policy reused is in order to learn the new policy. Actually, the gain obtained by each past policy can be used to rank the similarity of the past policies with respect to the new one. In this case, the most similar policy to Π_Ω is Π_5, followed by Π_1, Π_2 and Π_3.

Furthermore, the gain estimated above can be computed very fast, and in only 25 episodes, the gain of reusing the policy Π_5 significantly outperforms the gain of reusing the other policies.

4. REUSING A LIBRARY OF POLICIES

We describe now the PRQ-learning algorithm for the efficient reuse of the policies stored in a Policy Library. We describe a similarity function that estimates the usefulness of reusing a specific policy for learning a new one.

4.1 A Similarity Function Between Policies

The exploration strategy π-reuse, as defined in Table 1, returns the learned policy Π_{new}, and the average gain obtained in its learning process, W. Let W_i be the gain obtained while executing the π-reuse exploration strategy, reusing the past policy Π_i. We can use such value to measure the usefulness of reusing the policy Π_i to learn the new policy Π_{new}. The next definitions formalize this idea.

Definition 4. *Given a policy Π_i that solves a task $\Omega_i =< \mathcal{D}, R_i >$, and a new task $\Omega =< \mathcal{D}, R_\Omega >$, the Reuse Gain of*

[2]This parameter setting has been chosen after an informal experimentation, so different values of the parameters could provide better results. However they are good enough to evaluate the algorithm and to move on the next steps of the research on Policy Reuse. Additional information about the properties of this parameter setting can be found in [5].

the policy Π_i on the task Ω, W_i, is the gain obtained when applying the π-reuse exploration strategy with the policy Π_i to learn the policy Π.

Then the most useful policy to reuse, Π_k, from a Library Policy, $L = \{\Pi_1, \ldots, \Pi_n\}$, is the one that maximizes the Reuse Gain when learning such a task, as defined in equation 3:

$$\Pi_k = \arg_{\Pi_i} \max(W_i), i = 1, \ldots, n \quad (3)$$

To solve this equation we need to compute the Reuse Gain for all the past policies. Interestingly, such a gain can be estimated on-line at the same time that the new policy is computed. This idea is formalized in the PRQ-Learning algorithm.

4.2 The PRQ-Learning Algorithm

The goal of the PRQ-learning algorithm is to solve a task Ω, i.e. to learn an action policy Π_Ω. We have a Policy Library $L = \{\Pi_1, \ldots, \Pi_n\}$ composed of n past optimal policies that solve n different tasks respectively. Then two main questions need to be answered: (i) given the set of policies $\{\Pi_\Omega, \Pi_1, \ldots, \Pi_n\}$, which consists of the policies in the Policy Library plus the ongoing learned policy, what policy is exploited? (ii) once a policy is selected, what exploration/exploitation strategy is followed?

The answer to the first question is as follows: let W_i be the Reuse Gain of the policy policy Π_i on the task Ω. Also, let W_Ω be the average reward that is received when following the policy Π_Ω greedily. The solution we introduce consists of following a softmax strategy using the values W_Ω and W_i, as defined in equation 4, with a temperature parameter τ. This value is also computed for Π_0, which we assume to be Π_Ω. Equation 4 provides a way to decide whether to exploit the past policies or the new one.

$$P(\Pi_j) = \frac{e^{\tau W_j}}{\sum_{p=0}^{n} e^{\tau W_p}} \quad (4)$$

The answer to the second question (what exploration strategy to follow once a policy is chosen) is an heuristic that depends on the selected policy. If the policy chosen is Π_Ω, the algorithm follows a completely greedy strategy. However, if the policy chosen is Π_i (for $i = 1, \ldots, n$), the π-reuse action selection strategy, defined in previous section, is followed instead. In this way, the Reuse Gain of each of the past policies can be estimated on-line with the learning of the new policy. Thus, the values required in Equation 4 are continuously updated each time a policy is used.

All these ideas are formalized in the PRQ-Learning algorithm (Policy Reuse in Q-Learning) shown in Table 2. The algorithm gets as input: a new task to solve Ω; the policy library L; the temperature parameter of the softmax policy selection equation τ, and a decay parameter $\Delta\tau$; and a set of previously defined parameters: $K, H, \psi, \upsilon, \gamma, \alpha$.

The algorithm initializes the new Q function to 0, as well as the estimated reuse gain of the policies in the library. Then the algorithm executes the K episodes iteratively. In each episode, the algorithm decides which policy to follow. In the first iteration, all the policies have the same probability to be chosen, given that all W_i values are initialized to 0. Once a policy is chosen, the algorithm uses it to solve the task, updating the Reuse Gain for such a policy with the reward obtained in the episode, and therefore, updating the probability to follow each policy. The policy being learned can also be chosen, although in the initial steps it behaves as a random policy, given that the Q values are initialized to 0. While new updates are performed over the Q function, it becomes more accurate, and receives higher rewards when executed. After executing several episodes, it is expected that the new policy obtains higher gains than reusing the past policies, so it will be chosen most of the time.

PRQL($\Omega, L, \tau, \Delta\tau, K, H, \psi, \upsilon, \gamma, \alpha$)

- Given:
  1. A new task Ω we want to solve
  2. A Policy Library $L = \{\Pi_1, \ldots, \Pi_n\}$
  3. An initial value of the temperature parameter, τ, and an incremental size, $\Delta\tau$, for the Boltzmann policy selection strategy
  4. A maximum number of episodes to execute, K
  5. A maximum number of steps per episode, H
  6. The parameters ψ and υ for the π-exploration strategy
  7. The parameters γ and α for the Q-learning update equation
- Initialize:
  1. $Q_\Omega(s, a) = 0, \forall s \in \mathcal{S}, a \in \mathcal{A}$
  2. Initialize W_Ω to 0
  3. Initialize W_i to 0
  4. Initialize the number of episodes where policy Π_Ω has been chosen, $U_\Omega = 0$
  5. Initialize the number of episodes where policy Π_i has been chosen, $U_i = 0, \forall i = 1, \ldots, n$
- For $k = 1$ to K do
  - Choose an action policy, Π_k, assigning to each policy the probability of being selected computed by the following equation (equation 4):
    $$P(\Pi_j) = \frac{e^{\tau W_j}}{\sum_{p=0}^{n} e^{\tau W_p}}$$
    where W_0 is set to W_Ω
  - Execute the learning episode k
    - If $\Pi_k = \Pi_\Omega$, execute a Q-Learning episode following a fully greedy strategy
    - Otherwise, use the π-reuse exploration strategy to reuse Π_k, i.e. call π-reuse($\Pi_k, 1, H, \psi, \upsilon$)
    - In any case, receive the reward obtained in that episode, say R, and the updated Q function, $Q_\Omega(s, a)$
  - Set $W_k = \frac{W_k U_k + R}{U_k + 1}$
  - Set $U_k = U_k + 1$
  - Set $\tau = \tau + \Delta\tau$
- Return the policy derived from $Q_\Omega(s, a)$

Table 2: PRQ-Learning.

4.3 Experiments

We present the experiments performed with the PRQ-Learning algorithm. We demonstrate three main claims: Firstly, that the performance can be improved if we can bias the exploration with past policies, even if we have several and we do not know apriori which one is the most similar and/or useful to reuse. Second, that it is possible to determine which is the most useful policy simultaneously while learning the new policy. And third, that a balance between

exploring, exploiting past policies, and exploiting the new policy being learned can be successfully achieved.

We use the PRQ-Learning algorithm for learning the task Ω, defined in Figure 1(f). We assume that we have 3 different libraries of policies, so we distinguish three different cases. In the first one, the policy library is $L_1 = \{\Pi_2, \Pi_3, \Pi_4\}$, assuming that the tasks Ω_2, Ω_3 and Ω_4, defined in Figure 1(b), (c) and (d) respectively, were previously solved. All these tasks are very different from the one we want to solve, so their policies are not supposed to be very useful in learning the new one. In the second case, Π_1 is added, so $L_2 = \{\Pi_1, \Pi_2, \Pi_3, \Pi_4\}$. The third case uses the Policy Library $L_3 = \{\Pi_2, \Pi_3, \Pi_4, \Pi_5\}$

The PRQ-Learning algorithm is executed for the three cases. The learning curves are shown in Figure 3. The parameters used are the same used in Section 3.2. The only new parameters are the ones of the Boltzmann policy selection strategy, $\tau = 0$, and $\Delta\tau = 0.05$, obtained empirically.

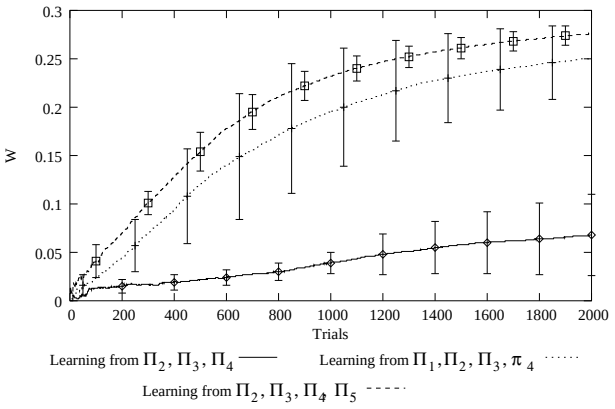


Figure 3: Learning curve when learning the task of Figure 1(f) reusing different sets of policies.

Figure 3 shows two main conclusions. Firstly, when a very similar policy is included in the set of policies to be reused, the improvement on learning is very high. For instance, when reusing Π_1 and Π_5, the average gain is greater than 0.1 in only 500 iterations, and more than 0.25 at the end of the episode. Secondly, when no similar policy is available, the learning curve is similar to the results obtained when learning from scratch with the 1-greedy strategy (which is the strategy followed by PRQ-Learning for the new policy, as defined by the PRQ-Learning algorithm). This demonstrates that the PRQ-learning algorithm has discovered that reusing the past policies is not useful, so it follows the best strategy available, which is to the 1-greedy strategy with the new policy.

In summary, we can say that the PRQ-learning algorithm has demonstrated to successfully reuse a predefined set of policies. The remaining issue consists of investigating how to acquire such a set of policies. The next section focuses on how an agent can build a library of policies.

5. BUILDING A LIBRARY OF POLICIES

We now describe the *PLPR* algorithm (Policy Library through Policy Reuse), an algorithm to build a library of policies. The algorithm is based on an incremental learning of policies that solve different tasks. The tasks to be solved are not known apriori, and are sequentially given. Otherwise, a method to learn them in parallel could be applied [9].

5.1 The PLPR Algorithm

The PLPR algorithm works as follows. Initially the Policy Library is empty, $PL = \emptyset$. When the first task Ω_1 is solved, the corresponding learned policy Π_1 is learned without reuse. Π_1 is added to the Policy Library and $PL = \{\Pi_1\}$. When a second task needs to be solved, the PRQ-Learning algorithm is applied reusing Π_1. Π_2 is learned. The algorithm makes a decision on whether to add Π_2 to the Policy Library or not. This decision is based on how similar Π_1 is to Π_2, following the similarity function we now introduce.

Definition 5. *Given a policy, Π_i that solves a task $\Omega_i =< \mathcal{D}, R_i >$, a new task $\Omega =< \mathcal{D}, R_\Omega >$, and its respective optimal policy, Π, Π is δ-similar to Π_i (for $0 \leq \delta \leq 1$) if $W_i > \delta W^*_\Omega$, where W_i is the Reuse Gain of Π_i on task Ω and W^*_Ω is the average gain obtained in Ω when an optimal policy is followed.*

The interesting aspect of this concept is that for any optimal policy Π, if we know a past policy which is δ-similar to it, we also know that such optimal policy can be easily learned just by applying the π-reuse algorithm with the past policy. The gain obtained in the learning process (the reuse gain) will be at least δ times the maximum gain in such a task. From this definition, we can formalize the concept of δ-similarity with respect to a Policy Library, L.

Definition 6. *Given a Policy Library, $L = \{\Pi_1, \ldots, \Pi_n\}$ in a domain $\mathcal{D}$, a new task $\Omega =< \mathcal{D}, R_\Omega >$, and its respective optimal policy, Π, Π is δ-similar with respect to L iff $\exists \Pi_i$ such as Π is δ-similar to Π_i, for $i = 1, \ldots, n$.*

If the algorithm finds that a policy Π is δ-similar with respect to a Policy Library L, then it knows that the policy Π can be easily learned by reusing the policies in L. Table 3 presents the PLPR algorithm, which is executed each time that a new task needs to be solved. It gets as an input the Policy Library and the new task to solve, and outputs the learned policy and the updated Policy Library.

PLPR Algorithm

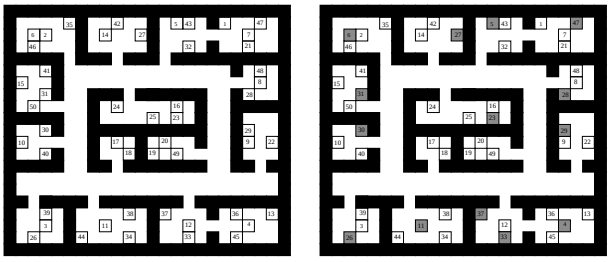
- Given:
  1. A Policy Library, L, composed of n policies, $\{\Pi_1, \ldots, \Pi_n\}$
  2. A new task Ω we want to solve
  3. A δ parameter
- Execute the PRQ-Learning algorithm reusing L. Receive from this execution Π_Ω, W_Ω and W_{max}, where:
  - Π_Ω is the learned policy
  - W_Ω is the average gain obtained when the policy Π_Ω was followed
  - $W_{max} = \max W_i$, for $i = 1, \ldots, n$
- Update PL using the following equation:

$$L = \begin{cases} L \cup \{\Pi_\Omega\} & \text{if } W_{max} < \delta W_\Omega \\ L & otherwise \end{cases} \quad (5)$$

Table 3: PLPR Algorithm.

Equation 5 is the update equation for the Policy Library. It requires the computation of the most similar policy in the

library, which is the policy Π_j such as $j = \arg_i \max W_i$, for $i = 1, \ldots, n$. W_{max} is the gain obtained by reusing such a policy. The new policy learned is inserted in the library if W_{max} is lower than δ times the gain obtained by using the new policy (W_Ω), where $\delta \in [0, 1]$ defines the similarity threshold, i.e., whether the new policy is δ-similar with respect to the Policy Library.



The parameter δ hence plays an important role. If $\delta = 0$, the Policy Library stores only the first policy learned, given that the average gain obtained by reusing it will be greater than zero in most cases, due to the positive rewards obtained by chance. If $\delta = 1$, most of the policies learned are inserted, as $W_{max} < W_\Omega$, given that W_Ω is maximum if the optimal policy has been learned. Different δ values in the range $(0, 1)$ provide different sizes of the library. Thus δ defines the "resolution" of the library.

The PLPR algorithm has an interesting side effect in terms of learning the structure of the domain. The Policy Library is initialized to empty, and a new policy is included only if it is different *enough* (depending on the δ threshold) from the previously stored ones. When the policies stored are *fully representative* of the domain, no more policies are stored. Therefore the obtained library can be considered as the *Basis-Library* of the domain, and the stored policies can be considered as the *core-policies* of such domain.

5.2 Experiments

We present the experiments performed to learn a Basis-Library in the navigation domain (Section 3). We perform a task consisting of the executing $K = 2000$ episodes. Like in the previous experiments, each episode consists of a sequence of actions until the goal is achieved or until the maximum number of actions, $H = 100$, is reached.

A number, 50, of different tasks are sequentially performed, each of them with a different goal area, located in different positions of the different rooms of the domain, as shown in Figure 4(a). The figure does not represent a unique task with 50 different goals, but the 50 different goal areas of the 50 different tasks. The results provided are the average of 10 different executions, in which the 50 different tasks are sequentially performed following a random order. In these experiments, we use the same parameter settings as earlier (see Section 4.3).

(a) 50 different goal areas (b) Core-Policies

Figure 4: Office Domain.

The first element to study is the size of the Policy Library built while performing the tasks with the PLPR algorithm, i.e., the number of core-policies stored in the Policy Library. Figure 5 shows in the y axis the size of the Policy Library, and in the x axis, the number of tasks performed up to that moment. As introduced above, when $\delta = 0$, only 1 policy is stored. When $\delta = 0.25$, the number of core-policies is around 14. Interestingly, this is very close to the number of rooms in the domain (15). While increasing δ, the number of core-policies increases and when $\delta = 1$, almost all the learned policies are stored.

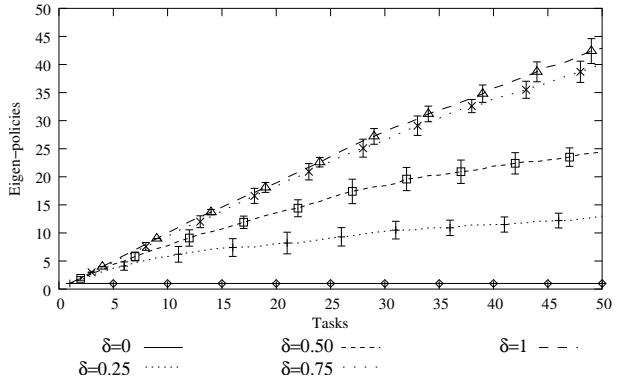


Figure 5: Number of eigen-policies obtained.

Figure 4(b) shows an example of the core-policies obtained in one of the executions with $\delta = 0.25$. The figure represents the resulting Policy Library composed of 14 core-policies. In the figure, we assume that a policy is represented by the goal area of the task that it solves. A core-policy is represented also by a shaded goal area. The figure demonstrates that one and only one core-policy has been learned for most of the rooms. The algorithm has discovered that if two different tasks are given two goal areas in the same room, their respective policies are very similar, so only one of them needs to be stored in the Policy Library. We therefore observe that the PLPR algorithm learns the *structure* of the domain as represented by the core-policies.

Figure 6 shows the average gain obtained when performing the 50 different tasks with the PLPR algorithm, for the different values of δ. In most of the cases, $\delta = 0.25, 0.50, 0.75$ and 1, the average gain increases up to more than 0.2, and no significant differences exist between them. Only in the case of $\delta = 0$, the average gain stays low, around 0.16, given that $\delta = 0$ generates a Policy Library with only one policy (the first one learned).

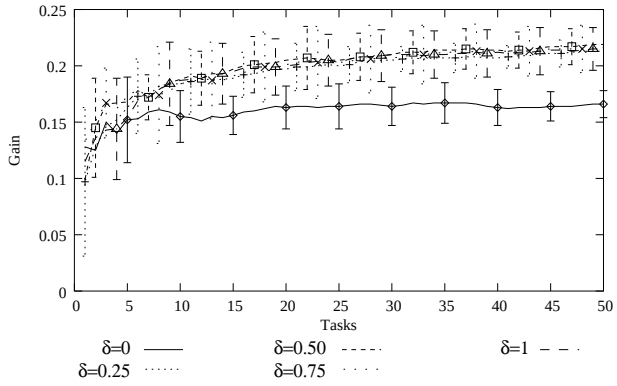

Figure 6: Results of PLPR.

For comparison purposes, we executed the same learning process with different exploration strategies as learning from scratch. In those cases, while new policies are learned from scratch, the average gain obtained stabilizes around 0.12 for all the strategies, without very significant differences. Therefore, Policy Reuse can almost reach a 100% gain in the performance of the 50 tasks over the results obtained when the 50 tasks are learned from scratch.

6. CONCLUSIONS

We have introduced different algorithms to address the main challenges of policy reuse in a reinforcement learning agent. First, the PRQ-Learning algorithm allows to probabilistically bias an exploration learning process by reusing a Policy Library; the algorithm significantly improves the learning performance over exploration strategies that learn from scratch. Second, the PLPR algorithm incrementally builds the Policy Library; the library is built at the same time as new policies are learned and past policies are reused. And last, our method to build the Policy Library allows the learning of the structure of the domain in terms of a set of core-policies.

Future ongoing research includes the extension of Policy Reuse to reuse across different representational frameworks, including different agents or domains. We envision multiple agents sharing and reusing policies previously learned to improve the solvability horizon of individual non-reuse based learning agents.

ABSTRACT

Multi-agent learning is a growing area of research. An important topic is to formulate how an agent can learn a good policy in the face of adaptive, competitive opponents. Most research has focused on extensions of single agent learning techniques originally designed for agents in more static environments. These techniques however fail to incorporate a notion of the effect of own previous actions on the development of the policy of the other agents in the system. We argue that incorporation of this property is beneficial in competitive settings. In this paper, we present a novel algorithm to capture this notion, and present experimental results to validate our claims.

General Terms

Multi-Agent Learning

Keywords

Multi-Agent RL, Opponent Modeling, Learning Reactions to Actions

1. INTRODUCTION

Acting intelligently in a dynamic environment shared with other competing agents is a hard task, as daily life as well as a host of work on learning in multi-agent settings demonstrates. Without the presence of a teacher, and with only the observed actions and rewards to learn from, the framework of Reinforcement Learning (RL) (Sutton & Barto, 1998) is an obvious choice. Conceptually, the focus moves from the realm of Markov Decision Problems to that of Game Theory (GT) and stochastic games (Shoham, Powers, & Grenager, 2004).

Recent work has proposed a number of extensions from the single agent setting to the multi-agent domain. State-of-the-art Multi-Agent Reinforcement Learning (MARL) algorithms improve on single-agent RL approaches by incorporating models of the *current* opponent agent's behavior. This allows an agent to model the current "environment" including opponents, against which it has to optimize its own behavior by playing a best-response. In a multi-agent setting, the policy that maximizes payoff will depend on the *changing* actions of adversaries. Importantly, the adaptations of adversaries are likely to be reactions to *ones own* actions. This point is largely ignored in current (MARL) algorithms. Such strategic reasoning can be paramount when an agent is repeatedly interacting with the same opponents, and earlier actions influence the future behavior of these learning adversaries.

The Prisoner's Dilemma (PD) is illustrative in that in repeated play the optimal policy differs from blindly playing the myopic best response, and that it can be profitable to have a good estimation of the opponents reactions to ones own play. In one single game, two competing agents can each choose from actions cooperate or defect ({C,D}), and the maximum *joint* payoff is achieved when both agents choose to Cooperate. However, when the other agents plays Cooperate, an agent obtains an even larger payoff from playing Defect. From a game theoretical perspective then, for the single shot game {D,D} is the dominant strategy and a Nash-Equilibrium (see Section 2).

In iterated play of the PD (iPD) game, there is no longer a clear dominant strategy, as both agents can achieve a higher aggregated *and* individual reward by cooperating and playing the joint action {C,C}, *provided* there is some strategic incentive to rarely unilaterally defect. That is: defecting as a strategy is discouraged by the likely *negative future* reaction of the opponent (see also the famous Folk Theorem discussed in Section 2).

It is important to notice that just modeling the *current* behavior of the opponent in iPD can lead to {D,D} outcome in repeated play when the reaction of the opponent to ones own play of defection is not taken into account. An agent that does not take into account the changing behavior of the opponent may estimate that a cooperating opponent may be exploited, and ignores the fact that defection will result in an opponent that also defects. When repeatedly playing a game against an adversary, the question is which moves one should play to maximize the individual reward given the *dependent* adaptive behavior of the adversary.

We argue that current state-of-the-art MARL algorithms (M. H. Bowling & Veloso, 2002; M. Bowling, 2004; Tesauro, 2003; Conitzer & Sandholm, 2003; Greenwald & Hall, 2003; Banerjee & Peng, 2004; Weinberg & Rosenschein, 2004) (see also Shoham et al. (2004) for a more in depth discussion) do not incorporate a sufficient notion of the longer term im-

pact of their actions on the dynamics of the environment. This environment includes other adaptive agents that react to moves of their opponents as well. For example, current MARL algorithms that play the iPD will universally converge to the worst possible outcome of {D,D} in self-play[1](Crandall & Goodrich, 2005). The one exception to the full defection converge outcome in repeated play of the iPD we are aware of is a recent paper by Crandall and Goodrich (2005), which we will discuss further below.

In this paper, we present a novel MARL framework called Strategic Opponent Policy Modeling (StrOPM) that goes beyond current Myopic Opponent Policy Modeling (MOPM) MARL approaches. StrOPM, as most other MARL's, takes into account the current (estimated) policy of the opponents and the rewards for actions. Importantly, our algorithm also estimates how the policies of the opponents change over time due to actions played by StrOPM. The policy of the agent using the StrOPM algorithm is adjusted to increase the expected future reward by taking into consideration 1) the immediate and future rewards of actions 2) the estimated policy of the opponent, and 3), most importantly, the impact of the chosen actions on the future policy of the opponent. The last point is the novel contribution of our work.

Our algorithm is a policy-gradient like method with roots in Q-learning. Q-like values for states are calculated based on estimated values of actions and estimated opponent policies. Policies are updated along the gradient of expected increased rewards. To more accurately model the (future) changes in the environment due to an agent's own actions, the agent computes a continuously updated estimate of the *change* in the choice of opponents actions due to its own actions. StrOPM then adjusts the reward gradient by this estimate to account for the opponent's likely *re*action.

We present our results for the well studied domain of iterated-play two-player two-action matrix games. We show that our algorithm quickly arrives at the desired Nash-Equilibrium for games that are unproblematic. These games are relatively straightforward in the sense that optimal play in a single-shot play of the game is also a good solution to iterated play of the game.

Importantly, we show that the proposed StrOPM algorithm achieves cooperation ({C,C}) in repeated play of the PD. After an initial exploration period, StrOPM learns that defection leads to reciprocal defection, and an overall lower value of future play than a high level of cooperation. The agents learn to optimize their own interest as a function of the played game and the reciprocal behavior of the evolving opponent. The (possible) cooperation strategy is not a precoded option in the algorithm, but is achieved by optimizing beyond the immediate best response to the current opponent play. The StrOPM agents in self-play exhibit a learned Tit-For-Tat strategy (Axelrod, 1984). The Tit-For-Tat algorithm plays C until the opponent defects upon which a D is played followed by again C until the next defection to encourage cooperation. The StrOPM agents learn this strategy and cooperates to reach a good equilibrium, and yet also evolves a threat state where defection is returned in order to guard against exploitation by the opponent.

We also compare our approach to the recent algorithm M-Qubed of Crandall and Goodrich (2005) for the studied matrix games. M-Qubed achieves the (C, C) equilibrium in the iPD by a meta step. The M-Qubed algorithm is designed to balance play of a best-response strategy with the precoded strategy of playing one action consistently. In particular, the algorithm during play continuously considers the value of switching to the pure, precoded strategy of playing C. Using a precoded strategy may lead to being exploited, or be unsuitable for more complex settings, as we will show.

We present results for StrOPM versus M-Qubed and show that the two type of agents playing against each other can together achieve cooperation, but from entirely different principles. The StrOPM algorithm in self-play finds good strategies significantly faster than M-Qubed for the iPD game. When playing against each other, this high speed of learning leads to an initial period where StrOPM exploits M-Qubed. Furthermore, StrOPM is shown to exploit the M-Qubed algorithm in a simple matrix game where the pre-coded strategy of playing one action predictably can result in inferior strategies in repeated play. Using precoded strategies has limited application. For example, precoded strategies cannot be used when the number of possible precoded strategies must be large, the precoded strategies cannot be determined, or do not generalize to novel, or more complex settings. Fundamentally, a MARL should remain flexible in novel settings.

In summary, we have presented three important contributions. First of all, we have signaled the need for Multi-Agent learning algorithms to take into account the impact of their actions on the learned policy of the opponents. This concept is as yet lacking in the MARL community. Secondly, we presented a novel framework that allows agents to apply the above observation to achieve desired outcomes for representative iterated matrix games, and, more importantly, also for the iPD. The latter is known to be difficult for MARL approaches; the presented StrOPM framework solves the iPD game by learning and recognizing "threat states", where it will punish an opponent's uncooperative behavior with a Tit-for-Tat type strategy (and also learns the reciprocal reaction). Lastly, we demonstrate the danger of incorporating pre-coded fixed strategies in learning algorithms as these are vulnerable to exploitation or may not be suited to novel or more complex settings.

Structure. The remainder of this document is structured as follows. In Section 2, we present iterated matrix games, and the iterated Prisoners Dilemma. In Section 3, we present our general framework. We present a Multi-Agent RL framework, StrOPM, that in the limit plays best-response against stationary opponents. Importantly, StrOPM can reason strategically in games where it is relevant in how an opponent will react to the history of play. In Section 4, we present experimental results. In Section 5, we discuss and conclude.

2. MODEL AND PROBLEM SETTING

In this section, we give some introductory definitions and notation from Game Theory, Reinforcement Learning, and the iterated matrix games we study as problem domain. We discuss the iterated Prisoners Dilemma as a game of special interest.

2.1 Agents and Matrix games

We consider multi-agent Reinforcement Learning for iterated play of games, more specifically **matrix games**, and introduce some well-known concepts from Game Theory (GT).

[1]An agent playing against an identical opponent.

In general, let S denote the set of states in the game and let A_i denote the set of actions that agent/player i may select in each state $s \in S$. Let $a = (a_1, a_2, \ldots, a_n)$, where $a_i \in A_i$ be a joint action for n agents, and let $A = A_1 \times \cdots \times A_n$ be the set of possible joint actions. **Zero-sum games** are games where the rewards of the agents for each joint action sum to zero. **General sum games** allow for any sum of values for the reward of a joint action.

A **strategy (or policy)** for agent i is a probability distribution $\pi(\cdot)$ over its actions set A_i. Let $\pi(S)$ denote a strategy over all states $s \in S$ and let $\pi(s)$ (or π_i) denote a strategy in a single state s. A strategy may be a **pure strategy** (an agent selects an action deterministically) or according to a **mixed strategy** (a strategy that plays a random action, according a probability distribution). A **joint strategy** played by n agents is denoted by $\pi = (\pi_i, \ldots, \pi_n)$. Let a_{-i} and π_{-i} refer to the joint action and strategy of all agents except agent i.

We focus on the more restricted **matrix game**, defined by a set of matrices $R = \{R_1, \ldots, R_n\}$. Let $R(\pi) = (R_1(\pi), \ldots, R(\pi_n))$ be a vector of expected payoffs when the joint strategy π is played. Also, let $R_i(\pi_i, \pi_{-i})$ be the expected payoff to agent i when it plays strategy π_i and the other agents play π_{-i}. A strategy is **dominant** if, regardless of what any other players do, the strategy earns a player a larger payoff than any other strategy. Also, let $R_i(\begin{bmatrix} a_i \\ a_{-i} \end{bmatrix})$ be the payoff for agent i playing action a_i while the other agents play action a_{-i}.

A **stage game** is a single iteration of a matrix game, and a **repeated game** is the indefinite repetition of the stage game between the same agents. While matrix games do not have state, agents can encode the previous w joint actions taken by the agents as state information, as for example illustrated by Sandholm and Crites (1995).

Each individual matrix game has certain classic game theoretic values. The **minimax** value for player i is $m_i = \max_{\pi_i} \min_{a_{-i}} R_i(\pi_i, a_{-i})$, i.e. the least reward that can be achieved if the game is known and the game is only played once. A **Best-Response** (BR) to the opponents strategy π_{-i} is defined by $BR = \pi^* = \max_{\pi} R_i(\pi, \pi_{-i})$. This corresponds to the (expected) most reward that can be gained from playing, under the assumption that the game is known; the game is only played once; and the opponent strategy is known.

A **Nash Equilibrium** (NE) is a joint strategy such that no agent may unilaterally change its strategy without lowering its expected payoff in the one shot play of the game. Nash (1951) showed that every n-player matrix game has at least one such NE. A **Pareto optimal** solution of the game is a joint strategy such that no agent may unilaterally increase its expected payoff without making another agent worse off. A (joint) strategy π_1 is said to **Pareto dominate** a strategy π_2 if the expected payoff for π_1 is at least as high as for π_2 and higher for at least one of the agents. A joint strategy is **Pareto deficient** if it is not Pareto optimal.

In the studied matrix games, we assume that an agent can observe its own payoffs as well as the actions taken by all agents in each stage game, but only after the fact. All agents concurrently choose their actions. A possible adaptation of the agents' policy, i.e. learning as a result of observed opponent behavior, only takes effect in the next stage game. Repeated games are modeled as a series of stage games with the same opponent(s). Each agent then aims to maximize its reward from iterated play of the same matrix game.

R=0.35 R=0.35	T=0.5 S=0
S= 0 T=0.5	P=0.1 P=0.1

Table 1: Example payoffs for the (symmetrical) PD

We restrict our investigation to two-player, two-action games as these are well classified (Rapoport, Guyer, & Gordon, 1976). The arguments and formalism presented in the rest of the paper are however applicable to more general settings. The next section discusses the Prisoners Dilemma (PD), a special two-player two-action game.

2.2 The iterated Prisoner's Dilemma

We present the iterated **Prisoners Dilemma** (iPD) as a special matrix game. In this game, each player has a choice of two operations: either **cooperate** (C) with the other player or **defect** (D). The payoff matrix for joint actions is shown in Table 1. If both players cooperate, they both receive a given payoff R. However, if one player plays Cooperate, and the other plays Defect, the defector receives a payoff $T > R$, and the cooperator receives a much lower payoff $S < R$. If both players play Defect, they receive the low payoff P, that is however better than the payoff S ($P > S$). For each individual, the incentive is thus present to defect, hoping that the other player plays "cooperate. Myopic play by even one of the players already quickly leads both players to arrive at the suboptimal outcome of both players receiving a low reward P. Furthermore, the PD has as constraint that $R > \frac{(T+S)}{2}$; full cooperation is better than playing $\begin{bmatrix} C \\ D \end{bmatrix}$ and then $\begin{bmatrix} D \\ C \end{bmatrix}$ for the agents over two stage games.

The PD game is of particular interest as it has specific properties that make it unique among the matrix games. The PD is the only game of the taxonomy of two-player, two-action games listed by Rapoport et al. (1976) for which the natural outcome is stable (a NE), but Pareto-deficient: there are outcomes that Pareto-dominate the NE. This unique property also makes it non-trivial for competitive learning algorithms in repeated play; how can learners consider the possible future gains that are non-existent in the single shot game?

Most multi-agent learning algorithms to date have focused on an individual agent learning a (myopic) Best Response to the *current* strategies of the other agents. Play between such agents using this approach often converge, and have as goal to converge, to a one-shot NE. However, a famous result from game theory (the **folk theorem**) (Myerson, 1991) suggests that the goal of reaching a one-shot NE may be inappropriate in repeated games.

The folk theorem implies that, in many games, there exists NEs for repeated games, repeated Nash-Equilibria (rNEs), that yield higher individual payoffs to all agents than do one-shot NEs, i.e. the rNE Pareto dominates the NE. Hence, in repeated games, a successful set of agents should learn to play profitable rNEs. However, since many repeated games have an infinite number of rNEs, the folk theorem does little

to indicate which one the agents should play. Littman and Stone (2003) present an algorithm for computing rNEs that satisfies a set of desiderata, but how to learn these strategy online is unknown. Additionally, an agent may have preferences between rNEs and play one above the other, if allowed by its opponents.

It is however not given that the mainstream, or state of the art RL algorithms, will (approximately) learn these rNE equilibriums in self play or against various classes of opponents. As discussed in Section 1, and by Crandall and Goodrich (2005), the claim is that current MARL algorithms will not converge to good rNE for iPD-like games.

3. THE StrOPM FRAMEWORK

Here, we refine the StrOPM framework. We show (very successful) experimental results with an instantiation of the framework for matrix games in Section 4.

We can formulate the goal of an agent i as wanting to maximize the total reward it obtains from playing T times against an adversary:

$$R_i^{tot} = \sum_{t=0}^{t=T} val_i(\pi_{i,t}, \pi_{-i,t}). \quad (1)$$

where π_t is the policy at time t and val_i the expected reward for a agent i using policy $\pi_{i,t}$ and opponent policies $\pi_{-i,t}$. Thus, we want to specify or learn the time-varying policy $\pi_{i,t}$ that maximizes the reward obtained.

We make several observations: first, we have to start playing from some policy $\pi_{i,t=0}$, and we may not know the payoff of (joint) actions yet. We may also not know the policy of the adversary yet, nor to what extent it is adaptive.

We assume that we can define a state representation for an agent i that includes sufficient history to make the evolution of both its own policy and the opponent's policy Markovian: $\pi_{i,t+1} = f(s(t), \pi_{i,t})$, where $f(s(t), \pi_{i,t})$ is the state dependent function that adapts the agent's policy based on the agent's current policy $\pi_{i,t}$ and the current state $s(t)$. Likewise, the agent assumes that the opponent behaves similarly Markovian: $\pi_{-i,t+1} = g(s(t), \pi_{-i,t})$, where $g(s(t), \pi_{-i,t})$ is an unknown function that adapts the adversarie's policy. We assume that part of the state information in the $g(s(t))$ term depends on the actions taken by the agent i.

At its core, the StrOPM algorithm attempts to estimate this unknown adaptive function $g(s(t), \pi_{-i,t})$, and then computes forward all possible future action sequences resulting from the thus evolving policies $\pi_{i,t}$ and $\pi_{-i,t}$. It then updates the policy $\pi_{i,(t+1)}$ in the direction of those future action sequences that promise the most reward.

In the StrOPM framework, an agent applies reinforcement learning to a state-based policy as described in Algorithm 1. At each epoch of learning, the agent adapts its policy along the gradient of increasing reward. The gradient of reward is calculated including the expected changing behavior of the opponent, as a reaction of the agent's own actions. The StrOPM algorithm tracks the changes in observed opponent policy, on a state by state basis, over time. It is assumed that these changes in the opponent behavior, at least in part, reflect reaction to actions chosen by the StrOPM algorithm . The StrOPM algorithm not only tracks the changing behavior of the opponents, but also how these changes are potentially caused by the agent's own action. The policy of the StrOPM is then optimized with expected future reactions taken into account.

We describe the StrOPM algorithm from the perspectives of an agent i and its opponents, agents $-i$. We use this notation with subscripts to indicate policy, states, action, etc ... of the two types of agents. E.g., a_i and a_{-i} are actions of agents i and $-i$ respectively.

States. The set of states that an agent i can visit, S_i, fulfills the unichain assumption (Puterman, 1994): One set of "recurrent" class of states. Starting from any state in the class, the probability of visiting all the states in the class is 1. We introduce a **transition function** $T : S_i \times A_i \times A_{-i} \rightarrow S_i$ to return the next state of agent i upon playing a (joint) action from the current state.

Policies. For a state $s \in S_i$, $\pi_i(s)$ is the state-based policy of agent i, and $\pi_{-i}(s)$ is the estimate of the opponent $-i$ policies when agent i is in state s. The opponent policy is estimated online using Exponential Moving Average (EMA). The estimate of $\pi_{-i}(s)$ after observing action a_{-i} is adjusted according, for action a_i:

$$\pi_{-i,t+1}(s)(a_{-i}) = (1 - \alpha_{EMA1})\pi_{-i,t}(s)(a_{-i}) + \alpha_{EMA1}. \quad (2)$$

After this update, the policy $\pi_{-i,t+1}(s)$ is normalized to retain $\pi_{-i}(s)$ as a probability distribution by equally reducing the probabilities of the other actions to retain $\pi_{-i}(s)$ as a probability distribution.

Actions to update the policy. We introduce **policy update actions**. A policy update action $pua_i(s)$ dictates whether the likelihood of an action a_i should be increased for state s. Additionally, we introduce the *null* policy update action $pua_{null}(s)$ to indicate that the policy should not be changed.

Let $\pi_i(s)^{pua_i}$ be the policy achieved by applying the policy update action $pua_i(s)$ to $\pi(s)_i$. The policy $\pi(s)_i$ of agent i given $pua_i(s)$ not equal to the null action is updated according to:

$$\pi_{i,t+1}(s)^{pua_i} = (1 - \alpha_{LEARN})\pi_{i,t}(s)(a_i) + \alpha_{LEARN}, \quad (3)$$

where α_{LEARN} is the learning rate. The probabilities $\pi_i(s)(\cdot)$ for actions $a_j \neq a_i$ are then normalized to retain $\pi_i(s)$ as a probability distribution.

We wish to select policy update action $pua_i(s)^*$ in (3) that maximizes a measure of expected future payoff of the changed policy. Below, we explain how to compute this.

Estimation of impact actions. We introduce $\xi(\pi_{-i}(s), a_i)$ to estimate the impact of an agent i playing an action a_i on the development of the policies $\pi_{-i}(s)$ of the opponent. This function predicts the change in policy of the opponents upon playing action a_i; i.e.

$$\pi_{-i,t+1}(s) = \xi(\pi_{-i,t}(s), a_i). \quad (4)$$

As a first implementation of this function, we take the approach that the changes in the opponent policy are, at least in part, caused by an agent's own actions. Our StrOPM implementation estimates the change in policy as a continuation of the change in policy from estimation of the opponent policy N epochs in the past, i.e. how was the opponent policy at time $t - N$? This is done for each state: for state s reached after playing action joint action the change in policy for this new state is estimated as a linear extrapolation of

the change in the estimated opponent policy:

$$\xi(\pi_{-i,t}(s), a_i) = \frac{\pi_{-i,t}(s) - \pi_{-i,t-N}(s)}{N} + \pi_{-i,t}(s), \quad (5)$$

where we limit ξ to $[0, 1]$.

Thus estimating the change in opponent policies, the question becomes how to compute the value of proposed policy updates. Here, we make use of the unichain assumption that says we only need to consider loops starting from and returning to the current state to compute this value. The algorithm then updates the policy for the possible loops to increase the expected average reward.

Loops. From a state s_0, a single loop $L(s_0)$ is defined as:

$$L(s_0) = s_0, \begin{bmatrix} a_{i,0} \\ a_{-i,0} \end{bmatrix}, s_1, \begin{bmatrix} a_{i,1} \\ a_{-i,1} \end{bmatrix}, s_2, \ldots, s_{(n-1)}, \begin{bmatrix} a_{i,(n-1)} \\ a_{-i,(n-1)} \end{bmatrix}, s_0, \quad (6)$$

for a sequence of joint moves for agent i starting in s_0, going through $s1$, $s2$, ... to s_n and ending again in s_0. Each next state reached is through a joint move; $T(s_j, \begin{bmatrix} a_{i,j} \\ a_{-i,j} \end{bmatrix}) = s_{j+1}$. All intermediate states reached in the loop are unique, and not equal to s_0. For brevity, we denote the $j-th$ state s_j in the sequence by $L(s_0)^j$, the $j-th$ action pair $\begin{bmatrix} a_{i,j} \\ a_{-i,j} \end{bmatrix}$ by $L(s_0)_j$, and $L(s_0)_{j+}$ and $L(s_0)_{j-}$ the components of the $j-th$ action pair: $a_{i,j}$ and $a_{-i,j}$. The length of the sequence $L(s_0)$, $|L(s_0)|$, is equal to n; the number of joint actions played before the considered state is reached again.

Sets of loops. Let $Bag(s, n) = \{L(s) \,|\, |L(s)| \leq n\}$, i.e. $Bag(s, n)$ are all the loops starting in state s with length of at most n . The probability of a particular loop $L(s)$ occurring, denoted by $Pr(L(s))$ is:

$$Pr(L(s)) = \prod_{0 \leq j < |L|} Pr(L(s)_{j+} | \pi_{i,j}(L(s)^j)) \times Pr(L(s)_{j-} | \pi_{-i,j}(L(s)^j)), \quad (7)$$

where $L(s)_j$ and $L(s)^j$ are the respective elements in the loop as defined above, $\pi_{i,j}$ and $\pi_{-i,j}$ are the respective policies at time j, evolving according to Equation (4), and $Pr(\cdot)$ denotes the probability of a specific transition along the sequence given the respective policies $\pi(s)$.

The expected reward over the possible loops can then be expressed as the weighted expected value of individual loops:

$$E(Bag(s, n)) = \sum_{L(s) \in Bag(s,n)} Pr(L(s)) \times E(L(s)), \quad (8)$$

where $E(L(s))$ is the expected average reward for each joint action of a loop starting in state s:

$$E(L(s)) = \frac{\sum_{0 \leq j < |L(s)|} V(L(s)_j)}{|L(s)|}, \quad (9)$$

where $V(L(s)_j)$ denotes the estimated the value of the $j-th$ joint action in the loop, $L(s)_j$, to agent i.

Learning the value of joint actions. The values $V_i : A_i \times A_{-i} \rightarrow \Re$ track the estimates the value of a single joint action to agent i and through V_i, agent i learns its part of the rewards of the game, dependent upon the actions of the opponent. The function V_i is updated using EMA:

$$V_{i,t+1} = (1 - \alpha_{EMA2}) V_{i,t} + \alpha_{EMA2} \times r_t, \quad (10)$$

where r_t is the reward received by agent i in epoch t, and $0 < \alpha_{EMA2} \leq 1$ is the learning rate for the update.

Strategic Updating. Let the opponent changes in policy be estimated by $\xi(\pi_{-i}(s), a_i)$, we can then compute the policy update with highest expected payoff:

$$pua_i(s)^* = \max_i E(Bag(s, n))^{\xi}_{pua_i(s)}, \quad (11)$$

where $E(Bag(s, n))^{\xi}_{pua_i(s)}$ denotes the expected average reward for the possible loops of at most length n, starting in state s, after effecting policy update action $pua_i(s)$ and taking $\xi(\pi_{-i}(s), a_i)$ as the estimated opponent adaptation. Our StrOPM algorithm thus obtained is outlined in Algorithm 1.

Algorithm 1 StrOPM

```
Initialize π_i(s), π_{-i}(s) for all s ∈ S_i and V for all all joint actions. Set the initial state.
Do in each epoch sequentially for each agent i in state s:
loop
    calculate the highest valued pua_i(s)* using E(Bag(s,n))^ξ_{pua_i(s)} as value for the individual policy update actions.
    Update policy π_i(s) using the highest valued policy update pua_i(s)* action.
    Play action a_i ∈ A_i based on the chosen policy update action pua_i(s)*. StrOPM plays action a_i for chosen policy update action pua_i(s) = pua(s)* if pua* is not the null policy update action. Otherwise choose the action according to π_i(s).
    Receive reward R_i([a_i; a_{-i}]) for the joint action determined by agents −i.
    Update the estimate of the reward for the joint action V([a_i; a_{-i}]) and the opponent policy π_{-i}.
    set the current state to T(s, [a_i; a_{-i}]).
end loop
```

4. EXPERIMENTS

We first investigate the StrOPM algorithm for various well-known two-player, two-action games.

In Figures 1b,d,f, we show the results for StrOPM in a variety of games. Figure 1b shows the results for self-play for the game of "matching pennies", Figure 1d for a variant of a coordination game[2], and Figure 1f for the game of Chicken (see also Rapoport et al. (1976)). The corresponding payoff matrices are plotted above the respective graphs in Figures 1a,c,e. Experiments are averaged over 50 runs. A learning

[2]In the simple coordination game, the two agents must learn to either play $\begin{bmatrix} C \\ D \end{bmatrix}$ or $\begin{bmatrix} D \\ C \end{bmatrix}$ to achieve the highest reward.

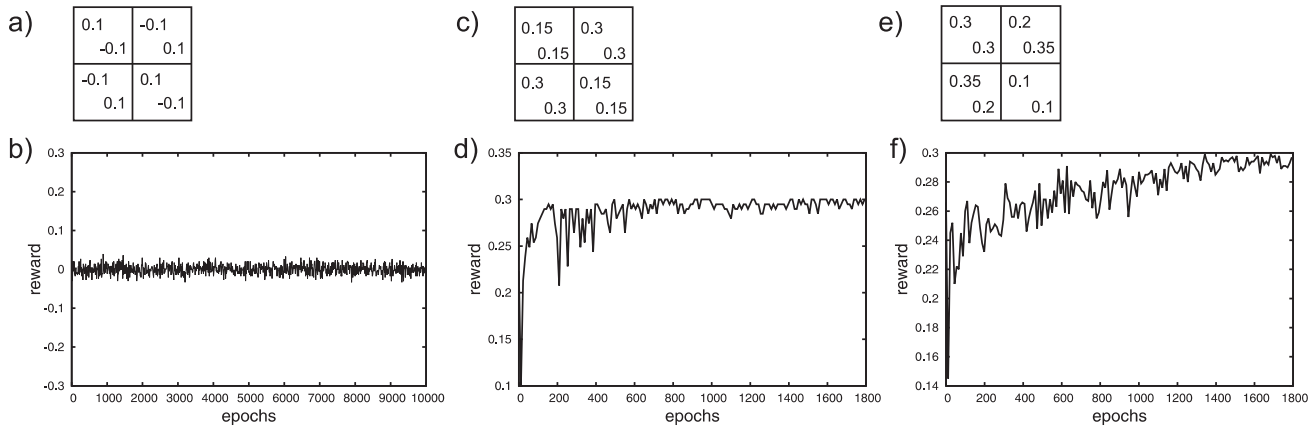

Figure 1: a) payoff matrix for "Matching Pennies", reward representation as in Table 1. b)two StrOPM players playing Matching Pennies. c,d) payoff matrix and two StrOPM players playing a Coordination Game. e,f) payoff matrix and two StrOPM players playing a game of Chicken.

rate of 0.01 was used for all the EMA equations of Section 3. The StrOPM algorithm looks back $N = 10$ epochs in Equation 5. Additionally, we added an $\epsilon = 0.01$ probability of the StrOPM agent taking an exploration move in each epoch to ensure all states are sufficiently sampled in play. Note that we reuse the payoff labels C and D for ease of exposition.

In the games shown in Figure 1, the StrOPM algorithm finds the optimal Nash-Equilibria rapidly, as was to be expected since these games are unproblematic in the sense that the Nash-Equilibria of the games is also a good solution for iterated play of the game. The results show that the StrOPM algorithm finds good solutions for these diverse games quickly, as it should since it is not designed with a bias for any particular matrix game.

StrOPM in the iPD. Of greater interest than the previous games is the iterated Prisoner's Dilemma, as it is a much harder, open problem for MARLs and is also the motivating example for the work of Crandall and Goodrich (2005).

In Figure 2a, we present results of the StrOPM algorithm for self-play in the iPD game of Figure 2a (using the payoff matrix of Table 1). To highlight the difference between a forward-thinking algorithm like StrOPM, and more reactive MOPM algorithms, we compare in Figure 1 the results for the StrOPM algorithm in self-play with that of self-play for an MOPM player in the form of a reduced variant of StrOPM that does not anticipate reactions to its actions. With the latter, we mean that the used ξ functions do not predict a change in policy of the opponent, i.e $\xi(\pi_{-i}, a_i) = \pi_{-i}$. As such, the StrOPM implementation reverts to an opponent modeler type player that simply moves its policy to a best-response to the recently observed play of the opponent.

The StrOPM learner in self-play (Figure 2a, solid line) converges to playing the (optimal) Cooperate-Cooperate ($\{C, C\}$) strategy with reward 0.35. The full cooperation equilibrium is reached as the StrOPM learner estimates that leaving the full cooperation state leads to states where more and more defection is expected. Additionally, the full cooperation state is expected to lead to more cooperation. In contrast, the MOPM variant quickly learns cooperation is risky and moves to full defection(Figure 2a, dashed line).

Furthermore, a closer study of the state-based policy of the StrOPM players reveals that the agents in self-play repeatedly exhibited a learned Tit-For-Tat strategy (Axelrod, 1984). The Tit-For-Tat algorithm plays C until the opponent defects upon which a D is played followed by again C until the next defection to encourage cooperation. For a four state agent, with each state encoding the last joint action of play, the policy is to play C in state $\begin{bmatrix} C \\ C \end{bmatrix}$, play D from state $\begin{bmatrix} C \\ D \end{bmatrix}$, and C from $\begin{bmatrix} D \\ D \end{bmatrix}$. The StrOPM agents learn this strategy and play C to cooperate and reach a good equilibrium, except for occasional exploratory moves. At the same time the StrOPM players also evolve a "threat" state where defection is retaliated in order to guard against exploitation by the opponent. The need, and the possibility, for learning a threat state as in the Tit-For-Tat play of the iPD is an interesting venue of research for iterated play of games. For example, a StrOPM player playing against a hard-coded Tit-For-Tat player quickly learned to cooperate (not shown), but did not evolve such a threat state.

As a negative result, a StrOPM agent playing against a MOPM agent converged to mutual defection (not shown) as the MOPM player learned to play defect. The MOPM agent playing agains a hard coded Tit-For-Tat player was however able to achieve full cooperation as the MOPM player was consistently taught by the Tit-For-Tat agent that defection was not worthwhile. This strategy was however not yet available to the StrOPM agent as it still had to be learned. This indicates that players in the iPD must both be reasonably savy, be that though their learning algorithm or a-priori imparted strategies, for mutual cooperation to emerge.

Ongoing preliminary results (not shown here) however indicate that generalised StrOPM-type agents are able to achieve high levels of cooperation in the generalised n-player iPD, the nIPD (Yao & Darwen, 1994). For example, for three agents, full cooperation is reached in the 3IPD game. In ('t Hoen & La Poutré, 2005), we have shown that agents participating in a sequence of auctions for individual items with as goal to win a bundle of these items can face a nIPD-like problem. Each of the agents has an individual incentive

to bid strategically. The prices paid for the items are however much higher if all the agents follow this strategy. A venue of research is to investigate whether the concepts of the StrOPM algorithm can be applied to this more complex setting to arrive at more beneficial outcomes from the perspective of the buyers.

StrOPM versus M-Qubed:. In Figure 2b we show results for an agent using the StrOPM algorithm (using the same settings as above) playing against an agent using the M-Qubed algorithm by Crandall and Goodrich (2005). We choose M-Qubed an a state-of-the-art MARL algorithm to compare StrOPM to, as Crandall & Goodrich claim it performs on par with other state-of-the-art MARLs on simple matrix games, and is additonally capable of successfully solving the iPD game.

M-Qubed as introduced in Crandall and Goodrich (2005) operates as a mix of a Q-learning type algorithm and a pure strategy player. The algorithm learns Q-like values that encode the received reward and the discounted future reward. The algorithm investigates the policy of playing according to the Q-like values various exploration strategies. At the same time, the algorithm considers whether to play any of its actions consistently to promote possibly good interactions with the opponent. A parameter $\beta \in [0, 1]$ is used in M-Qubed and adapted in play to learn the best overall strategy; M-Qubed plays a game using the Q-values with probability $(1 - \beta)$ or it plays the highest valued action as a pure strategy with probability β. We used for M-Qubed the same settings as Crandall & Goodrich note in their work[3].

When a StrOPM player plays against a player using M-Qubed, the full average reward of 0.35 is not reached as alternating Cooperate/Defect followed by Defect/Cooperate patterns often emerged, giving an average reward of 0.25 per epoch. This is not the optimal C, C outcome, but still much better than the typical D, D outcome other MARLs arrive at. This result suggests that the switching policy in M-Qubed is repeately "tripped". The non-linear switching policy threshold is hard to approximate in StrOPM's linear opponent change model. Including more history of non-linear update terms in future extensions may solve this issue.

The trouble with precoded strategies. The M-Qubed algorithm has a clear potential weakness since it has to decide between the pure (or at least precoded) strategy of playing full cooperation, and a myopic Q-Learning type strategy. We would expect it to perform badly when the optimal strategy involves a more complex strategy that is not precoded. Our StrOPM algorithm on the other hand is not biased to playing precoded strategies.

We tested this hypothesis in the game with the payoff matrix of Figure 3a, dubbed "Switching Bait", which we specifically designed so that the highest (average) joint reward is achieved when agents alternate Cooperate/Defect and Defect/Cooperate (or at least play these two joint actions equally often). Playing the Cooperate/Defect, Defect/Cooperate mixed strategy yields an average reward of 0.45 per epoch for both agents.

In experiments playing the Switching Bait game, M-Qubed

[3]These settings allowed us to successfully replicate the results in Crandall and Goodrich (2005).

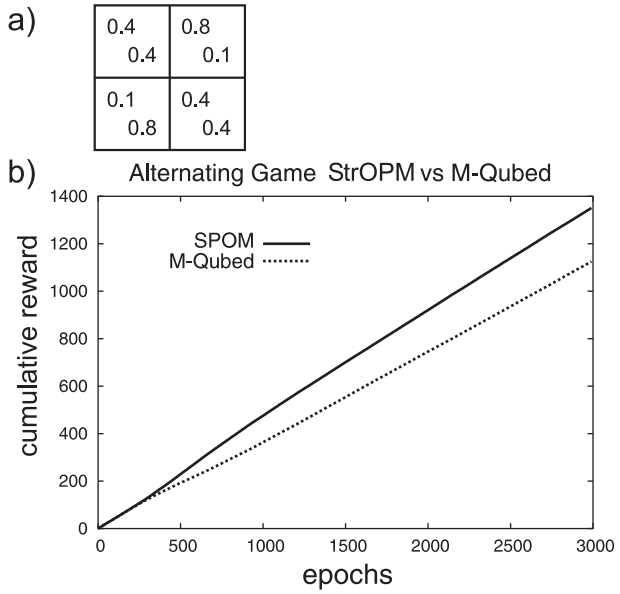

Figure 3: a) payoff matrix for "Switching Bait" game b) respective cumulative reward obtained by a StrOPM player playing against an M-Qubed player.

was frequently not able to find the optimal mixed strategy in selfplay, as it predominantly converged to playing C or D and achieves a reward of only 0.4 per epoch. Higher rewards of $\frac{0.8+0.1}{2}$ where achived by one of the M-Qubed learners by playing C and D alternatingly, while the other M-Qubed player plays C or D continouously for an average reward of $\frac{0.1+0.4}{2}$. For the Switching Bait new game, M-Qubed often decides to play the safer strategy of full cooperation or defection.

The StrOPM algorithm, unlike M-Qubed, is not biased to playing pure strategies. For the Switching Bait game, it often finds the alternating Cooperate/Defect pattern and matches it to the opponent's Defect/Cooperate pattern in self play. Importantly, a StrOPM player playing againts an M-Qubed player was found to either achieve this mutually beneficial equilibrium or was repeatedly able to exploit M-Qubed if the opponent decided to play a (precoded) pure strategy. An example of this latter behavior is shown in Figure 3b, where the cumulative payoff achieved during play is plotted. The StrOPM algorithm achieves a higher payoff as M-Quebed opts for the safer, pure strategy. This clearly demonstrates the weakness of using precoded fixed strategies (as in M-Qubed).

5. DISCUSSION AND CONCLUSIONS

We have presented a number of important contributions in this paper. First, we argued the need for Multi-Agent learning algorithms to take into account the impact of their actions on the adaptive policy of the opponents. We then presented a novel framework that allows agents to apply the above observation to achieve desired outcomes for representative iterated matrix games, and, importantly, also for the iterated Prisoner's Dilemma. The latter is notoriously difficult to solve for current state-or-the-art MARL approaches. Our MARL framework allows an agent to learn profitable strategies for long term behavior. Finally, we demonstrated

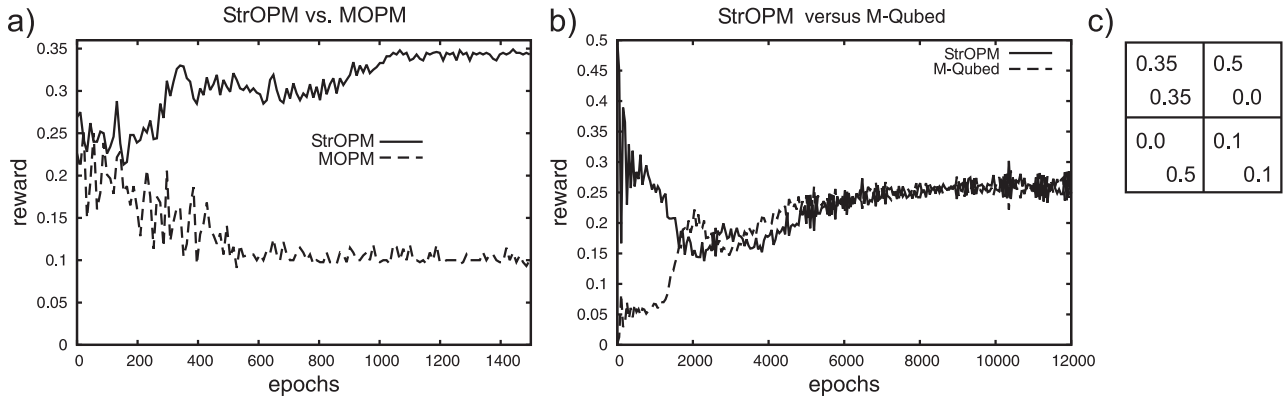

Figure 2: a) StrOPM players playing the iPD (solid line) and the MOPM-variant (dashed line). b) A StrOPM player playing vs M-Qubed for the iPD. c) iPD payoff matrix

that incorporating fixed precoded strategies in MARL algorithms makes agents vulnerable to exploitation, especially when mixed strategies can be optimal (of which there is a continuous spectrum). Additionally, fixed precoded strategies may not be suited to novel settings.

The important novel component of this work is the concept of learning the changes in opponents policy due ones own action. This is an idea that can in fact be incorporated into the quickly growing literature on MARL. One can foresee more and more complex nested opponent models (Hu & Wellman, 1998) to extract every bit of reward from complex games like iPD. Although perfectly learning about an opponent while at the same time perfectly learning to adjust oneself is problematic (Nachbar & Zame, 1996), there is still much scope to be "smarter" than your opponents.

Our future challenge is to apply our new concept to large, complex state spaces. One interesting direction may be to integrate our framework with new ideas about state space representations like Predictive State Representations (Wolfe, James, & Singh, 2005).

ABSTRACT

Coordinating agents in a complex environment is a hard problem, but it can become even harder when certain characteristics of the tasks, like the required number of agents, are unknown. In those settings, agents not only have to coordinate themselves on the different tasks, but they also have to learn how many agents are required for each task. To achieve that, we have elaborated a selective perception reinforcement learning algorithm to enable agents to learn the required number of agents. Even though there were continuous variables in the task description, the agents were able to learn their expected reward according to the task description and the number of agents. The results, obtained in the RoboCupRescue, show an improvement in the agents overall performance.

1. INTRODUCTION

In a cooperative multiagent environment, agents have to divide up the different tasks among themselves in order to accomplish them efficiently. However, if agents are faced with complex tasks, it might be hard for them to determine how many agents are required to accomplish each task, which is important information for the coordination process. Without this information, agents would not be able to divide up the different tasks efficiently.

To learn the required number of agents for each task, we have developed a selective perception reinforcement learning algorithm, which is useful to manage a large set of possible task descriptions with discrete or continuous variables. It enables us to regroup common task descriptions together, thus greatly diminishing the number of different task descriptions. Starting from this, the reinforcement learning algorithm can work with a relatively small state space.

Our tests in the RoboCupRescue simulation environment show that the agents are able to learn a compact representation of the state space, facilitating their task of learning good expected rewards. Furthermore, they were also able to use those expected rewards to choose the right number of agents to assign to each task. This information helped the agents to efficiently coordinate themselves on the different tasks, thus improving the group performance.

In the remaining sections of this paper, we introduce the RoboCupRescue simulation which motivated the development of our learning algorithm. Next, we describe our selective perception reinforcement learning algorithm. Then, we present the results obtained by testing our algorithm in the RoboCupRescue simulation.

2. DOMAIN

The resource allocation problem that motivated this work requires an efficient allocation of *FireBrigade* agents to the tasks of extinguishing fires. Therefore, throughout this paper, we consider *FireBrigade* agents to be resources that are allocated to fires. Those *FireBrigade* agents evolve in the RoboCupRescue simulation [4] which takes the form of an annual competition in which participants are designing rescue agents (fire fighters, policemen and paramedics) trying to minimize damages, caused by a big earthquake, such as civilians buried, buildings on fire and blocked roads.

For this article, only the agents responsible for extinguishing fires are considered, i.e. the *FireBrigade* agents which extinguish fires and the *FireStation* agent which is their communication center. All those agents are in contact by radio, but they are limited on the number of messages they can send and on the length of those messages. Furthermore, in the simulation, each individual agent receives visual information of only the region surrounding it. Therefore, agents rely on the communication to acquire some knowledge about the environment. Since the center agent has more communication capabilities, it normally has a better global view of

the situation than the *FireBrigade* agents.

As mentioned before, the task of the *FireBrigade* agents is to extinguish fires. Therefore, at each step in time, each *FireBrigade* agent has to choose which burning building to extinguish. However, in order to be effective, *FireBrigade* agents have to be coordinated on the same burning buildings, because more than one agent is often required to extinguish a building on fire. For this article, we do not consider the importance of a task. We suppose that the agents have a utility function allowing them to place the different fires in order of priority. Their assignment to different burning buildings depends on the number of available agents and on their distance from those fires.

The main decision for the agents is to choose how many agents to send to the most important fires. However, the problem is that they do not know how many agents are required for each building on fire. The required number of agents depends on the characteristics of the task. For example, a small building on fire may require only two agents to extinguish it, but a bigger one may require 10 agents. In order to be effective, agents have to learn the right number of agents to assign to each task which is described as:

- the intensity of the fire (3 possible values),
- the building's composition (3 possible values),
- the building's size (continuous value),
- the building's damage (4 possible values).

Therefore, there are many possible task descriptions. In fact, with the continuous attribute "building's size", there is an infinite number of task descriptions. In the results section, we show an important reduction of this huge number of possible situations. But first, in the next sections, we present our selective perception reinforcement learning algorithm.

3. PROBLEM DEFINITION

In this article, we are considering agents accomplishing tasks in an uncertain and dynamic environment where most tasks require more than one agent to be accomplished. In this case, agents are forced to be coordinated and they need to know the required number of agents to accomplish each task. This can be hard to estimate if subtle changes in a task description can change the required number of agents.

To make this estimation, we propose a new approach that uses a selective perception reinforcement learning algorithm to learn the expected reward if a certain number of agents tries to accomplish a certain type of task. An advantage of learning expected rewards instead of directly learning the number of agents is that the rewards can encapsulate the time needed to accomplish a task. A task taking more time to be accomplished has a smaller expected reward, due to the discount factor.

The method we propose is inspired by the *Utree* [5] and the *Continuous Utree* [10] algorithms. Like those methods, the agent is dynamically learning a tree representation of the state space in order to reduce the number of states considered. In our case however, we do not consider states, but task descriptions and our objective is not to find a policy for the agent, but to evaluate the capability of a given group of agents to accomplish a task. Therefore, the only implicit action is to accomplish a task, but it is never explicitly considered in the model. Our model can be described as a tuple $< D, N, R, T >$ where:

- D is the set of all possible task descriptions.
- N is the number of available agents.
- R is a reward function that gives the reward if a task is accomplished.
- T is a transition function that gives the probability to go from one task description to another. In other words, it gives the probability that the task description changes while some agents are accomplishing it.

The transition function is useful to take the dynamic aspects of the environment into consideration. It takes time to accomplish a task and, during this time, some characteristics of the current task may change and this may have an impact on the required number of agents.

Moreover, a task description is described in a factored way by a set of discrete or continuous attributes: $\{A_1, A_2, \ldots, A_n\}$. The number of different task descriptions can be huge, especially if there are continuous attributes. The primary objective of building a tree representation of the task description space is to reduce the number of task descriptions considered. The next section explains how the tree is built and how it is used to estimate the required number of agents to accomplish each task.

4. TREE CONSTRUCTION

Our algorithm uses a tree structure similar to a decision tree in which each leaf of the tree represents an abstract task description that regroups many task descriptions. This compact representation is iteratively expanded when new experiences are gathered by the learning agents.

At the beginning, all tasks are considered to be the same, so there is only the root of the tree. After each simulation, agents add new experiences to the tree and the tree is expanded. Those experiences are tasks that the agents tried to accomplished in the simulation with the rewards they obtained. All experiences are stored in the leaves of the tree. To expand the tree, the algorithm tests for each leaf l whether it would be interesting to divide the experiences stored in l by adding a new test on a task's attribute. The addition of a new test refines the agents' view of the task description space.

An advantage of this algorithm is that it distinguishes only tasks that really need to be distinguished. Therefore, the task description space is reduced, thus facilitating the reinforcement learning process.

4.1 Tree Structure

The algorithm presented here is an instance-based algorithm in which a tree is used to store all agents' experiences which are kept in the leaves of the tree. The other nodes of the tree, called center nodes, are used to divide the instances with a test on a specific attribute. Each leaf of the tree also contains a Q-value indicating the expected reward if a task that belongs to this leaf is chosen. In our approach, a leaf l of the tree is considered to be a task description (a state) for the learning algorithm.

An example of a tree is shown in Figure 1. Each rectangular node represents a test on the specified attribute.

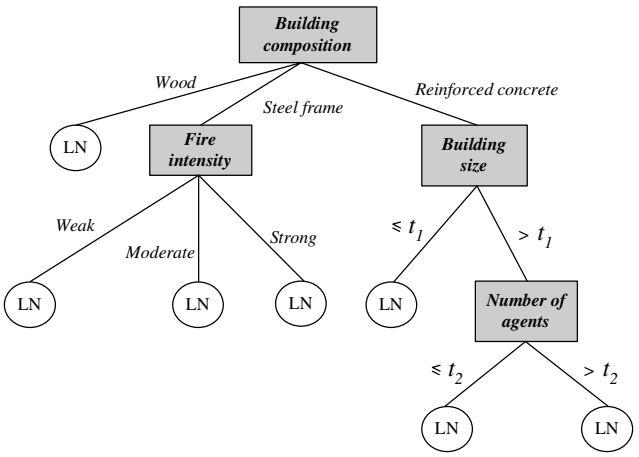

Figure 1: Structure of a tree.

The words on the links represent possible values for discrete variables. The tree also contains a center node testing on a continuous attribute, the "Building size". A test on a continuous attribute always has two possible results, it is either less or equal to the threshold or greater than the threshold. The oval nodes (LN) are the leaf nodes of the tree where the agents' experiences and the Q-values are stored.

4.2 Recording of the Agents' Experiences

In the RoboCupRescue, each simulation has 300 time steps. During a simulation, each *FireBrigade* agent records, at each time step t, its experience about which fire it is trying to extinguish. More precisely, an experience is recorded as an "instance" that contains the task it tried ($d_t \in D$), the number of agents that tried the same task (n_t) and the reward it obtained (r_t). Each instance also has a link to the preceding instance and the next one, thus making a chain of instances. Consequently, an instance at time t is defined as:

$$i_t = \langle i_{t-1}, d_t, n_t, r_t, i_{t+1} \rangle \quad (1)$$

In our case, we have one chain for each fire f that an agent chooses to extinguish. A chain contains all instances from the time an agent chooses to extinguish the fire f until it changes to another fire. Therefore, during a simulation, each *FireBrigade* agent records many instances organized in many instance chains. They keep all those instances until the end of the simulation.

The learning process takes place after a simulation, when the agents have time to learn. At this time, the *FireBrigade* agents regroup all their instances together, then the tree is updated with all those new instances and the resulting tree is returned to each agent. By regrouping their instances, agents can accelerate the learning process.

4.3 Update of the Tree

This section presents the algorithm used to update the tree using all the new recorded instances. Algorithm 1 shows an abstract version of the algorithm and the following subsections present each function used in more detail.

4.3.1 Add Instances

The first step is simply to add all the new instances, recorded by the *FireBrigade* agents, to the leaves they belong to. To find those leaves, the algorithm starts at the root of the tree and heads down the tree choosing at each center node the branch indicated by the result of the test on the instance's attribute, which could be one of the attributes of the task description d or the number of agents n.

Procedure UPDATE-TREE(*Instances*)

Inputs: *Instances*: all instances to add to the tree.
Static: *Tree*: the tree.

for all i in *Instances* **do**
  ADD-INSTANCE(*Tree*, i)
end for
UPDATE-Q-VALUES(*Tree*)
EXPAND(*Tree*)
UPDATE-Q-VALUES(*Tree*)

Algorithm 1: Algorithm used to update the tree.

4.3.2 Update Q-values

The second step updates the Q-values of each leaf node to take into consideration the new instances which were just added. The updates are done with the following equation:

$$Q'(l) \leftarrow \hat{R}(l) + \gamma \sum_{l'} \hat{T}(l, l') Q(l') \quad (2)$$

where $Q(l)$ is the expected reward if the agent tries to accomplish a task belonging to the leaf l, γ is the discount factor, $\hat{R}(l)$ is the estimated immediate reward if a task that belongs to the leaf l is chosen, $\hat{T}(l, l')$ is the estimated probability that the next instance would be stored in leaf l' given that the current instance is stored in leaf l. Those values are calculated directly from the recorded instances:

$$\hat{R}(l) = \frac{\sum_{i_t \in I_l} r_t}{|I_l|} \quad (3)$$

$$\hat{T}(l, l') = \frac{|\{i_t \mid i_t \in I_l \wedge L(i_{t+1}) = l'\}|}{|I_l|} \quad (4)$$

where $L(i)$ is a function returning the leaf l of an instance i, I_l represents the set of all instances stored in leaf l, $|I_l|$ is the number of instances in leaf l and r_t is the reward obtained at time t when n_t agents were trying to accomplish the task d_t.

To update the Q-values, the equation 2 is applied iteratively until the average squared error is less than a small specified threshold. The error is calculated using the following equation, which is the average squared difference between the new and the old Q-values:

$$E = \frac{\sum_{l} (Q'(l) - Q(l))^2}{nl} \quad (5)$$

where nl is the number of leaf nodes in the tree.

4.3.3 Expand the Tree

After the Q-values have been updated, the third step checks all leaf nodes to see if it would be useful to expand a leaf and replace it with a new center node, thus dividing the instances more finely and refining the agent's representation of the task description space, in order to help the agent to predict rewards.

Before trying to split a leaf node, the algorithm first checks if there are enough instances stored in the leaf. If the number of instances is too small, the algorithm does not try to split the leaf node. This is done to make sure that the statistical measures used to split the nodes are meaningful and that the algorithm is not overfitting the data.

If there are enough instances, the algorithm tries different tests to divide the instances more finely. To find the best test, the agent tries all possible tests, i.e. it tries to divide the instances according to each attribute describing a task or the number of agents. After all attributes have been tested, it chooses the attribute that maximizes the error reduction as shown in equation 6 [8].

The error measure considered is the standard deviation on the instances' expected rewards ($sd(I_l)$). Therefore, a test is chosen if, by splitting the instances, it ends up reducing the standard deviation on the expected rewards. If the standard deviation is reduced, it means that the rewards are closer to one another. Thus, the tree moves toward its objective of dividing the instances in groups with similar expected rewards, in order to help the agent to predict rewards. In fact, the test is chosen only if the expected error reduction is greater than a certain threshold, if not, it means that the test does not add enough distinction, so the leaf is not expanded.

The expected error reduction obtained when dividing the instances I_l of leaf l is calculated using the following equation where I_k denotes the subset of instances in I_l that have the kth outcome for the potential test:

$$\Delta error = sd(I_l) - \sum_k \frac{|I_k|}{|I_l|} \times sd(I_k) \qquad (6)$$

The standard deviation is calculated on the expected reward of each instance which is defined as:

$$Q_I(i_t) = r_t + \gamma \hat{T}(L(i_t), L(i_{t+1})) \times Q(L(i_{t+1})) \qquad (7)$$

where $\hat{T}(L(i_t), L(i_{t+1}))$ is calculated using equation 4 and $Q(L(i_{t+1}))$ using equation 2.

As mentioned earlier, one test is tried for each possible instance's attribute. For a discrete attribute, we divide the instances according to their value for this attribute. For instance, if an attribute has three possible values, it generates three subsets, thus adding three children nodes to the tree. We then use Equation 6 and record the error reduction for this test. For a continuous attribute, we have to test different thresholds to find the best one. A continuous attribute always divides the instances in two subsets, the first one is for the instances with a value less or equal to the threshold for the specified attribute and the second subset is for the instances with a value greater than the threshold.

To find the best threshold, we have used the technique described by Quinlan [7]. The instances are first sorted according to their value for the attribute being considered. Afterwards, we examine all $m-1$ possible splits, where m is the number of different values. For example, with an ordered list of values $\{v_1, v_2, ..., v_m\}$, we try all possible thresholds. So, we try the value v_1 as a threshold, thus dividing the instances in two subsets, those less or equal and those greater than v_1. We calculate and record the error reduction for this division. Then, we do the same thing for the other possible values, v_2 to v_{m-1}. At the end, we keep only the threshold with the best error reduction value.

Function NUMBER-AGENTS-REQUIRED(d)

Inputs: d: a task description.
Static: *Tree*: the tree learned.
N: the number of available agents.
Threshold: the limit to surpass.

for $n = 1$ to N **do**
  $expReward \leftarrow$ EXPECTED-REWARD($Tree$, d, n)
  if $expReward \geq Threshold$ **then**
    return n
  end if
end for
return ∞

Algorithm 2: Algorithm used to find the required number of agents for a given task description d.

When the tree has been updated, the UPDATE-Q-VALUES function is called again to take the new tree structure into consideration.

4.4 Use of the Tree

During a simulation, all learning agents use the same learned tree to estimate the number of agents that are required to accomplish a task. Since the number of agents is considered as an attribute when the tree is learned, if different numbers of agents are tested, different leaves and thus different rewards may be found, even with the same task description. Consequently, to find the required number of agents for a particular task, the algorithm can test different number of agents and look at the expected rewards returned by the tree.

Algorithm 2 presents the function used to estimate the required number of agents for a given task. In this algorithm, the function EXPECTED-REWARD returns the expected reward if n agents are trying to accomplish a task described as d. To do so, it finds the corresponding leaf in the tree, considering the task description d and the number of agents n, and records the expected reward for this abstract task.

The EXPECTED-REWARD function is called for all possible number of agents until the expected reward returned by the tree is greater than a specified *Threshold*. If the expected reward is greater then the *Threshold*, it means that the current number of agents should be enough to accomplish the task. If the expected reward is always under the *Threshold*, even with the maximum number of agents, the function returns ∞, meaning that the task is considered impossible with the available number of agents N. The *Threshold* value is set empirically and it corresponds to the minimum expected reward needed to accomplish a task. The agent stops when the *Threshold* is exceeded because the objective here is to find the minimum number of agents for each task.

4.5 Algorithm Characteristics

First of all, let's look at the algorithm complexity. The first step of the algorithm used to update the tree is to add all the new instances recorded during the last simulation. In the worst case, this step takes $O(|I|D_{\max})$, where $|I|$ is the number of instances to add and $D_{\max}$ is the maximal depth of the tree. Therefore, as the tree grows, this step takes more time. However, in our RoboCupRescue experiments, the maximum depth of the tree was always relatively small (≤ 30).

The second step is to update the Q-values using Equa-

tion 2. The reward and the transition function (Equations 3 and 4) do not take time, because they are simply updated each time a new instance is added to a leaf. The complexity of Equation 2 depends on the number of subsequent leaf nodes link to the current leaf node. To update the Q-values, the algorithm has to visit all the leaves and in the worst case, all the leaves are connected together, thus the complexity is $O(|L|^2)$, where $|L|$ is the number of leaves in the tree. This complexity is multiplied by the number of iterations needed until convergence of the Q-values. Since the Q-values are normally only slightly modified when the new instances are added, it generally does not take a lot of iterations to converge. Most of the time, it took less then 10 iterations in our tests.

The third step of the algorithm is to expand the tree. To achieve that, the algorithm has to visit all the leaves of the tree one time. For each leaf, it has to evaluate all possible splits using all the attributes describing a task. For a discrete attribute, there is only one split to try. For a continuous attribute, there are as many possible splits as there are different values for this continuous attribute in the current leaf. In the worst case, there are as many attribute values as there are instances in the leaf. Therefore, the complexity in the worst case is: $O(|L|n_d n_c|I|_{\max})$, where $|L|$ is the number of leaves in the tree, n_d and n_c are the number of discrete and continuous variables used to describe a task and $|I|_{\max}$ is the maximum number of instances in a leaf.

The last step of the algorithm does another update of the Q-values. Consequently, the total complexity of the algorithm is: $O(|I|D_{\max}) + 2O(|L|^2) + O(|L|n_d n_c|I|_{\max})$. The most expensive step is the expansion step, because it manipulates all the instances stored in all the leaves of the tree. In our tests, the time to update the tree was not a big factor since it was executed offline. It always took less time to learn the tree than to run a simulation.

Moreover, for this algorithm, we suppose that all the *FireBrigade* agents have the same vision of the situation, i.e. they see the same fires. In the RoboCupRescue it is almost always the case, because the agents are close from one another when they are extinguishing fires and the fires can be seen from a far distance.

Another hypothesis is that all the agents have the same learned tree. The tree is learned offline after each simulation, using all the instances gather by the *FireBrigade* agents during the simulation. The communications between the agents are really limited during a simulation, thus we wanted the agents to have some common ground on which to base their decisions in order to reduce the amount of communication necessary to maintain the coordination between the agents.

In the next section, we present some experiments in which we described in more detail how the learned trees are used. We also present results showing the quality of the solutions found and the speed at which the tree grows when we add new instances.

5. EXPERIMENTS

In this section, we present how our learning algorithm can be used in the RoboCupRescue simulation to help the *FireBrigade* agents to coordinate themselves on the buildings on fire to extinguish. Since there could be a lot of fires, agents do not consider all fires at once. They choose separately which fire area to extinguish and which specific building in the chosen fire area to extinguish. Fire areas are simply

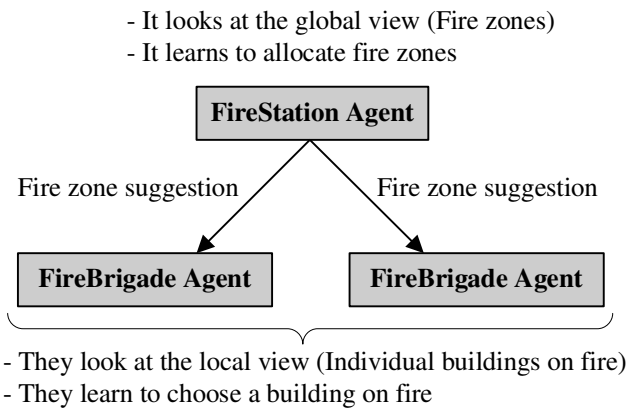

Figure 2: Illustrates how the agents collaborate to choose which fires to extinguish.

groups of close buildings on fire. To make their decision, agents use the tree created offline to estimate the required number of agents for each building on fire. All agents have the same tree and it does not change during a simulation.

As previously stated, the *FireStation* agent has a better global view of the situation and therefore it can suggest fire areas to *FireBrigade* agents. The *FireBrigade* agents have however a more accurate local view, consequently they choose which particular building on fire to extinguish in the given area. By doing so, as illustrated on Figure 2, we can take advantage of the better global view of the *FireStation* agent and the better local view of the *FireBrigade* agent at the same time.

5.1 Fire Areas Allocation

To allocate the fire areas, the *FireStation* agent has a list of all fire areas. For each fire area, it has to estimate the number of agents that are required to extinguish this area. To do so, it makes a list of all the buildings that are at the edge of the fire area. Agents only consider buildings at the edge because those are the buildings that have to be extinguished to stop the propagation of the fire. For each burning building at the edge, the agent finds the number of agents required to extinguish the fire (Algorithm 2). It then estimates the required number of agents for the fire area as the maximum number of agents returned for one building in the area. The *FireStation* agent does the same thing with all fire areas, ending up with a number of agents (n_z) for each area.

Afterwards, for each area z, the *FireStation* agent calculates the average distance of the n_z closest *FireBrigade* agents from z. Then, it chooses the fire area z with the smallest average distance. Consequently, the n_z closest *FireBrigade* agents from the chosen z are assigned to z. The *FireStation* agent then removes the assigned area and *FireBrigade* agents from its lists and continues the process with the remaining agents and the remaining fire areas. It continues until there is no agent or fire area left. At the end, the *FireStation* agent sends to each *FireBrigade* agent their assigned fire area.

5.2 Choice of Buildings on Fire

When choosing a building to extinguish, a *FireBrigade* agent builds a list of buildings on fire it knows about in

the fire area specified by the *FireStation*. This list is sorted according to a utility function that gives an idea about the usefulness of extinguishing a fire. The utility function gives a value to a fire based on the buildings and the civilians in danger if this fire propagates to buildings close by.

All *FireBrigade* agents have approximately the same list of buildings on fire. To choose their building on fire they go through the list, one building at a time. For each building, they use the tree to find the expected required number of agents to extinguish the fire, by using Algorithm 2.

The *FireBrigade* agents are assigned to the burning buildings following a prefixed order given to them at the beginning of the simulation. Knowing the sorted list of buildings on fire, the order of all *FireBrigade* agents and the number of agents required for each fire, each *FireBrigade* agent can choose the fire it should extinguish. For example, suppose that there are two fires requiring 5 and 3 agents respectively and that the *FireBrigade* agent A has to choose one of them. If the agent A's rank is 3, it would choose the first fire, because the five first agents have to go to the first fire. However, if the agent A's rank is 7, it would choose the second fire, because the agents ranked 6, 7 and 8 have to go to the second building on fire. With this coordination process, if all *FireBrigade* agents actually have the same information, they should be well coordinated on which buildings to extinguish.

6. RESULTS AND DISCUSSION

As mentioned before, experiments have been done in the RoboCupRescue simulation environment. We have made our tests on a situation with a lot of fires, but with all roads cleared. The simulations started with 8 fires, but the 15 *FireBrigade* agents were beginning to extinguish fires only after 30 simulation steps to leave some time for the fires to propagate. This gave us a hard situation to handle for the *FireBrigade* agents. Those agents started with an empty tree and they learned from one simulation to another to distinguish the tasks that had to be distinguished and the expected rewards associated with those tasks.

If we look back at our model in Section **??** ($< D, N, R, T >$), we can see that D is the set of all possible fire descriptions. In our experiments, a task was described by: the intensity of the fire (3 possible values), the building's composition (3 possible values), the building's size (730 different buildings), the building's damage (4 possible values) and the number of *FireBrigade* agents (15 possible values). Therefore, there were 394 200 possible task descriptions. N is the number of possible *FireBrigade* agents, which was 15. R is the reward function, which was simply 100 to extinguish a fire and 0 otherwise. Finally, T is the transition function which was estimated using the instances stored in the leaves of the tree as explained in Equation 4.

To compare the results obtained by our agents, we have compared them with two other strategies (see Figure 3). The first one is the team ResQFreiburg [1] which finished first at the 2004 RoboCupRescue simulation world competition. This team uses data-mining techniques to evaluate the propagation of the fires and a priority function to choose which fire to extinguish. If we look at the performance of ResQFreiburg, they only obtained an average percentage of intact buildings of 59%.

The second one is our strategy, but without the learning part, thus all agents were going to the first building on the list. This comparison shows the advantage of learning the required number of agents to accomplish a task. If all agents go to the same building, they obtained an average percentage of intact buildings of 63% and after learning, they obtained 84%. This is a huge improvement showing that the information learned is really useful. They learned how many agents are required for all possible situations so they were able to divide the tasks efficiently between the different agents. The improvement in the performances is mainly due to the fact that agents are able to split themselves on the first two or three tasks and accomplish them all at once. Thus, the more efficient they become at estimating the required number of agents, the faster they become at accomplishing all their tasks.

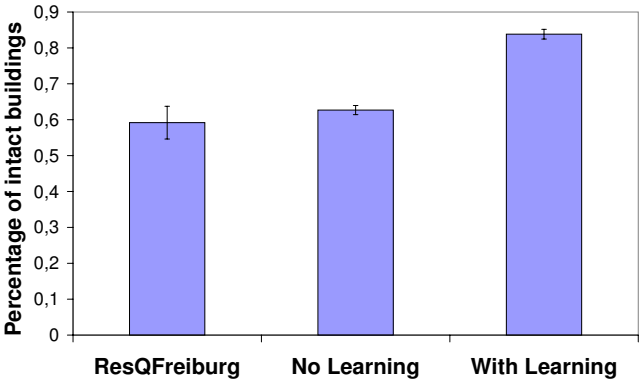

Figure 3: Comparison with other strategies.

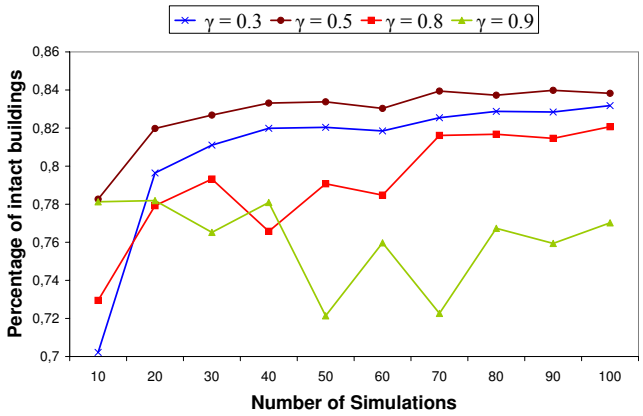

Figure 4: Percentage of intact buildings over 100 simulations for different γ values.

Another interesting result is that our agents were able to attain such good performances with trees having less than 2000 leaves. Therefore, they were just distinguishing 2000 task descriptions out of the 394 200 possible task descriptions. In other word, our agents were able to perform efficiently with an internal task description space of only 0.5% of the complete task description space. This shows a very good reduction of the task description space, enabling the learning algorithm to work on an easier problem.

Moreover, Figure 4 presents results with different γ values for the equation 2. It shows the evolution of the percentage of intact buildings at the end of a simulation. Every point represents an average over 10 simulations. We have tested

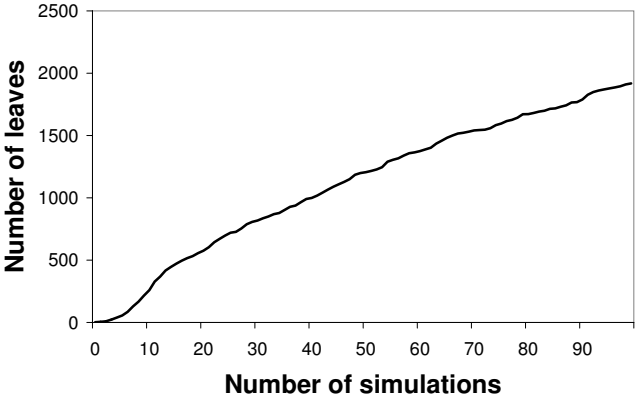

Figure 5: Number of leaves in the tree over 100 simulations.

all γ values from 0 to 1 with an increment of 0.1, but here we present only four representative learning curves. As we can see, with high γ values, the learning process is less effective. With 0.9, the agents do not get better at all, and with 1, it was even worse. With a value of 0.8, the agents have some trouble to learn at the beginning, but eventually they start to catch up after approximately 70 simulations. We have observed that with a higher gamma value, agents normally need more time to learn. With the small γ values of 0.3 and 0.5, the learning curves are quite smooth.

In each simulation, agents were able to gather approximately 2000 instances. Of course, with our algorithm, the necessary memory always grows to store all those instances, but since they were not taking too much space, this was not really a problem. Moreover, after the learning phase, the instances are not necessary anymore, therefore when the tree is used at the execution time it is really small.

Since we are expanding a tree, the growth could be exponential. However, it is not the case, because we are only expanding leaves that help to predict rewards. Therefore, the growth of the tree is controlled and in our tests it was even sub-linear (see Figure 5).

7. RELATED WORKS

In cooperative multiagent learning, most researchers have focused on coordinating agents' actions, but most of them consider that the characteristics of the tasks are known [9, 2]. In our case, an important characteristic of the tasks was unknown, i.e. the required number of agents for each task. Thus we focused our attention on developing an algorithm enabling agents to learn this important task's characteristic. Some researchers consider that the number of agents is unknown, but for very simplified tasks needing only one or two agents [3].

Other researchers have used tree structures to represent and learn the state space of the agent. One of them is McCallum with its U-tree algorithm [5]. He has used a tree structure to store Q-values for all possible basic actions that an agent can take. In our work, we use the tree to calculate the expected reward of a particular task description, considering a certain number of agents accomplishing it. It still has to find the actions to accomplish this task. The learned tree is used to estimate the number of agents needed to accomplish a task and not to find the action of the agent. Also, instead of generating all possible subtrees like McCallum, we use an error reduction estimation measure, borrowed from the decision tree theory [8], that enables us to find good tests. In our case, the generation of subtrees would really be expensive since our state space is very large.

There are different ways that can be used to expand the tree ([5, 6, 10]), but we have used an approach that has been shown to be effective in decision tree algorithms ([8]) and that enabled us to have a fast algorithm and to consider continuous attributes.

The way we manage our instance chains is also quite different. In our work, there is not only one chain, but many chains, one for each attempt to extinguish a fire or a fire zone. Our concept of instance chain is closer to the concept of *episode* described by Xuan, Lesser and Zilberstein [11].

8. CONCLUSION

In this article, we have presented a learning algorithm which is useful to learn the required number of agents for each different tasks in a complex cooperative multiagent environment. To achieve that, we have adapted a selective perception learning algorithm that learns a tree representation of the task description space. Our algorithm enables us to reduce the number of different task descriptions considered by regrouping tasks that have similar rewards. In this context, agents can learn to distinguish only between tasks that really need to be distinguished.

Afterwards, the learned expected rewards are used by our coordination algorithm to find the required number of agents to accomplish a task, both at the global and the local decision level. We added an attribute "number of agents" in the task description, which enabled us to use a greedy algorithm to find the minimum required number of agents to accomplish a given task.

With our learning approach, our agents were able to obtain good results in the RoboCupRescue simulation with an internal task description space of only 0.5% of the complete task description space. All the results presented in this article show that our approach is efficient for learning the required number of agents to accomplish a task and to coordinate agents on those tasks in a partially observable, dynamic and uncertain real-time environment.

ABSTRACT

Standard game theory assumes that the structure of the game is common knowledge among players. We relax this assumption by considering extensive games where agents may be unaware of the complete structure of the game. In particular, they may not be aware of moves that they and other agents can make. We show how such games can be represented; the key idea is to describe the game from the point of view of every agent at every node of the game tree. We provide a generalization of Nash equilibrium and show that every game with awareness has a generalized Nash equilibrium. Finally, we extend these results to games with *awareness of unawareness*, where a player i may be aware that a player j can make moves that i is not aware of.

1. INTRODUCTION

Standard game theory models implicitly assume that all significant aspects of the game (payoffs, moves available, etc.) are common knowledge among the players. While such common knowledge may seem unreasonable, there are well-known techniques going back to Harsanyi [7] for transforming a game where some aspects are not common knowledge to one where they are common knowledge. All these techniques assume that players are at least *aware* of all possible moves in the game. However, this is not always a reasonable assumption. For example, sleazy companies assume that consumers are not aware that they can lodge complaints if there are problems; in a war setting, having technology that an enemy is unaware of (and thus being able to make moves that the enemy is unaware of) can be critical; in financial markets, some investors may not be aware of certain investment strategies (complicated hedging strategies, for example, or tax-avoidance strategies).

In a standard game, a set of strategies is a Nash equilibrium if each agent's strategy is a best response to the other agents' strategies, so each agent i would continue playing its strategy even if i knew what strategies the other agents were using. To understand the relevance of adding the possibility of unawareness to the analysis of games, consider the game shown in Figure 1. One Nash equilibrium of this game has A playing across$_A$ and B playing down$_B$. However, suppose that A is not aware that B can play down$_B$. In that case, if A is rational, A will play down$_A$. Therefore, Nash equilibrium does not seem to be the appropriate solution concept here. Although A would play across$_A$ if A knew that B were going to play down$_B$, A cannot even contemplate this possibility, let alone know it.

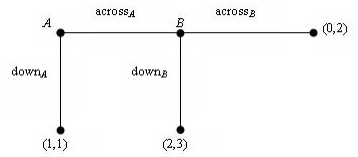

Figure 1: A simple game.

Our goal is to find appropriate solution concepts for extensive games with possibly unaware players, and more generally, to find ways of representing multiagent systems where some agents may not be aware of features of the system. To do this, we must first find an appropriate representation for such games. The first step in doing so is to explicitly represent what players are aware of at each node. We do this by using what we call an *augmented game*. An augmented game describes how awareness changes over time. For example, perhaps A playing across$_A$ will result in B becoming

aware of the possibility of playing down_B. In financial settings, one effect of players using certain investment strategies is that other players become aware of the possibility of using that strategy. Strategic thinking in such games must involve taking this possibility into account.

We cannot in general represent what is going on using only one augmented game. The standard representation of a game implicitly assumes that (it is common knowledge that) the modeler and the players all understand the game the same way. This is no longer true once we allow for the possibility of unawareness, since a player's description of the game can now involve only those aspects of the game that he is aware of. Thus, the full description of the game with awareness is given by a set of augmented games, one for the modeler and one for each game that at least one of the agents thinks might be the true game in some situation.

Continuing with the game in Figure 1, the augmented game from the point of view of the type of B that is unaware of the possibility of playing down_B would just include A's moves down_A and across_A and the move across_B. In that augmented game, player A is also unaware of the move down_B. By way of contrast, the augmented game from the point of view of the type of B that is aware of down_B would include the move down_B, but may also allow for the possibility that A is not aware that B is aware of this move.

The standard notion of Nash equilibrium consists of a collection of strategies, one for each player. Our generalization consists of a collection of strategies, one for each pair (i, Γ'), where Γ' is a game that agent i considers to be the true game in some situation. Intuitively, the strategy for a player i at Γ' is the strategy i would play in situations where i believes that the true game is Γ'. To understand why we may need to consider different strategies consider, for example, the game of Figure 1. B would play differently depending on whether or not he was aware of down_B. Roughly speaking, a set of strategies, one for each pair (i, Γ'), is a *generalized Nash equilibrium* if the strategy for (i, Γ') is a best response for player i if the true game is Γ', given the strategies being used by the other players in Γ'.

We argue that this notion of equilibrium correctly captures our intuitions. We then show that every game with awareness has a generalized Nash equilibrium by associating with a game with awareness a standard game (where agents are aware of all moves) such that there is a one-to-one correspondence between generalized Nash equilibria of the game with awareness and Nash equilibria of the standard game.

For ease of exposition, for most of the paper we focus on games where agents are not aware of their lack of awareness. That is, we do not consider games where one player might be aware that there are moves that another player (or even she herself) might be able to make, although she is not aware of what they are. Such awareness of unawareness can be quite relevant in practice. For example, in the war setting described above, even if one side cannot conceive of a new technology available to the enemy, they might believe that there is some move available to the enemy without understanding what that particular move is. This, in turn, may encourage peace overtures. To take another example, an agent might delay making a decision because she considers it possible that she might learn about more possible moves, even if she is not aware of what these moves are.

If we interpret "lack of awareness" as "unable to compute" (cf. [1]), then awareness of unawareness becomes even more significant. Consider a chess game. Although all players understand in principle all the moves that can be made, they are certainly not aware of all consequences of all moves. A more accurate representation of chess would model this computational unawareness explicitly. We provide such a representation.

Roughly speaking, we capture the fact that player i is aware that, at a node h in the game tree, there is a move that j can make she (i) is not aware by having i's subjective representation of the game include a "virtual" move for j at node h. Since i does not understand what can happen after this move, i does not develop the game tree after this move; i simply describes what she believes will be the payoffs after the move. Thus, our representation is quite similar in spirit to how chess programs analyze chess games. They explore the game tree up to a certain point, and then evaluate the board position at that point. We can think of the payoffs following a virtual move by j in i's subjective representation of a chess game as describing the evaluation of the board from i's point of view. This seems like a much more reasonable representation of the game than the standard complete game tree!

Recently, Feinberg [2, 3] also studied games with awareness. Feinberg [3] gives a definition of extended Nash equilibrium in normal-form games. Although his definition stems from much the same intuitions as ours, it is expressed syntactically. Each player is characterized by a complete description of what moves and players he is aware of, what moves and players he is aware that each other player is aware of, and so on through all levels of iterated awareness. Feinberg [2] deals with extensive-form games and defines solution concepts only indirectly, via a syntactic epistemic characterization. His approach lacks a more direct semantic framework, which our model provides. He also does not deal with awareness of unawareness.

2. MODELING AWARENESS

The first step in dealing with awareness is modeling it. To this end, we consider *augmented games*. We start with a standard game, described by a game tree Γ (as in Figure 1). An augmented game Γ^+ *based on* Γ essentially augments Γ by describing each agent's *awareness level* at each node, where player i's awareness level at a node h is essentially the set of runs (complete histories) in Γ that i is aware of at node h. A player's awareness level may change over time, as the player becomes aware of more moves.

Our formal definition of augmented game is based on the definition of extensive game given by Osborne and Rubinstein [8]. We start by briefly reviewing Osborne and Rubinstein's definition.

A *(finite) extensive game* is a tuple $(N, M, H, P, f_c, \{\mathcal{I}_i : i \in N\}, \{u_i : i \in N\})$, where

- N is a finite set consisting of the players of the game.
- M is a finite set whose elements are the moves available to players (and nature) during the game.[1]
- H is a finite set of finite sequences of moves (elements of M) that is closed under prefixes, so that if $h \in H$

[1]Osborne and Rubinstein did not make M explicit in their definition of an extensive game; we find it convenient to make it explicit here.

and h' is a prefix of H, then $h' \in H$. Intuitively, each member of H is a *history*. We can identify the nodes in a game tree with the histories in H. Each node n is characterized by the sequence of moves needed to reach n. A *run* in H is a terminal history, one that is not a strict prefix of any other history in H. Let Z denote the set of runs of H. Let $M_h = \{m \in M : h \cdot \langle m \rangle \in H\}$ (where we use $\cdot$ to denote concatenation of sequences); M_h is the set of moves that can be made after history h.

- $P : (H - Z) \to N \cup \{c\}$ is a function that assigns to each nonterminal history h a member of $N \cup \{c\}$. (We can think of c as representing nature.) If $P(h) = i$, then player i moves after history h; if $P(h) = c$, then nature moves after h. Let $H_i = \{h : P(h) = i\}$ be the set of all histories after which player i moves.
- f_c is a function that associates with every history for which $P(h) = c$ a probability measure $f_c(\cdot \mid h)$ on M_h. Intuitively, $f_c(\cdot \mid h)$ describes the probability of nature's moves once history h is reached.
- $\mathcal{I}_i$ is a partition of H_i with the property that if h and h' are in the same cell of the partition then $M_h = M_{h'}$, i.e., the same set of moves is available for every history in a cell of the partition. Intuitively, if h and h' are in the same cell of $\mathcal{I}_i$, then h and h' are indistinguishable from i's point of view; i considers history h' possible if the actual history is h, and vice versa. A cell $I \in \mathcal{I}_i$ is called an (i-)*information set*.
- $u_i : Z \to \mathrm{R}$ is a payoff function for player i, assigning a real number (i's payoff) to each run of the game.

In the game of Figure 1,

- $N = \{A, B\}$, $H = \{\langle\rangle, \langle \mathrm{down}_A \rangle, \langle \mathrm{across}_A, \mathrm{down}_B \rangle, \langle \mathrm{across}_A, \mathrm{across}_B \rangle\}$,
- $P(\langle\rangle) = A$, $P(\langle \mathrm{across}_A \rangle) = B$,
- $I_A = \{\langle\rangle\}$, $I_B = \{\langle \mathrm{across}_A \rangle\}$,
- $u_A(\langle \mathrm{down}_A \rangle) = u_B(\langle \mathrm{down}_A \rangle) = 1$,
- $u_A(\langle \mathrm{across}_A, \mathrm{across}_B \rangle) = 0$, and
- $u_B(\langle \mathrm{across}_A, \mathrm{across}_B \rangle) = 2$.

In this paper, as in most work in game theory, we further assume that players have *perfect recall*: they remember all the actions that they have performed and the information sets they passed through. Formally, we require that

- if h and h' are in the same i-information set and h_1 is a prefix of h such that $P(h_1) = i$, then there is a prefix h'_1 of h' such that h_1 and h'_1 are in the same information set; moreover, if $h_1 \cdot \langle m \rangle$ is a prefix of h (so that m was the action performed when h_1 was reached in h) then $h'_1 \cdot \langle m \rangle$ is a prefix of h'.

An *augmented game* is defined much like an extensive game; the only essential difference is that at each nonterminal history we not only determine the player moving but also her awareness level. Since the awareness level is a set of runs in a game Γ, we say that $\Gamma^+ = (N^+, M^+, H^+, P^+, f_c^+, \{\mathcal{I}_i^+ : i \in N^+\}, \{u_i^+ : i \in N^+\}, \{A_i^+ : i \in N^+\})$ is an *augmented game based on the (standard) extensive game* $\Gamma = (N, M, H, P, f_c, \{\mathcal{I}_i : i \in N\}, \{u_i : i \in N\})$ if the following conditions are satisfied:

A1. $(N^+, M^+, H^+, P^+, f_c^+, \{\mathcal{I}_i^+ : i \in N^+\}, \{u_i^+ : i \in N^+\})$ is a finite extensive game with perfect recall.

A2. $A_i^+ : H_i^+ \to 2^H$ describes i's awareness level at each nonterminal history after which player i moves. For each $h \in H_i^+$, $A_i^+(h)$ consists of a set of histories in H and all their prefixes. Intuitively, $A_i^+(h)$ describes the set of histories of Γ that i is aware of at history $h \in H_i^+$. (Having $A_i^+(h)$ consist of histories rather than just runs makes it easier to deal with awareness of unawareness.)

A3. $N^+ \subseteq N$.

A4. If $P^+(h) \in N^+$, then $P^+(h) = P(\overline{h})$, where $\overline{h}$ is the subsequence of h consisting of all the moves in h that are also in M, and $M_h^+ \subseteq M_{\overline{h}}$. Intuitively, all the moves available to i at h must also be available to i in the underlying game Γ.

A5. If $P^+(h) = c$, then either $P(\overline{h}) = c$ and $M_h^+ \subseteq M_{\overline{h}}$, or $M_h^+ \cap M = \emptyset$. The moves in M_h^+ in the case where $M_h^+ \cap M = \emptyset$ intuitively capture uncertainty regarding a player's awareness level.

A6. If h and h' are in the same information set in $\mathcal{I}_i^+$, then $A_i^+(h) = A_i^+(h')$. Intuitively, i's awareness level depends only on the information that i has.

A7. If h is a prefix of h' and $P^+(h) = P^+(h')$, then $A_i^+(h) \subseteq A_i^+(h')$. This is a perfect recall requirement; players do not forget histories that they were aware of.

A8. If h and h' are in the same information set in Γ^+, then $\overline{h}$ and $\overline{h}'$ are in the same information set in Γ.

A9. If h and h' are histories in both Γ^+ and Γ (i.e., $h = \overline{h}$ and $h' = \overline{h}'$), and $\overline{h}$ and $\overline{h}'$ are in the same information set in Γ, then h and h' are in the same information set in Γ^+.

A10. For all $i \in N^+$ and $h \in H_i^+$, if $h', h'' \in A_i(h)$, h' and h'' are in the same information set in Γ, then $h' \cdot \langle m \rangle \in A_i(h)$ iff $h'' \cdot \langle m \rangle \in A_i(h)$.

A11. $\{\overline{z} : z \in Z^+\} \subseteq Z$; moreover, for all $i \in N^+$, $h \in H_i^+$, if z is a terminal history in $A_i^+(h)$ (i.e., if $z \in A_i(h)^+$ and z is not a strict prefix of another element of $A_i(h)^+$), then $z \subseteq Z$. Thus, the runs in Z^+ correspond to runs in Z, and players understand this fact.

A12. For all $i \in N^+$ and runs z in Z^+, if $\overline{z} \in Z$, then $u_i^+(z) = u_i(\overline{z})$. Thus, a player's utility just depends on the moves made in the underlying game. (By A11, we have $\overline{z} \in Z$. We have included the clause "if $\overline{z} \in Z$" so that A12 is applicable when we consider awareness of unawareness, where we drop A11.)

Conditions A1–A12 are intended to capture our intuitions regarding information sets, awareness, and common knowledge. To allow us to focus on issues directly related to awareness, we have implicitly assumed that there is common knowledge of (1) who moves at histories in the underlying game (this is captured by the fact that $P^+(h) = P(\overline{h})$ unless $P^+(h) = c$ and $M_h^+ \cap M = \emptyset$), (2) what the payoffs are in the underlying game (since $u^+(\overline{z}) = u(z)$), and (3) what the information sets are in the underlying game (see A8–A10).

Our approach is flexible enough to allow us to drop these assumptions; see the full paper for details.

To fully understand A8–A10, we must first discuss our view of information sets. As pointed out by Halpern [5], special attention must be given to the interpretation of information sets in game trees. This issue requires even more care in games with awareness. The standard intuition for information sets is that a player considers all the histories in his information set possible. But this intuition does not apply in augmented games. In an augmented game, there may be some histories in an i-information set that i is not aware of; player i cannot consider these histories possible. We interpret an i-information set to be the set of all histories where player i receives the same sequence of signals. A8-A10 reflect this interpretation under our assumption that (modulo awareness) information sets are common knowledge.

For the remainder of the paper, we use the following notation: for a (standard or augmented) game Γ^s, we denote the components of Γ^s with the same superscript s, so that we have M^s, H^s, and so on. Thus, from here on we do not explicitly describe the components of a game.

An augmented game describes either the modeler's view of the game or the subjective view of the game of one of the players, and includes both moves of the underlying game and moves of nature that change awareness. For example, consider again the game shown in Figure 1 and suppose that

- players A and B are aware of all histories of the game;
- player A is uncertain as to whether player B is aware of run $\langle \text{across}_A, \text{down}_B \rangle$ and believes that he is unaware of it with probability p; and
- the type of player B that is aware of the run $\langle \text{across}_A, \text{down}_B \rangle$ is aware that player A is aware of all histories, and he knows A is uncertain about his awareness level and knows the probability p.

Because A and B are actually aware of all histories of the underlying game, from the point of view of the modeler, the augmented game is essentially identical to the game described in Figure 1, with the awareness level of both players A and B consisting of all histories of the underlying game. However, when A moves at the node labeled A in the modeler's game, she believes that the actual augmented game is Γ^A, as described in Figure 2. In Γ^A, nature's initial move captures A's uncertainty about B's awareness level. At the information set labeled $A.1$, A is aware of all the runs of the underlying game. Moreover, at this information set, A believes that the true game is Γ^A.

At the node labeled $B.1$, B is aware of all the runs of the underlying game and believes that the true game is the modeler's game; but at the node labeled $B.2$, B is not aware that he can play down_B, and so believes that the true game is the augmented game Γ^B described in Figure 3. At the nodes labeled $A.3$ and $B.3$ in the game Γ^B, neither A nor B is aware of the move down_B. Moreover, both players think the true game is Γ^B.

As this example should make clear, to model a game with possibly unaware players, we need to consider not just one augmented game, but a collection of them. Moreover, we need to describe, at each history in an augmented game, which augmented game the player playing at that history believes is the actual augmented game being played.

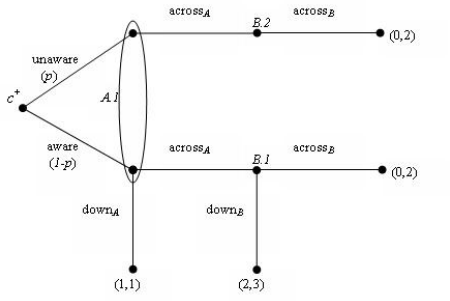

Figure 2: The augmented game Γ^A.

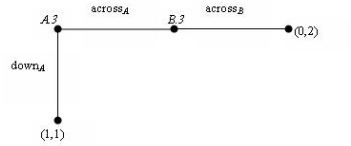

Figure 3: The augmented game Γ^B.

To capture these intuitions, we define a *game with awareness based on* $\Gamma = (N, M, H, P, f_c, \{\mathcal{I}_i : i \in N\}, \{u_i : i \in N\})$ to be a tuple $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$, where

- $\mathcal{G}$ is a countable set of augmented games based on Γ, of which one is Γ^m;
- $\mathcal{F}$ maps an augmented game $\Gamma^+ \in \mathcal{G}$ and a history h in Γ^+ such that $P^+(h) = i$ to a pair (Γ^h, I), where $\Gamma^h \in \mathcal{G}$ and I is an i-information set in game Γ^h.

Intuitively, Γ^m is the game from the point of view of an omniscient modeler. If player i moves at h in game $\Gamma^+ \in \mathcal{G}$ and $\mathcal{F}(\Gamma^+, h) = (\Gamma^h, I)$, then Γ^h is the game that i believes to be the true game when the history is h, and I consists of the set of histories in Γ^h he currently considers possible. For example, in the examples described in Figures 2 and 3, taking Γ^m to be the augmented game in Figure 1, we have $\mathcal{F}(\Gamma^m, \langle\,\rangle) = (\Gamma^A, I)$, where I is the information set labeled $A.1$ in Figure 2, and $\mathcal{F}(\Gamma^A, \langle \text{unaware}, \text{across}_A \rangle) = (\Gamma^B, \{\langle \text{across}_A \rangle\})$.

It may seem that by making $\mathcal{F}$ a function we cannot capture a player's uncertainty about the game being played. However, we can capture such uncertainty by folding it into nature's move. For example, we capture A's uncertainty about whether B is aware of being able to move down_B in the augmented game Γ^A illustrated in Figure 2 by having nature decide this at the first step. It should be clear that this gives a general approach to capturing such uncertainty.

The augmented game Γ^m and the mapping $\mathcal{F}$ must satisfy a number of consistency conditions. The first set of conditions applies to Γ^m. Since the modeler is presumed to be omniscient, the conditions say that the modeler is aware of all the players and moves of the underlying game.

M1. $N^m = N$.

M2. $M \subseteq M^m$ and $\{\overline{z} : z \in Z^m\} = Z$.

M3. If $P^m(h) \in N$, then $M^m_h = M_{\overline{h}}$. If $P^m(h) = c$, then either $M^m_h \cap M = \emptyset$ or $M^m_h = M_{\overline{h}}$ and $f^m_c(\cdot \mid h) = f_c(\cdot \mid \overline{h})$.

M1, M2 and M3 enforce the intuition that the modeler understands the underlying game. He knows all the players and possible moves, and understands how nature's moves work in the underlying game Γ. It may seem somewhat surprising that there is no analogue of the second part of M3 (i.e., the constraint of f_c^m) for all augmented games. While it makes sense to have such an analogue if nature's moves are in some sense objective, it seems like an unreasonable requirement that all player's should agree on these probabilities in general. This is especially so in the case that a player suddenly becomes aware of some moves of nature that he was not aware of before. It does not seem reasonable to assume that this awareness should come along with an understanding of the probabilities of these moves. Of course, we could require such an analogue of M3. Since the set of games that have such a requirement is a subset of the games we consider, all our results apply without change if such a requirement is imposed.

Although the modeler understands the underlying game Γ, Γ^m is not uniquely determined by Γ. There may be many modeler's games based on Γ, where the players have different awareness levels and the awareness changes in different ways.

The game Γ^m can be thought of as a description of "reality"; it describes the effect of moves in the underlying game and how players' awareness levels change. The other games in $\mathcal{G}$ describe a player's subjective view of the situation. The constraints on the mapping $\mathcal{F}$ that we now describe capture desirable properties of awareness.

Consider the following constraints, where $\Gamma^+ \in \mathcal{G}$, $h \in H^+$, $P^+(h) = i$, $A_i^+(h) = a$, and $\mathcal{F}(\Gamma^+, h) = (\Gamma^h, I)$.

C1. $\{\overline{h} : h \in H^h\} = a$.

C2. If $h' \in H^h$ and $P^h(h') = j$, then $A_j^h(h') \subseteq a$ and $M_{\overline{h}'} \cap \{m : \overline{h}' \cdot \langle m \rangle \in a\} = M_{h'}^h$.

C3. If h' and h are in the same information set in Γ^+ and $\overline{h}' \in a$, then there exists $h'' \in I$ such that $\overline{h}'' = \overline{h}'$.

C4. If $h' \in I$, then $A_i^h(h') = a$ and $\mathcal{F}(\Gamma^h, h') = (\Gamma^h, I)$.

C5. If $h' \in H^+$, $P^+(h') = i$, $A_i^+(h') = a$, then if h and h' are in the same information set of Γ^+, then $\mathcal{F}(\Gamma^+, h') = (\Gamma^h, I)$, while if h is a prefix or a suffix of h', then $\mathcal{F}(\Gamma^+, h') = (\Gamma^h, I')$ for some i-information set I'.

C6. If $h' \in I$, then $\overline{h}$ and $\overline{h}'$ are in the same information set in Γ;

C7. If $\Gamma^h = \Gamma^+$, then $h' \in I$ iff h and h' are in the same i-information set in Γ^+.

C8. For all histories $h' \in I$, there exists a prefix h_1' of h' such that $P^h(h_1') = i$ and $\mathcal{F}(\Gamma^h, h_1') = (\Gamma', I')$ iff there exists a prefix h_1 of h such that $P^+(h_1) = i$ and $\mathcal{F}(\Gamma^+, h_1) = (\Gamma', I')$. Moreover, $h_1' \cdot \langle m \rangle$ is a prefix of h' iff $h_1 \cdot \langle m \rangle$ is a prefix of h.

C9. There exists a history $h' \in I$ such that for every prefix $h'' \cdot \langle m \rangle$ of h', if $P^h(h'') = j \in N^h$ and $\mathcal{F}(\Gamma^h, h'') = (\Gamma', I')$, then for all $h_1 \in I'$, $h_1 \cdot \langle m \rangle \in H'$.

C10. If h' and h'' are histories in both Γ^+ and Γ^h, then h' and h'' are in the same i-information set in Γ^+ iff h' and h'' are in the same i-information set in Γ^h.

Suppose that $\mathcal{F}(\Gamma^+, h) = (\Gamma^h, I)$. Player i moving at history h in Γ^+ thinks the actual game is Γ^h. Moreover, i thinks he is in the information set of I of Γ^h. C1 guarantees that the set of histories of the underlying game player i is aware of is exactly the set of histories of the underlying game that appear in Γ^h. C2 states that no player in Γ^h can be aware of histories not in a. The second part of C2 implies that the set of moves available for player j at h' is just the set of moves that player i is aware of that are available for j at $\overline{h}'$ in the underlying game. C3 guarantees that for all histories h' indistinguishable from h that player i is aware of, there exists some history $h'' \in I$ differing from h' at most in some moves of nature that change awareness levels. C4 says that at all histories in I player i indeed thinks the game is Γ^h and that the information set is I. C5 says that player i's subjective view of the game changes only if i becomes aware of more moves and is the same at histories in H^+ that i cannot distinguish. C6 captures the assumption that at all histories i considers possible, he must have gotten the same signals as he does in the actual history.

C7 says that if while moving at history h player i thinks that Γ^+ is the actual game, then he considers possible all and only histories in the information set containing h. C8 is a consequence of the perfect recall assumption. C8 says that if, at history h, i considers h' possible, then for every prefix h_1' of h' there is a corresponding prefix of h where i considers himself to be playing the same game, and similarly, for every prefix of h there is a prefix of h' where i considers himself to be playing the same game. Moreover, i makes the same move at these prefixes.

The intuition behind condition C9 is that player i knows that player j only make moves that j is aware of. Therefore, player i must consider at least one history h' where he believes that every player j made a move that j was aware of. It follows from A11, C1, C2, and C9 that there is a run going through I where every player j makes a move that player i believes that j is aware of.

Since we assume that players have (modulo awareness) common knowledge about information sets, if Γ^+ is the game from the point of view of player j (or the modeler) and there are histories h' and h'' in both Γ^+ and Γ^h, then player j (or the modeler) knows that player i gets the same signals in both h' and h'' iff he knows that player i knows that he gets the same signals in those histories. C10 captures that intuition.

Just as Γ^m is not uniquely determined by Γ, $\mathcal{F}(\Gamma^+, h)$ is not uniquely determined by Γ^+ and h. Moreover, even if $A_i(h) = A_i(h')$, we may have $\mathcal{F}(\Gamma^+, h) = (\Gamma^h, I)$ and $\mathcal{F}(\Gamma^+, h') = (\Gamma^{h'}, I')$ with $\Gamma^h \neq \Gamma^{h'}$. We do not require that the awareness level determines the game a player considers possible. This extra flexibility allows us to model a situation where, for example, players 2 and 3, who have the same awareness level and agree on the awareness level of player 1, have different beliefs about the game player 1 considers possible.

A standard extensive game Γ can be identified with the game $(\{\Gamma^m\}, \Gamma^m, \mathcal{F})$, where (abusing notation slightly) $\Gamma^m = (\Gamma, \{A_i : i \in N\})$ and, for all histories h in an i-information set I in Γ, $A_i(h) = H$ and $\mathcal{F}(\Gamma^m, h) = (\Gamma^m, I)$. Thus, all players are aware of all the runs in Γ, and agree with each other and the modeler that the game is Γ. We call this the *canonical representation of* Γ as a game with awareness.

One technical issue: We have assumed that the set $\mathcal{G}$ of

games in a game Γ^* with awareness is countable. For our purposes, this is without loss of generality. We are ultimately interested in what happens in the game Γ^m, since this is the game actually being played. However, to analyze that, we need to consider what happens in other games in $\mathcal{G}$. For example, if h is a history in Γ^m where i moves, we need to understand what happens in the game Γ^h such that $\mathcal{F}(\Gamma^m, h) = (\Gamma^h, \cdot)$, since Γ^h is the game that i thinks is being played at history h in Γ^m. It is not hard to see that the set of games we need to consider is the least set $\mathcal{G}'$ such that $\Gamma^m \in \mathcal{G}'$ and, for every $\Gamma' \in \mathcal{G}$ and history h in Γ' such that $\mathcal{F}(\Gamma', h) = (\Gamma'', \cdot)$, $\Gamma'' \in \mathcal{G}'$. $\mathcal{G}'$ is guaranteed to be countable, even if $\mathcal{G}$ is not.

Finally, we remark that our notion of a game with awareness as consisting of the modeler's game together with description of which game each agent thinks is the actual game at each history has much in common with the intuition behind Gal and Pfeffer's [4] notion *Networks of Influence Diagrams*; we discuss the connections in detail in the full paper.

3. LOCAL STRATEGIES AND GENERALIZED NASH EQUILIBRIUM

3.1 Local Strategies

In this section, we generalize the notion of Nash equilibrium to games with awareness. To do that, we must first define what a strategy is in a game with awareness. Recall that in a standard game, a strategy for player i is a function from i-information sets to a move or to a distribution over moves, depending on whether we are considering *pure* (i.e., deterministic) strategies or *behavioral* (i.e., randomized) strategies. The intuition is that player i's actions depend on what i knows; the strategy can be viewed as a *universal plan*, describing what i will do in every possible situation that can arise. This makes sense only because i is presumed to know the game tree, and thus to know in advance all the situations that can arise.

In games with awareness, this intuition no longer makes sense. For example, player i cannot plan in advance for what will happen if he becomes aware of something he is initially unaware of. We must allow i's strategy to change if he becomes aware of more moves. Let $\mathcal{G}_i = \{\Gamma' \in \mathcal{G} :$ for some $\Gamma^+ \in \mathcal{G}$ and h in Γ^+, $P^+(h) = i$ and $\mathcal{F}(\Gamma^+, h) = (\Gamma', \cdot)\}$. Intuitively, $\mathcal{G}_i$ consists of the games that i views as the real game in some history.Thus, rather than considering a single strategy in a game $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ with awareness, we consider a collection $\{\sigma_{i,\Gamma'} : \Gamma' \in \mathcal{G}_i\}$ of what we call *local strategies*, one for each augmented game in $\mathcal{G}_i$. Intuitively, a local strategy $\sigma_{i,\Gamma'}$ for game Γ' is the strategy that i would use if i were called upon to play and i thought that the true game was Γ'. Thus, the domain of $\sigma_{i,\Gamma'}$ consists of pairs (Γ^+, h) such that $\Gamma^+ \in \mathcal{G}$, h is a history in Γ^+, $P^+(h) = i$, and $\mathcal{F}(\Gamma^+, h) = (\Gamma', I)$.

Define an equivalence relation $\sim_i$ on pairs (Γ', h) such that $\Gamma' \in \mathcal{G}$ and h is a history in Γ' where i moves such that $(\Gamma_1, h_1) \sim_i (\Gamma_2, h_2)$ if $\mathcal{F}(\Gamma_1, h_1) = \mathcal{F}(\Gamma_2, h_2)$. We can think of $\sim_i$ as defining a *generalized information partition* in Γ^*. It is easy to check that a $\sim_i$ equivalence class consists of a union of i-information sets in individual games in $\mathcal{G}$. Moreover, if some element of a $\sim_i$ equivalence class is in the domain of $\sigma_{i,\Gamma'}$, then so is the whole equivalence class. At all pairs (Γ', h') in a $\sim_i$ equivalence class, if $\mathcal{F}(\Gamma', h') = (\Gamma^{h'}, I)$, player i thinks he is actually playing in the information set I of $\Gamma^{h'}$. Thus, we require that $\sigma_{i,\Gamma'}(\Gamma_1, h_1) = \sigma_{i,\Gamma'}(\Gamma_2, h_2)$ if (Γ_1, h_1) and (Γ_2, h_2) are both in the domain of $\sigma_{i,\Gamma'}$ and $(\Gamma_1, h_1) \sim_i (\Gamma_2, h_2)$.

The following definition summarizes this discussion.

DEFINITION 3.1. *Given a game with awareness $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$, a* local strategy $\sigma_{i,\Gamma'}$ *for agent i is a function mapping pairs (Γ^+, h) such that h is a history where i moves in Γ^+ and $\mathcal{F}(\Gamma^+, h) = (\Gamma', I)$ to a probability distribution over $M'_{h'}$, the moves available at a history $h' \in I$, such that $\sigma_{i,\Gamma'}(\Gamma_1, h_1) = \sigma_{i,\Gamma'}(\Gamma_2, h_2)$ if $(\Gamma_1, h_1) \sim_i (\Gamma_2, h_2)$.*

Note that there may be no relationship between the strategies $\sigma_{i,\Gamma'}$ for different games Γ'. Intuitively, this is because discovering about the possibility of a different move may cause agent i to totally alter his strategy. We could impose some consistency requirements, but we have not found any that we believe should hold in all games. We believe that all our results would continue to hold in the presence of reasonable additional requirements, although we have not explored the space of such requirements.

3.2 Generalized Nash Equilibrium

We want to define a notion of generalized Nash equilibrium so as to capture the intuition that for every player i, if i believes he is playing game Γ', then his local strategy $\sigma_{i,\Gamma'}$ is a best response to the local strategies of other players in Γ'.

Define a *generalized strategy profile* of $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ to be a set of local strategies $\vec{\sigma} = \{\sigma_{i,\Gamma'} : i \in N, \Gamma' \in \mathcal{G}_i\}$. Let $EU_{i,\Gamma'}(\vec{\sigma})$ be the expected payoff for i in the game Γ' given that strategy profile $\vec{\sigma}$ is used. Note that the only strategies in $\vec{\sigma}$ that are needed to compute $EU_{i,\Gamma'}(\vec{\sigma})$ are the strategies actually used in Γ'; indeed, all that is needed is the restriction of these strategies to information sets that arise in Γ'.

A *generalized Nash equilibrium* of $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ is a generalized strategy profile $\vec{\sigma}$ such that for all $\Gamma' \in \mathcal{G}_i$, the local strategy $\sigma_{i,\Gamma'}$ is a best response to $\vec{\sigma}_{-(i,\Gamma')}$, where $\vec{\sigma}_{-(i,\Gamma')}$ is the set of all local strategies in $\vec{\sigma}$ except $\sigma_{i,\Gamma'}$.

DEFINITION 3.2. *A generalized strategy profile $\vec{\sigma}^*$ is a* generalized Nash equilibrium *of a game $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ with awareness if, for every player i, game $\Gamma' \in \mathcal{G}_i$, and local strategy σ for i in Γ',*

$$EU_{i,\Gamma'}(\vec{\sigma}^*) \geq EU_{i,\Gamma'}((\vec{\sigma}^*_{-(i,\Gamma')}, \sigma)).$$

The standard definition of Nash equilibrium would say that $\vec{\sigma}$ is a Nash equilibrium if σ_i is a best response to $\vec{\sigma}_{-i}$. This definition implicitly assumes that player i can choose a whole strategy. This is inappropriate in our setting. An agent cannot anticipate that he will become aware of more moves. Essentially, if $\Gamma_1 \neq \Gamma_2$, we are treating player i who considers the true game to be Γ_1 to be a different agent from the version of player i who considers Γ_2 to be the true game. To understand why this is appropriate, suppose that player i considers Γ_1 to be the true game, and then learns about more moves, and so considers Γ_2 to be the true game. At that point, it is too late for player i to change the strategy he was playing when he thought the game was Γ_1. He should just try to play optimally for what he now considers the true game. Moreover, while player i thinks that the game Γ_1 is the true game, he never considers it possible that

he will ever be playing a different game, so that he cannot "prepare himself" for a change in his subjective view of the game.[2]These considerations suggest that our notion of Nash equilibrium is appropriate.

It is easy to see that $\vec{\sigma}$ is a Nash equilibrium of a standard game iff $\vec{\sigma}$ is a (generalized) Nash equilibrium of the canonical representation of Γ as a game with awareness. Thus, our definition of generalized Nash equilibrium generalizes the standard definition.

Consider the game with awareness shown in Figures 1 (taking this to be Γ^m), 2, and 3. We have $\mathcal{G}_A = \{\Gamma^A, \Gamma^B\}$ and $\mathcal{G}_B = \{\Gamma^m, \Gamma^B\}$. Taking $dom(\sigma_{i,\Gamma'})$ to denote the domain of the strategy $\sigma_{i,\Gamma'}$, we have

$dom(\sigma_{A,\Gamma^A}) = \{(\Gamma^m, \langle\,\rangle), (\Gamma^A, \langle\text{unaware}\rangle), (\Gamma^A, \langle\text{aware}\rangle)\}$,
$dom(\sigma_{B,\Gamma^m}) = \{(\Gamma^m, \langle\text{across}_A\rangle), (\Gamma^A, \langle\text{aware, across}_A\rangle)\}$,
$dom(\sigma_{A,\Gamma^B}) = \{(\Gamma^B, \langle\,\rangle)\}$, and
$dom(\sigma_{B,\Gamma^B}) = \{(\Gamma^A, \langle\text{unaware,across}_A\rangle), (\Gamma^B, \langle\text{across}_A\rangle)\}$.

Each of these domains consists of a single generalized information set. If $p < 1/2$, then the unique generalized Nash equilibrium is $\sigma_{A,\Gamma^A} = \text{across}_A$, $\sigma_{A,\Gamma^B} = \text{down}_A$, $\sigma_{B,\Gamma^m} = \text{down}_B$, $\sigma_{B,\Gamma^B} = \text{across}_B$. Thus, in the modeler's game, A plays across_A, B plays down_B, and the resulting payoff vector is $(2, 3)$. On the other hand, if $p > 1/2$, then the unique generalized Nash equilibrium is $\sigma_{A,\Gamma^A} = \text{down}_A$, $\sigma_{A,\Gamma^B} = \text{down}_A$, $\sigma_{B,\Gamma^m} = \text{down}_B$, $\sigma_{B,\Gamma^B} = \text{across}_B$. Thus, in the modeler's game, A plays down_A, and the payoff vector is $(1, 1)$. Intuitively, even though both A and B are aware of all the moves in the modeler's game, A considers it sufficiently likely that B is not aware of down_B, so A plays down_A.

We now show that every game with awareness has at least one generalized Nash equilibrium. We proceed as follows. Given a game $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ with awareness, let ν be a probability on $\mathcal{G}$ that assigns each game in $\mathcal{G}$ positive probability. (Here is where we use the fact that $\mathcal{G}$ is countable.) We construct a standard extensive game Γ^ν by essentially "gluing together" all the games $\Gamma' \in \mathcal{G}$, except that we restrict to the histories in Γ' that can actually be played according to the players' awareness level. The components of Γ^ν are independent of ν except for nature's initial move (as encoded by f_c^ν). In Γ^ν, the set of players is $\{(i, \Gamma') : \Gamma' \in \mathcal{G}_i\}$. The game tree of Γ^ν can be viewed as the union of the pruned game trees of $\Gamma' \in \mathcal{G}$. The histories of Γ^ν have the form $\langle\Gamma^h\rangle \cdot h$, where $\Gamma^h \in \mathcal{G}$ and h is a "pruned" history in H^h. The move that a player or nature makes at a history $\langle\Gamma^h\rangle \cdot h$ of Γ^ν is the same as the move made at h when viewed as a history of Γ^h. The only move in Γ^ν not determined by Γ^* is nature's initial move (at the history $\langle\,\rangle$), where nature chooses the game $\Gamma' \in \mathcal{G}$ with probability $\nu(\Gamma')$. We leave the details of the construction of Γ^ν to the full paper.

THEOREM 3.1. *For all probability measures ν on $\mathcal{G}$*

(a) Γ^ν is a standard extensive game with perfect recall; and

(b) if ν gives positive probability to all games in $\mathcal{G}$, then $\vec{\sigma}$ is a Nash equilibrium of Γ^ν iff $\vec{\sigma}'$ is a generalized Nash equilibrium of Γ^*, where $\sigma_{i,\Gamma'}(\langle\Gamma^h\rangle \cdot h') = \sigma'_{i,\Gamma'}(\Gamma^h, h')$.

[2]In games with awareness of unawareness, an agent may consider it possible that he will become aware of more information. But this too is incorporated in his view of the game, so he can still do no better than playing optimally in his current view of the game.

Although a Nash equilibrium does not necessarily exist in games with infinitely many players, Γ^ν has three special properties: (a) each player has only finitely many information sets, and (b) for each player (i, Γ'), there exists a finite subset $N(i, \Gamma')$ of N^ν such that (i, Γ)'s payoff in Γ^ν depends only on the strategies of the players in $N(i, \Gamma')$, and (c) Γ^ν is a game with perfect recall. This turns out to be enough to show that Γ^ν has at least one Nash equilibrium. Thus, we get the following corollary to Theorem 3.1.

COROLLARY 3.1. *Every game with awareness has a generalized Nash equilibrium.*

4. MODELING AWARENESS OF UNAWARENESS

In this section, we describe how to extend our representation of games with awareness to deal with awareness of unawareness. In an augmented game that represents player i's subjective view of the game, we want to model the fact that i may be aware of the fact that j can make moves at a history h that i is not aware of. We do this by allowing j to make a "virtual move" at history h. A virtual move is always a terminal move; associated with it there is a payoff vector. Intuitively, these payoffs are agent i's subjective feeling about what would happen if some move she is unaware of is made by agent j. Player j may have several virtual moves available at history h, and may make virtual moves at a number of histories in the augmented game. These virtual moves do not necessarily correspond to a move in the underlying game Γ (i.e., i may falsely believe that j can make a move at h that he is unaware of), and even if j's virtual move does correspond to a move in Γ, the payoffs after the virtual move may bear no relationship to the actual payoffs after that move in Γ. Agent i's subjective game may include virtual moves for i himself; i may believe that he will become aware of more moves (and may take active steps to try and learn about these moves).

To handle awareness of unawareness, we consider a generalization of the notion of augmented game. We continue to refer to the generalized notion as an augmented game, using "augmented game without awareness of unawareness" to refer to the special case we have focused on up to now. Formally, $\Gamma^+ = (N^+, M^+, H^+, P^+, f_c^+, \{\mathcal{I}_i^+ : i \in N^+\}, \{u_i^+ : i \in N^+\}, \{A_i^+ : i \in N^+\})$ is an *augmented game based on the (standard) finite extensive game* $\Gamma = (N, M, H, P, f_c, \{\mathcal{I}_i : i \in N\}, \{u_i : i \in N\})$ if it satisfies conditions A1–A3, A6–A10 and A12 of augmented games, and the following variants of A4 and A5:

A4′. If $P^+(h) \in N^+$, then $P^+(h) = P(\overline{h})$, and $M_h^+ \subseteq M_{\overline{h}} \cup (M^+ - M)$. Moreover, every history $h \cdot \langle m\rangle \in H^+$ with $m \in M_h^+ - M_{\overline{h}}$ is terminal. Intuitively, the moves in $M_h^+ - M_{\overline{h}}$ are virtual moves.

A5′. If $P^+(h) = c$ and $M_h^+ \cap M \neq \emptyset$, then $M_h^+ \subseteq M_{\overline{h}} \cup (M^+ - M)$. Moreover, if $m \in M_h^+ - M$ and $M_h^+ \cap M \neq \emptyset$, then $h \cdot \langle m\rangle$ is terminal. Intuitively, if $M_h^+ \cap M \neq \emptyset$, then all the moves in $M_h^+ - M$ are virtual moves.

A *game with awareness of unawareness based on* Γ is defined as a tuple $\Gamma^* = (\mathcal{G}, \Gamma^m, \mathcal{F})$ just as before. The modeler's extended game Γ^m satisfies the same conditions M1-M3 as before, and the mapping $\mathcal{F}$ satisfies C1 and C3–C10 and the following variant of C2:

C2′. If $h' \in H^h$ and $P^h(h') = j$, then (a) $A_j^h(h') \subseteq a$, (b) $(M_{\overline{h}'} \cap \{m : \overline{h}' \cdot \langle m \rangle \in a\}) \cup (M_{h'}^h - M_{\overline{h}'}) = M_{h'}^h$, and (c) if $\mathcal{F}(\Gamma^h, h') = (\Gamma', I')$, then for all $h'' \in I'$, we have $M_{h''}' \subseteq M_{h'}^h$.

Part (a) of C2′ is the same as the first part of C2. Part (b) implies that the set of moves available for player j at h' is the set of moves that player i is aware of that are available for j at $\overline{h}'$ in the underlying game together with some virtual moves. It is not hard to check that in games without awareness of unawareness, part (c) follows from A4, C1, and C2, so it does not need to be explicitly stated in C2. However, now that A4 has been weakened to A4′, we must mention it explicitly.

Note that Γ^m is an augmented game with no awareness of unawareness; there are no virtual moves, since the modeler is indeed aware of all possible moves (and knows it). We can now define local strategies, generalized strategy profiles, and generalized Nash equilibrium just as we did for games with awareness. The same technique as that used to show Corollary 3.1 can be used to prove the following.

THEOREM 4.1. *Every game with awareness of unawareness has a generalized Nash equilibrium.*

5. CONCLUSION

We have generalized the representation of games to take into account agents who may not be aware of all the moves or agents, but may be aware of their lack of awareness. As we show in the full paper, our representation is also flexible enough to deal with subjective games when there is lack of common knowledge about the game, even if awareness is not an issue. We have also shown how to define strategies and Nash equilibrium in such settings. These generalizations greatly increase the applicability of game-theoretic notions in multiagent systems. In large games involving many agents, agents will almost certainly not be aware of all agents and may well not be aware of all the moves that agents can make. Moreover, by giving awareness a more computational interpretation, we can provide a more realistic model of a game like chess.

There is clearly much more to be done to understand the role of awareness (and lack of awareness) in multiagent systems. We list some of the many issues here:

- In a Nash equilibrium of an extensive-form game, it may be the case that the move made at an information set is not necessarily a best response if that information set is not reached. There are refinements of Nash equilibrium that are arguably more appropriate for an extensive-form game [8]. Our representation of games with awareness (of unawareness) allows for relatively straightforward generalizations of such refinements of Nash equilibrium. However, there are subtleties involved in showing that generalized versions of these refinements always exist.

- We have analyzed situations where agents may be unaware of some moves in the underlying game and may be aware of their unawareness. Of course, there are other cases of interest where additional properties may hold. For example, consider a large geographically-dispersed game where agents interact only with nearby neighbors. In such a game, an agent may be unaware of exactly who is playing the game (although she may realize that there are other agents besides her neighbors, and even realize that the moves made by distant agents may have an indirect effect on her). To model such a situation, we may want to have virtual moves after which the game does not end, and to allow agents to be aware of subsequences of histories in the underlying game. We suspect that extensions of the ideas in this paper can deal with such situations, but we have not worked out the details.

- There has been a great deal of work on computing Nash equilibria. As we have shown, a generalized Nash equilibrium of a game with awareness is a Nash equilibrium of a standard game. However, this standard game can be rather large. Are there efficient computational techniques for computing generalized Nash equilibrium in interesting special cases?

- If there is little shared knowledge regarding the underlying game, the set $\mathcal{G}$ of augmented games can be quite large, or even infinite. Is it important to consider all the iterated levels of unawareness encoded in $\mathcal{G}$? Halpern and Moses [6] showed that, in analyzing coordinated attack, no finite level of knowledge suffices; common knowledge is needed for coordination. Stopping at any finite level has major implications. On the other hand, Weinstein and Yildiz [9] provide a condition under which the effect of players' kth order beliefs is exponentially decreasing in k. While we strongly suspect that there are games in which higher-order unawareness will be quite relevant, there may be conditions under which higher-order awareness becomes less important, and a simpler representation may suffice.

ABSTRACT

We address the problem of learning in repeated n-player (as opposed to 2-player) general-sum games, paying particular attention to the rarely addressed situation in which there are a mixture of agents of different types. We propose new criteria requiring that the agents employing a particular learning algorithm work together to achieve a joint best-response against a target class of opponents, while guaranteeing they each achieve at least their individual security-level payoff against any possible set of opponents. We then provide algorithms that provably meet these criteria for two target classes: stationary strategies and adaptive strategies with a bounded memory. We also demonstrate that the algorithm for stationary strategies outperforms existing algorithms in tests spanning a wide variety of repeated games with more than two players.

1. INTRODUCTION

Recently there have been several proposals for criteria with which to evaluate learning algorithms in multi-agent environments and corresponding algorithms achieving these criteria [2, 6, 21, 20]. However, these approaches focus primarily on settings with two agents and do not adequately address the different situations arising from multiple opponents. While other research has focused on situations with more than two agents, it has for the most part either concentrated on games with common payoffs or assumed no cooperation is possible and focused on no-regret payoff guarantees for each agent. In this paper we will try to address how an agent should behave in general-sum games in which the opponents can be either cooperative or adversarial. Following the approach of [21], we propose new criteria focusing on payoff guarantees for the agent against various classes of opponents:

Targeted Group Optimality: *The payoffs achieved by all the agents using this algorithm are at least within ϵ of being Pareto-efficient over the set of possible outcomes given the actual strategies of any agents that are members of the target set.*

Safety: *Against any combination of opponents, the algorithm always receives at least within ϵ of its security value for the game.*

In the rest of this paper we will first start with a brief review of related work on learning in multi-agent systems, focusing on the limitations of current approaches. Building on this we detail our proposal for a set of desirable criteria for agents in n-player repeated games and confront some of the thorny issues that arise when playing against a mix of different opponent types during a single game. Next, we outline a novel algorithm achieving these criteria and show encouraging empirical results against a number of existing algorithms in a wide range of multi-agent environments. In the final section, we'll point out some of the successes and limitations of our approach and pose some open questions for future work in this domain.

Throughout this paper, we will focus our attention on the class of repeated games with average reward. In this setting the players repeatedly play a simultaneous move normal form game (the stage game), represented as a tuple, $G = (n, A, R_{1...n})$, where n is the number of players, $A = A_1 \times ... \times A_n$, where A_i is the set of actions for player i, and $R_i : A \rightarrow \Re$ is the reward function for agent i. We also use m to denote the maximum number of actions for an agent in G, and $|A|$ the number of stage-game outcomes in G. After each round, the agents accumulate their reward from the joint outcome and get to observe the previous actions of the other agents. Each agent is assumed to be trying to maximize its average reward for games with finite repetitions or the limit average for infinitely repeated games. For our purposes we assume that the full game structure and payoffs are known to all agents from the start of the game and that the payoffs in the game are bounded.

2. RELATED WORK

One of our main objectives in this paper is to develop a set of criteria for learning algorithms in repeated games with an

arbitrary number of players. In reviewing existing work, we start with work focusing explicitly on games with more than two players. Following this we consider proposals of criteria for learning algorithms and see how well they generalize to games with more than two players.

Many researchers have focused on the problem of coordinating multiple agents to achieve mutually beneficial outcomes, but have for the most part restricted their attention to team games [15, 14, 23, 4]. In a team game, all the agents get identical payoffs for each action, so the challenge is focused entirely on how the agents can independently coordinate on an optimal equilibrium. Additional related work has been carried out in the areas of multi-robot planning and multi-agent pursuit games, but most of these approaches assume explicit communication or sharing of information between the cooperative agents.

Bowling and Veloso[2] were among the first to propose specific requirements for effective learning in multi-agent systems with their two criteria of rationality and convergence:

Rationality: *If the other players' policies converge to stationary policies then the learning algorithm will converge to a stationary policy that is a best-response (in the stage game) to the other players' policies.*

Convergence: *The learner will necessarily converge to a stationary policy.*

While these criteria are suitably general to apply to games with any number of players, the WoLF algorithm they proposed is only guaranteed to achieve these criteria in two player games. Conitzer and Sandholm[6] then proposed a new algorithm that achieved the above criteria for arbitrary repeated games, but only when all the opponents were of the same type (either all stationary or all self-play).

Moreover, as we pointed out in [21], there are limitations to these criteria. The first limitation is that the property of convergence cannot be applied unconditionally, since one cannot ensure that a learning procedure converges against all possible opponents in finite time without sacrificing rationality. So implicit in that requirement is some restriction on the class of opponents. And indeed both [2] and [6] acknowledge this and choose to concentrate on the case of self-play, in which the opponents are identical to the agent in question. However, neither approach makes any guarantees about the behavior of the learning algorithm when there is a mixture of self-agents and stationary opponents.

The second limitation is that the requirement of convergence to a stationary strategy is particularly hard to justify. When combined with the requirement to play a best response to any stationary opponent, this requires the agents to converge to playing a Nash equilibrium of the stage game. While at first glance this may seem desirable, consider the game of Prisoner's Dilemma. Any algorithm satisfying the above criteria will be forced to Defect at each period in order to arrive at the unique Nash equilibrium. In the repeated game, however, two agents could instead use a strategy such as Tit-for-Tat, to achieve a much higher reward for each agent without providing the opponent with an incentive to deviate. (Tit-for-Tat starts by cooperating and thereafter repeats whatever action the opponent played last.)

Brafman and Tennenholtz addressed this problem directly in [3] and made a counter-proposal for how to consider equilibria in repeated games. They require that the learning algorithms form an Efficient Learning Equilibrium (ELE) in which any agent deviating from its algorithm will suffer a net loss of payoff within a polynomial number of stage games. They also propose an ELE algorithm based on the folk theorem that satisfies this requirement for 2-player repeated games in a perfect monitoring setting. However, once generalized to games with more than two players, the ELE algorithm requires a communication mechanism outside the game or is only applicable for a restricted number of games.

Game theory also addressed the issue of reasonable criteria for learning in multi-agent systems at numerous times with the proposals of universal consistency, no-regret learning, and the Bayes envelope dating back to at least [10] (see [8] for an overview of this history). There is a fundamental similarity in approach throughout, and we will take the approach of Fudenberg and Levine in [9] as being representative. They first proposed two criteria:

Safety: *The learning rule must guarantee at least the minimax payoff of the game.*

Consistency: *The learning rule must guarantee that it does at least as well as the best response (in the stage game) to the empirical distribution of play when playing against an opponent whose play is governed by independent draws from any fixed distribution.*

They then defined *universal consistency* as the requirement that a learning rule do at least as well as the best response to the empirical distribution of play regardless of the actual strategy the opponent is employing (this implies both safety and consistency) and propose an algorithm that achieves this requirement. Recently, these ideas have also been adopted by researchers in the artificial intelligence community (see [11], [12] and [25] for examples in both game theory and AI). In recent work [1], Bowling attempted to combine these criteria by proposing that an agent should both guarantee a no-regret payoff and achieve convergence in self-play. He then put forth GIGA-WoLF, a no-regret algorithm that provably achieves convergence in self-play for games with two players and two actions per player.

A limitation common to all these approaches is that the game theoretic basis they're derived from was initially focused on large-population games and therefore ignores the effect of the agent's play on the future play of the opponent. This can pose problems in smaller games. Let us again consider the game of Prisoner's Dilemma with a Tit-for-Tat opponent. The only universally consistent strategy would be to defect at every time step, ruling out the higher payoff achievable by cooperating. Clearly, a universally consistent (or no-regret) policy is not the best response in this richer strategy space.

In response to the existing work, we proposed a new set of criteria in [21]:

Targeted Optimality: *Against any member of the target set of opponents, the algorithm achieves within ϵ of the expected value of the best response to the actual opponent.*

Auto-Compatibility: *During self-play, the algorithm achieves at least within ϵ of the payoff of a Nash equilibrium that is not Pareto dominated by another Nash equilibrium.*

Safety: *Against any opponent, the algorithm always receives at least within ϵ of the security value for the game.*

In addition these requirements were required to hold with probability at least $1 - \delta$ after an initial polynomial period of time. Our first paper provided an algorithm that consid-

ered only stationary opponents, but a new algorithm meeting these criteria against memory-bounded opponents was presented in [20]. Unfortunately, neither of the algorithms can easily be generalized to situations with more than two agents. A critical component of the design of the two algorithms is a teaching component based on the Bully and Godfather algorithms proposed by Littman and Stone in [16]. This component relies on having a single opponent in order to calculate the best action or sequence of actions to play given that the opponent will play a best response.

3. NEW CRITERIA

In our work we seek to pull together the advances made in existing work and encourage the development of algorithms that can both cooperate with one another and achieve strong guarantees on payoff against a variety of opponents.

In the criteria of [21] we had three categories of opponents we cared about: members of the target class, identical (self-play) agents, and other (unconstrained) agents. When only considering games for two agents, these three categories are sufficient for all the scenarios. However, once we extend to games with more than two agents, we need to consider mixes of agent types. Since each agent can be any of the three types, there are seven different possible sets of opponent types. We divide those seven sets into two scenarios:

- Each of the opponents is either a self-agent or in the target class.
- At least one opponent is of the Unconstrained type.

We also need to consider the issues of coordination between the agents when selecting actions. Although other researchers may find different assumptions appropriate for particular settings, we have chosen to focus on the most pessimistic/conservative assumptions in which the self-agents have no communication mechanism outside the game. Thus they must choose independently if they are selecting actions according to a probability distribution.

For the first scenario, ideally the agents should achieve a "joint best response" against the given target class. This is clearly defined when there is only one self-agent. The agent just needs to adopt the best response to the joint play of the agents in the target class. However, it remains an interesting issue when there are at least two self-agents. The self-agents will need to distribute the payoffs between themselves since selfishly trying to maximize one's payoff will not help the agent in many cases. Each of the self-agents should also be able and willing to cooperate with other agents who are using the same or similar algorithms as long as this will help to increase its current payoff. Thus the self-agents should achieve a Pareto-optimal (PO) outcome among themselves, i.e. there is no other joint outcome that could provide a higher payoff for one self-agent without decreasing the payoff of some other self-agent given the strategies of the opponents in the target class.

The PO condition alone, however, is not sufficient. Each agent has a minimum payoff that it can guarantee by itself without the cooperation of any other agents. In the worst case when all other agents are trying to minimize its payoff, this minimum value is $V_{security}$, defined for agent i as $\max_{\pi_i \in \Pi_i} \min_{\pi_{-i} \in \Pi_{-i}} EV_i(\pi_i, \pi_{-i})$. In this formula, Π_i is the set of strategies for agent i, and Π_{-i} is the set of joint strategies for the other agents. Any strategy that achieve this value on expectation is called a security strategy. Note that if an agent has determined the strategies of the opponents in the target class, it can guarantee a new security value V_g which is at least $V_{security}$. Thus it is only rational for an agent to cooperate in a PO joint outcome if its payoff is at least V_g. Notice that the best response condition for one self-agent is a special case of this criterion, since the PO condition will guarantee that the agent is using an optimal strategy against the target class.

When there are opponents that are neither members of the target class nor self-agents, we instead require that each agent achieve at least V_g. Ideally, multiple self-agents could each exceed this value in some settings by cooperating with each other against the unconstrained agents.

Combining these two scenarios, we put forth the following new criteria:

Let n be the number of players in the game and m the maximum number of actions for a player. We require that for any choice of $\epsilon > 0$ and $\delta > 0$ there exist a τ, polynomial in $\frac{1}{\epsilon}, \frac{1}{\delta}, n$, and m, such that for any number of rounds $t > \tau$ the algorithm achieves the following payoff guarantees with probability at least $1 - \delta$:

Targeted Group Optimality: *When each of the agents in the game is either a self-agent or in the target class, the payoffs of all the self-agents are at least $V_g - \epsilon$ and within ϵ of a PO outcome, given the actual strategies of agents in the target class.*

Safety: *Against any set of opponents, the agent must achieve at least $V_g - \epsilon$.*

Note that the Target Group Optimality condition combines and generalizes the Targeted Optimality and Auto-Compatibility conditions from [21].

4. CORRSTRATEGY(S): AN ALGORITHM FOR STATIONARY OPPONENTS

Besides proposing the novel criteria, we also want to provide algorithms that provably achieve the criteria for different target sets. We first consider such an algorithm for stationary opponents which we call CorrStrategy(S).

4.1 Algorithm Description

CorrStrategy(S) is composed of four modules:

- **Learn Best Response**: Using observations about the opponents' play estimate and play a best-response strategy for the agent to the actual strategy of the opponents.
- **Coordinate**: Select a single, common deterministic joint strategy for all the self-play agents from among a set of Pareto-optimal possibilities.
- **Secure Value**: Play a strategy that ensures that the player receives at least the security value against any possible set of opponents.
- **Signal/Explore**: Observe the opponents' play and use explicit signaling to distinguish self-play agents from agents in the target class.

We show how these modules can be put together in Figure 1. The four bolded rectangles represent the modules. Note that in order to preserve clarity, we only show a detailed view of the "Coordinate" module, the most complex one. The agents following the framework will start with the "Signal" module and make transition between the modules based on

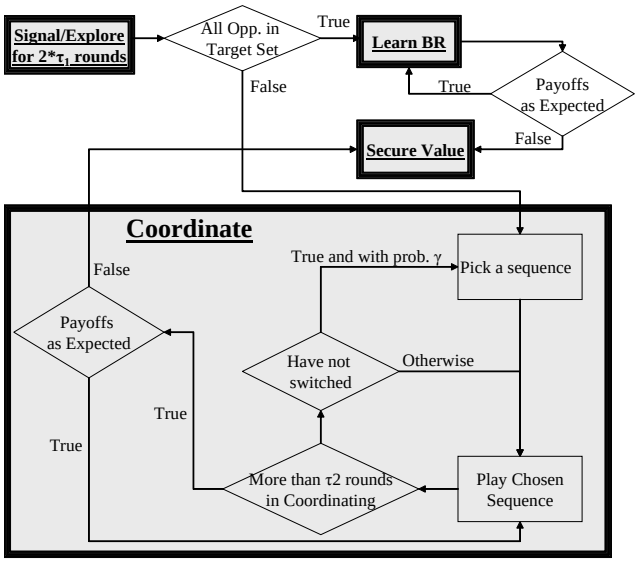

Figure 1: Flow of control for CorrStrategy(S).

the payoffs they receive and the observed behavior of the other agents in the environment.

It is necessary for the agents to distinguish between self-agents and members of the target class. Otherwise it would be possible for the agents to adopt best-responses assuming the other self-agents are stationary and play a Nash equilibrium with possibly non-PO payoffs. In general, it is not always trivial to distinguish between different types of opponents. One self-agent might appear stationary if the most rational action it needs to take always happens to be the same. This issue can be resolved easily if we allow the self-agents to explicitly signal each other in the "Signal" module.

Since the target class is stationary, the self-agents will signal each other by playing a pure strategy for τ_1 rounds and then switching to a different pure strategy for another τ_1 rounds. By the end of this block, the self-agents will be able to correctly partition all self-agents and stationary agents into two different sets with high probability. Agents whose distribution of actions during the last τ_1 rounds is within ϵ of the distribution from the full history are assumed to be stationary.

Each self-agent can now essentially reduce the current game to a smaller game by removing all stationary opponents and using the expected payoffs for each of the remaining outcomes instead. If there is only one remaining player in the sub-game, it transitions to the "Learn Best Response" module to find the best response to the stationary opponents. Using the sub-game, finding a BR strategy against stationary opponents is straightforward, since the agent can simply choose the action that gives the highest expected payoff. However, the agent still needs to keep monitoring its payoff in order to protect itself against an adversarial opponent that pretends to be stationary during the "Signal" phase and changes strategy later on. The agent can calculate its security value in the sub-game which is V_g. At any time, if its payoff drops below $V_g - \epsilon$, the agent will switch to the "Secure Value" module.

If there are multiple non-stationary agents left in the sub-game, the self-agents will make the transition to the "Coordinate" module instead. In this module, they will try to synchronize with each other in order to achieve the Targeted Group Optimality criterion. Each self-agent will first solve a linear program with size polynomial in the number of stage game outcomes, $|A|$, to find a PO outcome in the repeated game:

$$\begin{array}{ll} \text{maximize} & \sum_{i=1}^{|A|} \sum_{j=1}^{n} \alpha_i * PO_j(O_i) \\ \text{subject to} & \forall j (V_g(j) - \sum_{i=1}^{|A|} \alpha_i * PO_j(O_i) \leq \epsilon) \\ & \sum_{i=1}^{|A|} \alpha_i = 1 \end{array}$$

In the equations above, $PO_j(O_i)$ is the payoff of agent j in the stage game outcome O_i and $V_g(j)$ is the guaranteed value of agent j. We denote this linear program LP^*.

The solution to LP^* is a distribution over joint outcomes in the stage game that maximizes the sum of the payoffs for the self-agents in the repeated game. In this distribution, α_i is the frequency with which the stage-game outcome O_i should be played by the self-agents to achieve a PO repeated game outcome. The solution always exists because if every self-agent, j, plays its security strategy they are all guaranteed to receive at least $V_g(j)$. Since the self-agents are not allowed to communicate outside the game, they can't mix over joint outcomes so will instead have to approximate this distribution by repeating a deterministic sequence S of joint actions. S will specify which action each agent needs to choose at each step. By using Hoeffding's inequality, it can be proved that self-agents can have an arbitrarily close approximation to the PO outcome in the repeated game with S of length polynomial in $m, n, \frac{1}{\epsilon}$, and $\frac{1}{\delta}$.

As there are possibly many such sequences S, the self-agents also need to coordinate with each other to converge to the same one. Each self-agent will pick one such sequence at the beginning of the "Coordinate" module and then with probability γ in each round will switch to a different sequence. Let C be the group of self-agents who have already switched. The algorithm ensures that all the agents in C are always jointly maximizing the sum of payoffs for the self-agents. Whenever an agent attempts to switch to a different sequence, i.e. joining C, it will pick one that preserves this property. Note that since each agent joins the group C when it switches, it will only actually switch strategies once if all the agents are self-agents.

Since the agents in C are approximating some distribution over joint outcomes by using deterministic sequences, the switching agent just needs to observe this distribution and then find a correspondent deterministic sequence. To achieve this, the switching agent can re-solve LP^* with additional constraints to guarantee that in the new solution of LP^*, the distributions over joint outcomes of the agents in C are still the same.

$$\forall o \in \prod_{j \in C} A_j : \sum_{i=1}^{|A|} f(O_i, o) * \alpha_i = \pi(o)$$

In the above equation, o is the joint action of agents in C, $\pi(o)$ is the observed distribution for o , and $f(O_i, o) = 1$ if agents in C play o in outcome O_i and $f(O_i, o) = 0$ otherwise. If no agents have switched sequences, the agent will simply pick a different sequence that also approximates the solution for the current LP^*.

At the end of the process, there are two possibilities that occur with high probability: either all the self-agents are playing the same deterministic sequence of joint actions or there exist unconstrained agents. In the first case, the payoff profile for the self-agents is at most ϵ away from the payoff profile in the PO outcome they are trying to approximate.

However, they still need to monitor their payoffs to avoid the case in which there are unconstrained agents that only pretend to cooperate with the self-agents. Once the payoff for any self-agent drops more than ϵ below their target payoff in LP^*, the agents will switch to the "Secure Value" module to prevent being further exploited. This will also handle the second case where the unconstrained agents prevented them from converging to a common sequence. Note that in the case the unconstrained agents fully cooperate with the self-agents in a PO outcome, the self-agents will implicitly achieve the Safety requirement, and therefore can safely treat the unconstrained ones as self-agents.

A self-agent uses the "Secure Value" module to guarantee its payoff is at least the guaranteed value of $V_g - \epsilon$ in the presence of unconstrained agents. The agent can easily achieve this by calculating and adopting the security strategy for the sub-game obtained by removing all stationary opponents. While using this module, the self-agent still needs to monitor the opponents that are assumed to be stationary. Otherwise, unconstrained agents could impersonate members of the target set at the beginning of the game and then lower the payoff of a self-agent by changing strategies, or more subtly, by using a correlated joint mixed-strategy that still makes them appear stationary. In both cases, any harmful variations can be easily detected with high probability by replacing each stationary agent's actual play with random draws from their observed distribution and detecting if the payoffs to any of the self-agents change by more than ϵ. If such an unconstrained agent is detected, a new V_g can be calculated and a new security strategy played.

THEOREM 1. *CorrStrategy(S) is guaranteed to satisfy the Targeted Group Optimality and Safety criteria for the target class of stationary opponents after a number of rounds polynomial in $n, m, \frac{1}{\epsilon}$ and $\frac{1}{\delta}$.*

PROOF. Since we only consider games with bounded payoffs, we can assume, without loss of generality, that all the payoffs are normalized to be between 0 and 1. The proof can be constructed naturally from the following lemmas. The proofs for the lemmas can be constructed using Hoeffding's inequality and are omitted due to space constraints:

LEMMA 1. *For any given $\delta_1 > 0$, $0.5 > \epsilon_1 > 0$, there exists τ_1 polynomial in $\frac{1}{\epsilon_1}, \log(\frac{1}{\delta_1}), \log n$ and $\log m$ such that if an agent uses a full action history of length at least $2\tau_1$, and a recent action history of length τ_1, all self-agents will correctly partition stationary and self-agents into two different sets and the observed action distribution for all stationary opponents will be within ϵ_1 of the true distribution with probability at least $1 - \delta_1$.*

LEMMA 2. *For any given $\delta_2 > 0$, $\epsilon_2 > 0$, there exists a deterministic sequence of joint actions, S, with length polynomial in $\frac{1}{\epsilon_2}, \log(\frac{1}{\delta_2}), \log n$, and m that can approximate within ϵ_2 the distribution over PO outcomes of any solution to LP^*. When there is no unconstrained agent, the difference between the payoffs achieved by the self-agents using S and a PO outcome will be at most $n * m * \epsilon_2$ with probability at least $1 - \delta_2$.*

LEMMA 3. *Within the "Coordinate" block, for any given $\delta_3 > 0$, $T > 0$, and $\gamma \leq 1 - (1 - \delta_3)^{\frac{1}{n^2 T}}$, if each cooperating player attempts to change its distribution of actions on each round with probability γ, there exists a τ_2 polynomial in $\frac{1}{\delta_3}, T$ and n such that with probability at least $1 - \delta_3$, after τ_2 rounds all the self-agents will change their sequence exactly once and no two self-agents will change within T rounds of each other.*

From Lemma 1, by the end of the "Signal" module (after $2\tau_1$ rounds), the self-agents have correctly partitioned stationary players and coop players into two different sets with probability at least $1 - \delta_1$.

Consider first the case in which there are no unconstrained agents. Within the "Coordinate" module, once an agent decides to pick a different sequence, it has to recalculate the optimal solution to LP^*. From Lemma 1, we know that the observed distribution of each stationary opponent is within ϵ_1 of its true distribution. Since the payoffs are bounded between 0 and 1 and there are at most m actions, the payoff for the self-agent can be reduced by at most $m * \epsilon_1$ for each of the up to n stationary opponents. Thus if we choose ϵ_1 to be $\frac{\epsilon}{2mn}$ and ϵ_2 in Lemma 2 to be $\frac{\epsilon}{2mn}$, once all the self-agents converge to the same sequence, the payoff for each agent can only be at most ϵ away from the optimal payoff. From Lemma 3, if we set $T \geq L$, we can choose a γ such that no two agents will switch sequence within a period of L. Thus, each self-agent will always correctly determine the distribution of the agents that have already switched sequences. All self-agents will switch sequence once within a polynomial number of rounds and therefore converge to one sequence. Combining all of these conditions we have that the self-agents will converge to a sequence with payoffs within ϵ_3 of a PO outcome of the repeated game with probability at least $1 - \delta_1 - \delta_2 - \delta_3$. If we then set $\delta_1, \delta_2, \delta_3$ to be $\frac{\delta}{3}$ we satisfy Target Group Optimality. With these values, τ_1 and τ_2 are clearly polynomial in $m, n, \frac{1}{\epsilon}$, and $\frac{1}{\delta}$. Moreover, since the losses of the payoffs over the initial period of length $\tau = 2 * \tau_1 + \tau_2$ are bounded by τ, by allowing another $\frac{2\tau}{\epsilon}$ additional rounds to pass, the average payoffs of the agents for the entire game will converge within ϵ of a PO outcome.

Let us now consider the case when there is at least one unconstrained agent. Notice that in all the modules the self-agents switch to the Security Value module whenever their payoffs fall below $V_g - \epsilon$. If an agent has correctly divided the stationary and unconstrained agents it can now be guaranteed a payoff at least $V_g - \epsilon$ with probability at least $1 - \delta$ after a period polynomial in $\frac{1}{\epsilon}$, $\frac{1}{\delta}$, m, and n by the Hoeffding inequality. If on the other hand an unconstrained agent is simulating a stationary opponent, it will not be able to drive the agent's value below $V_g - \epsilon$ without causing its play to vary from that of its assumed stationary distribution and thus revealing itself. The agents can then update their estimates of V_g and adopt a new security strategy where the unconstrained agent is categorized correctly. Thus they will always achieve the Safety criteria.

Therefore, there exists a τ polynomial in $m, n, \frac{1}{\epsilon}$, and $\frac{1}{\delta}$ such that after an initial experimentation period of length τ, CorrStrategy(S) will satisfy the two criteria in section 3. □

THEOREM 2. *The computational complexity of CorrStrategy(S) for playing one round of the repeated game is polynomial in $|A|$, the size of the game.*

PROOF. To find the worst case complexity for one iteration, we can consider separately the complexity for each module of the algorithm as presented in Figure 1:

- Within the "Signal" module, once all the stationary

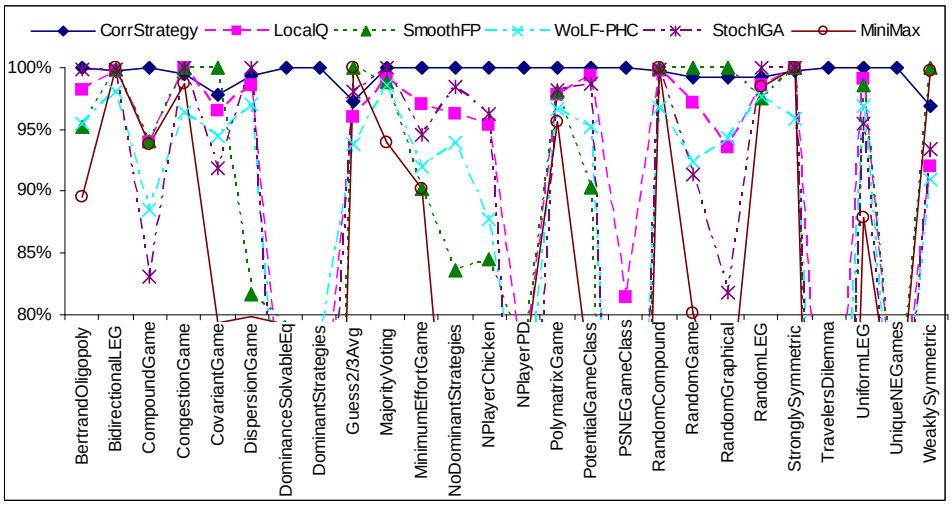

Figure 2: Percent of maximum value for 200K rounds averaged for each agent over all different pairs of opponents for selected games in GAMUT.

opponents are recognized, the self-agent can find the sub-game in $O(|A|)$ time.

- Within the "Learn Best Response" module, finding the best response in the sub-game is $O(m)$.
- Within the "Secure Value" module, solving the linear program for the security strategy can be done in time polynomial in $|A|$.
- Within the "Coordinate" module, in the worst step the agent has to switch to a different sequence. This process involves solving a linear program with the number of variables and constraints polynomial in the number of outcomes. Thus the complexity for the worst step within this module is also polynomial in $|A|$.

□

4.2 Experimental Results

Even though our algorithm has been proven to meet the proposed criterion, we want to demonstrate empirically that the algorithm performs well against a variety of opponents including those outside the target class. We will use the testing environment first described in [21] by testing against a number of existing approaches from the multi-agent learning literature over a wide variety of repeated games from GAMUT [18]. GAMUT is the result of a project to develop a comprehensive collection of game theoretic matrix games that have been described by researchers in either game theory or artificial intelligence. It contains generators for creating random instances of 34 individual base game classes as well as numerous additional variants and specialized parameter settings (more information and downloads are available at `gamut.stanford.edu`). The existing algorithms we tested against include Local Q-learning[24], a stochastic version of IGA[22], WoLF-PHC[2], JointQ-Max[5], and smooth fictitious play[9]. We also tested all the algorithms against random stationary strategies (Random), the security value strategy (MiniMax), and random strategies that condition their actions on the past outcome (Mem1).

Focusing our attention on settings with more than two players, our first test measured the average performance of a pair of players using the same algorithm playing against another pair of players using identical algorithms. In figure 2, we show the average payoffs of the five most successful algorithms as well as the performance of the MiniMax algorithm for a representative set of games in GAMUT. The payoffs have been normalized by dividing each algorithm's payoff by the best payoff achieved by any strategy for that game in order to make visual comparisons across games easier. We can see that CorrStrategy(S) performs well across all the games, achieving the highest or close to the highest payoff in nearly every game and unlike other algorithms, CorrStrategy(S) has no pitfalls in which its payoffs are significantly worse than the highest payoffs achieved. This is at least partly due to the fact that agents using CorrStrategy(S) can cooperate with agents using other algorithms as long as they each still achieve their security value.

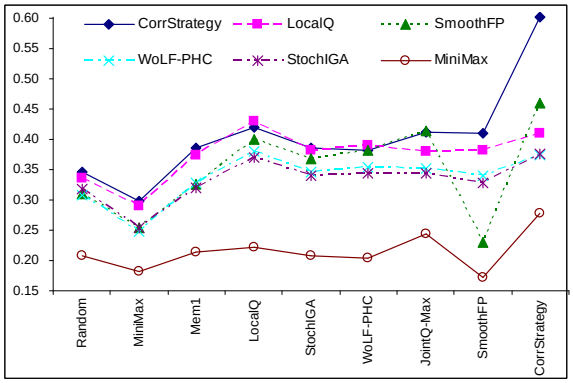

Figure 3: 2v2 By Opp: Value achieved against each pair of opponents averaged over all games.

In Figure 3, we show the results for the same algorithms averaged across games for each possible pair of opponents (note that all payoffs for each game are in the range $[-1, 1]$). We can see that CorrStrategy performs well against each of the different classes of opponents, but truly excels when playing against other CorrStrategy agents. Smooth fictitious play fares similarly well against several of the strategies, but fails to cooperate in self-play resulting in a payoff near that of the MiniMax algorithm. One of CorrStrategy's largest advantages lies in its ability to cooperate when pos-

sible while maintaining a security value guarantee against opponents outside its target set if cooperation fails.

To further investigate the contribution of this advantage to the strong results achieved by CorrStrategy(S), we ran two alternate experimental settings. In one setting we had each algorithm play by itself against a pair of algorithms using identical algorithms. In the second setting we instead let two versions of the algorithm being tested play against a single instance of an opponent algorithm. In Table 4.2 we can see the average results for these settings compared with the results in the four player setting shown earlier. As we would predict, CorrStrategy(S)'s advantage over the other algorithms increases in settings where it outnumbers its opponents, but its results remain competitive even when it is outnumbered in turn.

5. CORRSTRATEGY(A): AN ALGORITHM FOR ADAPTIVE OPPONENTS

As encouraging as the theoretical and experimental results for CorrStrategy(S) may be, we still have yet to address one of our critiques of existing research, which was the tendency to only focus on stationary opponents. Although we addressed this concern explicitly in [20], our algorithm depended critically on the assumption that there was only a single opponent. We are aware of very little additional work to date that deals with adaptive opponents explicitly, although de Farias and Megiddo [7] address it in the design of their experts algorithm and the rational learning approach of Kalai and Lehrer [13] can in principle handle adaptive algorithms of arbitrary complexity as long as they are assigned positive probability in the prior.

In the remainder of this section, we'll outline a way to extend our CorrStrategy algorithm to deal with opponents whose play may be a function of the prior history of the game. We do this by expanding the target set against which we can guarantee a best-response. Note however that we still need to limit the capabilities of the opponents in some way. If we were to consider opponents whose future behavior could depend arbitrarily on the entire history of play, we would lose the ability to learn anything about them in a single repeated game, since we would only ever see a given history once and an opponent's past strategy may bear no relation to their future play.

We therefore adopt the model for bounded memory we used in [20] and assume a limit on each opponent's ability to condition on the history. This model requires that the opponents play a conditional strategy where their distribution over actions can only depend on the most recent k periods of past history, $F_i : o^{-1} \times ... \times o^{-k} \rightarrow \Delta A_i$, where o^{-t} is the outcome of the game t periods ago. Additionally, the opponents have a default past history they assume at the start of the game. Note that even this simple model allows us to capture many methods, such as Tit-for-Tat, that current approaches are unable to properly handle.

Taking the set of conditional strategies with history k as our new target set, we propose the extension CorrStrategy(A). CorrStrategy(A) shares the same basic algorithmic framework as CorrStrategy(S) with the following changes:

- For the "Signal/Explore" module, the self-agents play a uniform mixed strategy for a period long enough to gather sufficient observations to calculate each opponent's distribution of play for each possible history of length k. The self-agents then switch to a pure strategy that is distinct from the prior observed distribution of their play in order to signal each other. Opponents using a consistent distribution for each history are assumed to belong to the target class.

- For the "Learn Best Response" module, we calculate a best response against conditional strategies. This approach maintains counts of each opponent's actions after each history of length k, which it uses to solve an optimization problem over the deterministic conditional strategies the self-agents should themselves play in order to maximize the sum of their payoffs.[1]. Given sufficient observations, we can guarantee an ϵ-best response against any members of our target opponent set.

- Note that in order to use this new best-response function in CorrStrategy(A), we need to insure that the algorithm observes each length k history a sufficient number of times. This will be satisfied as long as the initial exploration phase continues for a length of time exponential in k. This exponential exploration period is unavoidable since we need to consider the possibility of opponents that only play a desirable action distribution for a single one of the exponential possible histories.

- For the "Coordinate" block, the optimization problem needs to take into account all possible sequences of actions for the adaptive opponents in the target set.

THEOREM 3. *CorrStrategy(A) is guaranteed to satisfy the Targeted Group Optimality and Safety criteria for the target class of conditional strategies with bounded memory k.*

The proof of Theorem 3 follows the same framework as the proof of Theorem 1 but we need to take into account a much longer initial period for signaling and observing opponent's distributions and also a longer sequence S to approximate the PO outcome. The initial experimentation period τ required will unfortunately now depend on m^k and $(\frac{1}{\lambda})^{(m^{nk})}$, where λ is the minimum probability the opponent assigns to any action ($\lambda = 1$ for opponents that condition only on the coop player's actions). Note that our worst case time complexity also grows similarly as we may now need to solve an optimization problem with up to m^k variables, although both of these bounds (computational complexity and amount of training) are based on extremely pessimistic

[1]For conditional strategies that only depend on the self-agents' actions, we can simply calculate the cycle of joint agent actions with the highest expected reward out of all possible unique action sequences (those that don't contain a length k repeated subsequence)

assumptions and are likely to prove tractable in practice for larger games with small values of k.

6. CONCLUSIONS AND FUTURE WORK

Even though there have been several recent proposals for different criteria to evaluate learning algorithms in multi-agent systems, little attention has been given to two important scenarios: learning in games with more than two players, and learning against adaptive opponents. We have addressed both scenarios by proposing a new set of criteria for learning in games with any number of players that takes a target class as parameter, allowing the designer to choose a class of opponents of interest. This set of criteria encourages learning algorithms to allow cooperation between agents while still guaranteeing a basic security guarantee for each agent. We then designed two algorithms that can achieve the criteria against two target classes: stationary strategies and adaptive strategies with bounded memories. Moreover, our implementation of the algorithm for stationary strategies outperforms a wide range of opponents across the games of a comprehensive test-bed of repeated games.

One interesting problem we will continue to investigate is how to improve the guaranteed payoff for self-agents against adversaries outside their target class. In many settings the agents should be able to work together in order to reduce the adversarial effects of their opponents and guarantee payoffs above their individual security values. In addition, we are continuing to extend our approach to other models of adaptive opponents. A common approach used in the literature on bounded rationality [17, 19] is to assume the players can be modelled by finite automata with k states. It should prove relatively straightforward, although computationally demanding, to extend our CorrStrategy(A) algorithm to handle deterministic automata by again replacing the best response function and optimization functions. Automata where the state transitions and action selection are non-deterministic pose a more challenging problem.

We are also looking at several ways to expand the set of environments these algorithms can be employed within. Of particular concern is looking for ways to weaken the requirement of full prior knowledge about the payoffs of the game. The major challenge seems to lie in creating the capability to cooperate without knowing or being able to observe the space of payoffs available to the other players. An additional area for further consideration would focus on games in which the agents have only partial observability of the previous actions of the other players.

ABSTRACT

In concurrent cooperative multiagent learning, each agent simultaneously learns to improve the overall performance of the team, with no direct control over the actions chosen by its teammates. An agent's action selection directly influences the rewards received by all the agents, resulting in a co-adaptation among the concurrent learning processes. Co-adaptation can drive the team towards suboptimal solutions because agents tend to select those actions that are rewarded better, without any consideration for how such actions may affect the search of their teammates. We argue that to counter this tendency, agents should also prefer actions that inform their teammates about the structure of the joint search space in order to help them choose from among various action options. We analyze this approach in a cooperative coevolutionary framework, and we propose a new algorithm, iCCEA, that highlights the advantages of selecting informative actions. We show that iCCEA generally outperforms other cooperative coevolution algorithms on our test problems.

1. INTRODUCTION

Multiagent learning is challenging because the problem dynamics are often complex and fraught with local optima. Of particular interest to us is cooperative multiagent learning, where multiple agents learn to work together as a team to accomplish common goals [16]. More specifically, we are interested in *concurrent learning*, where each agent performs its own learning and has little or no control over the other agents' selection of actions.

Multiagent learning is problematic for existing machine learning techniques because the concurrent learning processes are not independent. Consider an agent that observes an environment containing other agents and that tries to improve its performance. This leads to a modification in its behavior, which is then sensed by the other agents, who then change their behaviors in order to improve their performance as well. This "moves the goalpost" on the original agent: its newly-learned behavior may no longer be appropriate. Thus as the agents co-adapt to one another, the environment is essentially changing beneath the agents' feet. Moreover, the agent itself contributes directly to how the landscape changes. Learning in the face of this dynamic is not easy: such co-adaptation can result in cyclical or chaotic adaptive behavior, and may gravitate towards suboptimal solutions.

Most cooperative multiagent learning algorithms assume the agents are rational: each agent searches for actions that fare well when used in combination with the actions currently favored by its teammates. This "best-response" approach usually results in the learners converging to Nash equilibria. Such "rational" convergence to equilibria may well be movement away from globally *team-optimal* solutions [13, 23]. To counter this, we argue that agents must *also* explore actions that inform their teammates about the structure of the space of rewards for joint actions. For example, if an agent identifies an action that helps other agents rank their available actions better, the agent should explore that action to help guide the teammates' learning processes.

Though we believe it to be general, we will demonstrate the application of this approach to a particular multiagent learning method of interest to us, namely *cooperative coevolution* [10, 22]. Coevolution is the use of evolutionary computation learning techniques in a multiagent setting. Ordinarily, evolutionary computation employs only a single learner to discover a global solution to an optimization problem: the learner first creates an initial pool of randomly-generated candidate solutions (a "population" of "individuals"), then assesses their quality ("fitness") independently of one another, then forms a new population of individuals through iteratively selecting, copying, and modifying ("breeding") individuals from the previous population with an emphasis on the fitter members of that previous population. The new population replaces the old one, and this cycle of fitness assessment, breeding, and population replacement continues until a sufficiently fit individual is discovered or until resources have expired. Each iteration of this cycle is known as a "generation".

Cooperative coevolutionary algorithms (CCEAs), in the form we will discuss here, use not one but multiple populations, each involved in its own separate learning cycle of fitness assessment, population formation, and population replacement. However, indi-

viduals in a given population are no longer assessed independently, but rather in the context of individuals chosen from the other populations. Each population represents a sub-component of a full solution to the problem, and as part of its fitness assessment, an individual in a given population may be evaluated only by combining it with one individual from each of the other populations to form a complete solution. It is in this fashion that coevolution involves multiple learners (each of the populations' evolutionary search procedures) whose learning trajectories are intertwined (via joint fitness evaluation), and so coevolution must deal with the same coadaptation challenges as other multiagent learning methods.

A natural approach to applying CCEAs to cooperative multiagent learning is to assign one population to each of the learning agents in the team. Each individual in the population represents a potential behavior for the agent, and so from now on, for consistency, we will refer to actions rather than individuals. An action may be as simple as a single action in trivial environments, or as complex as policies involving internal states and memory for real-world problems. Thus each population represents a finite sample from an infinite space of possible actions. As the team reward permits only the evaluation of joint actions, an action in one agent's population may be evaluated when combined with actions from the other agents' current populations. Multiple such combinations are generally used.

Section 2 highlights related cooperative multiagent learning algorithms. Following, Section 3 introduces a novel learning algorithm where agents pay special attention to informative actions. We compare it against other cooperative multiagent learning techniques in Section 4. The paper concludes with a brief discussion of our findings, accompanied by directions for future work.

2. RELATED WORK

Two learning algorithms that are guaranteed to find the globally optimal joint action in a stateless environment are proposed in [3]. Both algorithms have two phases: agents first explore the entire space of joint actions (either deterministically or randomly); this is followed by a greedy selection of only the action (one per agent) that returned the highest reward. Both algorithms find the global optimum in polynomial time in the number of actions for each agent. However, scaling these algorithms to environments with states or with possibly infinite numbers of actions per agent may be problematic.

Instead of choosing actions deterministically or randomly, Claus and Boutilier [7] argue that agents should be more optimistic about their teammates: an agent should not prefer actions that do well in the context of the actions currently preferred by its teammates, but rather the agent should prefer actions that do well in the context of better actions that its teammates might learn. The application of this heuristic assumption results in additional multiagent reinforcement learning algorithms for stateless environments, such as the ones in [12, 11]. Research on scaling these algorithms from simple coordination games to more complex domains is reported in [2, 9, 15, 24].

The cooperative coevolution literature has followed a similar path. The properties of cooperative coevolutionary algorithms are analyzed in [5, 6, 26]; results of such experiments indicate that assessing the fitness of an action based on the maximum of multiple joint rewards works better than if it were based on the minimum or on the average. Recent work has analyzed the conditions under which coevolutionary systems gravitate towards suboptimal solutions [25], has provided a visual illustration of the basins of attraction for simple multiagent domains [20], and has proposed a biased CCEA that is more likely to find the global optimum [18].

Bucci and Pollack [4] apply recent advances from *competitive* coevolution research to improve CCEAs, resulting in the pCCEA algorithm. The authors argue that the aggregation of multiple joint rewards to compute the fitness of an action may result in loss of useful information. Instead, pCCEA uses all joint rewards to compute the set of actions in each population that are Pareto non-dominated: given two actions a_1 and a_2 for one agent, a_1 dominates a_2 if and only if (1) for any action b for the other agent, a_1 receives higher or equal reward when joined with b than a_2 does, and (2) there exists an action c for the other agent such that a_1 receives a strictly higher reward when joined with c than a_2 does. This set of non-dominated actions, termed an *archive*, is automatically copied to the next generation to help evaluate the new population of actions. After the evaluation is completed for that generation, a new archive is computed for each population. Our experiments in Section 4 indicate that pCCEA's archive tends to converge to the Pareto frontier, which unfortunately may be infinite in even simple cooperative multiagent domains.

3. THE iCCEA ALGORITHM

When multiple agents learn concurrently, each of them is afforded only a partial glimpse at the overall search space. Specifically, each agent may weight its actions using only a projection of the entire space, a projection that is influenced by the actions currently chosen by the other agents according to their own learning processes. Differences among such projections are illustrated in [17]: projections at early stages of learning may provide more information about the search space, because the agents' actions are more randomly distributed and so sample the joint space better. As the agents start to converge, the projections may become skewed, sometimes losing all information about the globally optimal solutions. As each agent's choice of actions influences the projections searched by the other agents, we may view each of the multiagent learning algorithms in Section 2 as recipes for agents to influence each other's learning processes.

We argue that the team of learning agents may benefit if each agent is concerned about the projection of the search space that it provides to its teammates via the actions it explores. In other words, agents should not necessarily explore only their most promising actions, but also those actions that provide the other agents with accurate projections of the joint search space. We propose a coevolutionary algorithm, iCCEA ("i" standard for "informative"), to illustrate the advantages of such an approach.

For simplicity, we present the pseudocode for the algorithm using only two agents (and hence two populations), although it may be extended to arbitrary numbers of agents. Given an agent, the other agent is referred to as its *teammate*. We will assume that all populations have equal size *PopSize*, though the algorithm can easily be extended to allow for different sizes. We define $Reward_p(i,a)$ as the reward received when an agent (whose actions are represented in population p) selects action i and its teammate selects action a.

iCCEA follows the standard architecture of a generational cooperative coevolutionary algorithm [22]. As is the case for other CCEAs, iCCEA assumes that an agent can perceive the actions chosen by its teammates. In iCCEA, as in pCCEA, each agent maintains a population of actions, a subset of which is defined as an *archive* responsible for ensuring that some actions exist primarily to keep the teammate's projection well informed. iCCEA agents learn concurrently, meaning, the populations advance through their generation cycles together, rather than one population advancing, then the other.

The evaluation process tests actions by combining them with actions from the teammate's archive, plus possibly some additional actions in the teammate's population. In addition to computing an action's fitness, the evaluation process stores the joint reward of any pair of actions that are evaluated together; this information is later used to update the archives of each agent.

Each generation, every action in a population is first evaluated by testing it in combination with every action from the teammate's archive. As the very first generation's populations have not built an archive yet, their entire population is used as an archive (an expensive process but one which ensures a thorough exploration of the joint space and good bootstrapping for the archive in future generations). If the maximum size of the archives is less than $MaxEvals$, the actions are also tested with enough randomly-chosen actions from the teammate's population (in the archive or not) to provide at least $MaxEvals$ tests per action. $MaxEvals$ establishes a threshold for the number of evaluations desired per each action: if the archive is too small, additional actions are sampled at random from the other population to provide additional assessments.

The fitness of action i is then set to maximum of F_i^j over all actions j in the teammate's population (F_i^j represents the fitness of action i when partnered with action j from the other population, and it equals $-\infty$ if i was not tested in combination with j). If the archive size is 1, this reduces to a common evaluation approach for CCEAs [22, 26]: the evaluation is equivalent to using the best action (from the previous generation) plus some actions chosen at random from the other population. The pseudocode for the evaluation process is:

iCCEA-Evaluation
Parameters
  $MaxEvals$: maximum evaluations per action
Initial Settings
  For each population p
    $ArchiveSize_p = PopSize$
Evaluation phase (at each generation)
  For each population p
    $p' =$ other population than p
    For each action i in p
      For each action j in p'
        $F_i^j = -\infty$
    For each action i in p
      For each action a in $Archive_{p'}$
        $F_i^a = Reward_p(i,a)$
        $F_a^i = Reward_{p'}(a,i)$
  $MaxArchive = \max_p ArchiveSize_p$
  Repeat for $\max(0, MaxEvals - MaxArchive)$ times
    For each population p
      Shuffle p
    For each index i in $1..PopSize$
      a_1 = action with index i in one population
      b_1 = action with index i in the other population
      $F_{a_1}^{b_1} = Reward_1(a_1, b_1)$
      $F_{b_1}^{a_1} = Reward_2(b_1, a_1)$
  For each population p
    $p' =$ other population than p
    For each action i in p
      $Fitness(i) = \max_{j \in p'} F_i^j$

We next assemble the archive through a process called archive selection, which is intended to select those actions which revealed features of the projected joint space useful to the other teammate. Specifically, we would like to select as an archive a minimal set of actions from each agent's population such that when assessing the fitness of actions in a given population, testing them against the full teammate's population would not change the rank ordering of their fitnesses beyond just testing against the teammate's archive. The hope is that this archive would provide an accurate evaluation and ranking of the teammate's actions in the next generation as well. Rank order is all that matters because the evolutionary selection procedure we use later compares individuals not on raw fitness, but solely on their relative rank order in the population.

We'd like the archive set to be as small as possible, because as each action in an agent's population is tested in combination with *every* action from the other agent's archive, large archives imply a prohibitive $O(n^2)$ evaluation cost. Therefore we add actions to the archive only if they cause actions in the other population to improve significantly enough so as to effect the ranking — causing actions to *worsen* is not considered helpful information. Of the various actions which change this ranking, we will select the ones which do so by raising fitnesses to the highest levels.

The archive selection process starts from the empty set and proceeds iteratively. For each action i not in an agent's archive, and for each action x in its teammate's population, we compute the fitness of x if evaluated in combination with all actions in the current archive, that is, $M1Fit_x = \max_{j \in Archive_p} F_x^j$. We also compute the fitness of x if i were added to the current archive, $M2Fit_x^i = \max_{j \in Archive_p \cup \{i\}} F_x^j$. Note that $M2Fit_x^i \geq M1Fit_x$. Our first criterion for adding i to the archive (it improves upon the current ordering of the teammate's population) translates into finding two actions x and y such that adding i to the archive would change their ranking relative to one another ($M1Fit_x \leq M1Fit_y$ and $M2Fit_x^i > M2Fit_y^i$, or equivalently $M3Fit_{x,y}^i \neq -\infty$ for a simpler shorter notation). Of all actions i that meet this first criterion, we greedily prefer the one that changed the ranking by raising the fitness of a teammate's action to the highest level. Note that the first action to be selected for the archive is always the action with the highest fitness. The pseudocode is:

iCCEA-Archive-Selection
Parameters
  $MaxArchiveSize$: maximum archive size
Archive Selection (at each generation)
  For each population p
    $p' =$ other population than p
    $Archive_p = \emptyset$
    While $Size(Archive_p) \leq MaxArchiveSize$
      For each action x in p'
        $M1Fit_x = \max_{j \in Archive_p} F_x^j$
        For each action i in $p - Archive_p$
          $M2Fit_x^i = \max_{j \in Archive_p \cup \{i\}} F_x^j$
          For each action y in p'

$$M3Fit_{x,y}^i = \begin{cases} M2Fit_x^i & \text{if } M1Fit_x \leq M1Fit_y \text{ and } M2Fit_x^i > M2Fit_y^i \\ -\infty & \text{otherwise} \end{cases}$$

      For each action i in $p - Archive_p$
        $MaxFit_i = \max_{x \in p'} \max_{y \in p'} M3Fit_{x,y}^i$
      Select $a =$ argmax$_i MaxFit_i$
      If $MaxFit_a = -\infty$
        Break from while loop
      Add a to $Archive_p$
    End while

The breeding and population reassembly phase of iCCEA proceeds similarly to the one in pCCEA: the archive members are selected from the old population and are copied directly into the new population, and remainder of the new population is filled with children bred using standard evolutionary computation methods[1] applied to the old population (including the old archive). The whole previous population (including the archive) competes for breeding. The pseudocode is straightforward:

iCCEA-Breeding
Breeding phase (at each generation)
  For each population
    Select its new archive with iCCEA-Archive-Selection
    Copy the archive into the new population
    Fill the remainder of the new population using standard EC breeding with a rank-based selection procedure (such as tournament selection)

4. EXPERIMENTS

In this section, we investigate the behavior of four different coevolutionary algorithms, and we compare them in terms of performance and in terms of the number of evaluations they require to achieve that performance. The first algorithm is the pCCEA algorithm introduced in [4]. Second is the cCCEA algorithm, which is a traditional CCEA algorithm that evaluates the fitness of an action as the maximum reward it receives when in combination with any of the actions in the teammate's population. cCCEA is guaranteed to converge to the global optimum if the population size is sufficiently large [18]. Third is the iCCEA algorithm proposed in Section 3. Fourth, rCCEA evaluates the fitness of an action as the maximum when partnered with six actions from the teammate's population: five chosen at random, plus the fittest action from the teammate's *previous-generation* population. We included this algorithm in the comparison because it uses a small fixed number of evaluations in each generation, such as is preferable for applications of multiagent learning to real problems.

We will test these algorithms using a class of problem domains called the *maximum of two quadratics* (or MTQ). These problems include a global optimum and a local suboptimum, where the suboptimum covers a much wider range of the search space and is thus difficult to escape. The problems have been used before by [4, 19].

We will assume that each action is a real-valued number from 0 to 1 inclusive. This defines a metric space for actions: in some sense action 0.5 is more similar to action 0.6 than action 0.9 is. While other techniques search for optima among sets of actions that have no "distance" relation among them, EC methods assume a distance relation: when breeding an action to form a new one, they will generally make more small (distance) changes than large changes.

The joint reward function for the MTQ class is defined as:

$$\text{MTQ}(x,y) \leftarrow \max \begin{cases} H_1 * (1 - \frac{16*(x-X_1)^2}{S_1} - \frac{16*(y-Y_1)^2}{S_1}) \\ H_2 * (1 - \frac{16*(x-X_2)^2}{S_2} - \frac{16*(y-Y_2)^2}{S_2}) \end{cases}$$

where x and y may take values (actions) ranging between 0 and 1. Different settings for H_1, H_2, X_1, Y_1, X_2, Y_2, S_1, and S_2 affect the difficulty of the problem domain in one of the following aspects. H_1 and H_2 affect the heights of the two peaks: higher peaks may increase the chance that the algorithm converges there. S_1 and S_2 affect the area that the two peaks cover: a higher value for one of them results in a wider coverage of the specific peak. This makes it more probable that the coevolutionary search algorithm will converge to this peak, even though it may be suboptimal. Different values for X_1, Y_1, X_2, and Y_2 result in changes in the locations of the centers of the two quadratics, which also affect the relatedness of the two peaks: similar values of the x or y coordinates for the two centers imply higher overlaps of the projections along one or both axes (the projections of the joint action space for one or both agents may retain more information about the globally optimal solution even if the other agent's population starts to converge to the suboptimal solution). In these experiments, we set $S_1 = \frac{16}{10}$, $X_1 = \frac{3}{4}$, $Y_1 = \frac{3}{4}$, $H_2 = 150$, $S_2 = \frac{1}{32}$, $X_2 = \frac{1}{4}$, $Y_2 = \frac{1}{4}$; H_1 was varied across experiments, but it was always less than 125.

MTQ using such settings is fairly difficult to optimize: the probability that a random sample has a function value within 0.01 of the optimal solution (which has a value of 150) can be computed as $\pi * \left(1 - \frac{149.99}{150}\right) * \frac{S_2}{16} = 0.0000004090615$. Given 51200 random samples (approximately the number of action evaluations performed during a typical evolutionary run), the probability that one of them exceeds a function value of 149.99 is $1 - (1 - 0.0000004090615)^{51200} = 0.02072615$.

As we will see in the next sections, the median of the results for the proposed iCCEA method is significantly higher than 149.99, which implies that iCCEA finds better approximations of the global optimum in more than 50% of the runs. This shows that iCCEA significantly outperforms random search in this domain, and implicitly the algorithms proposed in [3].

To further increase the difficulty of the problem domains with respect to the algorithms we analyze, we created a second class of problem domains, SMTQ, which is defined as:

$$\text{SMTQ}(x,y) \leftarrow \max \begin{cases} H_1 * (1 - \frac{16*(x_1^r-X_1)^2}{S_1} - \frac{12*(y_1^r-Y_1)^2}{S_1}) \\ H_2 * (1 - \frac{16*(x_2^r-X_2)^2}{S_2} - \frac{12*(y_2^r-Y_2)^2}{S_2}) \end{cases}$$

where x_1^r, y_1^r, x_2^r, and y_2^r are the original x and y values (which ranged between 0 and 1) rotated around the centers of the two peaks by $\frac{\pi}{4}$:

$$x_1^r = (x - X_1) * \cos\frac{\pi}{4} + (y - Y_1) * \sin\frac{\pi}{4} + X_1$$

$$y_1^r = (x - X_1) * \cos\frac{\pi}{4} - (y - Y_1) * \sin\frac{\pi}{4} + Y_1$$

$$x_2^r = (x - X_2) * \cos\frac{\pi}{4} + (y - Y_2) * \sin\frac{\pi}{4} + X_2$$

$$y_2^r = (x - X_2) * \cos\frac{\pi}{4} - (y - Y_2) * \sin\frac{\pi}{4} + Y_2$$

Observe that the two peaks have ellipsoid shapes aligned diagonally with the axes, as opposed to circular shapes in the MTQ problem domains. The two Nash equilibria from the MTQ class have now become an infinity of Nash equilibria in the SMTQ class. This creates an additional difficulty for the coevolutionary search. We used the same values for H_2, X_1, Y_1, X_2, Y_2, S_1, and S_2 as for the MTQ class.

The experiments used the ECJ package [14]. Each population contained 32 actions. cCCEA and rCCEA used elitism of size 1, meaning that the fittest individual in each population in the previous generation is automatically copied into the next generation's population. The entire archive survived automatically from one generation to the next for iCCEA and pCCEA. Unless stated otherwise, iCCEA used $MaxEvals = 5$ and $MaxArchiveSize = \infty$. The

[1] [1, 8] are good references for standard evolutionary algorithms.

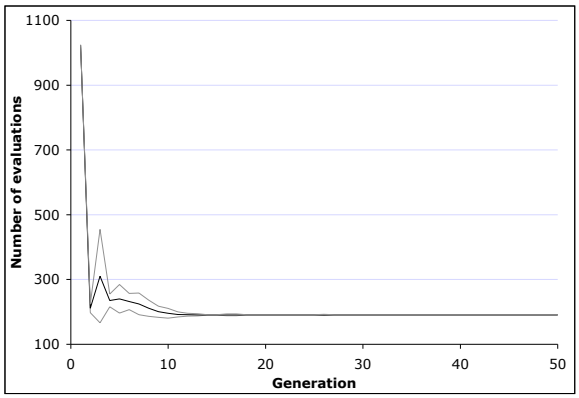

Figure 1: Average number of evaluations for the iCCEA algorithm in the MTQ domain instance with $H_1 = 50$

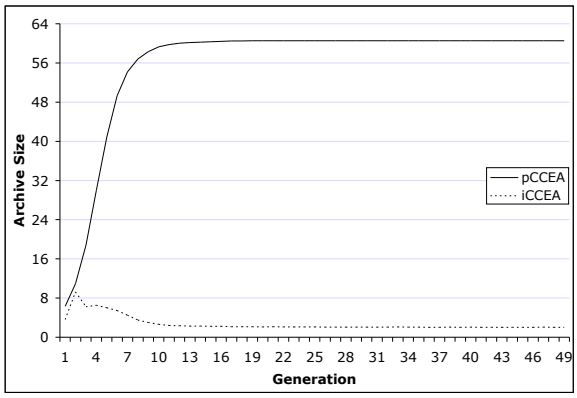

Figure 2: Average archive size for the iCCEA and the pCCEA algorithms in the MTQ domain instance with $H_1 = 50$

Table 1: Results of the four methods in the MTQ domain instance with $H_1 = 50$

Method	First Quartile	Median	Third Quartile	Average # Evals
pCCEA	148.62776	149.74876	149.94931	51200
cCCEA	149.99971	149.99995	149.99998	51200
iCCEA	149.99990	149.99997	149.99998	10676.5
rCCEA	50	50	149.99998	19200

Table 2: Results of the four methods in the SMTQ domain instance with $H_1 = 50$

Method	First Quartile	Median	Third Quartile	Average # Evals
pCCEA	133.21958	146.85126	149.49486	51200
cCCEA	149.99975	149.99995	149.99998	51200
iCCEA	149.99991	149.99997	149.99998	10982.34
rCCEA	50	149.99986	149.99998	19200

EC breeding method created children by selecting a parent, copying it, then "mutating" the copy by adding a gaussian random variable from a distribution with mean 0 and standard deviation 0.01, bounding the value to between 0 and 1. Parents were selected using "tournament selection", whereby two random parents are picked with replacement from the population, and the fitter of the two is selected. Runs lasted 50 generations.

The quality of a technique was defined as the average, over 250 independent runs, of the fitness of the best action (one per population) in the last generation of that run. The results usually have a peculiar bimodal distribution, with many values close to one of the two peaks. For this reason, we report information on the quartiles, as opposed to mean and standard deviation. For the same reason, we verify statistical significance via non-parametric t-tests combined using the Bonferroni correction. Sometimes these non-parametric tests will return the opposite result than a regular parametric test would, and although some conclusions are different from the ones reported in [4], we believe our comparison methodology is well-founded.

4.1 Experiment 1: MTQ and SMTQ, $H_1 = 50$

In the first experiment, we set H_1 to 50 to have a wide difference between the height of the two peaks. In this case, coevolution may have difficulties finding the global optimum primarily because its coverage is significantly smaller than that of the suboptimal peak.

Table 1 presents the performance of the four methods in the MTQ instance ($H_1 = 50$), as well as the number of evaluations required to achieve that performance. Although the differences appear small, the large number of observations (250) leads to statistically significant differences among the methods with confidence 95%. The results indicate that rCCEA performs worst, followed by pCCEA, cCCEA and iCCEA. There are statistically significant differences between all pairs of methods. And importantly, iCCEA achieves a significant reduction in the number of evaluations as compared to the other methods.

Figure 1 plots the number of evaluations required by the iCCEA algorithm at each generation. The algorithm starts with a complete round-robin evaluation (requiring 32×32 evaluations), followed by a drastic decrease in the number of evaluations. This is due to the fact that the number of actions needed to accurately rank the other population (hence the archive size) decreases significantly. In contrast, in the pCCEA algorithm the Pareto front in the MTQ domain is not discrete, and thus the archive grows rapidly in size until it occupies the whole population (Figure 2). At this point, learning stagnates.

Table 2 presents the results of the four methods in the SMTQ domain, as well as the number of evaluations required to achieve that performance. The rCCEA and pCCEA methods perform worst (with no statistically significant difference among them). cCCEA is better than both rCCEA and pCCEA. iCCEA significantly outperforms all other methods. The dynamics of the archive size for pCCEA and iCCEA are very similar to those in the MTQ domain: pCCEA's archive again rises to consume most of the population, while iCCEA's archive size rises to 8 early but converges to approximately 5. This is summed over both populations. The average archive size for each population is half the value: an average size of 4 early on, and 2.5 later.

4.2 Experiment 2: MTQ and SMTQ, $H_1 = 125$

Similar to the experiments in [4], we set H_1 to 125 to create a more deceiving domain instance: the actions on the suboptimal peak have higher fitness and they are thus more likely to be selected.

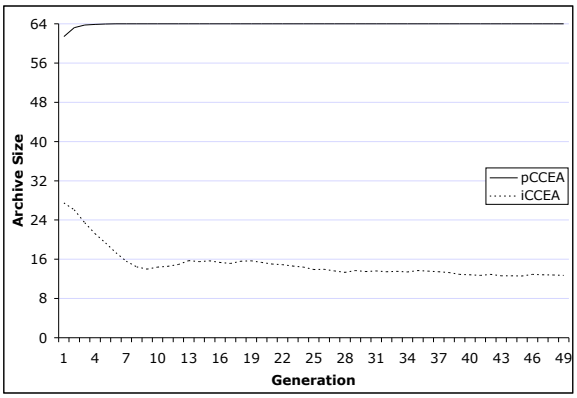

Figure 3: Average archive size for the iCCEA and the pCCEA algorithms in the OneRidge domain

Tables 3–4 present the results of the four methods in the MTQ and SMTQ domain instances with $H_1 = 125$. The results are consistent with the ones in Section 4.1: iCCEA is always better than cCCEA, which is in turn always better than pCCEA (with confidence 95%). The rCCEA method is worst: it finds the global optimum in only 16% of the runs in both the MTQ and the SMTQ domain ($H_1 = 125$). As before, iCCEA requires significantly fewer evaluations than the other methods. The average archive size is slightly higher (statistically significantly higher for iCCEA) than in the case of $H_1 = 50$, but it follows the same trend as that shown in Figure 2.

4.3 Experiment 3: The OneRidge Domain

Our last experiment examined the performance of the search methods in the OneRidge domain proposed in [21]. The OneRidge domain is defined as:

$$OneRidge(x,y) \leftarrow 1 + 2 * \min(x,y) - \max(x,y)$$

where x and y range between 0 and 1. OneRidge is particularly difficult for concurrent learners because it contains a very large number of Nash equilibria: for any value v between 0 and 1, (v,v) is a Nash equilibrium. This implies that for almost any Nash equilibrium (except for the global optimum $(1,1)$) there are an infinite number of better Nash equilibria that are infinitesimally close; unfortunately, both agents need to concurrently change their actions for the team to advance to these better solutions. To better study the algorithms' capacity to follow this ridge to the global optimum, we randomly initialized the populations of actions for each agent to only values smaller than 0.5.

If SMTQ adds more non-linear interactions among the agents, OneRidge goes even further. As a consequence, the methods have a very different ranking based on their performance in this domain (as shown in Table 5). cCCEA performs best, followed in order by rCCEA, iCCEA, and finally pCCEA; there are statistically significant differences among all the methods.

This poor performance of pCCEA and iCCEA seems unexpected at first. To shed more light onto the behavior of the two algorithms, we plotted the average archive size for pCCEA and iCCEA in Figure 3. As expected, the Pareto frontier in the OneRidge domain makes pCCEA think that *every possible action* is interesting and needs to be added to the archive; consequently, the size of pCCEA's archive is close to 64 even in the very first generations, and so learning stagnates. Unlike MTQ and SMTQ, it is relatively easy in the OneRidge domain to improve upon a joint action by small variations in the actions chosen by each agents. As a consequence, both cCCEA and rCCEA are able to improve until outperforming pCCEA.

Table 3: Results of the four methods in the MTQ domain instance with $H_1 = 125$

Method	First Quartile	Median	Third Quartile	Average # Evals
pCCEA	142.31862	149.03314	149.83407	51200
cCCEA	125	149.99974	149.99998	51200
iCCEA	125	149.99994	149.99998	11277.47
rCCEA	125	125	125	19200

Table 4: Results of the four methods in the SMTQ domain instance with $H_1 = 125$

Method	First Quartile	Median	Third Quartile	Average # Evals
pCCEA	125	145.66753	149.38516	51200
cCCEA	125	149.99977	149.99998	51200
iCCEA	125	149.99995	149.99998	11406.65
rCCEA	125	125	125	19200

Table 5: Results of the four methods in the OneRidge problem domain

Method	First Quartile	Median	Third Quartile	Average # Evals
pCCEA	1.45762	1.47224	1.48298	51200
cCCEA	1.89700	1.91584	1.93125	51200
iCCEA	1.50217	1.51778	1.53398	21545.3
rCCEA	1.82785	1.84294	1.86300	19200

The poor performance of iCCEA in this domain has a slightly different cause: the archive mechanism was designed to inform the concurrent learning processes of multiple Nash equilibria that are surrounded by large basins of attraction which cannot be avoided by small variations in actions. Given that OneRidge has no such equilibria, the archives serve little purpose, and they instead act to slow the optimization process by reducing the random exploration of the space. As shown in Figure 3, the average archive size of iCCEA is higher than *MaxEvals* (which was set to 5), and thus actions are not evaluated when in combination with random actions from the other population.

Revised Experiment. To test this hypothesis, we restricted the maximum archive size of iCCEA to only one action (*MaxArchiveSize* = 1 in iCCEA-Archive-Selection), and we performed another 250 runs in the OneRidge domain. The median performance of the algorithm was 1.84439, with a first quartile of 1.82448 and a third quartile of 1.86095. This is indistinguishable from the performance of the rCCEA method in Table 5. We further doubled the maximum number of generations for the iCCEA algorithm with a maximum archive size of 1 (this setting still involved only around 40% of the budget used by cCCEA and pCCEA), and we ran it another 250 times. The global optimum was consistently and precisely found in all of them. This is significantly better than all other algorithms we tested in this domain.

5. DISCUSSION AND CONCLUSIONS

It is rational for learning agents to explore those actions that are rewarded better. However, each agent's experimentation with a particular action directly affects the way the other agents perceive the search space. Therefore, we argue that agents may benefit from also exploring those actions that inform their teammates about the structure of the search space. We suggest that cooperating agents should be altruistic: the entire team may benefit if each agent helps its teammates to rank their actions better. We demonstrated this idea in a new cooperative coevolutionary algorithm, iCCEA, which requires significantly fewer evaluations to outperform other cooperative multiagent learning methods on our test problems. We also noted that too much altruism may hurt performance: an agent may waste resources when attempting to inform its teammates about the many Nash equilibria in the space. Restricting the number of informative actions an agent may choose solved the problem in our simple experiments, but we are exploring alternatives that can automatically balance the information provided to other learning agents with the desirability of searching for optimal joint actions. Future work will also examine formal models and guarantees for concurrent learners employing informative actions, as well as demonstrate such methods in complex multiagent domains.

ABSTRACT

This paper examines agent-based systems designed for a variety of human learning tasks. These are typically split into two areas: "training", which generally refers to adult learning of job-related skills, frequently but not exclusively in military settings; and "education", which generally refers to child and adult learning in academic settings, including primary and secondary schools, colleges and universities. While the terms may indicate diverse areas within the field of human learning, from the standpoint of agent-based systems development, many of the more prominent issues are held in common; as well, these issues can be generalized to most interactive agent-based environments. Here, we categorize three major trends in development of agents to assist human learners: pedagogical agents, peer learning agents and demonstrating agents. We highlight recent work within each of these categories, bringing to light common themes and issues.

Design, Human Factors, Experimentation

Keywords

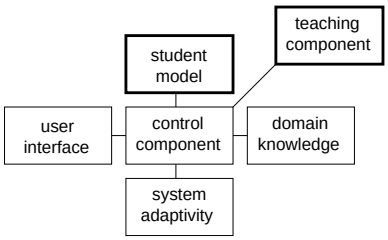
learning, training, education, pedagogical agents

1. INTRODUCTION

The primary goal in a human learning environment is for the learner to advance. Software applications built for this environment, unlike applications for other environments, are not designed to simplify or perform a task *for* the user, but rather to help the user *learn* how to accomplish the task herself. This goal is strikingly different from typical interactive systems, where agents are constructed specifically to assist users by handling tedious or complicated jobs. Such systems address tasks such as browsing [33], sorting email and filtering news group messages [13, 17, 29, 30], or finding other users who share similar interests [4, 15, 28]. By embedding personalized agents and applying a variety of adaptive techniques, these systems can be thought of as tools designed to relieve the user's burden by taking over repetitive or complex duties from an overwhelmed human.

Malone [37, 38] makes an important distinction between *toys* and *tools* when discussing computer games. He defines toys to be systems that exist for their own sake, with no external goals; in contrast, tools are systems that exist because of their external goals. Good tools should be easy to use, in order to expedite the user's external goal. Good games are difficult to play, in order to increase the challenge provided to the player. Whereas typical interactive systems are like good tools, systems built for human learning should of course be easy to use, but primarily should provide challenges for the human learner. The external goal is for the user to learn how to perform a given task, so the system should make the process of learning how to accomplish that task easy — the *process*, not the task [64].

Systems designed to aid human learners are typically split into two categories:



- **training**, which generally refers to adult learning of job-related skills, frequently but not exclusively in military settings; and
- **education**, which generally refers to child and adult learning in academic settings, including primary and secondary schools, colleges and universities.

While the terms "education" and "training" may indicate diverse areas within the field of human learning, from the standpoint of computer systems development, many of the more prominent issues are held in common. We use the general term "interactive learning system" (ILS) to include not only the more specific (and perhaps more familiar) term "intelligent tutoring system" (ITS), but also to provide a broader definition encompassing environments that are designed for more exploration on the part of the student than ITS's (which are typically more structured and scripted according to highly engineered, domain-dependent models). A typical ILS consists of the following components [39, 63]: (1) *domain knowledge* — a representation of the topic that the student is learning; (2) *teaching component* — an instructional model that is used to guide the student through the knowledge domain; (3) *user interface* — the interaction mechanism that lies between the human student and

the computerized system; (4) *student knowledge* — a "user model" of the student in relation to the domain knowledge, indicating how much of and how well the student knows the domain; (5) *system adaptivity* — the means by which the system adapts automatically to the student's behavior, backtracking when the student makes mistakes and moving ahead when the student demonstrates proficiency with portions of the domain; and a (6) *control component* — the central part of the system architecture which holds all the pieces together.

Figure 1a illustrates these components and their relationships to each other. This architecture is quite similar to that of a typical interactive system for non-learning applications, as shown in Figure 1b. The *student model* is replaced by a *user model*, and there is no *teaching component*. In both cases, different types of agent technology are included at different levels. For example, where *interface agents* are used in non-learning applications to help a user navigate a complex domain, *pedagogical agents* are implemented in a learning application to guide users through a problem space. Understanding and embracing the special characteristics that learning tasks require of an application is necessary in order to adapt techniques from non-learning applications to those designed for education and training. While the focus in this article is on agent-based environments for human learning, we also highlight the relevance of issues for any agent-based interactive application.

(a) interactive learning system

(b) interactive system

Figure 1: Typical system architectures

There are three main types of agents embedded in human learning environments. The first are *pedagogical agents* [23], personalized assistants that interact directly with a learner and explicitly guide her through the domain. Referring back to Figure 1a, pedagogical agents are involved in the teaching component and user interface. Typically they consult the user model in order to understand the student and provide feedback that encourages the learner within her appropriate "zone of proximal development" [71]. The second type of agents are *peer learning agents*, the explicit use of agents as interactive partners in the learning process itself [27, 58]. These agents are built into the user interface and, as with pedagogical agents, have knowledge of the user. While these agents may have teaching capabilities, they are typically less engineered for guiding learning overtly than pedagogical agents. The third type of agents are *demonstrating agents*, where the agents themselves are interactive mediums for learning; for example, interactive agent-based simulations [54, 73] or educational robotics [19, 65]. These agents embody the domain knowledge and are removed from the other components of the learning system. An open area for future work is the development of systems which combine this third type of agent with one or both of the others.

Many systems employ an underlying agent architecture that is not necessarily apparent to the user. Agents can be implemented as part of any system component, but are particularly useful for the control component and providing a means for system adaptivity (e.g., [63, 67]). This is a natural approach as the use of independent modules that have specific tasks to perform while being able to interact with other independent modules fits nicely with the agent paradigm and with the principles of high cohesion and low coupling in software engineering. An example is the Dynamic Adaptive Learning study [67] that uses an agent-based architecture involving a student agent, evaluation agent, record agent, learning object agent and modeling agent. In this architecture, the agents cooperate to determine the appropriate learning objects to be presented to the student.

This paper focuses on discussing the three primary types of agents in use by learning systems today. Thus the work is organized as follows: section 2 describes the use of pedagogical agents; section 3 discusses ways in which agents act as peers in learning envionments; and section 4 highlights examples of environments in which students learn about various phenomena by interacting with agents that demonstrate aspects of the phenomena. Section 5 delves into the topic of testing and evaluation, briefly outlining key components of assessment in human learning and evaluation of computer-aided learning systems. Finally, we close by discussing current open issues.

2. PEDAGOGICAL AGENTS

Much like a narrator in a movie who provides voice-over to explain scenes but never actually appears in the film, a *pedagogical agent* will "pop up" when the learner indicates that she needs help. There are three methods used to determine when this help is needed: (1) directly, upon request by the user, for example by clicking a "help" button; (2) indirectly, by the system monitoring the learner's performance and automatically detecting when she seems to need assistance; and (3) mixed initiative, which relies on a combination of (1) and (2).

The work of Lucas *et al.* [35] involves the use of pedagogical agents that assist learners when the agent perceives that the user needs help, based on a model of the learner and the learning goals of the system. Animated Pedagogical Agents (APA)s are used to assist students in distance learning environments. The initial project involves popping up and providing guidance in the use of a calculator. The APAs work in conjunction with the initial loader (instantiated by the FIPA-OS Agent-Loader) and a graphical interface agent called the CalcAgent for handling the display, input and output to the calculator. Mbalad and Anyouzoa [46] have also used pedagogical agents to support online distance learning.

Johnson *et al.* [25] present comprehensive research on

animated pedagogical agents, highlighting issues that are faced when developing computer-based learning companions. Questions are addressed such as when to initiate dialog, as above, as well as how to include non-verbal communication and how to design for a wide range of client technologies. Animated agents can mimic human gestures and emotion-driven expressions, which can help engage students more than static avatars. Several agents were developed and tested, including: Steve (Soar Training Expert for Virtual Environments), Adele (Agent for Distance Learning, Light Edition) and Herman the Bug. Steve is embedded in an immersive three-dimensional environment that includes sound and was designed for naval training. Adele was built for use by university students over the internet, using standard workstation platforms and web technology. Herman the Bug is a "talkative" agent that gives advice to young students about plants, while teaching about botany. Animated agents can provide a number of advantages, such as navigational guidance, interactive demonstrations, gesturing for attention and use of other non-verbal communication devices. Empirical results using animated pedagical agents are positive, with some cautions. For example, there is evidence that young students may be distracted from the learning task by the agent's interface; however, a well-designed agent can keep students on-task and avoid this pitfall.

More recent work in this realm has focused on *interactive pedagogical drama* [41], where animated pedagogical agents become actors in a pseudo theatrical environment and learners either become immersed as participants in the drama or act as observers, like members of an audience. There are advantages to each approach; the former, active approach, requires learners to act in the drama which can be challenging and motivating, while the latter gives learners an opportunity to participate passively, with time for reflection and perhaps impartial analysis. Johnson [24] and Marsella *et al.* [41] use an interactive pedagogical drama for a system called "Carmen's Bright IDEAS" in which an adult human is guided through scenarios designed to improve problem-solving skills. Carmen, a character in the drama, is the mother of a pediatric cancer patient. She has a job and has another (healthy) child to take care of. When using the system, the learner observes Carmen's thoughts and can choose actions for her, in sessions with a counselor, discussions with her child's doctor, interactions with her boss, and so on. The pedagogical goal is for the human user of the system to improve her problem-solving skills and gain insight into similar situations in her own life.

The underlying architecture of Carmen's Bright IDEAS has been developed into a generalized framework called *Thespian* [62, 59] and applied to other domains. The Tactical Language Training System (TactLang) is a military application in which the learner engages in role-playing activities to acquire knowledge of the language, idiom and customs of particular geographic regions. One example is a drama which unfolds in a village cafe in the Middle East and the learner interacts with characters who are speaking Arabic. The system architecture integrates *PsychSim*, a multiagent system for mental modeling [52], with a story-line and basic script as well as pedagogical goals and social norms to guide agent-agent and agent-human interaction. The premise is that such an architecture will aid in rapid deployment of interactive pedagogical dramas.

3. PEER LEARNING AGENTS

There are many learning environments where agents interact with human learners as peers. These agents appear less intrusive than pedagogical agents. Many agent-based learning systems leverage game technology to provide both motivation and a situated, simulated training environment [31]. Human learners engage with agents as opponents or partners. These agents act more like peers than pedagagical agents who are more like tutors or instructors. The primary issues in developing peer learning agents involve (1) developing believable situated environments in which the human learner and agent peer interact, and (2) providing believable agents and a natural mode of interaction.

To address the issue of developing situated environments, which can become very expensive, many projects take advantage of a number of free or off-the-shelf game engines. For example, the TactLang mission environment (mentioned above) employs a modified version of the game engine Unreal Tournament, known as Gamebots [1]. Many games include *simulation elements* [3] that provide practical experience and *game elements* that offer an environment of engagement, discovery and competition [6]. Simulations can be particularly useful to provide training in several categories of skill sets: internalising processes, understanding systems, decision-making, perspective-shifting, team-building and cooperation [16].

Further, Wilkinson [74] states: "optimal learning occurs in the simulation of real world, problem-based activities. This happens in a safe environment where errors are expected, and failure deepens learning experience". The notion of a safe environment is particularly critical for the Mission Rehearsal Exercise (MRE) project [69]. Safety is also a key consideration in the training simulation being developed by Richards *et al.* [55] where agents are created in a game environment to allow the user to explore various risk scenarios. This project is focused on addressing issues concerning the agents' acquisition and reuse of knowledge and the language, cognitive and behavioural abilities of the agents to provide a more believable, engaging and immersive learning environment.

A number of game engines are available, with various strengths. Well-known engines include: Torque, Doom, Unreal Tournament, Aurora, Hammer, Embryo and Quake. Only some, however, are complete systems of high calibre, such as Hammer 4 and Doom 3. Simulation games have also been used in business environments, for example in teaching administrative skills. Off-the-shelf game simulations such as Doom II have been used in conjunction with free tools downloaded from the internet to provide cost-effective military training, for example, where real-world environments or locations may be unavailable to troops. The Gamebots project, mentioned earlier, started at the University of Southern California's Information Sciences Institute and is a prime example of the use of a game engine for agent-based training that was created for wider applications in artificial intelligence research. A good overview and lists of game engines is provided by Isakovic [21]. A shorter discussion is provided in Barles *et al.* [5].

To address the issue of providing believable agents, one strategy currently being explored by many comes from examining human characteristics such as emotion and empathy and extending agents to handle and even emulate such traits. Selvarajah and Richards [60] have developed an agent-based

emotion architecture to be used for psychological testing of subjects in a three-dimensional virtual reality Cocktail Party World. The study compared an avatar and an agent world to see whether agents reacting to the emotions of the subject and other agents in their vicinity was more realistic than the avatar world in which emotions were scripted. It was found that the agent world more deeply affected the subjects than the avatar world.

Similarly, van den Broek [70] developed empathic agents that mimic human empathy in a study concerning stress levels in individuals, where stress was detected through analysis of human voice recordings. In both of these studies, the goal was not to use agents to teach the subjects, like pedagogical agents would, but rather to add human abilities to the agent software so that the results would be more sociologically valid, a key concern and common shortcoming of laboratory style testing with humans. Also related to better understanding humans is the work of Sehaba and Estrailier [58], who use an agent approach to help rehabilitate children with autism. A multiagent system is used to model the knowledge of the therapists, the child's profile and the dynamics of the interaction.

A key difference between agent systems for human learning and other agent systems is the need for human communication languages as well as agent communication languages (ACL). In general, it is unrealistic to expect a human to communicate with a software agent using a FIPA-compliant ACL. The burden is on the system developer to create a communication channel that bridges the human-agent gap. It is common to use a personal agent to bridge this gap. Lazzari *et al.* [32] use personal agents in their Remote Assistant for Programmers (RAP) system to allow human users to interact with other humans and other parts of the system, which are represented by other types of agents. Personal agents are created for each online and offline user. Personal agents handle a range of tasks such as selecting answer types, submitting queries, finding answers, finding experts, receiving expert ratings, selecting experts, receiving answers and rating answers. Some of these tasks are performed in conjunction with other agents in the system. As in the case of RAP, personal agents are tailored to the particular human user based on a user profile, stereotype or model and often require a high degree of sophistication. This is clearly true in the case of the User Observation Agent (UOA) used in the studies of the behaviour of autistic children by Sehaba and Estrailier [58]. This agent takes input from a software/hardware system known as FaceLab to capture features of the face and the orientation of the gaze. In addition, the UOA takes into account actions with the mouse, touch screen and keyboard.

In a similar vein, Kim [27] uses agents as learning companions. The idea is motivated by the pedagogical strategy of providing a learner with peer support. This work reveals that the competency of the learner has a large impact on the nature of the interaction with agents as learning companions, referred to as PALs. Strong students, identified by their GPA[1], preferred for the PALs to take a leading role and expected to be given correct advice. Weak students preferred to control the PAL and asked for assistance only when they wanted it and were happy with some wrong answers, as they found that a PAL that was always correct was intimidating. These interesting findings emphasize the varied influence of agents for human-based learning. Not only will differences in settings and interfaces affect learners, but also the personalities of the learners themselves will be a factor. Refer to section 5 for discussion of issues relating to assessment of agent-based learning systems.

[1]Grade point average

4. DEMONSTRATING AGENTS

The notion of agency is useful for teaching and demonstrating a wide range of phenomena in the world. From introductory programming concepts [7] to dynamic systems [73], innovative researchers and teachers have developed virtual and embodied agents that interact with students of all ages. These environments take advantage of the popular and proven *constructionist* [49] pedagogical paradigm, motivating students and helping them to learn by doing. Here we highlight two complementary directions within this paradigm that concentrate on the use of agency to provide meaningful learning experiences: multiagent simulation and educational robotics.

Multiagent simulation allows students to program agents using simple commands and view graphically, and instantly, the effect of their code. This not only teaches students about programming concepts, but also provides powerful lessons in modeling. Students observe the world, invent rules about it, program them and analyse how well their rules represent the phenomena in the world they are attempting to model. Sengupta and Wilensky [61] use the NetLogo [48] agent simulation package to assist physics students to better understand the field of electromagnetics at the micro level. By modeling concepts such as electrons and atoms as agents, students are able to discover for themselves the emergent phenomena and learn to predict the behaviours in a way that produces deeper learning and understanding. The NetLogo Investigations in Electromagnetics (NIELS) studies demonstrate how learning in the domain can be broken down: "thinking in levels using multi-agent based models allows the students to establish concrete relationships between submicroscopic objects (e.g., electrons) which are shrouded in mathematical equations in traditional Physics instruction."

Blikstein and Wilensky [8] also employed the NetLogo environment, but this time to understand the difficult concepts involved in Materials Science. The MaterialSim system is a modeling-for-understanding framework that uses multiagent modeling languages where each agent is a basic computational construct with simple rules which control their behaviour and from which more complex higher level behaviours emerge. The study included classroom observations, pre/post interviews and data analysis of the usage session.

The simulation system Swarm [14, 68], based on the simple notion of ants in a nest gathering sugar, has been used to model, test and refine complex economic and language theories. Examples of other multiagent simulation environments include AgentSheets [2, 54] and RePast [53]. While the nature and architecture of environmental agents differs significantly from that of pedagogical agents, the use of modeling and simulation as a learning medium is shared by other applications. Examples are the training for risk situations project [55], MRE [69] and related projects.

Educational robotics refers to the use of robots in classrooms to teach a wide variety of topics, not necessarily robotics in particular. With the advent of the LEGO Mind-

storms Robotics Invention Kit [47] in the late 1990's, today robots are being used all over the world to engage students from early primary through undergraduate classrooms [7, 65]. While some courses focus more on the hardware and engineering design aspects of robotics [42, 43], others concentrate on control mechanisms, agency, behavior-based paradigms and multiagent systems [44, 50, 76]. Many include some type of contest in the course to help motivate students as well as take advantage of fully tested and readily available environments, such as Botball [9] and RoboCup [56, 65]. A broad range of experience reports have been published detaling lessons learned using robotics with younger students, in primary and secondary school classrooms and after-school programs [19].

As well as hands-on, hardware-based approaches, a number of simulators have been developed recently to give students who do not have access to robot hardware an opportunity to explore the concepts behind controlling robots or to speed up development by providing a rapid-prototyping environment where debugging can occur more quickly than on real robots. Chu *et al.* [12] have developed an agent-based simulation environment for children, designed to be used in conjunction with the popular RoboLab [57] graphical programming interface and LEGO Mindstorms robot. The motivation is to give students an opportunity to learn about agent-based programming by using RoboLab in a "safe and friendly" place – they can "try out" programs in the simulator before loading them onto the robot platform and before being faced with real-world, physical constraints and issues such as noise.

When dealing with varying robotic platforms, even with a relatively simple one like the LEGO Mindstorms, it is effective for students to be able to classify and specify behavior patterns for their robots. Behavior patterns can range from basic behaviors, such as "move forward for 4 seconds", to complex behaviors such as "open a gate". Due to the complexity of defining and implementing robot behaviors, many control architectures are designed to build complex behaviors out of simple, low-level commands [45]. Another approach by Goldman [18] provides a custom behavior-based interface to RoboLab and an XML-based translator for downloading on to the Sony AIBO robot.

5. TESTING AND EVALUATION

One of the more prominent issues that separates human learning systems from other agent-based and interactive system development is the aspect of testing and evaluation. It is expected that not only the software learning environment be fully debugged and tested, but also, particularly amongst education researchers, the system must be evaluated with respect to its effectiveness as a learning environment. This section provides a brief description of evaluation in this context.

While there is no fixed standard for evaluating the effectiveness of interactive learning systems, there are two generally accepted categories of assessment [34, 40]:

- *formative assessment* tests the design and behavior of a system in-progress, generally performed by computer scientists, system designers and builders; and
- *summative assessment* evaluates the effectiveness of a completed system, generally performed by educators and/or psychologists.

Researchers begin by identifying what is being evaluated. Design and performance aspects need to be examined differently. The nature of the testing will vary depending on whether the goal is to assess the theoretical basis underlying the system or the software components themselves.

Each of a learning system's components (see Figure 1a) can be evaluated individually. Domain knowledge should be checked for accuracy and coverage. The teaching component can be evaluated for the range of instructional method(s) offered, its level of adaptability and the degree to which its instruction is based on proven educational and psychological methods. The user interface can be examined by comparing multiple user interfaces for the same underlying engine and looking, in particular, for improvement in student learning. System adaptivity can be compared using interactions at different skill levels. The control component can be evaluated using various system performance measures, such as speed. Finally, and probably the most important, improvement in student knowledge (i.e., learning) can be measured using the same criteria in a computer-based environment that are employed within standard educational and/or psychological testing. These include: (1) *validity* — does the test show evidence that it measures what it says it measures? (2) *reliability* — are multiple results for the same subject consistent? (3) *objectivity* — is the test administered and scored the same way for every participant? (4) *standardisation* — can results be translated into a meaningful representation of student performance?

The techniques for performing assessments vary depending on which component is being evaluated, where in the system development cycle the evaluation is being performed and who is performing the evaluation. Similar to typical HCI lifecycle models, such as the star life cycle [51] that involves evaluation after each step, evaluation of learning systems typically follows an iterative cycle. Beginning with *system development* and extending through to *experimental research*, steps may be revisited at any time during the formative phases of system development. Once summative assessment begins, in the experimental research phase, the system cannot change; otherwise, the summative results will be invalid. *Pilot testing* often occurs late during formative assessment, bridging the gap to summative assessment. There are three methods of pilot testing: (1) *one-to-one*, which is performed early in the development cycle, with one student, instructor, trainer or researcher providing feedback; (2) *small-group*, which is performed later in the development cycle, with a small group of students, instructors or trainers providing feedback; and (3) *field*, which is performed near the end of development, emulating experimental conditions with teachers or trainers and students in a "live" (i.e., classroom) setting.

Other techniques are more pertinent during summative assessment. In *criterion-based evaluation*, a general list of guidelines is developed and systems are evaluated based on their adherence to these guidelines, for example, program construction, behavior and characteristics. While developing relevant criteria is not an easy task, this method may prove useful in formative assessment and in comparing different systems. With *expert knowledge and behavior* assessment, system performance is compared to that of a human expert performing the same task. Software systems may be subjected to a standard *certification* process, through careful examination by qualified human experts. In *sensitivity*

analysis, the responsiveness of a system is tested on a variety of different user behaviors. This may be particularly useful for evaluating system adaptivity. After system development and pilot testing are complete, *experimental research* can begin. The conditions should be the same as those during the field testing phase.

Two mechanisms for collecting evaluation data are common:

- *quantitative*, in which numerical data is analysed, frequently by comparing scores on pre- and post-tests and surveys, to measure changes in student performance and attitudes; and
- *qualitative*, in which interviews and surveys are conducted and observations are made.

Mixed methods research [22] combines the two, but typically, at least in the education arena, researchers tend to adhere to the methods of one category or the other. Quantitative methods rely on standards type testing, with multiple choice style questioning and Likert scale surveys. System logs are also examined. Qualitative, or "open", methods encompass data taken in both written and oral forms, as part of interviews, questionaires and open surveys containing short-answer questions (rather than multiple choice). Transcripts are "coded" and analysed based on measures such as frequency of broad term usage, often borrowing techniques from natural language processing in order to compute semantic similarity between answers.

Reviewing the literature describing agent-based systems issues, written from an agents research perspective (as opposed to an education research perspective), the primary type of evaluation is formative assessment, particularly testing the accuracy and functionality of system design and early pilot testing. Within the sampling of literature referenced earlier in this article, a wide range of test environments have been used, including formal primary, secondary and undergraduate classrooms, research laboratories, industrial workplaces, military bases and distance learning (or "e-learning") settings. As well, there are broad differences in the maturity of systems presented. Some have completed only the design phase while others have been fully implemented. Many have undergone some aspects of formative testing, including architecture and system design reviews, and user interface studies. Few have reached the summative testing phases, but some have conducted focus groups and pilot studies.

Many systems which are designed do not get past the prototype phase for various reasons. Firstly, gaining access to human subjects, particularly minors, may be difficult. Hurdles can include: availability of representative population; costs for setup and recruitment and human ethics requirements. One of the more serious issues is that learning systems take so long to develop, by the time they are operational, the customer does not need or want them any more. This is frequently due to the large costs (in time and money) associated with building a teaching component into a system, which adds to the typically unwieldy costs of developing software on time and within budget [10]. Nonetheless, just as one would expect user evaluation to be found in research publications concerning user interfaces, there is a higher expectation in the work reported on agent-based human learning systems that an evaluation with real users will be conducted, will be well designed and analysed carefully.

6. DISCUSSION

The types of research, application development and studies being performed using agent technology for human learning are varied. In some cases, the central theme of the project is to explore and extend current agent technologies and capabilities. In other cases, agent theory is not being developed but rather is being applied and the research focuses on the application.

Differences in learners' ages and genders must be considered when designing agents that will interact as pedagogical tutors or peer learners. While most learning systems using games are focused on making the learning more palatable for children, the motivation of Richards *et al.* [55] is quite different and in keeping with Kearsley [26] who has found that "instruction for adults needs to focus more on the process and less on the content being taught. Strategies such as case studies, role-playing, simulations and self-evaluation are most useful. Instructors adopt a role of facilitator or resource rather than lecturer or grader." Using these virtual environment technologies in conjunction with agent components allows production of less expensive and more accessible systems that offer increased control of the environment together with increased relevance to the real world.

Many studies have highlighted differences in the way females and males approach, interact with and think about technology. Inkpen [20] found gender differences in the way children approach game environments. Girls tended to perform better when another person was also playing on the same machine, but boys performed better when the other player was on a different machine. Girls were found to have less physical contact with their human partner or the mouse compared to boys. Brunner *et al.* [11] showed that females tend to view technology as a tool used to facilitate human interaction, whereas males tend to view technology as an object that can be used to extend their abilities and/or power. These gender-based attitudinal differences will effect a student's experience with a learning environment; as well, these issues generalize to any interactive agent-based system.

A more philosophical question addresses the intersection of agent-based technologies and interactive learning systems. What does each do for the other? Agent-based systems, since the infant stages of the field [36, 75], have been highly focused on finding effective, modular means to intelligently interact with human users in a personalized, but not annoying way (go away, Mr Clippy). The notion of an automated assistant is quite natural in a learning or tutoring environment. The difficulty comes in building generalizable systems because effective tutoring, by both humans and agents, involves deep understanding of the knowledge domain being taught. Knowledge engineering, identifying and fixing common bugs in students' learning paths and constructing tutoring agents that reflect the experience of a master teacher is a daunting endeavor, shadowed by the desire to avoid repeating the mistakes of expert systems. Agents have been shown to learn to adapt in dynamic environments, such as robotic soccer [66] and electronic markets [72]. If we view the human learner as an agent's changing environment, perhaps tomorrow's solutions will include agents that can learn to teach.

ABSTRACT

A long-standing challenge in interactive entertainment is the creation of story-based games with dynamically responsive story-lines. Such games are populated by multiple objects and autonomous characters, and must provide a coherent story experience while giving the player freedom of action. To maintain coherence, the game author must provide for modifying the world in reaction to the player's actions, directing agents to act in particular ways (overriding or modulating their autonomy), or causing inanimate objects to reconfigure themselves "behind the player's back".

Declarative optimization-based drama management is one mechanism for allowing the game author to specify a drama manager (DM) to coordinate these modifications, along with a story the DM should aim for. The premise is that the author can easily describe the salient properties of the story while leaving it to the DM to react to the player and direct agent actions. Although promising, early search-based approaches have been shown to scale poorly. Here, we improve upon the state of the art by using reinforcement learning and a novel training paradigm to build an adaptive DM that manages the tradeoff between exploration and story coherence. We present results on two games and compare our performance with other approaches.

reinforcement learning, drama management, interactive entertainment

1. INTRODUCTION AND MOTIVATION

We are interested in adding narrative structure to large open-world games in a way that is not pre-scripted and allows the player to interact with and influence the story. Many modern games have rich, non-linear plotlines, with multiple endings, complex story branching and merging, and multiple subplots. We would like the player to be able to have a significant impact on what happens, rather than following along with a prewritten script, or being in control at only a few decision points. However, in contrast to completely open games, the story that results should exhibit global narrative coherence and reflect the game author's aesthetic goals.

Traditionally, story in games is guided by local triggers. Progress in a linear story depends solely on how much of the story has unfolded. In slightly more complex situations, the author can specify condition-action rules (*e.g.* "`if` the player is in the room `and if` the player is carrying a gun, `then` have the non-player character (NPC) hide behind the counter"). The author must specify rules for every possible combination of conditions, a tedious (and intractable) burden for stories of any complexity. Further, the author will find it difficult to achieve a globally cohesive, pleasing story purely from local rules.

This difficulty has been recognized for some time, and grows worse as players demand both true interactive agency and rich stories. One solution is a *drama manager* that watches a story progress, reconfiguring the world to fulfill the author's goals. A drama manager may notice a player moving along a currently undesirable subplot, and attempt to lure the player toward a better one. To do so, it requests that one of the agents in the world take some action; for example, it may instruct an NPC to start a conversation with the player. It may even make requests of objects that appear inert to the player, such as telling a door to lock itself (of course, reconfiguring inert objects must be done carefully without the player noticing). Thus the drama manager acts as a central director of the agents in the game world, making requests of them when necessary to maintain a globally coherent story-line.

We base our work on a specific framework in which a story is represented as a sequence of discrete *plot points*, and the drama manager has a set of requests it can make of agents, which we call *DM actions*.

Plot points are important possible events in the story, such as a player discovering information or an object. DM actions are any requests for which the game author has implemented an agent that can respond to the request. Plot points have a set of (boolean) prerequisites defined as other plot points. For example, the plot point *found book* may have the pre-

requisite *found key*, if it's hidden in a locked room. Prerequisites restrict the set of plot-point sequences—and thus stories—to those that are physically possible. Note that in nonlinear games with many plot points there are still a large number of possible stories.

Plot points are abstractions of concrete events happening in the game world: For example, in a story that we use as a case study, *Anchorhead*, the player can find a safe in an old mansion. Finding the safe involves a number of concrete actions, such as entering the room in which it's located, reading a description of the room, possibly examining various objects in the room, searching the bookshelf on the wall, and finally picking up the book behind which the safe is hidden. The drama manager does not need to know the details of all these actions, since most do not impact the progression of the story; instead, it is only notified of the abstract plot point *found safe*. It is, however, an assumption of this approach that the abstract version of the story represented by a sequence of plot points is sufficient to judge story quality.

Drama-manager actions are similarly abstract, but correspond to sequences of concrete actions in the game world. For example, the DM action *hint safe location* may result in a complex series of concrete events, in which an NPC tries to draw the player into a conversation and let slip a hint. To the drama manager, what matters is the expected outcome of the request, so DM actions are given as an ordered pair (*action*, *plot point*), where *action* is one of: *cause*, *deny*, *temporarily deny*, *reenable*, or *hint*. These actions cause the plot point in question to, respectively, either: happen immediately (*e.g.* an NPC gives the player an item); become impossible for the duration (*e.g.* inconspicuously make an item disappear from the world entirely before the player has noticed it); become temporarily impossible (*e.g.* tell an NPC to refuse to speak to the player for now); become possible again (*e.g.* tell the NPC to be talkative again); or become more likely by leading the player towards the plot point (*e.g.* tell an NPC to hint about an item's location). Actions have constraints. They must be consistent (a plot point cannot be *reenabled* unless it has previously been *temporarily denied*), and there can also be constraints on when, from the author's perspective, the action makes sense (*e.g.* an action that *causes* something should only be taken at points in the story when it is plausible to cause its target plot point).

Finally, the author provides an evaluation function that takes a sequence of plot points and the history of drama-manager actions, and rates the completed story. This is the central feature of what we call *declarative optimization-based drama management* (DODM): The author specifies *what* constitutes a good story, and leaves to the drama manager the problem of *how* to bring it about in the complex environment of a continually-progressing game.

To specify an evaluation function, the author will generally annotate plot points or DM actions with some information and then specify a *feature* using that information, which is a numerical score rating how much a particular story exhibits some desired property. The final evaluation function is a weighted sum of these features, in accordance with the author's judgment of their importance. For example, the author may annotate plot points with the subplot they belong to, and assign a higher score to stories where the player progresses along one subplot for several plot points in a row; or, the author may annotate plot points with a description of the knowledge they provide to the player, and assign a higher score to stories where knowledge unfolds gradually and climaxes in a burst of revelations near the end (*e.g.* in a mystery story). Actions can be annotated with a judgment of how likely the player is to sense that the drama manager is fiddling with the world; stories would then be assigned scores in inverse proportion to how much total manipulation took place. These desired features may in many cases conflict in surprising and constantly changing ways; the drama manager is responsible for making these complex tradeoffs.

In short, the problem of drama management is to optimize the use of the available drama-manager actions in response to a player's actions, given the set of plot points and an evaluation function. This is well-modeled as a reinforcement learning (RL) problem. RL algorithms attempt to learn a policy that, given a world modeled by states and a (possibly unknown) transition function between states, specifies an action to take in each state in a manner that maximizes expected evaluation according to some function. In this case, state is specified by the sequence of plot points and drama-manager actions that have happened so far (order is important); actions are the drama-manager actions plus the null action (do nothing); transitions are the likelihood of plot points occurring in any given state, and are given by the combination of prerequisites for a plot point, the player, and any influence from drama-manager actions; and the evaluation function is the one provided by the author. Although nicely defined, this is a complicated reinforcement-learning problem: the player is difficult to model and highly stochastic, and the state space is extremely large.

In the rest of this paper, we present our approach to this problem. We review earlier search-based techniques, discuss our application of temporal-difference (TD) learning methods to the problem, and show how our novel approach to training, *self-adversarial / self-cooperative exploration* (SASCE), outperforms search-based methods and improves the performance of TD methods.

2. RELATED WORK

Using a drama manager to guide interactive drama was first proposed by Laurel [3]. The story and drama-manager formalism we use—and treating drama management as an optimization problem—was proposed by Bates as *search-based drama management* (SBDM) [1]. SBDM formulates the drama management problem similarly to a minimax game-tree search problem as has been used for games like chess; however, because the player in interactive drama is not truly an opponent, expectimax search is used, alternating maximizing nodes where the drama manager chooses its best available action with expectation-calculating nodes where the player is assumed to act according to some probabilistic model.

Weyhrauch [12] applied SBDM to a simplified version of the Infocom interactive fiction *Deadline*, named *Tea for Three*. Full-depth search is intractable, so he used shallow searches with static cutoff values calculated by sampling a small number of possible stories that could follow the cutoff and averaging their evaluations, achieving impressive results on *Tea for Three*. Lamstein & Mateas [2] proposed reviving the technique, but work by Nelson & Mateas [7] on a different story, *Anchorhead*, showed that the impressive performance of Weyhrauch's limited-depth sampling search did

not generalize to other stories.

In formulating drama management as an RL problem, temporal-difference (TD) learning [9] seems a natural candidate algorithm. In particular, the approach used by TDGammon [10] to learn a policy for playing backgammon as well as the best human players [11] seems a useful starting point. Some have argued (to some controversy) that these results are due in part to the particular stochastic properties of backgammon [8]. As we shall see, we address this concern by modifying the stochastic properties of the training regimen.

There have also been several other drama management systems that take quite different approaches.[1]

The Mimesis architecture [13] constructs story plans for real-time virtual worlds. The generated plans are annotated with a rich causal structure, and the system monitors for player actions that might threaten causal links, replanning or preventing player actions if a threat is detected. This approach differs substantially from ours in that authors specify concrete goals for the planner to achieve as part of the story, while an author in DODM specifies abstract and possibly conflicting features that the story as a whole should possess.

The Interactive Drama Architecture [4] takes a prewritten plot and tries to keep the player on the plot by taking corrective action according to a state-machine model of likely player behavior. This addresses a much different problem than ours, since we're interested in letting players' actions substantially affect the overall plot, rather than just incorporating their actions into variants of a prewritten plot.

The beat-based drama manager in *Façade* [6] sequences small pieces of story progression called dramatic beats, constructing the story out of these directly-chosen pieces. This is substantially different from the DODM approach, which for the most part lets the story run itself in the traditional way, stepping in to instruct the agents with DM actions only when it seems necessary. We hypothesize that this makes beat-based drama management better suited to tight story structures, where ideally all activity in the story world contributes to the story, while DODM lends itself more naturally to more open-ended games, especially in large worlds that may include much player activity not directly relevant to the story.

3. METHODS

In this paper, we focus on quantitatively evaluating the performance of the optimization component of DODM. Given a story world modeled by plot points, a set of available drama-manager actions, and an author-supplied evaluation function, we can determine to what extent the drama manager succeeds in maximizing story quality according to that evaluation function. To do so, we use the drama manager to guide simulated games many times, score each resulting game using the evaluation function, and plot the distribution of scores on a histogram. For a baseline distribution, we run the same simulations without a drama manager (equivalent to a null drama manager that never takes any DM actions). If the drama manager is successful, its distribution will be generally skewed towards the right compared to the baseline: high-quality stories will appear more often, and poor-quality stories will happen infrequently if at all. For the simulations, we use a fairly naive player model (proposed by Weyhrauch) that assumes the player is exploring the world; the player chooses uniformly from available plot points (plot points whose prerequisites are satisfied), with increased probability of doing something the drama manager has hinted at.

We compare three approaches to optimizing the selection of DM actions: the limited-depth sampling search (SAS+) proposed by Weyhrauch; standard temporal-difference (TD) learning; and TD learning with our modified training regimen (SASCE). We evaluate our results on two different stories: one a variant of the *Tea for Three* story used by Weyhrauch, and the other the *Anchorhead* story used by Nelson & Mateas; we also perform more detailed analysis on a subset of *Anchorhead*. We use the same plot points, DM actions, and evaluation functions specified and described by Weyhrauch and by Nelson & Mateas.

3.1 SAS+

Weyhrauch's search-based drama manager [12] chooses actions by performing expectimax search, a modification of standard minimax game-tree search in which the "opponent" (in this case the player) is assumed to be acting probabilistically according to the player model rather than adversarially. Since full-depth search in even fairly small stories is intractable, he proposes a sampling search, SAS+. Full-width search is performed to a fixed cutoff depth; from each node at the cutoff, a fixed number of possible plot-point sequences that could follow that node are sampled and scored; and the average of their scores is the evaluation of that node. To avoid dead ends, temporarily-denied plot points are reenabled prior to sampling, but the drama manager otherwise takes no action during sampling.

3.2 TD learning

Temporal-difference learning [9] is a reinforcement-learning technique that, over many thousands of simulated games, estimates the values of story states (a story state is either a partly- or fully-completed story). For completed stories, the state value is simply what the evaluation function says it is; for partial stories, it is the expected value of the complete story (*i.e.* the average of all stories that are continuations of that partial story, weighted according to likelihood). The drama manager's policy is then to simply pick whichever DM action leads to the highest-valued successor state.

A full description of TD learning is beyond the scope of this paper, but the general idea is that as a simulation run progresses, the value of each state encountered is estimated based on the current estimate of its successor. Since at the end of each story we can use the evaluation function to get the real value for the last state, the real values propagate backwards, and all states' estimates should eventually converge to the true values. Since there are far too many possible story states to store the value estimates in a lookup table, we follow Tesauro [10] in training a neural network as a function approximator to estimate a function from states to their values.

In story-based games, the order of plot points is of course important, so the state cannot simply include what has happened, but also the order in which it happened. We encoded state as an $n \times n$ precedence matrix, M, where n is the number of plot points and $M_{i,j}$ indicates whether plot point i

[1]The interested reader is directed to [5] for a more complete review of the drama-management literature (as of 1997).

happened after plot point j.[2] For example, in a story where there are four possible plot points, and in which plot points 3, 4, and 2 have occurred so far (in that order), the precedence matrix would look like:

$$M = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}$$

3.3 SASCE

Self-adversarial / self-cooperative exploration (SASCE) is our modified training regimen for TD learning. Our experiments on TD learning both with and without SASCE were identical except for the player model used for training. Typically in machine learning we assume that training data is drawn from the same distribution as the test data. In this domain the TD learner would therefore be trained on a player similar to the one it is expected to encounter when deployed. In our case, this is the player exploring the world.

Instead, the SASCE player model uses the drama manager's current value function to select its actions. Because the SASCE player model uses the agent's state-value estimates, it can choose to act cooperatively or adversarially. A cooperative player model would select actions that put the player in the highest-rated subsequent state, while the adversarial player would move to lower-rated states. The basic idea behind SASCE is to convert the asymmetric non-adversarial drama management problem into a *pseudo-adversarial* or *pseudo-cooperative* problem. This feedback loop is intended to force meaningful exploration of the state space.

We implemented the player model to select states based on an exponential distribution:

$$p(s_i) = \frac{e^{\alpha\beta(s_i)V(s_i)}}{\sum_{s_j \in S} e^{\alpha\beta(s_j)V(s_j)}}.$$

Here s is a state; $V(s)$ is the agent's current state-value estimate; α is a parameter controlling the "desire" of the model to cooperate (large positive values are more strongly cooperative and large negative more adversarial); and $\beta(s)$ is function that responds to the "desires" of the drama manager. In our case, $\beta(s) = 1.0$ for all states except for those the manager has explicitly attempted to increase the likelihood of (*e.g.* by providing a hint). In those cases, $\beta(s)$ is some constant $c_a > 1$ associated with action a.

In practice, we train using a *mixed strategy*. The mixed-strategy player has three parameters. It has both cooperative and adversarial values for α and a probability (q) that the player will use the adversarial value of α. The goal of the mixed strategy is to keep from learning a worst-case policy: Since we don't expect the player to *actually* be acting adversarially, we don't want the policy to optimize only for that case.[3]

[2]This bears some resemblance to the more common bigram encoding, which specifies for each pair of events i, j whether that *sequence* appeared in the history. The precedence matrix trades off some information about exact sequences for a gain in information about global ordering.

[3]The reader may wish to improve upon our results by using our mixed strategy only as a bootstrapping mechanism. Although space limitations preclude a lengthy discussion, an attempt to simulate this by gradually annealing α and q towards an exploring player provided no extra benefit.

	Tea for Three		***Anchorhead* subset**	
Method	Mean	Median	Mean	Median
SAS+	**96.3%**	**96.7%**	42.5%	50.5%
TD	81.2%	81.8%	80.4%	70.5%
TD/SASCE	91.3%	93.3%	**82.8%**	**83.6%**

Table 1: Summary of results using SAS+ search and TD learning with and without SASCE. Numbers are in percentiles relative to the non-drama-managed distribution of story qualities (see text).

4. RESULTS

We first present results on *Tea for Three* and a subset[4] of *Anchorhead*, demonstrating that TD learning outperforms SAS+ on complex domains, and further that using SASCE improves TD learning's performance on both relatively simple and complex domains. We analyze this subset of *Anchorhead* extensively to understand why the policies behave as they do. We then present some results on a larger portion[5] of *Anchorhead* in which none of the policies perform well, but demonstrate that adding more DM actions improves performance markedly, illustrating some potential authorship pitfalls.

4.1 *Tea for Three* and an *Anchorhead* subset

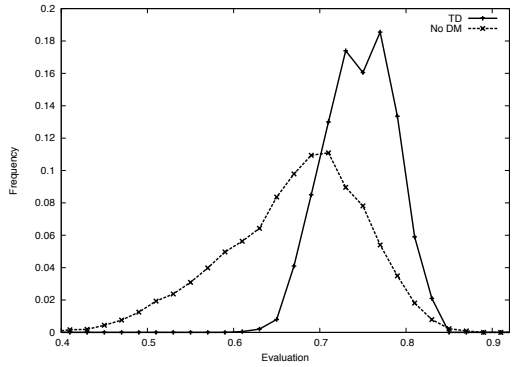

Table 1 summarizes the performance of SAS+ sampling search, TD learning trained conventionally, and TD learning trained using the SASCE training regimen, each evaluated on both *Tea for Three* and a subset of *Anchorhead*. Performance is summarized by calculating the mean and median story quality of each drama-managed distribution, and reporting that in terms of a percentile of the non-drama-managed distribution (*e.g.* a percentile of 70% for the mean would say that the average story quality using drama management is better than 70% of stories without using drama management).

There are three interesting things to note. First and foremost, training TD using SASCE consistently improved its performance by all measures on both stories. Secondly, while search does marginally better than SASCE on the simpler *Tea for Three* story, its performance degrades significantly on the *Anchorhead* subset—which has a more complicated relationship between story structure and evaluation—while the RL methods continue to perform well. Finally, SASCE greatly improves median performance on the *Anchorhead* subset in comparison to conventionally-trained TD learning.

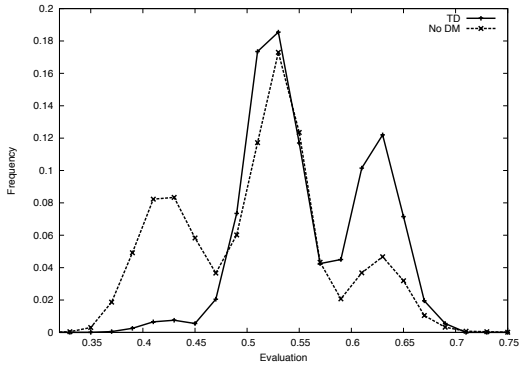

Figure 1 shows the detailed distributions on each story both without drama management and using TD learning without SASCE. Notice in the non-drama-managed distributions that the stories are qualitatively quite different: *Tea for Three* has a relatively smooth unimodal distribution, while the *Anchorhead* subset is distinctly trimodal. This suggests that there are points in the *Anchorhead* subset that have significant influence on the ultimate outcome. It is at these points that SASCE learns to make better decisions.

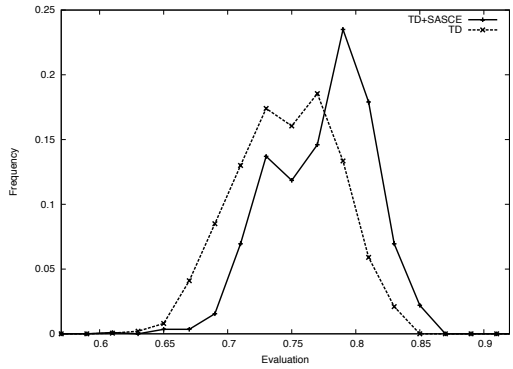
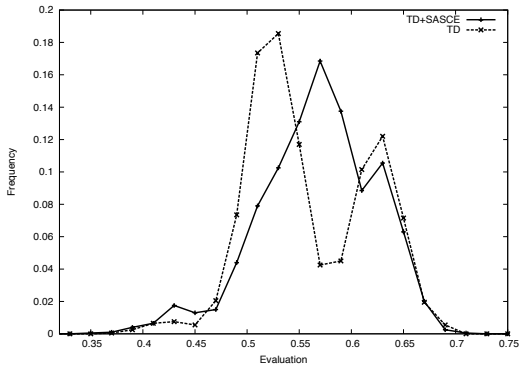
[4]The subset includes all the plot points from one major subplot, and all DM actions relevant to those plot points.

[5]The larger portion is the one used by Nelson & Mateas [7], itself a subset of the very large original interactive fiction piece.



(a) *Tea for Three*



(b) *Anchorhead* subset

Figure 1: Story-quality distributions for conventionally-trained TD learning versus no drama management.

(a) *Tea for Three*

(b) *Anchorhead* subset

Figure 2: Story-quality distributions for TD learning trained using SASCE versus trained conventionally.

This also suggests why search performs so poorly in the *Anchorhead*-subset domain: its relatively short horizon doesn't allow it to effectively make long-term global decisions. As a result it only performs well in "easy" domains where local decisions can result in globally good results, as noted in [7]. We were able to reproduce these results, but also show that reinforcement learning is able to make global decisions in both types of domains effectively.

While not shown in a figure, the story-quality distribution using search on *Anchorhead* remains trimodal like the distribution of randomly-generated stories, lending support to the hypothesis that search fails to find the important decision points that steer between the different types of stories. By contrast, the TD-learned policy's distribution is bimodal and almost entirely missing the stories that form the lowest of the three modes (see Figure 1(b)), indicating that it successfully learns how to avoid the worst batch of stories.

The policy trained with SASCE does even better, with a unimodal distribution that is shifted higher (see Figure 2(b)), indicating that it is not missing any major decision points. To give a more detailed idea of how SASCE improves TD learning, Figure 2 shows the full distributions of story qualities using each method on both stories we evaluated. Remember, qualitatively the goal is to shift the distribution to the right as far as possible, reducing the frequency of lower-scored stories and increasing that of higher-scored stories. Notice how in Figure 2(a), SASCE is consistently better: On the lower side of the distribution (below the mean) its frequencies are lower, while on the higher side they're higher. In Figure 2(b), the improvement takes on a different shape, keeping roughly the same proportion of highly-scored stories, but increasing the quality of the lower- and middle-scored stories significantly, pushing the main peak (and the median) towards the upper end of the range.

Recall that, using SASCE, a player model can be adversarial (negative α), cooperative (positive α), or mixed (choos-

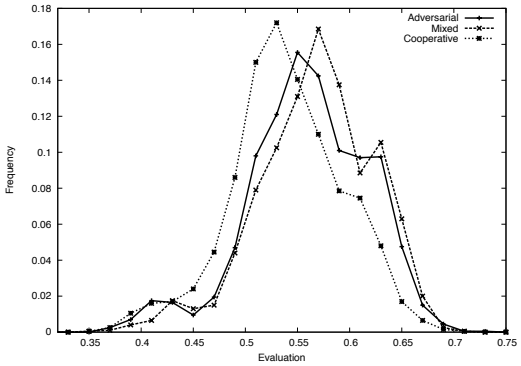


Figure 3: Story-quality distributions on the *Anchorhead* subset using different values of q for training. The three values shown are $q = 0.0$ (cooperative), $q = 0.5$ (mixed), and $q = 1.0$ (adversarial).

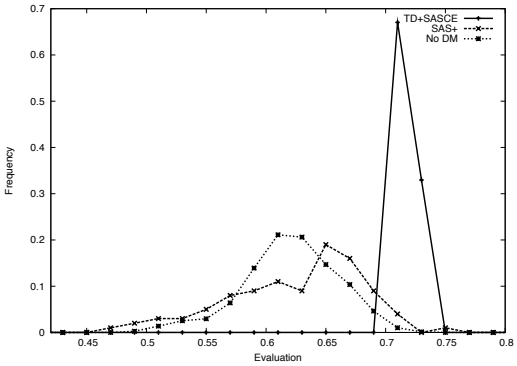

Figure 5: Story-quality distributions on *Anchorhead* with synthetic actions (see text) for SASCE-trained TD learning, SAS+ search, and no drama management.

ing an adversarial player with probability q, and a cooperative player with probability $1 - q$). Interestingly, all mixed models except the fully cooperative player ($q = 0.0$) improved TD learning, both quantitatively and qualitatively. In the examples shown here, as in most of our experiments, training on the mixed player gave the best performance, as shown in Figure 3, although the mean and median are not significantly different. Training on the fully cooperative player consistently gave the worst performance. All types of SASCE players display a roughly unimodal histogram, in stark contrast to the bimodal histogram seen in conventionally-trained TD learning, and the trimodal distribution of the unmanaged stories (Figure 1(b)). This lends some further support to our hypothesis that the modes are due to distinct decision points.

Intuitively, training against an (even occasionally) adversarial player forces the drama manager to learn how to maximize the worst-case performance. That is, the manager learns how to take actions that will prevent the player from arriving in a state where it can then easily do harm to the story. This proves useful for a wide variety of actual player types, including players who are exploring. A cooperative player acts as an antidote for those cases where such states can also lead to remarkably good outcomes.

It is worthwhile to try to understand in more detail how the policies learned by the various methods differ. To that end, we use them simultaneously to guide our simulated player until they reach a point at which they disagree on which action to take. Table 2 shows the average number of plot points occurring prior to disagreement for each pair of policies. Search is making different decisions very early. TD without SASCE diverges from SASCE-trained TD around the fifth plot point. Interestingly, the policies trained with adversarial and mixed players diverge not much later, but have much more similar distributions, suggesting that the important decisions have already been made by the fifth or sixth plot point (on average).

Finally, while space prevents a full discussion, it is worth noting that when there was a disagreement between policies on which action to take, we kept track of the plot point that preceded the disagreement and the pair of conflicting actions. We found that there were a small number of plot points after which most of these disagreements occurred, and the disagreements themselves were mostly between a few pairs of conflicting actions. That suggests that there are likely several key decision points directing stories into one of the three major classes in the trimodal story-quality histogram, and these decision points are where the policies differed most noticeably.

4.2 *Anchorhead*

On the larger portion of the *Anchorhead* story, which in-

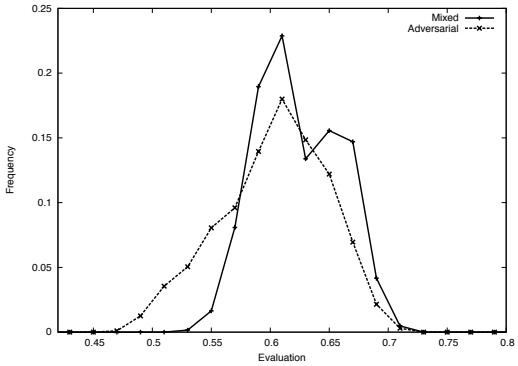

Figure 7: Story-quality distributions on *Anchorhead* for TD learning with mixed-strategy SASCE training ($q = 0.6$ in this case) and completely adversarial SASCE training ($q = 1.0$).

cludes two subplots that may interleave leading to two possible endings, none of the policies do particularly well, as illustrated in Figure 4.

In order to determine whether the policies were performing poorly because of their inability to find a good policy, or because the available DM actions in this state space simply did not permit for a very good policy, we ran a "synthetic" test in which there was a causing, hinting, temp-denying, and reenabling DM action for every plot point ("synthetic" because many of these DM actions could not plausibly be implemented in the real story). This ought to give the drama manager complete control, and indeed as shown in Figure 5, the TD-learned policy is now consistently very good; SAS+ search, however, still does rather poorly, as it is unable to navigate the now even larger state space to make effective use of the added actions. While this does not *prove* that the poor performance without these added actions is due to a lack of sufficient actions, rather than inability to learn a good policy, it does lend some support to that hypothesis, and suggest that the drama manager should be given more actions to work with.

The shape of Figure 5 illustrates a further issue: Although the goal as specified is to maximize story quality, it is not clear that this type of narrow distribution is the sort we actually want, especially since when we examined the plots produced, we found them to be nearly all identical: the drama manager found a very small range of good stories, and used DM actions to cause those stories to always happen. However, we would prefer there be a range of possible stories that could emerge during gameplay, especially if replay value is important. In non-synthetic examples this may turn out to not be an issue most of the time, but it does suggest that perhaps we should extend the evaluation function so that it takes into account the diversity of possible stories as an explicit goal, rather than rating each story in isolation.

Interestingly, SASCE still noticeably improved the performance of TD learning in this case, as illustrated in Figure 6. Furthermore, mixed-strategy training in particular is what improved performance: the completely adversarial version of SASCE did poorly, as shown in Figure 7. These consistent results across all the stories we tested lend some support to our hypotheses that SASCE forces the right type of exploration for this domain, and that a mixed-strategy version of SASCE in particular balances forcing exploration with an adversarial player without learning a policy optimized only for the adversarial case.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we presented a declarative optimization-based drama manager. This style of drama management centrally coordinates the behavior of agents in a game by making requests of them (*DM actions*) in a manner that maximizes story quality according to some author-specified evaluation function. We demonstrated the use of reinforcement learning to learn, ahead of time, policies for taking these actions, rather than performing online search in the time-constrained environment of a real game. We showed that reinforcement learning performs on par with search in simple domains, and far outperforms search in more complex domains. Furthermore, we presented a training method, SASCE, that trains on player models that use the drama manager's current value estimates in such a way as to force exploration useful for this domain; we demonstrated that it improves learning performance in all cases we examined.

One avenue of future work involves a more complete understanding of why training on the sort of player model presented here yields improved performance over training on the same player used for evaluation (a "known correct" player model).

There are other player types in addition to the ones we have explored here. For example, there are players who really want to move through the story quickly, and players who are simply trying to delay ending the game (while an explorer, this type of player is not quite captured by our model). Initial experiments on other players suggest results similar to those presented here, but further investigation is warranted.

Ultimately, we would like to test our learned policies on dozens of actual human players interacting in the concrete world of our chosen stories, and see what distribution this induces in the abstract world of plot point sequences. Unsurprisingly, because players are experiencing concrete events in the story world, what seems like a logical model of player

behavior in the abstract world has the potential to be inaccurate. For example, it is reasonable to expect a player to unlock a door shortly after finding a key; however, if the door is in a dark corner of the room, the player may not see it. In the future we plan to build an agent that represents the player in the concrete world rather than in our abstract plot point world so that we can model these types of influences.

In any case, developing and using a wider range of player models for evaluation would allow us to better understand the relationship between the player model used for training and that used for evaluation. In particular, we are interested in how robust policies are when used with different sorts of players. For example, if we determine that policies trained under varying player models perform better or worse against different player models used for evaluation, we hope to develop techniques to identify in real-time the best policy to use to optimize a given player's experience.

Finally, we are interested in further evaluating the authorial affordances offered by this style of drama management, both in easing the design of large games and in offering possibilities for new types of games difficult or impossible to design without a system of this sort.

ABSTRACT

In many Multi-Agent Systems (MAS), self-interested agents need to cooperate in order to maximize their own utilities in time. The goal of this work is to improve cooperation among agents that use best-response Reinforcement Learning (RL) algorithms (Q-Learning), by the introduction of two new principles (*Change or Learn Fast* and *Change and Keep*) that foster the reaching of Pareto efficient stable outcomes.

Categories and Subject Descriptors

I.2.11 [**Distributed Artificial Intelligence**]: Multiagent systems

1. INTRODUCTION

In this paper we focus on problems of cooperation among *self-interested agents*, where no explicit communication is possible and agents can only perceive the actions taken by the other agents at the previous time step.

Several algorithms [5, 2, 3] have been proposed to make agents able to learn Pareto efficient (PE) solutions.

In Section 2, we introduce two new principles to foster cooperation. Section 3 presents comparative results in a multi-agent social dilemma and Section 4 contains conclusions and future research directions.

2. MAKING Q-LEARNING COOPERATIVE

A matrix game is a tuple $\langle \mathcal{N}, \{\mathcal{A}_i\}_{i\in\mathcal{N}}, \{R_i\}_{i\in\mathcal{N}} \rangle$, where $\mathcal{N}$ is a collection of n agents, $\mathcal{A}_i$ is the set of actions available to agent i, and R_i is its payoff matrix. At each iteration t, let $\mathbf{a}^t = [a_1^t, a_2^t, ..., a_n^t]$ be the executed joint action, a_i^t the action taken by the i-th agent and $\mathbf{a}_{-i}^t$ the joint action of all the players but i, r_i^t is the reward received by i-th agent.

In this paper, we adopt a version of Q-learning where states are represented by the previous joint action ($\mathbf{a}^{t-1}$).

The desired outcome of our algorithms is to let a MAS of Q-learners collectively learn equilibrium points that payoff dominate the best response dynamics of normal Q-learners.

The main problem of pairing best-response agents in a repeated game is that they may end up in cyclic or suboptimal behaviors. In fact, many parallel learning processes may cause the environment to be non-stationary, thus preventing agents from predicting the correct outcome of their actions. In the following we introduce two variants of the Q-learning algorithm, aimed at improving cooperation of self-interested non-communicating Q-learning agents by taking into account the non-stationarity induced by the learning processes.

2.1 CoLF Principle

Algorithm 1 COLF – Change Or Learn Fast

Let $\alpha_S > \alpha_{NS}$, and λ be learning rates
$P(\mathbf{a}, a_i) \leftarrow S(\mathbf{a}, a_i) \leftarrow 0, Q(\mathbf{a}, a_i) \leftarrow \frac{r_{max}}{1-\gamma} \forall \mathbf{a} \in \mathcal{A}, a_i \in \mathcal{A}_i$
choose a random action a_i^0
execute a_i^0
read the joint action $\mathbf{a}^0$
$t \leftarrow 1$
for all steps **do**
  choose action a_i^t according to exploration strategy
  execute a_i^t and get the payoff r_i^t
  read the joint action $\mathbf{a}^t$
  $\Delta r_i^t \leftarrow |r_i^t - P(\mathbf{a}^{t-1}, a_i^t)|$
  if $\Delta r_i^t > S(\mathbf{a}^{t-1}, a_i^t)$ **then**
    $\alpha \leftarrow \alpha_{NS}$
  else
    $\alpha \leftarrow \alpha_S$
  end if
  $Q(\mathbf{a}^{t-1}, a_i^t) \leftarrow (1-\alpha) Q(\mathbf{a}^{t-1}, a_i^t) + \alpha \cdot \left(r_i^t + \gamma \cdot \max_{a_i} Q(\mathbf{a}^t, a_i)\right)$
  $S(\mathbf{a}^{t-1}, a_i^t) \leftarrow (1-\lambda) S(\mathbf{a}^{t-1}, a_i^t) + \lambda \cdot \Delta r_i^t$
  $P(\mathbf{a}^{t-1}, a_i^t) \leftarrow (1-\lambda) P(\mathbf{a}^{t-1}, a_i^t) + \lambda \cdot r_i^t$
  $t \leftarrow t+1$
end for

The CoLF (Change or Learn Fast) principle is inspired by the work of Bowling and Veloso [1], where a variable learning rate is considered. To foster cooperation, we propose to modify the learning rate of a Q-learning algorithm according to the following rule: if the payoff achieved by an agent is unexpectedly changing, then learn slowly, otherwise learn quickly. This principle aids in cooperation by giving less importance to "unexpected" payoffs, while allowing to speed up learning when the most of the agents are playing near-stationary strategies.

Algorithm 1 summarizes how the Q-learning algorithm changes with the introduction of the CoLF principle. The P-values are exponential averages of the collected payoffs with weight factor λ, while the S-values are exponential averages of the absolute differences between the current payoff and the respective P-value.

2.2 Change&Keep Principle

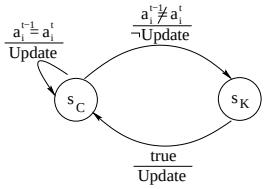

Figure 1: CK finite-state machine. For each state transition are reported both the trigger condition (above the line) and whether the update phase occurs or not (below the line). In state s_C the agent performs the usual action selection, while in state s_K it repeats the previous action.

The Change&Keep (CK) principle is based on the following observation: when an agent, due to either learning or exploration, decides to choose a different action, it typically collects an uninformative payoff. In fact, these (non-stationary) changes cannot be foreseen by other agents, and the related payoffs may be misleading, thus negatively affecting cooperation.

The idea of the CK principle is to discard the payoff received in correspondence to a change in the action selection (thus suspending the Q-value update), repeat the same action, and use the corresponding payoff for performing the suspended update. In this way the agent gives time for the other agents to react to its new action, thus using a more informative payoff for the update of its Q-table. Fig. 1 illustrates the two-states finite-state machine that describes the CK principle.

3. EXPERIMENTAL RESULTS

In this section, we compare the performance (in self-play) of Q-learning with those obtained by our variants (CK, CoLF, and CK-CoLF, which is obtained by combining both CK and CoLF principles together) in the MASD game [5]. In MASD, N agents hold M resource units each. At each iteration, let $a_i \in [0, M]$ be the amount of units contributed by agent i towards a group goal G. The utility of agent i given the joint action $\mathbf{a}$ is $P_i(\mathbf{a}) = \frac{\left[\frac{1}{N}\sum_{j=1}^{N} a_j\right] - k a_i}{M(1-k)}$, where $k \in \left(\frac{1}{N}; 1\right)$ is a constant that indicates how much each agent estimates its contribution towards the selfish goal. The payoff function is such that when all the agents put M units in the group goal, each agent is rewarded with 1 and when nobody puts units in the group goal, a payoff of 0 is produced. If each agent adopts a random strategy the expected average payoff is 0.5. All the algorithms used an ϵ-greedy exploration (where $\epsilon = \max(0.2 - 0.00006t, 0)$) joined with a relaxation search (as proposed in [5]) obtained by setting the initial values of the Q-table to high values.

In the learning rate performance comparison we used the following parametrization: $\gamma = 0.95$, and, for the CoLF principle, $\lambda = 0.1$. In Fig. 2 we report the results with different learning rates. The use of low learning rates in Q-learning (see Fig. 2(a)) allows to get higher payoffs but, as a drawback, the time required to reach a cooperative solution considerably increases. The results of CK (Fig. 2(b)) with the same learning rates show that it converges almost in the same time as Q-learning but the learning curve is steeper and outperforms Q-learning for every α. In CoLF, we adopted $\alpha_{NS} = 0.1$ and $\alpha_S = 4 \cdot \alpha_{NS}$. As can be noticed in Fig. 2(c), the CoLF principle makes agents able to achieve higher payoffs than those obtained by Q-learning with constant learning rate. The algorithm succeeded in exploiting both the low learning rate in terms of convergence payoff performance and the high learning rate in terms of learning speed. Finally, Fig. 2(d) show how the introduction of the CoLF principle into the CK algorithm, improves the learning speed, while still reaching the PE solution.

We have experimentally verified (see Fig. 3) that high discount factors allow to achieve better performances, but with a lower learning speed. In fact, using 0.8 as discount factor, Q-learning and CoLF are not able to achieve a cooperative solution, which is obtained by adding the CK principle. On the other hand, all the algorithms achieve a cooperative solution, but they require much longer time to converge. We have also tested the performances of the four algorithms in different versions of the MASD problem obtained by varying the k factor. For higher values of k the agents become more selfish and the reaching of the cooperative solution is more difficult. The sensitivity analysis in Fig. 4 shows the performances of the four algorithms with different values of k. None of the four algorithms is able to cooperate with $k = 0.9$ since the selfish behavior is highly fostered. The problem becomes easier and easier as k decreases.

4. DISCUSSION

As shown by the previous experiments, the CoLF principle is mainly concerned with non-stationarity caused by the other agents. It learns slow when gathering unexpected payoffs and fast otherwise. On the other hand, the CK principle deals with non-stationarity induced in the MAS by the behavior of the agent itself. Since actions selected following a non-stationary learning policy may not be foreseen by other agents, whenever an agent changes its action, according to the CK principle, it does not perform the update and repeats the same action and updates the related value with the last received payoff. The experiments carried out in the MASD framework show that the proposed principles applied to a best-response learning algorithm (Q-learning) largely improve its cooperation capabilities in self-play, both in terms of performance and learning speed.

ABSTRACT

We consider the problem of dialogue adaptation in our Smart Personal Assistant (SPA), which uses a plan-based dialogue model. We present a novel way of integrating learning into a BDI architecture so the agent can learn to select the most suitable plan amongst those applicable, enabling the SPA to tailor its responses according to the conversational context and the user's physical context, device and preferences.

1. INTRODUCTION

The Smart Personal Assistant (SPA) [9] is an application for desktops and PDAs that allows users to conduct spoken dialogues with the system to remotely access and manipulate their e-mail and calendar. The SPA consists of a dialogue manager agent and a collection of task assistants, each specializing in a particular task domain. The dialogue manager [5] is implemented using a BDI agent architecture, which has a set of plans for processing user requests. This BDI approach allows a high level of abstraction in designing the dialogue model, which consists of complex but modular plans, each associated with a communicative goal or dialogue aspect. There are also plans for handling domain-specific tasks. The control flow of the dialogue is not specified directly, but derived automatically using the plan selection mechanism as part of the BDI interpretation cycle. This approach preserves modularity within the dialogue model at the level of plans, allowing domain-independent discourse-level plans to be reused for other domains. The belief state of the dialogue manager contains the past and current states of the dialogue as a stack of conversational acts performed by the user, the dialogue manager and other task assistants. These conversational acts constitute a hierarchy of dialogue segments, each having a segment purpose which represents a task-specific intention of the user.

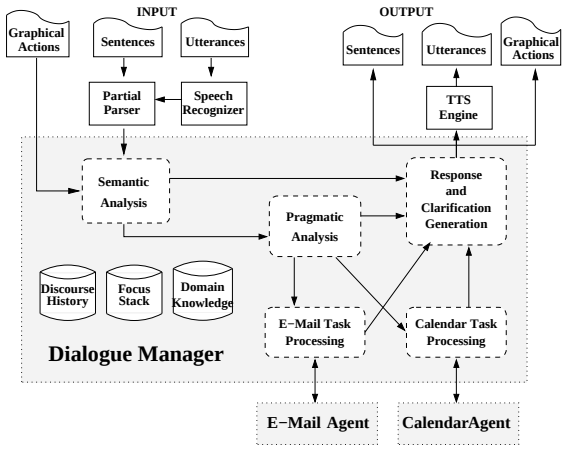

Figure 1: Dialogue manager's plans and beliefs

The dialogue manager has about forty plans, which can be roughly grouped into five classes according to their function, as in Figure 1. The first group, *semantic analysis*, is for classifying the user's requests into a task domain and formulating its semantic representation using the agent's linguistic knowledge. The second group, *pragmatic analysis*, is for determining the user's underlying conversational act and associated task-specific intention, which may involve resolving references. The *e-mail* and *calendar task processing* groups contain domain-specific plans for performing domain tasks, which requires interaction with the other task assistants. The last group is for generating responses to the user, including system requests for clarification.

In this paper, we consider the problem of dialogue adaptation in the SPA. The motivation is that the usability of the SPA on a mobile device with small screen and limited band-

width can be enhanced by adaptively tailoring responses according to the conversational context and the user's physical context, device and preferences. For example, e-mail messages are often too long to fit on one PDA screen, thus showing only a message summary could sometimes be more desirable. Similarly, in different conversational contexts, the same information might be presented to the user in different ways, e.g. using a different modality, format or layout. Because the SPA's dialogue manager uses plans for generating responses, the problem of dialogue adaptation becomes the problem of learning which dialogue plan should be selected and executed in a given context.

There has been comparatively little work in the area of dialogue adaptation; existing work tends to be concerned with either adapting the system's questions for eliciting user preferences [7] or learning strategies in a game-theoretic approach to dialogue modelling such as the Email Voice Interactive System (ELVIS) by Walker *et al.* [8] and the work by Jokinen *et al.* in the Interact project [3]. In the game-theoretic approach, training dialogues are used to build an adaptivity model using reinforcement learning. However, the dialogue models are less complex than that of the SPA.

There have been very few attempts to incorporate learning within BDI models of agency [1, 6], of which none has looked at the problem of how the agent learns to select the most appropriate plan amongst those applicable in a given context. Typically, this work provides a loose coupling of the agent architecture and the learner, while for the problem of learning plan selection, a closer integration is required.

2. AN ADAPTIVE DIALOGUE AGENT

To build an adaptive plan-based dialogue manager, there are two problems to be solved: (i) defining the possible system actions in any given situation, and (ii) defining the mechanism for the system to decide when to choose which action. Using the plan-based approach to dialogue management, system modularity is facilitated through the use of plans, each handling some dialogue aspect or domain task. Hence the possible choices of system action can be modelled as different plans applicable in the same situation, and the learner is used for the selection mechanism to choose the most suitable plan according to the agent's beliefs, which represent the user's context and/or preferences. Thus the learner accepts as input a set of possible plans and some of the agent's beliefs and outputs the most suitable plan(s).

The dialogue manager of the SPA is implemented using a Java-based PRS-style agent platform, JACK Intelligent Agents^{TM} [2]. JACK provides meta-level reasoning, posting a special `PlanChoice` event, as a way to overwrite the agent's plan selection mechanism, making the integration with learning easier. We have chosen to integrate the Alkemy symbolic decision tree learner [4] into the dialogue manager to develop an adaptive dialogue agent. In Alkemy, the learning individuals are represented in a typed, higher-order logic, which supports representation of domain data with complex structure. Moreover, Alkemy provides a highly-expressive predicate rewrite system to constrain the hypothesis space for the learner.

Figure 2 shows the learning problem for the meta plan to decide which plan to use to display a set of e-mail messages to the user. Decision tree learners are not able to learn a set of values, and in our learning problem it is necessary to predict more than one possible plan, so given the current

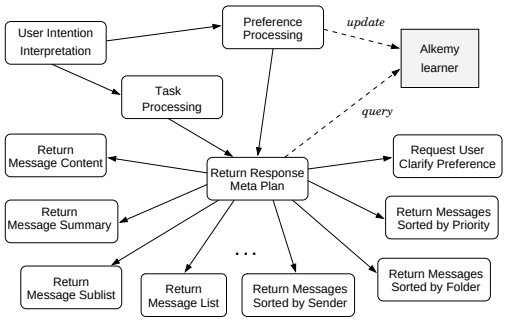

Figure 2: Example learning plan selection

context, for each available `Return Response` plan, a learning individual is generated that includes information about the current context and the plan name. This is classified as either `True` or `False`. If the result is `True`, the plan is considered an option; otherwise, the plan does not meet the user's preferences is not an option. If there is more than one plan classified `True`, they are all options, and in this case the `Request User Clarify Preference` plan is executed, asking the user to specify the preferred system action (i.e. the most preferred plan) and then updating the learner accordingly. The Alkemy specification for this learning problem includes the following data constructors:

$PDA,\ Desktop : Device\ ;$
$Speech,\ Text,\ None : Mode\ ;$
$Search,\ Read,\ Show,\ ...,\ Notify : Task\ ;$
$Low,\ High,\ Normal : Priority\ ;$
$Length = Int\ ;$
$Folder = String\ ;$
$ReturnMsgList,\ ...,\ ReturnMsgSortedBySender : Plan\ ;$
$True,\ False : Class\ ;$

The `Mode` element indicates the current modality of the dialogue, where `Text` corresponds to typed text and `None` means the user is currently using only the GUI. The dialogue result included in the learning individual includes a set of e-mail messages. Each message is represented by four components: the sender, the length, the folder and the priority. Thus each learning individual (training example) is of the `Product` type defined as follows:

$$Ind = Device \times Task \times Mode \times (Set\ Email) \times Plan;$$

Each learning example is pre-computed and sent as input to the learner. The individuals include information about the current context, e.g. the modality of interaction, the device, etc., the result set of e-mail messages and the name of the plan to be considered. The learning problem is to predict whether a plan is an option in the current context according to the user's preferences. Thus the function that needs to be learned is $ResponsePlan : Ind \rightarrow Class$.

Alkemy uses a predicate rewrite system for constructing the hypothesis space. Predicates are composed from basic functions called transformations. For example, a transformation on `Email` to extract its length is a projection of its second component as follows:

$$projLength : Email \rightarrow Int;$$
$$projLength : project(1);$$

The following predicate is true iff the e-mail set contains exactly one message whose length is less than thirty lines:

$$and\ (projEmails \circ numOfEmails(true) \circ eq1)$$
$$(projEmails \circ setEmailExists(projLength \circ lt30))$$

A part of the predicate rewrite system for our learning

problem is shown in Figure 3. The predicates are constructed by applying the predicate rewrites to expand the predicate tree starting from the root. For example, replacing *top* in (1) by (7) results in a predicate which is true iff the user's device is a PDA. Predicate rewrite (3) is useful when there is no e-mail message in the result. Expanding (4) or (5) results in predicates for checking the length or the priority of the only e-mail message in the result. The rule (6) is used for constraining the total number of messages. Note that defining this predicate rewrite system requires the expression of domain-specific knowledge. Furthermore, constraining the learner's hypothesis space is necessary because of the limited availability of training data.

(1) $top \rightarrowtail projDevice.top$;
(2) $top \rightarrowtail projPlan.top$;
(3) $top \rightarrowtail and\ (projEmails.numOfEmails(true).eq0)(top)$
(4) $top \rightarrowtail and\ (projEmails.numOfEmails(true).eq1)$
$(projEmails.setEmailExists1(projLength.top))$;
(5) $top \rightarrowtail and\ (projEmails.numOfEmails(true).eq1)$
$(projEmails.setEmailExists1$
$(projPriority.top))$;

Figure 3: The predicate rewrite system

We first show an example dialogue without adaptation:

```
User   Is there any new mail from Wayne?
SPA    You have one new message from Wayne Wobcke.
SPA    Displays the message from Wayne Wobcke.
User   Find all messages about meeting in the Inbox.
SPA    There are twenty messages about meeting in your Inbox.
       Displays the headers of the twenty messages.
User   Show me the one from John.
SPA    Here you are.
       Shows the content of the message from John Lloyd.
```

Now assume that the user is using a PDA for interacting with the SPA, with dialogue adaption enabled; the example dialogue above would become:

```
User   Is there any new mail from Wayne?
SPA    You have one new message from Wayne Wobcke.
       The message is more than thirty lines, should I
       show you just the summary?
User   Yes please.
SPA    Displays the summary of message from Wayne Wobcke.
       SPA learns to display only the summary
       if the message length is more than 30 lines.
User   Find all messages about meetings in the Inbox.
SPA    SPA has learned in the past to show only the first few
       messages if there are too many messages in the result.
       The message headers should also be sorted by sender.
       I am showing the first ten of twenty messages
       sorted by sender.
       Displays the first 10 message headers sorted by sender.
User   Show me the one from John.
SPA    Here is the summary of the message from John Lloyd.
       SPA shows user the summary of the message according
       the user's preferences that have been learned so far.
```

Note from the dialogue above how the dialogue manager has learned to adapt its responses according to the user's preferences. When the user requests the summary of the message from Wayne, the system has learned to show only the summary if the message body is more than thirty lines. Hence later on in the dialogue, the system immediately shows the summary of the e-mail message from John Lloyd because its length is also more than thirty lines. A typical example of a decision list representing the user's preferences that results in such adaptive behaviour is as follows:

```
if numOfEmail is 0 then
  if plan is ReturnResponse then True
else if numOfEmail is 1 and length is greater than 30 then
      if plan is ReturnSummaryContent then True
      else if numOfEmail is 1 and priority is HIGH then False
    else
      if numOfEmail is less than 15 then
        if plan is ReturnMessageSortedBySender then True
        else if plan is ReturnSubList then True
```

3. CONCLUSION

We have proposed a way of incorporating learning into a BDI agent architecture that allows the agent to learn the appropriate plan to select in a given context. The technique can be applied to plan-based dialogue systems to achieve dialogue adaptation, which is particularly useful in dialogue-based applications for mobile devices, where the interaction should be tailored to suit the current conversational context, the physical environment and the user's device and preferences.

ABSTRACT

We have developed a new series of multi-agent reinforcement learning algorithms that choose a policy based on beliefs about co-players' policies. The algorithms are applicable to situations where a state is fully observable by the agents, but there is no limit on the number of players. Some of the algorithms employ embedded beliefs to handle the cases that co-players are also choosing a policy based on their beliefs of others' policies. Simulation experiments on Iterated Prisoners' Dilemma games show that the algorithms using on policy-based belief converge to highly mutually-cooperative behavior, unlike the existing algorithms based on action-based belief.

1. INTRODUCTION

Each member's effort to maximize its own benefit constitutes social behaviors, such as competition and cooperation. One promising way to implement such behaviors on computers is to extend a reinforcement learning algorithm into multi-agent environments, in order to provide independent trial-and-error learning for each agent. If the agents are smart enough, such social behaviors would emerge spontaneously.

Nevertheless, past studies on N-agent reinforcement learning have limited to specific structure of games [1, 2, 3]. Such limitations are required due to the way to extend reinforcement learning framework. These studies rely on the following update rule, which is the same as the classical TD-learning except action is replaced by a vector of actions:

$$Q_i(s(t),\vec{a}(t)) \leftarrow (1-\alpha)Q_i(s(t),\vec{a}(t)) + \alpha\big[r_i(t)+\gamma V_i(s(t+1))\big], \quad (1)$$

where $s(t)$ is the state at time t, $\vec{a}(t) = (a_1(t),\ldots,a_N(t))$ is the vector of actions for all players taken at time t, $Q_i(s,\vec{a})$ and $V_i(s)$ are the expected action-state value and state value for agent i ($1 \le i \le N$), $r_i(t)$ is the reward given to agent i as a result of actions $\vec{a}(t)$, α is the learning rate, and γ is the discount factor.

A Major problem of this formulation is that it cannot deal with learning co-player agents. Equation 1 assumes that the expected value $V_i(s)$ for agent i only depends on the current state s [6]. This is equivalent to assume stateless co-players, i.e., the states of other agents are independent of the expected value. Learning agents change its behavior based on the learned information; it is hard to find the best policy against such learning co-players under the assumption of statelessness.

Recently, Weinberg and Rosenschein have tried to break this situation by proposing the NSCP-learner [7] that finds the best-response policy to other players' policies. In their algorithm, agent i maintains a model $\langle\pi_j\rangle_i$ of another agent j ($1 \le j \le N, j \ne i$)[1], and calculates V_i by using the models:

$$V_i^{\pi_i,\langle\vec{\pi}_i\rangle_i}(s) = \max_{\pi_i} \sum_{a_1,\ldots,a_N} \pi_i(s,a_i) \cdot \prod_{1\le j\le N, j\ne i} \langle\pi_j\rangle_i(s,a_j) \cdot Q_i(s,\vec{a}), \quad (2)$$

where the policy $\pi_i(s,a_i)$ is the probability of agent i's taking action a_i on condition of state s and $\langle\vec{\pi}_i\rangle_i$ is the vector of beliefs about policies of the co-player agents for agent i, i.e., $\langle\vec{\pi}_i\rangle_i = (\langle\pi_1\rangle_i,\ldots,\langle\pi_{i-1}\rangle_i,\langle\pi_{i+1}\rangle_i,\ldots,\langle\pi_N\rangle_i)$. In short, the agent uses models to anticipate the actions of the co-players and calculates the state value using the belief on their expected actions.

However, we'd like to point out that Weinberg's extension is not sufficient. Suppose two possible beliefs $\langle\pi_j\rangle_i, \langle\pi'_j\rangle_i$ about policies of agent j, which choose the same action a_j for the immediate response to state s but different actions afterwards. Then the state values for these policies, $V_i^{(\ldots,\langle\pi_j\rangle_i,\ldots)}(s)$ and $V_i^{(\ldots,\langle\pi'_j\rangle_i,\ldots)}(s)$ should be able to be different, whereas eq. 2 cannot.

In this paper, we propose a new way to extend the action-value function Q with the vector of *policies* to solve this problem. Although an agent cannot know the current policies of the co-player agents, one can develop a *belief* of policies of the co-player agents and use it for the extended action-value function. This extension also lets us to introduce an embedded policy belief, i.e., a belief

[1]Weinberg *et al.* used the notation $\hat{\pi}^j$, but in this paper, we use the angle-bracket notation to clarify whose model is on whose policy.

about the co-player's policy belief, for better estimation of the co-player's policy. The simulation results on Iterated Prisoners' Dilemma (IPD) games show that our algorithm show better results than agents based on existing algorithms. We expect that such an algorithm would lead us to study mathematical structure of communication, such as mutual-estimation structure [4].

2. ALGORITHMS

As a starting point, we suppose a simple agent called Level-0, which uses a single-agent Q-learning algorithm (Fig. 1). This agent treats the other agents as a part of an environment and pays no attention to them. As a result, such an agent can only derive a very primitive learning in a multi-agent environment.

In the following, we discuss agents that use information of other agent's policies. Since agent i cannot directly see policy π_j of another agent j, agent i needs to obtain an estimate $\langle\pi_j\rangle_i$ of j's policy. If agent j has a stationary policy, some kind of statistical method can accurately estimate the policy of agent j by collecting a sufficiently large sample of the co-player's actions. Such a statistical method can be also applied to an co-player agent whose policy changes but converges to a limit [7].

2.1 Level-1: Using Policy-based Beliefs

We can extend the algorithm of a Level-0 agent to choose actions with regard to the policy beliefs $\langle\pi_i\rangle_i$ of other agents. One simple way to do so is to regard the tuple of policy belief and the original state $(\langle\vec{\pi_i}\rangle_i, s)$ as an extended state. Accordingly, agent i has an extended policy $\pi_i^+(\langle\vec{\pi_i}\rangle_i, s; a)$ and extended action-value function $Q_i^{\pi_i^+}(\langle\vec{\pi_i}\rangle_i, s; a)$. Assuming that the belief is accurate and that the change to the policies of the other agents has the Markov property, the agent can learn to choose an optimal policy. Thus we can design a Level-1 agent, which obtains $\langle\pi_i\rangle_i$ by using some statistical estimation and use $Q_i^{\pi_i^+}$ to choose an action.

We can have another viewpoint on this algorithm, in which a Level-1 agent i chooses a policy, instead of just an action, by using its belief about the other agents' policies. To choose a policy, the agent uses a *metapolicy* Π_i, which maps the policy belief of the other agents $\langle\vec{\pi_i}\rangle_i$ to a policy π_i. Interestingly, a metapolicy Π_i is just a notational variant of an extended policy π_i^+, since we can obtain a policy from π_i^+ by fixing $\langle\vec{\pi_i}\rangle_i$. Figure 2 shows the algorithm of a Level-1 agent in the new notation.

Initialize $Q_i(\langle\vec{\pi_i}\rangle_i, s, a)$, $\langle\vec{\Pi_i}\rangle_i$, and $\langle\langle\vec{\pi}\rangle\rangle_i$
Repeat (for each episode):
  Observe the initial state s
  Repeat (for each step of episode):
    Derive Π_i from Q_i
    $\langle\vec{\pi_i}\rangle_i \leftarrow \langle\vec{\Pi_i}\rangle_i\left(\langle\langle\vec{\pi}\rangle\rangle_i\right)$; $\pi_i \leftarrow \Pi_i\left(\langle\vec{\pi_i}\rangle_i\right)$
    Choose a_i from π_i and s
    Take action a_i, observe $\vec{a}, r, s'$
    $\langle\vec{\Pi_i}\rangle_i' \leftarrow$ New belief, obtained by updating $\langle\vec{\Pi_i}\rangle_i$ with $\langle\langle\vec{\pi}\rangle\rangle_i$, s and $\vec{a}$
    $\langle\langle\vec{\pi}\rangle\rangle_i' \leftarrow$ New embedded belief, obtained by updating $\langle\langle\vec{\pi}\rangle\rangle_i$ with s and $\vec{a}$
    $\langle\vec{\pi_i}\rangle_i' \leftarrow \langle\vec{\Pi_i}\rangle_i'\left(\langle\langle\vec{\pi}\rangle\rangle_i\right)$
    $Q_i(\langle\vec{\pi_i}\rangle_i, s, a) \leftarrow (1-\alpha)Q_i(\langle\vec{\pi_i}\rangle_i, s, a) + \alpha\left[r + \gamma \max_{a_i'} Q_i(\langle\vec{\pi_i}\rangle_i', s', a_i')\right]$
    $s \leftarrow s'$; $\langle\vec{\Pi_i}\rangle_i \leftarrow \langle\vec{\Pi_i}\rangle_i'$; $\langle\langle\vec{\pi}\rangle\rangle_i \leftarrow \langle\langle\vec{\pi}\rangle\rangle_i'$
  until s reaches the end of the episode

Figure 3: Algorithm of a Level-2 agent of index i.

Assuming that the policy beliefs are accurate and their change has the Markov property, agent i can learn a metapolicy, which is optimal in the sense of choosing the best policy in response to the policies of the other agents. However, in playing with other Level-1 agents, this assumption becomes unrealistic, since the policy selected by a metapolicy changes rapidly.

2.2 Level-2: Using Embedded Beliefs

A more elaborated agent, which we call Level-2, develops a belief about metapolicies of other agents. As mentioned before, a metapolicy is a map from policy beliefs to a policy; to estimate the policy of agent j using a metapolicy, agent i needs to have an embedded belief within agent j. We denote $\langle\langle\pi_k\rangle_j\rangle_i$ to represent agent i's belief about agent j's belief about agent k's policy. Agent i can obtain a belief of agent j's policy, given metapolicy belief $\langle\Pi_j\rangle_i$ and embedded policy belief $\langle\langle\vec{\pi_j}\rangle_j\rangle_i$ about agent j:

$$\langle\pi_j\rangle_i = \langle\Pi_j\rangle_i\left(\langle\langle\vec{\pi_j}\rangle_j\rangle_i\right) \quad . \tag{3}$$

We denote the agent i's embedded beliefs of all the other agents as

$$\left\langle\overrightarrow{\langle\vec{\pi}_{\cdot}\rangle_{\bar{i}}}\right\rangle_i = \left(\left\langle\langle\vec{\pi_1}\rangle_1\right\rangle_i, \ldots, \left\langle\langle\vec{\pi}_{\overline{i-1}}\rangle_{i-1}\right\rangle_i, \left\langle\langle\vec{\pi}_{\overline{i+1}}\rangle_{i+1}\right\rangle_i, \ldots, \left\langle\langle\vec{\pi}_{\overline{N}}\rangle_N\right\rangle_i\right). \tag{4}$$

In a perfect information game, every agent shares the same information, and every agent knows that the information is shared. Thus, agent i has no reason to distinguish the embedded belief $\langle\langle\pi_k\rangle_j\rangle_i$ for agent j from the one $\langle\langle\pi_k\rangle_{j'}\rangle_i$ for agent j', and as a result, we can denote them as $\langle\langle\pi_k\rangle\rangle_i$. This reduces the representation of embedded beliefs from $\left\langle\overrightarrow{\langle\vec{\pi}_{\cdot}\rangle_{\bar{i}}}\right\rangle_i$ to $\langle\langle\vec{\pi}\rangle\rangle_i$.

A Level-2 agent obtains an embedded belief $\langle\langle\pi_k\rangle\rangle_i$ by using the same statistical estimation method as the one for Level-1's belief policy; the only difference is that Level-2 needs $\langle\langle\pi_i\rangle\rangle_i$, the embedded estimation of the policy of agent i itself within another agent.

Using $\langle\langle\vec{\pi_j}\rangle_j\rangle_i$, Level-2 agent i is able to develop a belief about the metapolicy $\langle\Pi_j\rangle_i$ of agent j. Assuming the space of the embedded policy is finite, one can perform statistical estimations for every possible $\langle\langle\vec{\pi_j}\rangle_j\rangle_i$. By using the embedded policy belief $\langle\langle\vec{\pi}_{\cdot}\rangle_{\bar{i}}\rangle_i$ and the metapolicy belief $\langle\Pi_j\rangle_i$, a Level-2 agent can derive a policy belief $\langle\vec{\pi_i}\rangle_i$ and perform reinforcement learning on $Q_i(\langle\vec{\pi_i}\rangle_i, s; a_i)$. Note that this extended action-value function is the same as the one in the Level-1 agent.

Figure 3 shows the algorithm of the Level-2 agent. The algorithm is the same as that of the Level-1 agent (Fig. 2), except that $\langle\vec{\pi_i}\rangle_i$ is now calculated from $\langle\langle\vec{\pi}\rangle\rangle_i$ and $\langle\vec{\Pi_i}\rangle_i$.

2.3 Level-n: Using Deeper Embedded Beliefs

We can go along this line to create higher-lever agents successively. For instance, a Level-3 agent maintains $\langle\langle\langle\vec{\pi_l}\rangle_k\rangle_j\rangle_i$, $\langle\langle\Pi_k\rangle_j\rangle_i$,

Table 1: Pay-off matrix for agents X and Y

X \ Y	C	D
C	3 \ 3	5 \ 0
D	0 \ 5	1 \ 1

and $\langle \Pi_j \rangle_i$; A Level-4 agent maintains $\langle\langle\langle\langle \vec{\pi}_m \rangle_l \rangle_k \rangle_j \rangle_i$, $\langle\langle\langle \Pi_l \rangle_k \rangle_j \rangle_i$, $\langle\langle \Pi_k \rangle_j \rangle_i$, and $\langle \Pi_j \rangle_i$; and so on. In any case, the innermost embedded policy belief is obtained by a statistical estimation, and applied to metapolicy beliefs to obtain a, presumably better, policy belief.

Although the number of embedded policy beliefs and metapolicy beliefs seems to increase exponentially, we can reduce it by assuming a perfect information game as in the Level-2 agent's case. Since agent i has no reason to distinguish $\langle\langle \Pi_k \rangle_j \rangle_i$ from $\langle\langle \Pi_k \rangle_{j'} \rangle_i$, we can combine them into $\langle\langle \Pi_k \rangle\rangle_i$. Similarly, $\langle\langle\langle \vec{\pi}_l \rangle_k \rangle_j \rangle_i$ for any k and j can be reduced to $\langle\langle\langle \vec{\pi}_l \rangle\rangle\rangle_i$. This sort of reduction limits the number of beliefs to a linear increase.

3. SIMULATION EXPERIMENTS

We conducted a series of simulation experiments, in which the proposed agents play the Iterated Prisoners' Dilemma [**?**], a simple two-player game. In every turn, each agent would independently choose an action, either cooperation (C) or defection (D). The agents would then observe the result, the choice of the other agent and the pay-off given as in Table 1. Each agent would strive to maximize the sum of the pay-offs for itself over many turns. Noise in action is introduced with the probability of ε ; thus an agent chooses unwanted action with a probability of $\varepsilon/2$.

In the experiments, we applied reinforcement-learning algorithms to the game. A state refers to the last step of the action history of the two agents, i.e., $s(t) = (a_{\text{other}}(t-1), a_{\text{self}}(t-1))$; thus there are four possible states. Since we only used a deterministic policy, a policy becomes a four-dimensional vector of C or D. In other words, the policy space has only $2^4 = 16$ elements.

We specified an agent's belief space of another's policy to be equal to the policy space of the agent itself, that is, a four-dimensional vector of C or D. The statistical estimation method of the policy belief is simple; whenever the agent observes an action different from the policy belief, the agent replaces the corresponding element of the belief vector to make the belief match the observation.

We also provide two series of variants for comparison with our algorithm. One is Level-0(H3) agent, which is the same as Level-0 agent except that it uses three steps of action history as the state of reinforcement learning so that this agent has the same table size as the Level-n agents ($n \geq 1$) without using beliefs. The other is Level-n(A) agents, which uses action beliefs $\langle \vec{a}_j \rangle_i$ instead of policy beliefs $\langle \vec{\pi}_j \rangle_i$. Metapolicy reduces to a map from expected opponent's action $\langle \vec{a}_j \rangle_i$ to a policy, and so do metapolicy beliefs. Note that the algorithm of the Level-1(A) agent is equivalent to the NSCP-learner algorithm [7] (see eq. 2). To distinguish from these variants, we denote agents based on our proposed algorithms as Level-n(P).

In all of the simulations described below, we fixed $\alpha = 0.03$ and $\gamma = 0.99$. Since our interest is in the ability of agents playing against peer agents, we focused on simulations that cover only the case that two equivalent agents play IPD games.

3.1 Results

Figure 4 shows averaged pay-off over 2,000 trials of the IPD game by two same-level agents. After the initial learning time, the proposed Level-n(P) agents ($n \geq 1$) obtained average pay-offs very close to 3, the best pay-off that can be obtained only by mutual cooperation. This shows clear contrast to the pay-offs obtained by Level-0, Level-0(H3), and Level-n(A) agents; in fact, in the experiments of each of these agents, the agents failed learning to act cooperatively in more than 30% of the trials. These results indicate that our Level-n(P) agents have better ability to recognize the situation with peer learning agent and to learn the optimal policy.

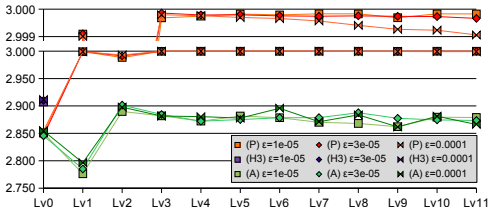

Figure 4: Average pay-off after learning with various ε values. Pay-off is averaged for 5×10^8 steps after 5×10^8 learning. The upper graph enlarges the top part of the lower graph.

Effects of having deeper embedded beliefs are not clear, except slight loss of pay-off is observed in case of $\varepsilon = 0.0001$. This indicates that there is some penalty to keep deeply embedded beliefs in noisy environments. However, since the penalty is very small, we can say that our algorithm is robust to the noise.

4. SUMMARY

We developed a new series of multi-agent reinforcement-learning algorithms that choose a policy based on beliefs about co-players' policies. The algorithms are applicable when a state is fully observable, and there is no limit on the number of players or a particular configuration of pay-offs. By assuming that the co-players also use policy-based beliefs to choose a policy, we also presented algorithms that use various depths of embedded policy beliefs.

We compared the algorithms of different embedding depths and algorithm variants through a series of simulation experiments on the IPD game. The results showed that the algorithms using policy-based belief converged to mutually cooperative behavior, unlike the existing algorithms based on action-based beliefs.

Rule Value Reinforcement Learning for Cognitive Agents

Chris Child and Kostas Stathis
City University, London, UK
{c.child, k.stathis}@city.ac.uk

ABSTRACT

RVRL (Rule Value Reinforcement Learning) is a new algorithm which extends an existing learning framework that models the environment of a situated agent using a probabilistic rule representation. The algorithm attaches values to learned rules by adapting reinforcement learning. Structure captured by the rules is used to form a policy. The resulting rule values represent the utility of taking an action if the rule's conditions are present in the agent's current percept. Advantages of the new framework are demonstrated, through examples in a predator-prey environment.

1. INTRODUCTION

The overall aim of our research is to build agents that can learn to act autonomously in a stochastic environment through experience gathered from interaction with the environment. Acquired stochastic logic rules are used to provide a compact model of the effects of agent action in the environment, and reinforcement learning techniques are used to plan within that model. RVRL provides a method for planning and action within this context.

If the environment the agent is modelling can be described in terms of a set of state variables, a factored state-model can be used. This describes the environment in terms of the dependencies between state variables and the evolution of these variables with respect to the actions taken by an agent.

The method used in this research is to create planning operators from experience of interactions with the environment. These rules predict how the environment will change when the agent takes an action. The general form of a stochastic planning operator is expressed as a rule of the form:

p: $e \leftarrow a, c$

p is the probability that the effects (e) of this operator will become true given the conditions (a, c) of the operator hold. a is the action taken by the agent, and c is a set of state variables representing the context of the agent's perception of the environment for the operator. Both a and c may be empty. In order to restrict the number of possible operators, e is defined to be a *single* state variable for each operator.

The process of building a rule set from experience requires the identification of conditions relevant to the effects of a rule. An effective method of building planning operators from experience is to use statistical significance to identify whether additional conditions are relevant to the outcome. This is the method used to create the rule sets in this work using ASDD [2]. ILP has also been used to learn rules of this form [3]. Precedence between rules is used to resolve conflicts in situations where two or more rule-sets match the conditions for the same output variable (for full details of the "precedence" algorithm, see [2]). This paper is an abridged version of the work presented in [1].

2. RULE VALUE REINFORCEMENT LEARNING

Section 1 outlined the use of rules to model an environment. The next task is to use this rule model to develop an effective policy. One method of achieving this is to use Q-Learning [1]. The update function for Q-learning is as follows:

$$Q(s, a) \leftarrow Q(s, a) + \alpha[R_s, + \gamma \max_{a'} Q(s', a') - Q(s, a)] \quad (2.1)$$

s and a are the states and actions. $Q(s,a)$ indicates the current Q value for the state action pair. This update rule gradually improves estimates on the target function Q. The α parameter is a step-size, indicating how quickly the new estimate should change the old one. γ indicates the discount factor, determining the influence of future rewards on the current state. If we use this function and take sample results (i.e. s' is taken to be the random result after taking action a in state s) the learning is one-step temporal difference (TD) learning.

2.1 The Rule Value Update Function

RVRL uses the same principle as TD learning to update a value associated with each rule, rather than each state. The main advantages of using a state-based aggregation method, such as RVRL, over standard reinforcement learning are that the agent:

a) Does not store a value-map containing every state-action.

b) Can generalize over many states, allowing each value to represent states with similar properties.

If a model of the environment is available, full backup values can be used. Rather than taking a random sample for s_{t+1}, the probability (P) of reaching each possible next state (s') given that action (a) was taken in state (s) can be used in the equation, and the best next action taken as the maximum action (a) for each possible next state, as in dynamic programming (DP). The update function for DP [4] is:

$$Q(s, a) \leftarrow$$

$$Q(s, a) + \sum_{s'} P_{ss'}^{a} \alpha[R_{s'} + \gamma \max_{a'} Q(s', a') - Q(s, a)] \quad (2.2)$$

The stochastic planning operators act as a model in RVRL. It is therefore possible to use an adaptation of equation (2.2). The rule values for operators cannot be updated directly using this equation because more than one rule will match the next state (`s'`) and would therefore be used to generate consecutive states due to several output variables being present. The rule learning function, therefore, replaces `Q(s',a')` with an average value for all matching rules which have precedence (and would therefore be used in generation of the successor state). The rules with precedence are used to give the most accurate representation of the dynamics of the environment in state s'.

`Q(s,a)` is replaced by the value of the rule which will be updated. All matching rules are updated in turn by the update function because their estimated value will be improved by the update, whether they have precedence or not. The update function for RVRL is defined as:

$$forEach\ (rule \in MatchingRules\ (s, a))$$

$$\left\{ \begin{array}{l} Q(rule) \leftarrow Q(rule) + \\ \sum_{s'} P_{ss'}^{a} \alpha[R_{s'} + \gamma \max_{a'} AvgQ(WinningRules(s', a')) \\ -Q(rule)] \end{array} \right\} \quad (2.3)$$

`AvgQ(WinningRules(s',a'))` returns the average rule value for rules which have precedence in state `s'` if action `a'` is taken. `AvgQ(WinningRules(s',a'))` finds the average value of the winning rules and returns the value. `MatchingRules(s,a)` returns all rules whose conditions match the current state and action. The values of all the returned rules are updated by equation (2.3).

2.2 Iterative Rule Value Evaluation

The process of building successor states described in [2], combined with the rule-value update function (2.3) allows continuous generation of next states from an initial state and updates the rule values until satisfactory values have been generated. This process is described by the following algorithm:

```
Initialise Q(rule) = 0, for all rule ∈ rules;
Repeat {
  Initialise s = random state, a = random action;
  Generate next states, s' and prob(s') for s,a
  totalValue = 0; totalReward = 0;
  For each s' ∈ successor states {
    totalReward += reward(s') * prob(s');
    maxActionValue = -∞;
    maxAction = null;
    For each a' ∈ actions {
       actionValue = AvgQ(WinningRules(s',a'));
       if (actionValue > maxActionValue)
         maxActionValue = actionValue; }
    totalValue += maxActionValue * prob(s'); }
  For each rules ∈ matchingRules(s,a) {
    Q(rule) = Q(rule) +
              α[totalReward + γ*totalValue;
              -Q(rule)]; }
} for n steps
```

The sampling (TD learning) equivalent to this method would take a sample next state `s'` rather than calculating the probability of each next state. The process is otherwise the same.

3. EXPERIMENTATION

We tested RVRL in a predator prey environment, consisting of a 4x4 grid surrounded by a wall and containing a predator agent (P) and a prey agent (A). P has caught A if A is on the same square as P at the end of A's move, represented as A being under P (or `Agent_U`). A selects a random action every move. Both P and A have four actions: move north (`Move_N`), east (`Move_E`), south (`Move_S`) and west (`Move_W`). An action moves an agent one square in the direction, unless there is a wall, in which instance there is no effect. P and A move alternate turns. An agent's percept gives the contents of the four squares around it and the square under it. Each square can be in one of three states: empty (`E`), wall (`W`) or agent (`A`).

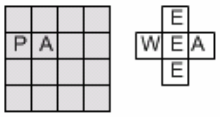

Figure 3-1: P, A in 4x4 grid. P's percept is shown to the right.

The task for RVRL was to construct an effective policy under the above, allowing the predator to catch the prey with optimal frequency. The task is complicated by the fact that the predator (P) is only adjudged to have captured the prey (A) if it moves into, or remains in, the predator's square at the end of its turn. P and A will continue to move after the prey is caught (continuous task).

In experiments it was found that, with a small amount of experience in the environment, P will tend to move next to A but not on-top of it. This is a good tactic as A is likely to move onto P and be caught. The optimal tactic, however, was found to be one in which P moves into A's square every move. This enables the predator (P) to be constantly in sight of the prey (A) and catch it whenever it moves into a wall. An example of a rule which captures this behaviour is: `Agent_N, Move_N`. Our experiments showed that RVRL gives high value to this rule and the `S, E` and `W` equivalents. Rules which attain higher value than the above have conditions such as: `{Agent_U, Move_N, Wall_N, Wall_E}`, in which P is on-top of the A in the NE corner of the map and choose action move north, into a wall (giving P a 50% chance of catching A). `Wall_N` and `Wall_E` are state variables representing that there is a wall north and east. The "effects" of the rules are not shown, because equal value will be learned for all rules with the same conditions. A sample of the final rule weights from rules learned from 60,000 moves experience after RVRL was run on the rule set for 15,000 iterations is given in Table 1.

Rules 1 and 2 have the same conditions but different actions (P is in the SW corner of the grid, with A underneath it). The rule has a positive value if P moves into a wall (1) and a negative value if the P moves away from the wall (2). P would, therefore, move into the wall and thus have the highest chance of catching A (50% chance of A moving into a wall).

Rules 3 and 4 have the same weight. If P takes the move north action (3), it will be on-top of A and will catch it if it moves into the wall to the west (25% chance). If P takes the move north

action in (4) it will move into the wall and therefore stay on-top of A. P will then catch A if it moves into the wall to the north (25% chance). These two situations should be of equal utility to the agent, which has been successfully learned by RVRL.

Table 1: Sample rule weights for rules learned from 60,000 moves experience and 15,000 iterations of RVRL.

No.	*Conditions*	*Value*
1	Move_W, Wall_W, Wall_S, Agent_U	0.43
2	Move_E, Wall_W, Wall_S, Agent_U	-0.03
3	Move_N, Wall_W, Agent_N	0.11
4	Move_N, Wall_N, Agent_U	0.11
5	Move_E, Agent_E	-0.07
6	Move_W, Agent_E	-0.21
7	Move_S	-0.28
8		-0.28

Rules 5 and 6 show the weights for moving east onto the prey to the east and moving west away from a prey to the east. Moving onto the prey has higher weight as expected. Rules 7 and 8 have the same value. Rule 7 is the value of moving south with no other information. Rule 8 has no conditions and is thus the value of taking a random move in the environment. These rules are both effectively random and thus have equal weight.

The performance of RVRL was compared with:

a) Dyna-Q: Q-Learning reinforcement learner with frequency based environment model.

b) SR-Q: A stochastic rule based model of the environment was used to build a state, action value map. This is the equivalent of running Q-learning, using the rule based model for experience to build the Q(s, a) map. This method is described in [2].

RVRL builds a Q(rule) map, assigning value to each rule. Table 2 gives a comparison of the three methods.

In each test case the methods were given the same experience with which to build the model. The predator and prey were run for a set number of steps, taking random moves at each step. Using the model, each method ran Q-learning (in the first two cases), or RVRL for 15,000 iterations to build a value map. Once the map had been created, each method ran for 40,000 steps in the predator prey environment, selecting the action with the highest utility at each step. The number of times P caught A was then recorded. Average moves taken for P to capture A is given in Table 2.

The two Q-learning based methods selected the best action at each step picking the highest valued action from all matching Q(s,a) values for the current state (s). RVRL picked the highest valued action from all matching `AvgQ(WinningRules(s,a))`.

Table 2: Moves per capture: Dyna-Q, Stochastic Rule model Q (SR-Q) and Rule Value Reinforcement Learning (RVRL).

Method	100	500	1000	10000	15000	30000	60000
Dyna-Q	17.5	16.4	12.0	8.8	7.4	6.2	4.6
SR-Q	13.1	13.4	11.5	9.2	8.8	7.1	4.7
RVRL	13.2	12.7	11.3	9.3	8.1	7.0	4.7

Moves per capture for P taking random moves is 16.01. A trail was also run on a "perfect" model (Dyna-Q built from 400,000 moves). In this instance P averaged 4.32 moves per capture.

The results in Table 2 for 100, 500 and 1000 moves training data show that RVRL is more effective than Dyna-Q when little experience has been gathered. In this case the Dyna-Q agent is forced to take a random move in many of the states encountered in the test, because it has no experience which matches the situation. With this limited model, Dyna-Q "expected" the prey to move in the same way as it did in the training data, resulting in picking a poor action. The RVRL agent, however, was able to make generalisations in two ways: first to generalise the *model* using the stochastic logic rules, which allows the system to predict future states from the current state, even when this state has not been seen before; second, RVRL learned values are applicable across multiple states, allowing learned values to be applied in unseen states. This allows the small amount of experience gathered to be generalised and used, which is demonstrated by the improved performance under these conditions. SR-Q is only able to make use of the first of these generalisations, and therefore performed slightly better than Dyna-Q, but not as well as RVRL.

As the state action map gains a larger amount of experience (10,000, 15,000 and 30,000 steps), its model becomes closer to a perfect model in this test environment, while the generalisations made by the rule learner become less effective. This is due largely to shortcomings in the ASDD modelling method with this level of training data [2] which is reflected in the similar performance of the SR-Q results, rather than shortcomings in the RVRL algorithm. When the learned rules become a near perfect representation of the environment (at 60,000 steps training data), the results show that RVRL is capable of learning near perfect valued rules, and thus the utility of taking an action in the current state, again demonstrating that the rule values are capable of capturing a policy at least as effectively as a state action model under these conditions.

4. CONCLUSIONS

This paper has presented the Rule Value Reinforcement Learning (RVRL) method. RVRL is a state-based aggregation technique, in that states which behave in a similar way with respect to a given action sequence and goal are given the same value. Results in our experimentation are extremely encouraging in that the algorithm is able to learn rule-values which accurately capture the utility of actions in the predator-prey environment without the need for a state-action map.

ABSTRACT

We present a method for learning a human understandable, executable model of an agent's behavior using observations of its interaction with the environment. By *executable* we mean that the model is suitable for direct execution by an agent. Traditional models of behavior used for recognition tasks (*e.g.*, Hidden Markov Models) are insufficent for this problem because they cannot respond to input from the environment. We train an Input/Output Hidden Markov Model where the output distributions are mixtures of learned low level actions and the transition distributions are conditional on features detected by the agent's sensors. We show that the system is able to learn both the behavior and human-understandable structure of a simulated model.

1. INTRODUCTION

An ethologist studying the behavior of an animal such as an ant or bee typically starts by defining a set of low-level actions the animal performs. Having defined such low-level actions, the scientist then determines high-level structure; that is, she models what causes the animal to switch between low-level actions. Similarly, a roboticist or agent developer might program a behavior by coding low-level control modes corresponding to primitive actions and combining these low-level control modes together through some kind of high-level action selection mechanism. In this paper we present a method for learning both low-level actions and a high-level switching model. The result is human-understandable, but also *executable* in the sense that it can be used as a control program in a simulation or as part of an agent.

More formally we assume we are given a model of the agent's perception, a set of perceptions that may cause the agent to switch actions, and example trajectories of the agent interacting in its environment (tracking data), some of which has been labeled by a human expert designating the action the agent is performing at a given time step. We further assume that the agent acts according to a Markov Process with inputs. Our task is then to compute an executable model of the agents behavior composed of controllers for low-level actions and rules for switching between them.

Our approach is to train an Input/Output Hidden Markov Model (IOHMM) where the output distributions are mixtures of learned low-level actions and the transitions are conditioned on perceptions of the agents. We first learn from labeled data a set of low-level actions that may be assigned to states in the model. Having learned these low-level actions, the problem is then to learn from unlabeled data a mapping between states and low-level actions as well as the transition rules between states. By dividing the problem this way, the human expert can simply label portions of the data where the agent is obviously performing a particular action (not necessarily data in which the agent switches actions).

Our work is in contrast to *activity recognition*. Although models of behavior learned in activity recognition are often generative, they are not usually suitable for re-creation. Hidden Markov Models (HMMs), for example, are generative models but are usually limited in their ability to recreate real activities because they cannot respond to input. Goldberg and Matarić use an HMM based model to learn a robot's behavior patterns online [5]. Our work is more similar in goal to *imitation learning*. The notion of primitives in [3] is similar to our notion of low-level actions. Such techniques generally differ from our work by focusing more on learning and detecting low-level actions while constrained by the kinematics of particular robots. Our work is most similar to that of [4]. The authors approach the problem from the perspective of control theory and recover from unlabeled data both low-level control modes and a high-level control program in the form of a motion description string. Other related work includes [7] where the authors learn decision trees for low-level control modes.

In order to test our learning algorithms, we programmed by hand a model of foraging inspired by the behavior of social insects, using the TeamBots simulation platform and motor schema-based control [1]. Our experimental method

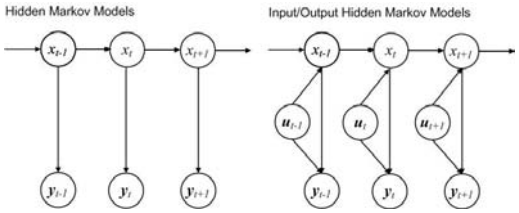

Figure 2: Networks for IOHMMs and HMMs

was to generate data from this known model, then see if we are able to automatically recover the behavior from the data. Figure 1 shows our model. From the simulation we created two data sets, one labeled with the action the agent is performing at each time step and one unlabeled. For both data sets we ran the model in simulation with 12 agents at 33 frames per second, waiting for all of the targets to be carried to base, recording at each frame the positions and orientations of all agents as well as the positions of all targets. Our goal is then to, from the labeled data set, learn the low-level actions of the agent and, from the unlabeled data set, learn the switching behavior.

2. IOHMMS AS EXECUTABLE MODELS

HMMs [6] represent the probability of an observation sequence $P(\mathbf{y}_1^T)$ where $\mathbf{y}_1^T = \mathbf{y}_1 ... \mathbf{y}_T$ is a sequence of observation vectors. IOHMMs [2] are a generalization of this model that represent the conditional probability of an observation sequence given an input sequence $P(\mathbf{y}_1^T | \mathbf{u}_1^T)$ where $\mathbf{u}_t$ is the input vector for time t. Figure 2 shows the dependency assumptions of the two models, where x_t is the discrete state of the model at time t. The essential difference between the two models, is that in an IOHMM the transition distributions $P(x_t | x_{t-1} = i, \mathbf{u}_t)$ and output distributions $P(\mathbf{y}_t | x_t = i, \mathbf{u}_t)$ are both conditional on the current input vector. The standard algorithm for training IOHMMs is an Expectation Maximization (EM) algorithm that is a straightforward extension of Baum-Welch for HMMs. After training, the model can be interactively executed on an input sequence in a manner similar to a finite state machine.

In our case, the input $\mathbf{u}_t$ is the tracking data at time t, including the position of the agent. The corresponding output $\mathbf{y}_t$ is the next position of the agent after moving. By using the model interactively in a simulator environment we can recreate the global behavior of the agent. Although consistent with previous papers on IOHMMs, our use of variable names and the terms *input* and *output* are different than their use in dynamic systems literature (where input often refers to input into the environment).

We model output distributions as mixtures over already learned low-level actions. Mixture distributions marginalize a distribution over a discrete variable, in this case a_t, the low-level action the agent is performing at time t. Normally, a mixture distribution in an IOHMM would have mixing weights conditioned on $\mathbf{u}_t$ as well as x_t. For our application, input-conditional mixing weights are undesirable because they complicate the meaning of a state–there is not a simple mapping between states and low-level actions. Our approach is to use unconditional mixing weights but also for the purposes of parameter estimation model the output distributions as generating both $\mathbf{u}_t$ and $\mathbf{y}_t$. This allows us to represent information about $\mathbf{u}_t$ without introducing input-conditional mixing weights. We further assume $\mathbf{u}_t$ and $\mathbf{y}_t$ are independent of x_t given a_t (that the low level actions are the same for each state). The overall model is something like an HMM/IOHMM hybrid: the transition distributions are conditional while the output distributions are not. With this model, assuming we have already calculated the values for the mixture components at each time step, which we factor into $P(\mathbf{y}_t | a_t, \mathbf{u}_t)$ and $P(\mathbf{u}_t | a_t)$, only the mixing weights need to be re-estimated during EM training.

We must also represent our transition distributions. In our experiments we avoid some complexity and maintain human understandability by conditioning the transition distributions on a set of binary sensory features calculated from $\mathbf{u}_t$, just as we have done in our simulated domain. We can then represent the transition distributions as look up tables. We experimented with ranking our binary features. We then took as our input the most important triggered feature. This ranking method greatly reduces the number of parameters and constrains the model to resemble hand-made models where only a single binary feature triggers a transition. Unfortunately, choosing a feature ranking requires domain knowledge. We also experimented with a standard binary encoding, allowing for a different transition rule for every possible combination of feature values.

When estimating probabilities in look up tables, it is standard to add a small constant to the counts for each entry to allow some probability mass everywhere. In our case, it is useful to add a small number to only the entries corresponding to self-transitions. In other words, given little evidence, an agent should remain in its current state.

3. LEARNING LOW-LEVEL ACTIONS

To estimate the mixing weights during EM from unlabeled data we need to estimate values for $P(\mathbf{y}_t|a_t, \mathbf{u}_t)$ for each time step and low-level action. To execute the resulting model, we also need to be able to sample from this distribution. Our approach to this problem is to learn a controller for each low-level action from labeled data.

From labeled data, we can calculate sensory features and corresponding motor commands for each low-level action (example inputs and outputs for each controller). In our experiments we solve the function approximation problem by using a modified version of k-nearest neighbor (KNN), randomly choosing from the k nearest neighbors with the probability of each weighted by the point's distance from the query point. By randomly choosing in this way we can model random actions like the Explore action. With the learned controller and a simulation environment, we can sample from $P(\mathbf{y}_t|a_t, \mathbf{u}_t)$ (*i.e.* simulate a single time step of the agent's motion). From this we can also estimate values for the distribution for unlabeled data using kernel density estimation. For each time step and action we run a simulation many times to produce distributions of points predicting the next position of the agent. We then compare these point distributions to the actual next position to decide which action the agent is performing.

We also learn a model for $P(\mathbf{u}_t|a_t)$ from labeled input vectors. We are not interested in sampling from this distribution as during execution our model does not generate $\mathbf{u}_t$, but we need to estimate its values in order to calculate the mixing weights, since we modeled the output distributions as joint distributions over $\mathbf{u}_t$ and $\mathbf{y}_t$. In our experiments, we again reduce $\mathbf{u}_t$ to a set of binary features, using the same features and encoding as we did for the transition distributions, and learn look up tables.

4. RESULTS

We used k-nearest neighbors on the agent's sense-action pairs to learn the low level controllers. For the sensory features we used distance and angle to the closest obstacle, closest target, closest agent, and the base as well as whether or not the agent is currently carrying a target. For the motor outputs we calculated the distance and angle the agent moved at each time step as well as whether the agent was carrying an object or not. We then tested the learned controllers in simulation using the original forage switching behavior. Our learned low-level controllers were able to recreate the original foraging behavior even on foraging arenas where the position of food items are moved from their original position as well as differently sized arenas with more attractors and more obstacles. Even though the agents were able to recreate the original foraging behavior by successfully gathering all the targets, there were still flaws. For example, the agents would frequently miss targets while moving towards them in the Move to Target controller, especially targets in corners.

With learned low-level actions, we trained 150 models with EM for both ranked and unranked input types, and 40 ranked and 32 unranked input models learned the correct structure of the behavior (that there was one state for each low level action). The likelihood scores for the models that learned the correct structure were all higher than the scores for the models that did not. Their likelihood scores were also greater than the original model's. Within these models, there were several clusters of models whose likelihood scores were identical within range of our convergence criteria. We tested models from each of these clusters. Figure 1 shows the model from the cluster with the highest likelihood score for the ranked input type. The unranked input type model is similar, except with more complicated conditions on the transitions. 14 ranked and 21 unranked models were within the maximum likelihood clusters.

All of the models that learned the correct structure were able to recreate the forage behavior in simulation when combined with the learned controllers. However, they also all had flaws that affected the behavior to varying degrees. For example, many models did not know what to do when they missed a target or another agent reached a target before them. Some would even remain stuck in Move to Target in this situation, in the worst case then becoming stuck against a wall. Subjectively the models with the maximum likelihood scores seemed to recreate the behavior the best.

5. CONCLUSIONS AND FUTURE WORK

We have presented a method for learning an executable model of behavior from observations. We tested our method on simulated data generated from a hand-constructed model. The learned models recreated the behavior of the original model and exhibited the same basic structure. We hope to next apply these techniques to actual insect tracking data.

ABSTRACT

We present a new multiagent learning algorithm ($RV_{\sigma(t)}$) that can guarantee both no-regret performance (all games) and policy convergence (some games of arbitrary size). Unlike its predecessor ReDVaLeR , it (1) does not need to distinguish whether its opponents are self-play or otherwise non-stationary, (2) is allowed to know its portion of *any* equilibrium that, we argue, leads to convergence in some games in addition to no-regret. Although the regret of $RV_{\sigma(t)}$ is analyzed in continuous time, we show that it grows slower than in other no-regret techniques like GIGA and GIGA-WoLF. We show that $RV_{\sigma(t)}$ can converge to coordinated behavior in coordination games, while GIGA, GIGA-WoLF may converge to poorly coordinated (mixed) behaviors.

1. INTRODUCTION

Multiagent learning (MAL) in a reinforcement learning setting has been an active field of study recently. The problem is simply of multiple controllers trying to learn individually "optimal" control policies in a shared Markov Decision Process (MDP), often called a *stochastic game* or a *Markov game*. The difficulty arises from the fact that all agents are learning simultaneously, which means the MDP faced by each agent is essentially *non-stationary*. Hence, the concept of "optimal" policy becomes ill-defined, and depends on the collective behavior of the other agents. Previous research has attempted to tackle this problem by considering various *opponent classes* such that there is a well-defined "optimal policy" for the learner *for each class of opponents*. Typically the research contributions in this aspect has been to design learning algorithms that learn the appropriate behaviors for the corresponding class of opponents, *without any access to the class information*. We follow this line of research to present a new MAL algorithm for repeated games, with the general philosophy of policy convergence against some classes of opponents but otherwise ensuring high payoffs.

Most MAL algorithms are guaranteed to learn the best response strategies against (eventually) stationary opponents, i.e., those that play stationary strategies after an unknown of rounds. Even single agent learning techniques like Q-learning can achieve this. Building on this property, some MAL algorithms (e.g., WoLF-IGA [4], AWESOME [5]) ensure, in addition, convergence to a Nash equilibrium strategy in *self-play*. i.e., when all agents are following the *same* learning algorithm. However, there is a significantly large class of opponents that is not covered by either of these two cases, i.e., opponents that are neither stationary, nor self-play. In order to fill this void, we proposed [1] that a MAL algorithm should additionally ensure that if the opponent belongs to neither of the above classes, then it will achieve *no-regret* (defined in section 2) payoffs - something that can be construed as reasonably good performance when facing uncertain opponents. Although we had presented an algorithm, ReDVaLeR [1], that achieved all three properties, there were some limiting knowledge requirements such as

- The ReDVaLeR agent needed to know whether its opponents are self-play, or otherwise non-stationary. In this paper, we study a variant of ReDVaLeR , called $RV_{\sigma(t)}$ [2], that eliminates this assumption.
- In case of self-play, all ReDVaLeR agents need to know their portions of the *same* Nash equilibrium. $RV_{\sigma(t)}$ eliminates this requirement for some classes of games. Specifically, $RV_{\sigma(t)}$ agents only need to know their portions of *any* equilibrium in any 2×2 game, and in a game of any size with a unique mixed equilibrium (established before in [2]). In this paper, we argue theoretically and empirically, that this also holds in some coordination games with multiple equilibria.

We also show that the expression (in continuous time) for regret of $RV_{\sigma(t)}$ can have a slightly better form than those (discrete time) of GIGA [6] and GIGA-WoLF [3]. In a class of coordination games, GIGA, GIGA-WoLF are found to converge to mixed equilibria that make miscoordination highly likely besides yielding poor expected payoff to both agents, while $RV_{\sigma(t)}$ is found to always achieve strict coordination with Pareto-dominating payoffs.

2. MULTIAGENT REINFORCEMENT LEARNING

A Multiagent Reinforcement Learning task is usually modeled as a Stochastic Game (SG, also called *Markov Game*), which is a Markov Decision Process with multiple controllers. We focus on stochastic games with a single state, also called repeated games, since we are more interested in dealing with uncertainties due to the other learners' changing behaviors. This refers to a scenario where a matrix game – given by an n-tuple of matrices, $\langle \mathbf{R}_1, \mathbf{R}_2, \ldots, \mathbf{R}_n \rangle$ where $\mathbf{R}_i$ is a payoff matrix of dimension $|A_1| \times |A_2| \ldots \times |A_n|$, such that the payoff of the ith agent for the joint action $(a_1, a_2, \ldots, a_n)$ is given by the entry $R_i(a_1, a_2, \ldots, a_n)$, $\forall i$ – is played repeatedly by multiple agents. We represent the action space of the ith agent as A_i. Table 1 shows examples of bimatrix games of a special class that we call *Simplified Coordination Games*. It is "simplified" because only coordinated action profiles have non-zero payoffs. This game has n pure equilibria (plus some mixed equilibria) given by the matrix diagonals, but players may prefer different ones (here row player prefers 3rd row, column player prefers 1st column).

Table 1: Simplified Coordination Games

Actions	C_1	C_2	C_3
R_1	(2,100)	(0,0)	(0,0)
R_2	(0,0)	(51,51)	(0,0)
R_3	(0,0)	(0,0)	(100,2)

A *mixed policy*, vector $\boldsymbol{\pi}_i \in \Delta(A_i)$ for agent i, is a probability distribution over A_i. We write the probability of the jth action of the ith agent at time t as $\pi_i^t(j)$. If the entire probability mass is concentrated on a single action (some actions), it is also called a *pure policy* (*partially mixed policy*). The joint policies of the opponents of the ith agent will be given by the vector $\boldsymbol{\pi}_{-i}$. We shall usually refer to the ith agent as the learner and the rest of the agents as the opponents. The expected payoff of the jth action of the learner against the opponent's current policy, $\boldsymbol{\pi}_{-i}^t$ is written as $V_i(j, \boldsymbol{\pi}_{-i}^t)$.

For a given time range $t = 0 \ldots T$, the regret of a learner (agent i), Rg_i^T is given by

$$Rg_i^T = \max_{\boldsymbol{\pi}_i} \sum_{t=1}^{t=T} V_i(\boldsymbol{\pi}_i, \boldsymbol{\pi}_{-i}^t) - \sum_{t=1}^{t=T} V_i(\boldsymbol{\pi}_i^t, \boldsymbol{\pi}_{-i}^t).$$

This compares the total payoff of the actual sequence of policies of the learner to the best response against the empirical distribution of the opponent.

3. OUR APPROACH: ReDVaLeR WITH VARIABLE σ

We make the usual assumptions about the boundedness of the game payoffs (only non-negative in our case); the learner's ability to use vanishing step sizes ($\eta \to 0$), and that the learner can observe its payoff vector $\mathbf{V}_i$, i.e., $V_i(j, \boldsymbol{\pi}_{-i}^t)$ for all actions j at any round. It *does not* need to observe the opponents' payoffs or policies/actions.

We use the ReDVaLeR algorithm from [1] with a time-varying schedule for σ in place of a constant. The discrete form of the algorithm (slightly different from [1]) is

$$\pi_i^{t+1}(j) = \frac{\pi_i^t(j) + \eta \pi_i^t(j) l_i^t(j) V_i(j, \boldsymbol{\pi}_{-i}^t)}{1 + \eta \sum_j l_i^t(j) \pi_i^t(j) V_i(j, \boldsymbol{\pi}_{-i}^t)} \quad (1)$$

for any j, η being a small step size and initial condition: $\pi_i^0(j) > 0$.

In contrast with [1], the learning rates $(l_i^t(j))$ for our algorithm, $RV_{\sigma(t)}$, are defined as

$$l_i^t(j) = \begin{cases} 1 + \sigma(t) & \text{if } \pi_i^t(j) < \pi_i^*(j) \\ 1 - \sigma(t) & \text{if } \pi_i^t(j) \geq \pi_i^*(j) \end{cases} \quad (2)$$

for a suitable σ-schedule as defined below, and $\boldsymbol{\pi}_i^*$ being the learner's portion of a Nash equilibrium [2] policy.

DEFINITION 1 (σ-SCHEDULE). *A time decaying schedule for $\sigma(t)$ is defined by the 3 conditions:*

1. *$\sigma(t)$ is continuous and $1 \geq \sigma(t) \geq 0, \forall t$,*
2. *$\sigma(t) \geq \sigma(t'), \forall t' \geq t$, and*
3. *$\sigma(t) \to 0$ as $t \to \infty$.*

3.1 Properties of $RV_{\sigma(t)}$

The following theorems (proofs can be found in [2]) summarize the main properties of $RV_{\sigma(t)}$ for $\eta \to 0$. We call games of arbitrary size having unique mixed Nash equilibrium as UME games.

THEOREM 1 (EVENTUALLY STATIONARY OPPONENTS). *If there exists a time τ_1 (unknown to the learner) such that all other agents play stationary policies at all times $t > \tau_1$, then for a given $\epsilon > 0$, there exists a time $\tau > \tau_1$, such that after τ an $RV_{\sigma(t)}$ agent i using σ-schedule in Definition 1, is guaranteed to converge to the set of ϵ-best response policies (i.e. payoffs are within ϵ of the best response payoff).*

THEOREM 2 (NO-REGRET). *If an $RV_{\sigma(t)}$ agent i uses the decaying σ-schedule of Definition 1 and $\pi_i^0(j) = 1/|A_i|$, then $\lim_{T\to\infty} \frac{Rg_i^T}{T} \leq 0$, i.e., the algorithm is asymptotically no-regret.*

THEOREM 3 (SELF-PLAY IN 2×2 GAMES). *In any 2×2 game, there exists a σ-schedule satisfying Definition 1, such that $RV_{\sigma(t)}$ will converge to a Nash equilibrium profile in self-play, even if they are given their portions of different equilibria.*

THEOREM 4 (SELF-PLAY IN UME GAMES). *There exists a σ-schedule satisfying Definition 1, which when followed by n $RV_{\sigma(t)}$ agents guarantees the convergence of their policies to the equilibrium profile in all UME games of any size, provided each agent knows appropriate loose-bounds on (1) the maximum game payoff of any agent, $R_{\max} = \max_i \bar{r}_i$, (2) the maximum size of action space among all agents, $\max_i |A_i|$, (3) the minimum equilibrium payoff among all agents, $\min_i V_i^*$, and (4) the total number of agents, n.*

3.2 Regret growth of $RV_{\sigma(t)}$

It has been argued in [2] that the σ-schedule $\sigma(t) = \frac{1}{1+\beta\sqrt{t}}$ for a small constant β (proportional to $1/(\bar{r}_i|A_i|)$) satisfies Definition 1 and all of the theorems simultaneously. This allows us to deduce a more direct expression for the regret in terms of the time variable, using the following lemma. Note that this lemma immediately leads to Theorem 2 for *any* σ-schedule satisfying Definition 1, and particularly for $\sigma(t) = \frac{1}{1+\beta\sqrt{t}}$.

LEMMA 5. *The regret of an $RV_{\sigma(t)}$ agent (for $\eta \to 0$) is given by $Rg_i^T \leq 2\bar{r}_i \int_0^T \sigma(t)dt + \log|A_i|$.*

Thus our unifying choice of $\sigma(t) = \frac{1}{1+\beta\sqrt{t}}$ yields a regret bound of

$$Rg_i^T \leq \left(\frac{4\bar{r}_i}{\beta}\right)\left(\sqrt{T} - \frac{\log(1+\beta\sqrt{T})}{\beta}\right) + \log|A_i|,$$

whereas GIGA-WoLF has

$$Rg_i^T \leq (2 + \bar{r}_i^2|A_i|)\sqrt{T} - |A_i|\bar{r}_i^2$$

and half that for GIGA. The presence of the log term in our expression for Rg_i^T might make it grow slower, though our analysis is in continuous time as opposed to discrete time analysis of GIGA and GIGA-WoLF. In order to make a more direct comparison, we experiment with all these methods *in discrete time*.

4. SIMPLIFIED COORDINATION GAMES

The following two lemmas (proofs omitted) and the experimental results suggest that $RV_{\sigma(t)}$ in self-play converges to playing coordinated actions even if they were given different pure equilibrium policies (e.g., the ones they prefer) at start. GIGA and GIGA-WoLF on the other hand can converge to poorly coordinated behavior with poor payoffs. Although the definition of this class of games and the following results are presented for two agent scenarios, it can be trivially extended to the multi-player case.

LEMMA 6. *Two $RV_{\sigma(t)}$ agents cannot converge asymptotically to uncoordinated pure policies in the SCGs.*

LEMMA 7. *If at a large enough time in the SCG, both $RV_{\sigma(t)}$ agents assign their highest probabilities to the same action (j), then the probability of both players playing j increases.*

Our experiments in this class of games used the game shown in Table 1 and various completely mixed starting policy profiles. Each $RV_{\sigma(t)}$ player was given its portion of the equilibrium policy that it would prefer, e.g., player 1 was given $[0, 0, 1]$ and player 2 was given $[1, 0, 0]$.

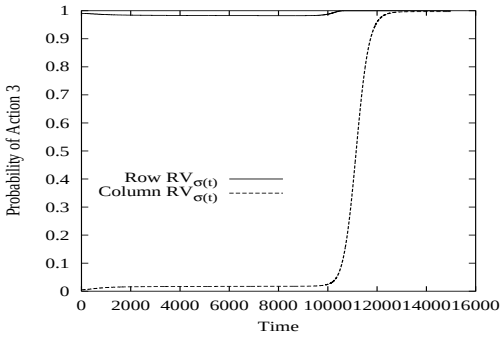

Figure 1: The probabilities of R_3 and C_3 of two $RV_{\sigma(t)}$ agents starting at $\langle[0.005, 0.005, 0.99], [0.99, 0.005, 0.005]\rangle$, in the coordination game in Table 1. Each agent used $\beta = 0.2$ and $\eta = 2 \times 10^{-3}$.

Two $RV_{\sigma(t)}$ agents always converged to a coordinated action profile, sometimes even to action profiles $\langle R_1, C_1\rangle$ and $\langle R_3, C_3\rangle$ depending on the starting point, in both games. Figure 1 show both $RV_{\sigma(t)}$ agents converging to their 3rd actions (i.e., R_3, C_3) even when each starts close to its desired policy and uses its desired equilibrium. Essentially, one agent learns to compromise while the other maximizes its payoff, reaching a coordinated profile. Which agent compromises depends more on the starting policies than the learning dynamics.

GIGA and GIGA-WoLF converge to either coordinated action profiles or to mixed equilibria e.g., $\langle[1/51, 0, 50/51], [50/51, 0, 1/51]\rangle$. This happens when they start close to their preferred policies like the $RV_{\sigma(t)}$ agents. Figure 2 show the sum

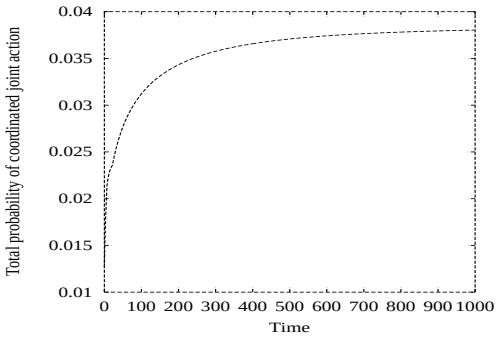

Figure 2: The sum of the joint probabilities of diagonal actions when two GIGA-WoLF agents start at $\langle[0.005, 0.005, 0.99], [0.99, 0.005, 0.005]\rangle$, in the coordination game in Table 1. Each agent used $\eta_1 = 2 \times 10^{-3}$.

of the coordinated joint actions of two GIGA-WoLF agents, i.e., $\sum_s \pi_1^t(s)\pi_2^t(s)$, which converges to the inner product of the mixed equilibrium profile that the agents converge to (in this case 0.038446751). If the agents had converged to a purely coordinated profile, then $\sum_s \pi_1^t(s)\pi_2^t(s)$ would have converged to 1. Thus figure 2 also shows the low probability of coordination of the resulting profile (3.8%). This not only means that the agents would play uncoordinated actions most of the times, but also that even the expected payoffs of *both* agents ($\approx$ 1.96 for both) are lower than at any coordinated action profile. Note that GIGA-WoLF converges to this same undesired equilibrium whether it uses $\eta_1 = 1$ or $\eta_1 = 2 \times 10^{-3}$ (like $RV_{\sigma(t)}$), where $\eta_t = \eta_1/\sqrt{t}$.

5. ACKNOWLEGDEMENT

We thank Mike Bowling for helping with the code of GIGA-WoLF. This work was supported in part by Grants from Army Research Office W911NF-05-1-0377 and Louisiana BOR LEQSF(2002-05)-RD-A-29.

ABSTRACT

In concurrent learning algorithms, an agent's perception of the joint search space depends on the actions currently chosen by the other agents. These perceptions change as each agent's action selection is influenced by its learning. We observe that agents that show lenience to their teammates achieve more accurate perceptions of the overall learning task. Additionally, lenience appears more beneficial at early stages of learning, when the agent's teammates are merely exploring their actions, and less helpful as the agents start to converge. We propose two multiagent learning algorithms where agents exhibit a variable degree of lenience, and we demonstrate their advantages in several coordination problems.

1. INTRODUCTION

This paper focuses on applications where multiple agents concurrently learn how to better interact with one another. Imagine a simple scenario where two agents learn to coordinate. The task is for the agents to each independently choose one action with the goal of maximizing the joint reward that they receive. Figure 1 illustrates a search space of joint rewards for a simple two-agent domain. The figure shows two peaks of different sizes. The lower peak represents a globally-suboptimal solution, and the wide coverage of that peak implies that solution quality changes only a little when either agent chooses a slightly different action. The higher peak represents the global optimum; its smaller coverage implies that the solution quality may change rapidly if either agent chooses a slightly different action.

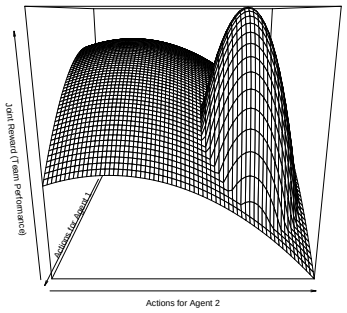

Figure 1: A bimodal search space for the possible rewards received by a two-agent team. Wider peaks may attract many search trajectories, even though such peaks may be globally suboptimal.

In concurrent multiagent learning, each agent is usually afforded only a partial glimpse of the search space. Specifically, each agent can only detect the rewards it receives for its own actions. However, these rewards also depend on the actions chosen by its teammate, and as a consequence, an agent's perception of the search space depends on what actions its teammate is currently choosing.

An agent's perception of the joint space is additionally affected by the approach it uses to aggregate the rewards obtained for each of its actions (when combined with different actions for the teammate). For example, Figure 2 shows different perceptions of the joint search space in Figure 1 for two aggregation methods. We observe that if an agent estimates the quality of its action as the *average* reward obtained when combined with multiple actions chosen by its teammate, the agent fails to perceive the potential of actions corresponding with the globally optimal peak. On the other hand, an agent that shows *lenience* towards its teammate by assessing the quality of its actions as the *maximum* reward received over multiple actions chosen by its teammate (thus ignoring the lower rewards usually associated with miscoordinations) perceives the higher potential of actions corresponding to the global optimum. If the goal is to discover globally optimal solutions, the agents should be able to tell that actions associated with such solutions are superior to others. In this paper, we focus on lenient learning as an approach to doing this.

We are particularly interested in *varying* the degree of lenience as time passes. As a consequence, we propose two algorithms that decrease the learners' degree of lenience with time. There are several reasons to vary the degree of lenience an agent exhibits. While an extremely high degree of lenience may be useful at early stages of learning to identify promising actions, ignoring many rewards may also be wasteful (in terms of evaluations) at later stages of learning once the agents start to converge. Additionally, ignoring rewards

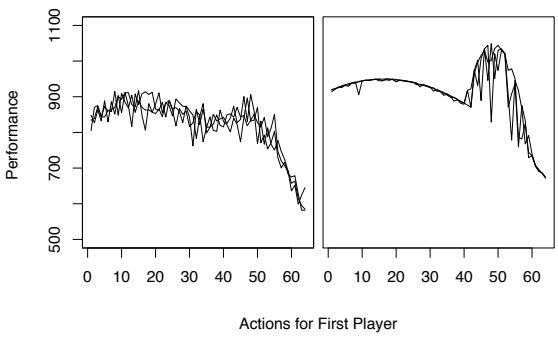

Figure 2: Two possible perceptions of the domain in Figure 1, for random actions of the teammate. (left) The average of ten joint rewards. (right) The maximum of ten joint rewards.

as the agents start to converge may be harmful to estimating the actual expected value in domains where agents receive noisy reward information. Finally, lenience may interfere with the learners' attempts to choose one of multiple equally-good solutions, if several exist.

2. LENIENT COEVOLUTION

Cooperative coevolutionary systems [6] are variants of evolutionary computation (a stochastic optimization technique) which apply multiple parallel learners (optimization processes) to work jointly on different aspects of the problem. This makes them a good fit for multiagent learning by decomposing the joint problem into several, likely intertwined, individual agent subproblems.

A standard approach to applying cooperative coevolutionary algorithms (CCEAs) to multiagent learning assigns each agent its own set (*population*) of higher-rewarded actions. The quality (*fitness*) of an action is determined by testing it in combination with actions from the other agent (as sampled from its current population either randomly or based on their performance during the past evaluation phase). When combined with these actions (called *collaborators* in coevolution parlance), an agent's action receives a reward equal to the joint reward for the entire team of agents. The fitness of the candidate action is then computed by aggregating multiple such rewards (e.g., by taking the average or the maximum, similar to the process used for Figure 2). Aside from this collaborative assessment, each agent follows its own independent evolutionary process in parallel with other agents.

Most cooperative coevolutionary algorithms assume that each action is evaluated as the maximum joint reward obtained with a fixed number of collaborators [8]; of them, one is usually the best action at the previous learning stage (*generation*), and the others are chosen at random. In terms of our earlier discussion, using the maximum joint reward translates into a constant level of lenience: the quality of the action is assessed by ignoring lower rewards. Given the observed variance in the impact that lenience can have on an agent's perception, we argue that a varying degree of lenience might be beneficial for CCEAs, especially when given fixed computation capabilities.

To do this, we experiment with a trivial ad-hoc setting: the fitness of each individual is assessed as the maximum reward obtained with ten collaborators for the first five generations; after that, only the maximum reward with *two* collaborators is used. This implies that the degree of lenience varies with time: the worst nine out of ten rewards will be ignored for each action in an agent's population during the first five generations, while only one out of two rewards will be ignored thereafter. While we found this trivial setting to be useful for this proof of concept investigation, readers with further interest in time-dependent collaboration schemes for CCEAs are referred to [5].

Experiments. To test our hypothesis that a variable degree of lenience is helpful, we applied CCEAs to four simple coordination games based on benchmark optimization problems with well-known properties: Two-Peaks (as in Figure 1), Rosenbrock, Griewangk, and Booth [7]. All domains were discretized such that each of the two agents had a set of 1024 actions. Each agent maintained a population of 32 actions. Agents kept unmodified their best action from one generation to another, and the remaining population of actions was created by mutating actions chosen via tournament selection of size 2 (two random actions were picked with replacement from the population, and the fitter of the two was selected). Mutation worked as follows: a coin was repeatedly tossed, and the action (an integer number) was increased or decreased (the direction chosen at random beforehand) until the coin came up heads, making sure it did not go outside the allowed bounds. The coin was biased such that it came up heads with probability 0.05. One of the collaborators was always set to the best action from the other agent's population at the previous generation; the others were chosen by a tournament selection of size 2.

We fixed the budget to 17600 evaluations of joint rewards. When choosing this budget, we felt that too small of a value might prevent differentiations among the algorithms because they would not be allowed to search enough. Similarly, too large of a budget might diminish the differences between methods that waste evaluations and methods that use them effectively. The value we chose seemed to be a good compromise.

The experiments were performed using the ECJ library [4], and they involved 250 runs per method. Performance was computed as the average of the best performing pair of actions (one per each agent) at the last generation. The results indicated that the CCEA with a variable degree of lenience was significantly better in all four problem domains than CCEAs involving a fixed degree of lenience (statistical significance was verified using t-tests assuming unequal variances at 95% confidence).

3. LENIENT MULTIAGENT REINFORCEMENT LEARNING

Drawing inspiration from dynamic programming concepts, reinforcement learning (RL) methods update the estimates of utilities for performing actions in various states of the environment, or for being in those states themselves. These utilities are used for both the exploration of the space, and for the exploitation of the agent's knowledge about the environment. As the memory requirements of traditional RL grow exponentially with the number of agents, multiagent reinforcement learning reduces the memory consumption by decomposing the utilities of joint actions into per-agent utilities of actions. We assume for simplicity that the environment has a single state, and we only focus on computing the utility of choosing different actions; this is similar to the analysis of multiagent RL in [1, 2, 3].

The proposed lenient multiagent reinforcement learning algorithm (LMRL) is based on the following idea: if at early stages of learning an agent receives rewards $r_1, r_2, ..., r_k$ when choosing action a_1 at various times, the agent only updates the utility of a_1 based on the maximum of $r_1, r_2, ..., r_k$, ignoring the others. The reason for this is that those rewards were obtained while the other learning agent selected some actions $b_1, ..., b_k$, most of which we poor choices to begin with and will be abandoned by the other

agent in the future due to low utility. But later, after each agent has largely converged to one or a few actions, it becomes more important to achieve accurate utility estimates. The agents therefore will decrease their degree of lenience to one another by ignoring fewer of the lower utilities.

To implement this idea, an agent always updates the utility of the action if the current reward exceeds the utility of that action. Agents associate a temperature with each action, and the level of lenience is inversely proportional to the temperature: the temperature is initially high and agents are thus more likely to ignore lower rewards. The temperatures of actions decrease as those actions are selected, and as a consequence the agents become more likely to incorporate the lower rewards into the utility estimates. As agents have non-zero probabilities of selecting an action at each time step, there is also a small (0.01) probability of ignoring small rewards at all times. Agents choose actions via Boltzman selection.

`Lenient Multiagent RL`
Parameters
$MaxTemp$: maximum temperature
α: temperature multiplication coefficient
β: exponent coefficient
δ: temperature decay coefficient
λ: learning rate
N: number of actions
Initial Settings
For each action i
$U_i =$ random value between 0 and 0.001
$Temp_i = MaxTemp$
Algorithm
Repeat
// Action Selection
$MinTemp = 10^{-6} + \min_{i=1}^{N} Temp_i$
$W_i = \frac{e^{\frac{U_i}{MinTemp}}}{\sum_{j=1}^{N} e^{\frac{U_j}{MinTemp}}}$
Use probability distribution W_1, ..., W_N to select action i
$Temp_i = Temp_i * \delta$
// Utility Update
Perform action i and observe reward r
$RandVal =$ random value between 0 and 1
If $(U_i \leq r)$ or $\left(RandVal < 10^{-2} + \beta^{-\alpha * Temp_i}\right)$ Then
$U_i = \lambda * U_i + (1-\lambda) * r$

Experiments. We tested LMRL in the Climb and Penalty domains introduced in [1], and in the two stochastic variations of the Climb domain discussed in [2]. We performed a preliminary sensitivity study for the parameters: as a result, we set $MaxTemp = 500$, $\alpha = 2$, $\beta = 2.5$, $\delta = 0.995$, and $\lambda = 0.95$. The agents spent 7500 moves learning. We compared LMRL's performance with that of FMQ [2] and with a straightforward application of RL to concurrent learning (also in [2]). We ran each algorithm 10000 times in each of the four problem domains.

The lenient multiagent RL algorithm consistently converged to the global optimum in the Climb, Penalty, and Partially-Stochastic Climb domains. According to [2], this is equivalent to the performance of FMQ in these problem domains, and it is also significantly better than the performance of traditional Q-learning approaches, as well as to an algorithm previously proposed in [3]. However, the lenience also helped the agents learn the global joint action in the Fully-Stochastic Climb domain in more than 93.5% of the runs. Contrast this to FMQ's poor performance in this domain as mentioned in [2]. We likewise found that FMQ converged to the global optimum solution in only around 40% of runs in this difficult domain, despite an extensive sensitivity study for parameter values.

4. CONCLUSIONS

This paper argues that multiple agents that learn concurrently can benefit from showing lenience to each other, especially during early interactions. We illustrated this concept with perceptions of the joint search space that each agent would perceive during different stages of learning. We then extended two popular multiagent learning algorithms, namely cooperative coevolution and multiagent reinforcement learning, to include lenience in the agents' decision processes, and we showed the superiority of these extensions in several coordination games.

Can Good Learners Always Compensate for Poor Learners?

ABSTRACT

Can a good learner compensate for a poor learner when paired in a coordination game? Previous work presented an example where a special learning algorithm (FMQ) is capable of doing just that when paired with a specific less capable algorithm even in games which stump the poorer algorithm when paired with itself. We argue that this result is not general. We give a straightforward extension to the coordination game in which FMQ cannot compensate for the lesser algorithm. We also provide other problematic pairings, and argue that another high-quality algorithm cannot do so either.

Reinforcement Learning, Multiagent Systems, Cooperative Games

1. INTRODUCTION

Concurrent learning is a subset of cooperative multiagent learning where the overall problem is divided into simpler subproblems such that each agent representing one subproblem, explores its space of actions with little or no control over its teammate's actions. Given concurrent learners, we might ask: what if each learner used a different algorithm? This is not implausible: for example, an agent (on the web, say) may not have control over the other learning agents. But while recent research on learning in competitive games has addressed heterogeneous learners [1], cooperative learning literature has largely assessed homogeneous learners.

We are aware of only one paper that focuses on concurrent heterogeneous cooperative learners: Kapetanakis and Kudenko analyze different combinations of a traditional reinforcement learning algorithm and an extension called FMQ [6]. The authors report that a two-agent team using the traditional algorithm cannot consistently learn the globally optimal solution. However, the optimal solution is achieved when both agents use FMQ. Moreover, an agent using FMQ can help another agent using the traditional algorithm to learn the global optimum in several coordination games. The authors thus conclude that a "smart" learner (FMQ) can still be successful even when it must work with less smart learners (the traditional algorithm).

We will argue that this is not necessarily so. We extend the research in [6] by including a difficult coordination game, as well as two new algorithms. One of these algorithms is a modified evolutionary algorithm: this extends the analysis to combinations with agents that use *entirely* different learning techniques, not just variations of the same learning method. The results of the experiments suggest the opposite conclusion from that in [6]: in difficult domains, good results are usually obtained only if both agents are "smart" enough. That is because it takes both agents to converge to an optimal solution, and poor learners may force "smart" ones to converge to suboptima.

2. SINGLE-STAGE COOPERATIVE GAMES

Markov decision processes (MDPs) are widely used in multiagent reinforcement learning to account for the presence of other agents in the environment [4, 8]. Single-stage cooperative games are a variation of MDPs where all agents receive the same reward [2]. More specifically, each agent independently chooses an action from its action set, and the actions from all the agents are combined into a *joint action*. All agents receive the same reward or penalty depending on the joint action. For example, using the Climbing game as shown in Table 1(a), if agent 1 chooses action b and agent 2 choose action a, then both agents receive a reward of -30. This process of choosing a joint action is repeated until (hopefully) the agents learn to select better actions due to past interactions. We assume that agents do not explicitly communicate or observe teammates' actions; the only feedback mechanism is the reward received for the agent's action.

Table 1 shows four single-stage cooperative games: the Climbing game and the Penalty game introduced in [2], and the partially- and fully-stochastic variations of the Climbing game as proposed in [5]. Note that in the partially- and fully-stochastic games, when $p = 0.5$, the average reward for a joint action is the same as the reward for the same joint action in the regular Climbing game. In

the regular, partially- and fully-stochastic Climbing games, the optimal joint action is (a,a). In the Penalty game, the known penalty, $k \leq 0$, produces three optimal joint actions — (a,a), (b,b), (c,c) — of which (a,a) and (c,c) are preferred since they have a higher reward. Researchers have used these games extensively to highlight the advantages of certain multiagent learning algorithms (for example, [2, 5, 7]).

Each of these games is challenging due to miscoordination penalties. The Climbing game has a severe penalty for choosing action a when the other agent chooses action b. However, there are no major miscoordination penalties associated with action c, potentially tempting the agents. The Penalty game introduces an additional miscoordination issue due to the presence of multiple optimal joint actions. While smaller values of k will make the individual actions a and c more attractive, there is still the problem of ensuring that the other agent will choose the same optimal action.

The stochastic variations of the Climbing game add more complexity due to the noisy reward function. As agents cannot perceive their teammates' actions, the different rewards they observe for the same action may be due to either (1) the other agent experimenting with various actions, or (2) the noisy reward function. While the highest reward of 14 is sometimes achieved when both agents choose action b, they need to learn to separate the effects of (1) and (2), and to realize that the average reward for the joint action (b,b) is lower than that of (a,a).

3. LEARNING ALGORITHMS

We experiment with four learning algorithms: three variations of reinforcement learning, and a genetic algorithm with a novel evaluation procedure. Two of these algorithms are not new: reinforcement learning and FMQ have been previously analyzed, in particular in [5]. We chose reinforcement learning as a standard benchmark, while FMQ appears to be one of the stronger algorithms to date. We devised the other two algorithms based on the notion of lenience of an agent towards its teammates.

3.1 Lenient Multiagent Reinforcement Learning

In an accompanying paper, we propose another RL algorithm, Lenient Multiagent Reinforcement Learning (LMRL), which selectively updates the utilities of actions based on *some* of the rewards. It is implemented as follows. We always update the utility of the action if the current reward exceeds the utility of the action. Otherwise, the utility is updated with a probability based on a current per-action *temperature*. If the temperature associated with an action is high, then agent is "lenient" towards low-reward pairings and so it does not update its utility to reflect them. At a lower temperature, the utility includes low-reward pairings with greater frequency.

The temperature of an action is decreased slightly every time that action is selected. As a consequence, actions that have been chosen more often have their utilities updated more often as well, while the utilities for actions that have been chosen rarely are mainly updated in response to higher rewards. This initially leads to an overoptimistic evaluation of the utility of an action. An agent may thus be temporarily fooled into choosing suboptimal actions. However, the utilities of such actions will decrease with time, and the agent is more likely to end up choosing the optimal action. There is also a small (0.01) probability of ignoring small rewards at all times: we found this to be important in our experimental setup because the agents have non-zero probabilities of selecting any action at each time step. Aside from these enhancements, the algorithm follows a traditional RL approach, including the Boltzman action selection based on the utility of each actions.

3.2 Lenient Evolutionary Algorithm

Evolutionary algorithms (EAs) are stochastic search techniques inspired by natural evolution [3]. EAs maintain a set of samples in the search space (referred to as a "population" of "individuals"). Each such individual is assigned a "fitness" (the quality of the individual). EAs then form a new population by repeatedly selecting, copying and modifying the highly fit individuals in the current population. The new population replaces the old one, and the cycle of fitness assessment and breeding continues until a termination criterion is met. Each iteration of this cycle is known as a "generation." See [3] for a more detailed discussion of evolutionary algorithms.

Cooperative Coevolutionary Algorithms (CCEAs) apply EAs to concurrent learning processes. A CCEA employs multiple (for our purposes, two) populations, each evolving independently. CCEAs pair populations to evaluate them together. We propose a new EA that, like CCEAs, evaluates individuals (representing actions) in combination with actions not just the other populations, but from other learning algorithms (such as RL or another EA).

This EA also allows an agent (individual) to show varying degrees of lenience to its teammate. For this purpose, the entire population is cloned multiple times and shuffled, and each clone is evaluated with an action chosen by the teammates. As the teammate is also co-adapting, the particular action it chooses may change at any time. The extra clones of the population are required only for evaluations and may be discarded afterwards. After each clone of an action receives multiple rewards, these rewards are aggregated into a single fitness for the original action. This fitness is computed as the average of the better K rewards that were obtained. Varying degrees of lenience are implemented by using the average of fewer of the better rewards at early generations (thus ignoring more of the rewards observed for an action). Initially, the best reward is used. As learning progresses, we compute the fitness as the average of more and more "top" rewards, thus reducing the lenience towards the teammate.

4. EXPERIMENTAL RESULTS

We ran each combination of learning algorithms in the four cooperative games. Experiments consisted of 30 trials of 1000 runs each. Each run lasted for 7500 joint action selections and their re-

	RL	FMQ	LMRL	EA
RL	468.5	998.4	0.8	218.5

EA	–	–	–	197.0

Table 3: Average number of iterations (out of 1000) that converged to the joint action for the stochastic game.

wards. We set $k = -10$ in the Penalty game. For all the reinforcement learning algorithms, temperature decayed as $T = T * 0.9995$ and the learning rate is 0.95. For FMQ, we set $c = 10$; LMRL used a temperature multiple coefficient of 2 and a exponent coefficient of 2.5. For the lenient evolutionary algorithm, we used a population of size 10, and the evolution lasted for 150 generations; we also set $C = 5$ clones per population, and K started at 1 and increased every 15 generations until reaching the maximum value of 5. (See our accompanying paper for a more detailed discussion of the parameters.) The lenient EA employed selection via binary tournament, and breeding randomized the action with probability 0.001. At the end of each run we determined if the converged joint action was optimal. We then computed the number of runs (out of 1000) that converged to the joint action, and averaged over 30 trials.

In the Climbing game, all but three learning teams discovered the optimal action more than 91% of the time. The reasons: RL-RL's use of all rewards caused it to be attracted occasionally to (b,c). RL-LMRL in turn was attracted to (c,c) and EA-EA to (b,b). Overall, FMQ and LMRL were the best learners in the Climbing domain, and they also did well when combined with one another. FMQ had a slight edge over LMRL as it also performed very well when teamed with RL. All teams discovered the optimal strategy more than 98% of time in the Penalty game. This improvement in performance was partly due to the fact that the Penalty game has twice the number of optimal solutions to which learning may converge.

The results for the partially stochastic Climbing game (Table 2) were similar (although more extreme) to the ones in the deterministic Climbing game. FMQ and LMRL were again the "smarter" algorithms: they found the optimal joint action in almost all runs when paired with themselves or each other. FMQ was also able to help RL converge to the optimum, but LMRL could achieve that in almost any run. The EA's performance deteriorated significantly across the board.

So far, FMQ has done well when partnered with most other algorithms. But Table 3 shows a different result. Only one pair (LMRL-LMRL) efficiently solved this problem. But more importantly, *every method but EA did best by far when paired with itself.* In general, heterogeneous parings performed very poorly! Notably, while FMQ helped RL in the partially stochastic game, in the fully stochastic game FMQ *hinders* RL compared to RL-RL (and for that matter, FMQ-FMQ). That is to say, the claim in [6] that the "smarter" FMQ algorithm can help poorer RL find the optima must change to "FMQ helps RL to converge to the optimum *for this problem domain*, but hinders it in others."

5. CONCLUSIONS

We extended the work in [6] to include two new learning algorithms that exhibit lenience toward teammates, as well as a difficult coordination game characterized by stochastic rewards for every joint action. The experiments indicate that only the lenient multiagent reinforcement learning algorithm can achieve near-optimal performance, and only when paired with itself. A good learner cannot compensate if its teammate converges to a suboptimal action. Contrary to the findings in [6], we find that a pair of traditional RL algorithms performs better than both an FMQ-FMQ pair, as well as a combination of an FMQ and an RL learner. It is *not* the case that FMQ, or even the often-better LMRL, can compensate for a mismatched teammate algorithm.

The issue that remains is: are there well-defined classes of problems and subsets of learning algorithms for the teammate with which a given learning algorithms works well? For example, exactly where and why does FMQ pair well with various learners? This is not an easy question to answer, but investigation along these lines may reveal more clues about the relationship classes of algorithms have with one another, and why some features of algorithms may be at odds with features of other algorithms. Until then we must recommend a homogeneous approach to multiagent learning, if given the choice.

ABSTRACT
This paper presents an agent learning architecture based on the constructivist approach. After a brief introduction, we show details about the proposed model. Firstly, we explain how the agent represents the knowledge. We introduce an innovative learning method, inspired by the constructivist description of the human learning process. The kind of environment regularities that can be discovered by the method is analyzed. Finally, we discuss how an extension of this agent architecture can lead to the construction of abstract concepts.

1. INTRODUCTION
The Constructivist Artificial Intelligence comprises all works on this science that refer to the Constructivist Psychological Theory [6]. The constructivist conception of intelligence was brought to the field of Artificial Intelligence in the early 90's, by the Drescher's pioneer work [2]. Relevant related works have been presented in [1], [3] and [7]. This paper proposes an agent learning architecture based on the constructivist paradigm. Our model differs from the previous works because it is guided by direct induction, instead of statistical correlation. This approach has two advantages: reduces computational costs and makes it easier to find high-level deterministic regularities. A previous description of our research has been presented in [5].

2. KNOWLEDGE REPRESENTATION
Our constructivist agent tries to construct knowledge to represent perceived regularities occurring in the environment. This representation is structured in a set of schemas. Each schema represents some regularity checked by the agent during its interaction with the world. A schema is composed of three vectors: context, action and expectation. The context and expectation vectors have the same length, and each of their elements is linked with one sensor. The action vector has their elements linked with the effectors.

In a schema, the context vector represents the set of equivalent situations where the schema is applicable. The action vector represents a set of similar actions that the agent can carry out in the environment. The expectation vector represents the expected result after executing the given action in the given context. Each element vector can assume any value in a discrete interval defined by the respective sensor or effector. In addition, some elements can undertake an undefined value. For example, an element linked with a binary sensor must have one of three values: true, false or undefined (represented, respectively, by '1', '0' and '#'). The undefined value generalizes the schema because it allows ignoring some properties to represent a set of situations. For example, a schema which has the context vector = (100#) is able to assimilate the situations (1000) and (1001).

There is compatibility between a schema and a certain situation when the schema's context vector has all defined elements equal to those of the agent's perception. Compatibility does not compare the undefined elements. This strategy gives more flexibility when the agent needs to represent a set of world states as a same situation. So, there is no need of considering each possible perception combination, what reduces the problem complexity. The use of undefined values, and the consequent capability to create generalized representations to similar situations, enables the construction of a tree.

Each node in that tree is a schema, and relations of generalization and specialization guide its topology. The root node represents the most generalized situation, which has the context and action vectors completely undefined. Adding one level in the tree is to specialize one generalized element, creating a branch where the undefined value is replaced by different defined values. This specialization occurs either in the context vector or in the action vector. The structure of the schemas and their organization as a tree are presented in Figure 1.

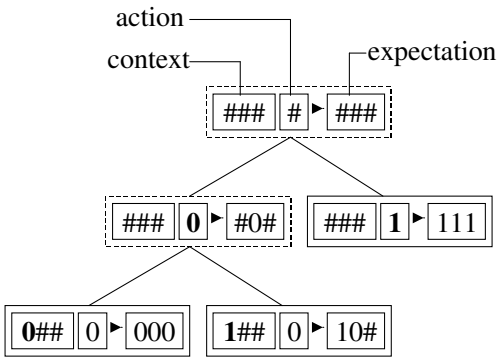

Figure 1. Schemas Tree. Each node is a schema composed of three vectors: context, action and expectation. The leaf nodes are decider schemas.

The context in which the agent is at a given moment (perceived through its sensors) is applied in the tree, exciting all the schemas that have a compatible context vector. This process defines a set of excited schemas, each one suggesting a different action to do in the given situation. The cognitive system chooses one to activate (based on an emotional value attributed to its expectations). Then the schema's action is performed (through the agent's effectors). This algorithm always chooses the compatible schema that has the most specific context, called "decider schema". Appended on each decider, there is a representation of the specific really experimented situations that happened in the past.

3. LEARNING METHODS

The learning process happens through the refinement of the set of schemas. The agent becomes more adapted to its environment as a consequence of that. After any situation, the agent's cognitive system checks if the result (context perceived at the instant following the action) is according to the expectation of the activated schema. If it fails in its prediction, the error between the result and the expectation serves as parameter either to correct the tree or to adjust the schema. If we consider context, action and expectation as a triple search space, then the learning problem is to induce a set of schemas in this search space that represents the environment regularities.

Our learning method combines top-down and bottom-up strategies. The context and action vectors are put together and this concatenated vector identifies the node in the schemas tree. The schemas tree grows up using the top-down strategy. The agent has just one initial schema. This root schema has the context vector completely general (without any differentiation) and expectation vector totally specific (without any generalization), created at the first situation experienced, according the result directly observed after the action. The context vector will be gradually specialized and differentiated. In more complex environments, the number of features the agent senses is huge, and, in general, only a few of them are relevant to identify the situation. The top-down strategy is better in this kind of environment, because it is a shorter way to begin with an empty vector and searching for these few relevant features, than to begin with a full vector and having to eliminate a lot of not useful elements. The expectation vector is equivalent to labels on the leaf nodes of the tree (called decider schemas).

The evolution of expectations uses the bottom-up strategy. Initially all different expectations are considered as different classes, and they are gradually generalized and integrated with others. The agent has two alternatives when the expectation fails. In a way to make the knowledge compatible with the experience, the first alternative is to try to divide the scope of the schema, creating new schemas with more specialized contexts. Sometimes it is not possible, then the only way is to reduce the schema expectation.

Three basic methods compose the learning function, namely: *differentiation*, *adjust* and *integration*. Differentiation is a necessary mechanism because a schema responsible for a too general context cannot have precise expectations. If a general schema does not work well, the mechanism divides it into new schemas, differentiating them by some perceptive element of context vector. In fact, the differentiation method takes an unstable decider schema and changes it into a two level sub-tree. The parent schema in this sub-tree preserves the context of the original schema. Its branches sustain the children, which are the new decider schemas. These deciders have their context vectors more specialized than their parent. They attribute a value to some undefined element dividing the scope of the original schema, each one engaging itself in a part of the domain. In this way, the previous correct knowledge remains preserved, distributed in the new deciders, and the discordant situation is isolated and treated only in its specific context. Differentiation is the method responsible to construct the schemas tree. Each level of the tree represents the introduction of some constraint into the context vector to describe compatible situations. Figure 2 illustrates the differentiation process.

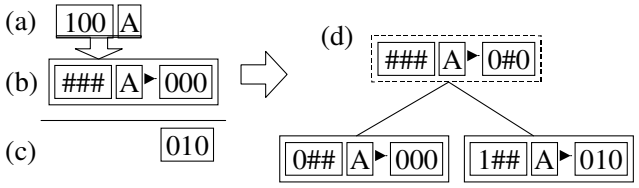

Figure 2. Differentiation method; (a) experimented situation and action; (b) activated schema; (c) real observed result; (d) sub-tree generated by differentiation.

The algorithm needs to choose what will be the differentiator element, and it could be from either the context vector or the action vector.

When some schema fails and it is not possible to differentiate it, then the cognitive system executes the adjust method. This method reduces the expectations of an unstable decider schema in order to make it more reliable. The algorithm simply compares the activated schema's expectation and the real result perceived by the agent after the application of the schema and changes the elements that are not compatible to each other for the undefined value '#'. As the mechanism always creates schemas with expectations totally determined and equal to the result of its first application, the walk performed by the schema is a reduction of expectations up to the point it reaches a state where only those elements that really represent the regular results of the action carried out in that context remain. Figure 3 illustrates that.

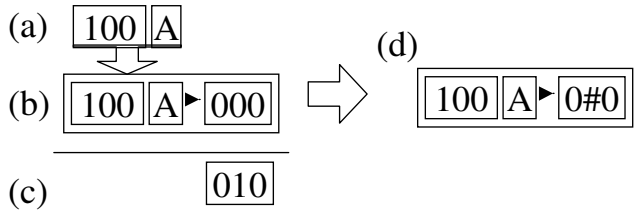

Figure 3. Adjust method; (a) experimented situation and action; (b) activated schema; (c) real observed result; (d) schema expectation reduction after adjust.

In this way, the schema expectation can change (and consequently the class of the situation represented by the schema), and the tree maintenance mechanism needs to be able to reorganize the tree when this change occurs.

Finally, successive adjustments in the expectations can reveal some unnecessary differentiations. When the cognitive system finds two schemas with similar expectations to approach different contexts, the integration method comes into action, joining these

schemas into only one, and eliminating the differentiation. The method operates as shown in figure 4.

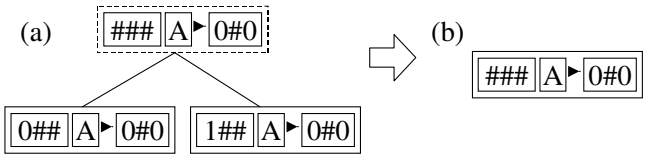

Figure 4. Integration method; (a) sub-tree after some adjust; (b) an integrated schema substitutes the sub-tree.

We have made some experiments in simple scenarios and exhaustive tests have shown that the agent ever converges to the expected behavior, constructing correct knowledge to represent the environment regularities, as well as the regularities of its body sensations, and also the regular influence of its actions over both. We may consider our results were successful, once the agent has learned about the consequences of its actions in different situations, avoiding emotionally negative situations, and pursuing those emotionally positive.

4. CONCLUSION AND FUTURE WORK

We have shown an agent architecture based on constructivist AI principles, which provides adaptive capability because the agent constructs its knowledge incrementally, by interaction with its environment. The agent has cognitive construction autonomy. We have presented a learning method composed by three functions: differentiation, adjust and integration. These functions operate over a schemas tree, which is transformed during the agent life in a way to describe the observed regularities of the world. Some experimental results have corroborated the mechanism ability to discover regularities and use this knowledge to adapt the agent behavior.

However, the learning method presented can be extended to be able to detect high-level regularities. Currently it can induce only stationary, deterministic, instantaneous and sensorimotor regularities. Therefore, we intend to introduce in our agent the following capabilities: temporal analysis, abstract concept creation, and probabilistic features. Furthermore, we want to improve the cognitive mechanism to chain the schemas, forming action sequences, and permitting the agent to create plans instead just reacting.

In the basic method, when some schema fails the first alternative is to differentiate it. If it is not possible, the mechanism repairs the schema by reducing its expectation. This alternative supposes that there is no regularity and the analyzed result is unpredictable. It is a possible explication to the fail, called "unpredictability hypothesis", but it is not necessarily true every time. In fact, there is no deterministic, instantaneous, sensorimotor regularity, but the agent must considering some alternative hypotheses, which represent other kind of regularities, and which can explain the fail.

First, the agent can postulate a “noise hypothesis”. It supposes that the error is caused by some perceptive noise, and it is a good explication to the schema’s fail if the error occurs with a very low frequency, and if the error is a random change in the element value. In this case, the best answer is to preserve the schema without modifications.

The second possible explication is the “stochastic regularity hypothesis” which says that a few different results are possible, each one with specific probabilities. The solution, if the hypothesis is right, is to create a special schema with stochastic expectations.

The third alternative is the “temporal context regularity hypothesis”. This resource permits the agent to perceive contexts distributed in the time, in addition to the capability of identifying regularities in the instantaneous perception. This hypothesis claims that is necessary to observe event sequences to explain the result of an action. It supposes that the result is a consequence of chained actions. The solution, in this case, is to utilize a special temporal schema, which improves the temporal window, analyzing more instants in the past to make its predictions.

The last option is the “abstract context regularity hypothesis”, which supposes that the error can be explained by considering the existence of some abstract property that is capable of differentiating the situation, but it cannot be directly perceived by the sensors. This abstraction requires the agent postulating the existence of a non-sensorial element. An abstract property in the agent's mind could represent two kinds of environment features: hidden properties (in partially observed worlds) and sub-environment identifiers (in non-stationary worlds).

With these new capabilities, the agent becomes able to overpass the sensorial perception constructing abstract concepts. By forming these new knowledge elements, the agent acquires new forms to structure the comprehension of its own reality in more complex levels.

After postulating these hypotheses, the agent needs to discover what of them is the correct one. It is not possible to do that a priori. The solution is to use a selectionist idea. During some time, the agent preserves all the hypotheses, and evaluates them. At the end, the best solution survives.

ABSTRACT

In this paper we propose a method for solving reinforcement learning problems in non-stationary environments. The basic idea is to create and simultaneously update multiple partial models of the environment dynamics. The learning mechanism is based on the detection of context changes, that is, on the detection of significant changes in the dynamics of the environment. Based on this motivation, we propose, formalize and show the efficiency of a method for detecting the current context and the associated model of prediction, as well as a method for updating each of the incrementally built models.

1. INTRODUCTION

Dealing with non-stationary environments has always been a difficult task for learning algorithms. Specifically, non-stationarity affects standard reinforcement learning (RL) methods in a way that forces them to continuously relearn the policy from scratch. Our goal in this paper is to complement model-based RL algorithms with a method for dealing with a class of non-stationary environments in which the dynamics obeys a set of restrictions.

The non-stationary environments that we deal with consist of those composed by several different stationary dynamics. We call each type of dynamics a *context* and assume that it can only be estimated by observing the transitions and rewards. Our method creates models for these contexts and determines how to switch to the most appropriate model *on-the-fly*. Partial models have been used for this purpose by other authors, such as Choi [1] and Doya [2]. However, their approaches require a fixed number of models, and thus implicitly assume that the approximate number of different environment dynamics is known *a priori*. Since this assumption is not always realistic, our method tries to overcome it by incrementally building new models.

2. MULTIPLE PARTIAL MODELS

Most RL problems are modeled as Markov Decision Processes (MDPs). MDPs are described by a set of states, $\mathcal{S}$, a set of actions, $\mathcal{A}$, a reward function $R(s,a) \rightarrow \Re$ and a probabilistic state transition function $T(s,a,s') \rightarrow [0,1]$. An experience tuple $\langle s,a,s',r \rangle$ denotes the fact that the agent was in state s, performed action a and ended up in s' with reward r. Given a MDP, the goal is to calculate the optimal policy π^*, which is a mapping from states to actions such that the future reward is maximized. In the next sections we assume that the reader is familiar with Q-Learning, a simple model-free RL algorithm, and with model-based Prioritized Sweeping. For more information, please refer to [3].

When dealing with non-stationary environments, both the model-free and the model-based RL approaches need to continuously relearn everything from scratch, since the policy which was calculated for a given environment is no longer valid after a change in dynamics. This causes a performance drop during the readjustment phase, and also forces the algorithm to relearn policies even for environment dynamics which have been previously experienced. Our hypothesis is that the use of multiple partial models makes the learning system capable of partitioning the knowledge into models, each model automatically assuming for itself the responsibility for "understanding" one kind of environment behavior. To each model, we assign a policy and a trace of prediction error of transitions and rewards.

3. RL WITH CONTEXT DETECTION

We propose that the creation of new models should be controlled by a continuous evaluation of the prediction errors generated by each partial model. In the following subsections we first describe how to learn contexts (i.e, estimate partial models), and then we show how to detect and switch to the most adequate model given a sequence of observations. Our method is called **RL-CD**, or Reinforcement Learning with Context Detection.

The class of non-stationary environments that we deal with is similar to the one studied by Hidden-Mode MDPs researchers [1]. We assume that the following properties hold: **1)** environmental changes are confined to a small number of contexts, which are stationary environments with distinct dynamics; **2)** the current context cannot be directly observed, but can be estimated according to the types of transitions and rewards observed; **3)** environmental context changes are independent of the agent's actions; and **4)** context changes are relatively infrequent.

3.1 Learning contexts

The mechanism for detecting context changes relies on a set of partial models for predicting the environment dynamics. A partial model m contains functions which estimate transition probabilities ($\hat{T}_m$) and rewards ($\hat{R}_m$). Standard model-based RL methods such as Prioritized Sweeping and Dyna can be used to compute the locally optimal policy $\pi_m(s)$.

Given an experience tuple $\varphi \equiv \langle s, a, s', r\rangle$, we update the current partial model m by adjusting its model of transition and rewards by $\Delta^{\hat{T}}_{m,\varphi}$ and $\Delta^{\hat{R}}_{m,\varphi}$, respectively. These adjustments are computed as follows:

$$\Delta^{\hat{T}}_{m,\varphi}(\kappa) = \frac{1}{\mathcal{N}_m(s,a)+1}\Big(\tau^{s'}_{\kappa} - \hat{T}_m(s,a,\kappa)\Big) \quad \forall \kappa \in \mathcal{S}$$

$$\Delta^{\hat{R}}_{m,\varphi} = \frac{1}{\mathcal{N}_m(s,a)+1}\Big(r - \hat{R}_m(s,a)\Big)$$

such that τ is the Kronecker Delta:

$$\tau^{s'}_{\kappa} = \begin{cases} 1, & \kappa = s' \\ 0, & \kappa \neq s' \end{cases}$$

The effect of τ is to update the transition probability $T(s,a,s')$ towards 1 and all other transitions $T(s,a,\kappa)$, for all $\kappa \in \mathcal{S}$, towards zero. The quantity $\mathcal{N}_m(s,a)$ reflects the number of times, in model m, action a was executed in state s. We compute $\mathcal{N}_m$ considering only a truncated (finite) memory of past M experiences:

$$\mathcal{N}_m(s,a) = min\Big(\mathcal{N}_m(s,a) + 1,\ M\Big) \tag{1}$$

A truncated value of $\mathcal{N}$ acts like a learning coefficient for $\hat{T}_m$ and $\hat{R}_m$, causing transitions to be updated faster in the initial observations and slower as the agent experiments more. Having the values for $\Delta^{\hat{T}}_{m,\varphi}$ and $\Delta^{\hat{R}}_{m,\varphi}$, we update the transition probabilities:

$$\hat{T}_m(s,a,\kappa) = \hat{T}_m(s,a,\kappa) + \Delta^{\hat{T}}_{m,\varphi}(\kappa), \quad \forall \kappa \in \mathcal{S} \tag{2}$$

and also the model of expected rewards:

$$\hat{R}_m(s,a) = \hat{R}_m(s,a) + \Delta^{\hat{R}}_{m,\varphi} \tag{3}$$

3.2 Detecting context changes

In order to detect context changes, the system must be able to evaluate how well the current partial model can predict the environment. Thus, an error signal is computed for each partial model. The *instantaneous error* is proportional to a *confidence value*, which reflects the number of times the agent tried an action in a state. Given a model m and an experience tuple $\varphi = \langle s, a, s', r\rangle$, we calculate the instantaneous error $e_{m,\varphi}$ and the confidence $c_m(s,a)$ as follows:

$$c_m(s,a) = \left(\frac{\mathcal{N}_m(s,a)}{M}\right)^2 \tag{4}$$

$$e_{m,\varphi} = c_m(s,a)\Big(\Omega(\Delta^{\hat{R}}_{m,\varphi})^2 + (1-\Omega)\sum_{\kappa\in\mathcal{S}} \Delta^{\hat{T}}_{m,\varphi}(\kappa)^2\Big) \tag{5}$$

where Ω specifies the relative importance of the reward and transition prediction errors for the assessment of the model's quality. Once the instantaneous error has been computed, the trace of prediction error E_m of the partial model is updated:

$$E_m = E_m + \rho\Big(e_{m,\varphi} - E_m\Big) \tag{6}$$

where ρ is the adjustment coefficient for the error.

The error E_m is updated after each iteration for every partial model m, but only the active model is corrected according to equations 2 and 3. A plasticity threshold λ is used to specify until when a partial model should be adjusted. When E_m becomes higher than λ, the predictions made by the model are considered sufficiently different from the real observations. In this case, a context change is detected and the model with lowest error is activated. A new partial model is created when there are no models with trace error smaller than the plasticity. The mechanism starts with only one model and then incrementally creates new partial models as they become necessary. Pseudo-code for RL-CD is presented in algorithm 1.

Algorithm 1 RL-CD algorithm

Let m_{cur} be the currently active partial model.
Let $\mathcal{M}$ be the set of all available models.
1: $m_{cur} \leftarrow newmodel()$
2: $\mathcal{M} \leftarrow \{m_{cur}\}$
3: $s \leftarrow s_0$, where s_0 is any starting state
4: **loop**
5: Let a be the action chosen, considering model m_{cur}
6: Observe next state s' and reward r
7: Update E_m, for all m, according to equation 6
8: $m_{cur} \leftarrow \arg\min_m (E_m)$
9: **if** $E_{m_{cur}} > \lambda$ **then**
10: $m_{cur} \leftarrow newmodel()$
11: $\mathcal{M} \leftarrow \mathcal{M} \cup \{m_{cur}\}$
12: **end if**
13: Update $\hat{T}_{m_{cur}}$ and $\hat{R}_{m_{cur}}$ (equations 2 and 3)
14: $\mathcal{N}_m(s,a) \leftarrow \min(\mathcal{N}_m(s,a)+1, M)$
15: $s \leftarrow s'$
16: **end loop**

The *newmodel*() routine is used to create a new partial model and initializes all estimates and variables to zero, except T_m, initialized with equally probable transitions. The values of parameters M, ρ, Ω and λ must be tunned according to the problem. Formal analytical investigation of these parameters is being developed but detailed discussions are not presented due to lack of space.

4. EMPIRICAL RESULTS

We now present some experiments which evaluate how well our system performs in non-stationary environments. The scenario used consists of a non-stationary toroidal grid of 15x15 cells. The agent is a cat whose goal is to catch a moving ball, which starts in a random column and row and can take one of following behaviors: **1)** moves to the left; **2)** moves to the right; **4)** moves down; or **3)** moves up.

The first experiment performed aims at testing the relative efficiency of classic model-free and model-based algorithms: Q-Learning (QL) and Prioritized Sweeping with Finite Memory (PS-M)[1]. The agent is trained for one of the ball behaviors at a time, until the algorithm converges to the optimal policy. After that, we change the environment dynamics by modifying the ball behavior and measure how fast each algorithm converges. It can be seen in figure 1 that, as the context changes, the time needed to recalculate the optimal policies, both in the model-free and the model-based approaches, is much superior to the convergence time of RL-CD. Even though PS-M performs better than Q-Learning, it still has to reestimate $\hat{T}$ after every context change. Our method, on the other hand, takes only a few steps until realizing that the context has changed. After that, it automatically selects the appropriate partial model for the new dynamics.

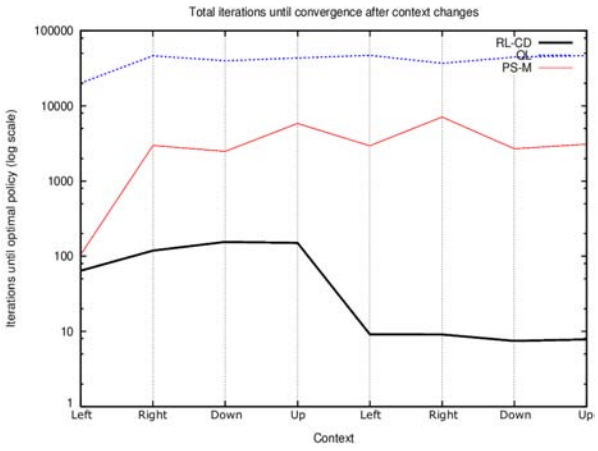

Figure 1: A comparison of convergence times for Q-Learning, PS-M and our approach.

It is also important to measure the average time the cat takes to catch the ball *while* the policy is being learned in a context. In order to implement this experiment, we runned the learning algorithms and changed the ball behavior 8 times. For each one of these, we performed 5 batches of 100 episodes, each episode corresponding to the cat being placed in a random place and running after the ball. We measured the average time of a batch as the average number of iterations needed to catch the ball during all episodes. The results are shown in figure 2.

In figure 2, vertical stripes are colored with different levels of gray, each indicating a different context. Each time the ball behavior changes, the average steps per episode grows (peaks in the graph), indicating that the algorithms take some time to relearn how to behave. During the first 4 contexts, our method is actually very similar to PS-M. However, as soon as the contexts begin to repeat, RL-CD is capable of acting optimally all the time, while the other algorithms present periods of relearning and suboptimal acting.

[1]We verified that standard PS requires exponential time to converge in non-stationary environments, and thus we designed and used **PS-M**, a modified PS with truncated memory instead of maximum likelihood estimation.

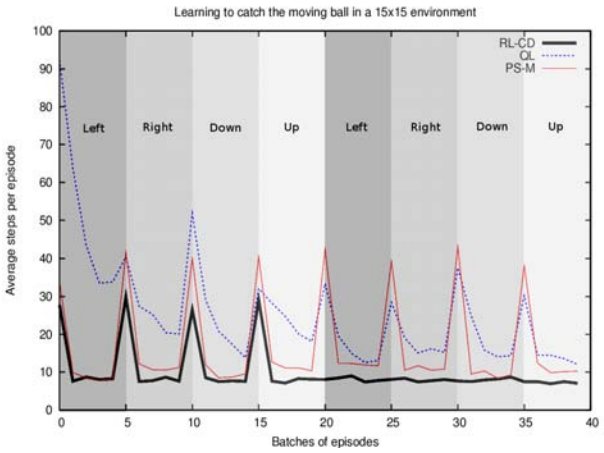

Figure 2: A comparison of performance for Q-Learning, PS-M and our approach.

From the empirical results discussed in this session we can imply that: **1)** our approach converges to the optimal policy much faster than classic model-free and model-based methods in non-stationary environments; and **2)** in our approach the readapting time is very small, which implies that the period of time with suboptimal acting is short.

5. CONCLUSIONS AND FUTURE WORK

In this paper we have introduced and formalized a simple method, called RL-CD, for solving reinforcement learning problems in non-stationary environments. We presented empirical results which show that both the classic model-free and model-based approaches have worse convergence times.

Formal analytical analysis of the RL-CD parameters is being developed, as well as a more detailed study regarding the trade-off between memory requirements and model quality in highly non-stationary environments. We are also studying the possibility of using context detection as a method for dimensionality reduction, since partial models might summarize the impact of a subset of hidden sensors which cause non-stationarity due to partial observations.

ABSTRACT
In this paper, we present an architecture for software agents that enables them to learn vocabulary through the observation of each other bodies and actions. Besides sensors, effectors, and action control, the architecture provides the equivalent of a body with visual appearance. The agent soft visual appearance is designed to be seen by other software agents, not by people. The paper describes the agent software body with visual appearance, the learning mechanism, the demonstration scenario and presents some results showing that the agent software body allows agents to learn vocabulary through observation and to ground the meaning of the symbols they learn. The paper emphasizes the important role of social interaction in learning processes.

1. INTRODUCTION
One of the most remarkable features of living bodies is their visual appearance, which enables them to communicate and to learn through mutual observation.

Having a body enables agents to benefit from the advantages embodiment accomplishes for living beings [1]. This work proposes a component based agent architecture with software visual appearance that enables agents to learn simple vocabulary (names of body parts and actions) through observation. This is a short version of the paper *"Software agents that Learn through observation"*[1]

[1] iscte.pt/~luis/papers/AAMAS2006Learning.pdf

Our work is centred on the problem of learning simple vocabulary (nouns and verbs) through observation. We have implemented some learning experiments that provided some evidence supporting the validity of our proposal. In our learning experiments there are only two agents: the Observed Agent, and the Observer agent. The Observer Agent learns the words spoken by the Observed Agent and grounds their meanings in its own body and actions using a vocabulary map. The Observed Agent shows parts of its body (e.g., hand) and executes simple actions (e.g., it shakes its hand) while it says words that represent nouns (e.g., "hand") or words that represent verbs (e.g., "shake") naming the shown body parts or executed actions. Nouns are related to parts of the body, verbs are related to actions of the body [3]. This process requires that agents have body that can be observed by other software agents.

The reminder of the paper is organized as follows. Section 2 describes related work. Section 3 describes the demonstration scenario, and the results that have been achieved in our learning experiments. Section 4 describes our proposal. Section 4.1 describes the component-based architecture which sensors, effectors, action control, Learning Mechanism, social skills, and soft visual appearance. Finally, in section 5, we present conclusions and describe future directions for further research.

2. RELATED WORK
Artificial Intelligence research was founded under the influence of classical cognitive theory and the issue of symbolic representation: the mind is a symbol system and cognition is symbol manipulation. Generation of complex behaviour through symbol manipulation was successfully demonstrated by classical artificial intelligence [4].

Modern cognitive science has reviewed old concepts of pure mental processes and started considering the importance of the body in cognitive processes. For modern AI researchers and philosophers, there cannot be intelligence without a body. Modern artificial intelligence researchers, like Tom Ziemke[1], Brooks[2], Kushmeric[5], Varela[7], and Mataric[6] have been studying the role of the body on the generation of intelligent behaviour in natural and artificial systems. Principles of software embodiment architectures have been proposed by Kushmeric [5], and Botelho and Figueiredo [1]. Kushmeric has developed a computational framework for analyzing embodiment and identified several ways embodiment may reduce the complexity of the methods used in the agent's tasks. Botelho and Figueiredo have proposed concrete architectural principles for embodied software agents [1], a class of software agent capable of exhibiting some of the beneficial roles embodiment accomplishes in living beings, such as facilitating learning processes and social interactions.

3. DEMONSTRATION SCENARIO

In our demonstration scenario, the observed and observer agents are anthropomorphic. Their bodies are composed of the following components: mouth (i.e., textual language effector), ear (i.e., textual language sensor), eye (static and dynamic visual sensor), hand, action control, learning mechanism, action capturing mechanism, vocabulary map, and graphic user interface. Even though they could have different bodies, we used two agents with identical bodies. The Observed Agent teaches two concepts: *hand* and *shake hand*. It shows its hand and says the word "hand", and it shakes its hand and says the phrase "shake hand". In the described experiments, "saying" and "hearing" are accomplished through the exchange of textual messages.

The proposed approach can be used for agents of different nationalities. Therefore it can be used in cases in which a French speaking agent needs to learn English or some other language. When learning the word "hand" and its meaning, the Observer Agent identifies two body parts as possible candidates to match the Observed Agent part that is named by the word "hand": *pied* (French word for foot) and *main* (French word for hand). Given the ambiguity, the Observer Agent asks the Observed Agent for help. The Observed Agent knows that *hand* is part of *arm* and *foot* is part of the *leg* therefore it can help the Observer Agent to choose the correct part. After disambiguating the meaning of the learnt word, the Observer Agent imitates the observed action: it shows its hand, generates the textual expression "*I have a hand*" and sends it to the Observed Agent. The Observed Agent recognizes the success of the learning experiment and sends a positive textual message to the Observer Agent. Finally, since the Observer Agent knows the learning has been successful, it creates an entry in its vocabulary map to the noun "hand" and its grounding: the source of information is the Observed Agent; the observer agent class for "hand" is called *hand*; and its own class for hand is called *main*.

In the second experiment, the Observed Agent shakes its hand and says the phrase "shake hand". The Observer Agent identifies its body parts *pied* and *main* as possible candidates to perform the action named by the phrase "shake hand". The Observed Agent knows that *hand* is part of *arm* and *foot* is part of *leg* therefore it can help the Observer Agent to choose the right part. Then, the Observer Agent performs the actions that can be done with the class *main*. This process ends when it determines that the action *agiter* (French word for "to shake") performed by its *main* matches the observed action (through the visual appearance of the Observed Agent). Therefore the Observer Agent shakes its hand, and generates the expression "To shake the hand" and sends it to the Observed Agent. This one recognizes that the learning process was successful hence it sends a positive textual message to the Observer Agent. Finally, the Observer Agent creates a new entry for the verb "to shake" and its grounding in its vocabulary map: the source of information is the Observed Agent; the observed agent class of the body part involved in the observed action is *hand*, its own class of the corresponding body part is *main*; the observed agent method that implements the action is called *shake*; and its own method that implements the observed action is called *agiter.*

These two learning experiments show that the proposed architecture can support simple forms of vocabulary learning through observation. The architecture supports both noun learning and verb learning. The experiments also emphasize the role of social interaction for disambiguating the result of the learning process. The experiments also show that the architecture enables the agent to ground the learnt symbols in its own body and actions. Although the used algorithms exhibit some limitations (e.g., they do not work for learning actions performed by several parts of the body), the general processes are independent of the agents specific make up. The same algorithms could have been applied to agents with FTP and SMTP sensors and effectors instead of hands and feet.

4. LEARNING SIMPLE VOCABULARY THROUGH OBSERVATION

The agent architecture supporting the described learning experiments includes the mechanisms required to create the software-equivalent to the agent visual appearance and the mechanisms required for learning through observation. The agent visual appearance can be seen (consulted) by its owner and by other agents.

4.1 Agent Architecture and Software Visual Appearance

The proposed agent architecture is a component-based architecture with several components providing the following functions: sensors, effectors, vocabulary map, control mechanism, learning mechanism, and software visual appearance (static composition and dynamic behavior).

Sensors support visual and textual language perceptions. Visual sensors are used to capture visual appearance while the textual language sensor is used to capture textual messages. The visual sensor captures dynamic and static information of the observed body. The learning mechanism is the algorithm used by the Observer Agent to learn through observation. The vocabulary map represents the words known to the agent together with their meanings. It grounds the meaning of each word through a relationship between known word and its type (verb / noun), the source of information from where the word was acquired (in our case, this is the identification of the Observed Agent or the special symbol *built-in*), the classes of the component named by the acquired words or the classes of the component that executed the action named by the acquired words (in the Observed Agent's body and in the Observer Agent's body), and the signatures of the methods of the agent program encoding the action named by the stored word (on the side of the observed agent and on the side of the observer agent). All these attributes are mandatory, except method signatures which are mandatory only when the type of word is verb.

The agent software visual appearance consists of static information regarding the composition of the agent body and dynamic information about the actions the agent executes. Software visual appearance (both static and dynamic information) is made publicly available to other agents by the agent software visual appearance component. The agent software visual appearance is a component that captures information regarding its static body composition, and information about its dynamic body actions. Static visual appearance includes information regarding the composition, properties and roles of the agent visible components. The information regarding the agent's components

and their roles is used by Observer Agents to create a static mental image of the parts integrating Observed Agents. This mental image is interpreted as the static visual appearance of the Observed Agent. Dynamic elements of the body are used by the Observer Agent to create a dynamic mental image of the actions of the Observed Agent. Dynamic visual image relates to what the agent is doing at each instant of time.

"Seeing another agent" means consulting its software visual appearance and performing the required inferences. The dynamic information maintained by the agent visual appearance is captured by a crosscutting mechanism called the Action Capturing Mechanism. The Action Capturing Mechanism captures all relevant elemental operations performed by the agent involving the visible parts of its body, including get and set operations (i.e., get and set the value of a visible attribute of any of the visible agent components), entry and exit operations (i.e., invoking and exiting a method that performs a visible action). Composite actions are made up of sequences of elemental actions therefore they can also be seen through the agent software visual appearance.

4.2 The Learning Mechanism

Learning is facilitated through textual interactions among the two agents. The Observed Agent initiates the interaction by showing a part or an action of its body, and saying a word naming the shown part or action. When the Observed Agent shows its body parts and actions, the relevant part/action is marked, in its soft visual appearance. Therefore the Observer Agent knows exactly what is being shown, and the Observed Agent does not need to have salience building mechanisms. In real life scenarios, learning vocabulary through observation would require that the Observed Agent would be capable of building salience on the parts and actions it shows because, when the Observer Agent looks at the Observed Agent body, it sees the whole body, not only the relevant parts and actions intended to be shown. We overcame this salience building problem through a simplification consisting of marking the salient parts of the visual appearance. The visual appearance does not contain the information about the type of word (noun or verb). There is no visual difference between showing a body part or perform an action: both are actions. The difference is given by the textual message said by the Observed Agent.

The Observer Agent triggers its learning mechanism when it hears and sees the Observed Agent showing its body parts or executed actions while saying its names. The Learning mechanism identifies the part of the body/action shown by the observed agent associating it to the heard word. It compares the observed part/action with its own body parts/action in order to select those that more closely mirror the observations. When the learning agent discovers the part or the action of its body matching the observations, it grounds the meaning of the learnt words in its own body and actions. When the Observer Agent learns a word, it generates sentences using the learnt word, using pre-coded sentence schemata and the vocabulary already mastered by the agent. The Observed Agent provides feedback regarding the accuracy of the learning results. When learning is perceived to be accurate, the Observed Agent generates a positive textual reaction. When learning is perceived to be inaccurate, the Observed Agent generates a negative textual reaction. This feedback allows the Observer Agent to know whether its learning was correct or incorrect.

5. CONCLUSION AND FUTURE WORK

The strongest contribution of this paper is to present a concrete software agent architecture exhibiting some of the features required to have a body with software visual appearance that can be seen by other software agents (not by people) through which it is possible to improve several cognitive tasks, in particular "learning simple vocabulary through observation". The proposed approach can be used to overcome some criticisms put forth against classical AI. Namely, through the proposed approach, it is possible for an agent to ground the meanings of acquired vocabulary. That is, in addition to being understood by third parties (agent designers and observers), learnt symbols acquire meaning to the agent itself. The proposed architecture and algorithms allow the agent to ground the meanings of the acquired vocabulary on the parts and actions of its body. This allows agents to create first person meanings for the symbols they process. The defined and implemented demonstration scenario shows that the proposed architecture and the used learning algorithms are general enough to support learning through observation in diverse application domains. The demonstration also shows that social interaction is an important condition for learning through observation. This is most apparent when the learning process generates ambiguity. The proposed learning process can also be used in different situations such as those in which an agent must learn a different communication language.

A direction for future work is to build the mechanisms necessary to increase the salience of the shown body parts and actions. We will explore the role of emotion as the basis for those processes.

ABSTRACT

In the context of pre-Bayesian games we analyze resource selection games with unknown number of players. We prove the existence and uniqueness of a symmetric safety-level equilibrium in such games and show that in a game with strictly increasing linear cost functions every player benefits from the common ignorance about the number of players. In order to perform the analysis we define safety-level equilibrium for pre-Bayesian games, and prove that it exists in a compact-continuous-concave setup; in particular it exists in a finite setup.

1. INTRODUCTION

In a *resource selection system*, Γ, there is a set of m resources, $j \in \{1, \cdots, m\}$. Each resource j is associated with a cost function $w_j : \{1, 2, \cdots, \cdots\} \to \Re$, where $w_j(k)$ is the cost for every user of resource j if there are k users. Together with a set of n players a resource selection system defines a game in strategic form– *a resource selection game*, $\Gamma(n)$. The action set[1] of every player i in $\Gamma(n)$ is the set of resources M, and the cost of i depends, via the resource-cost functions, on the resource she chooses and on the number of other players who choose this resource. Thus, resource selection games are special types of congestion games [23, 18]. A resource selection game is also referred to as a simple congestion game.[2] In many situations the assumption that every player knows the number of players is not reasonable. The goal of the current paper is to analyze resource selection games with unknown number of players. One approach for analyzing such situations is the Bayesian approach, where it is assumed that the distribution of the random set of players is commonly known. In this approach one is interested in Bayesian equilibrium. [3] The goal of this paper is to analyze resource selection games in the non-Bayesian setup in which the players do not have probabilistic information about the number of the other players in the game. We will use what we call pre-Bayesian games. A pre-Bayesian game is defined to be a Bayesian game without the state probability.[4]

In a classical pre-Bayesian game there is a fixed set of players $I = \{1, 2, \cdots, n\}$, each of them is endowed with a set of actions, $x_i \in X_i$. There is a set of states $\omega \in \Omega$. The payoff of player i, $u_i(\omega, x_1, x_2, \cdots, x_n)$ depends on the realized state, on her choice of action, x_i, and on the choices of all other players. However, the realized state is not known to the players. Every player receives a state-correlated signal, $t_i = \tilde{t}_i(\omega)$ on which she conditions her action. A pre-Bayesian game becomes a Bayesian game when a commonly known probability measure on the set of states is added to the system. The above description is not general enough for our purpose because the set of players is fixed. We generalize the model by allowing the set of active players as well as the action sets to depend on the state.

In pre-Bayesian games one can deal with ex-post equilibrium, which generalize the notion of dominant strategy

[1]When dealing with games in strategic form the choice set of a player is referred to as an action set or as a strategy set. We use "actions" rather than "strategies" because we keep the notion of strategy to describe the choice set of a player in "bigger" games.

[2]Simple congestion games and their generalization to player-specific games were discussed in [22, 16, 8, 27, 11]. Simple congestion games were also discussed in the price of anarchy literature, e.g., [12, 2]

[3]See [15, 14, 6] for such analysis in the context of auctions, and [19, 20, 21] for such analysis in the context of elections.

[4]Surprisingly, until recently such games did not have a name in the literature. Pre-Bayesian games have been also called *games in informational form* and *games without probabilistic information* [9, 7], *games with incomplete information with strict type uncertainty* [10], and *distribution-free games with incomplete information* [1].

equilibrium. Such equilibria rarely exist, and consequently only very special type of pre-Bayesian games have been discussed in Game Theory or in Computer Science. Hyafil and Boutilier (2004)[10] suggested minimax regret equilibrium as a solution to general pre-Bayesian games. In such equilibrium, every agent, after receiving her informational signal is using the minimax regret criterion in the decision making problem obtained by fixing the behavior of all other agents. They proved that such an equilibrium exists in every finite pre-Bayesian game. In this paper we define another type of equilibrium concept, safety level equilibrium. In such an equilibrium, every player, after receiving her informational signal use the maximin payoff (or minimax cost) criteria in the decision making problem obtained by fixing the behavior of all other agents. We use a more general definition of pre-Bayesian games and prove that a safety level equilibrium always exists. Independently, [1] also define safety level equilibrium. However, they restricted attention to a very particular information structure in which all players receive the same signal. All of the above mentioned existence results rely on Kakutani fixed point theorem, which is a standard tool in game theory for proving equilibria existence results.[5]

As we said, our main goal in this paper is to analyze resource selection games with unknown players, and we do it by analyzing safety-level equilibria in such games. However, for the sack of completeness we also define and prove existence of a third type of equilibrium, which is consistent with a large part of single agent setups of incomplete information in CS. We define competitive ratio equilibrium and prove that it exists.[6]

Once we have the right tool we proceed to analyze resource selection games with unknown number of players. We focus on a model with increasing resource cost functions. In order to derive results for the case in which the number of players is unknown we prove several results, some of them are interesting for themselves, about classical resource selection games with known number of players. In particular we prove that every resource selection game possesses a unique mixed-action symmetric equilibrium. When the number of players is k, the unique symmetric equilibrium mixed-action of every player is denoted by p^k. That is, $p^k = (p_1^k, p_2^k, \cdots, p_m^k)$, where p_j^k is the probability that a player chooses resource j.

In our pre-Bayesian model all active players know a common bound, n, on the number of active players, but the players do not know the true number of players, say k, $k \leq n$. Hence, the only signal a player receives is an "activity" signal. A state in this pre-Bayesian game is the set of active players. We prove that a resource selection game with unknown number of players has a unique symmetric safety level equilibrium. In this equilibrium, every active player is using the unique symmetric-equilibrium mixed-action, p^n in the game in which the number of players is commonly known and equals n.

Hence, when the number of players is k, every player uses p^k when the number of players is commonly known, and every player is using p^n when the number of players is unknown. Surprisingly, the lack of knowledge makes each of the players better off in the linear system, in which the resource cost functions are linear! That is, we show that in the linear model, when there are k players, and each of them is using p^n, the cost of each player is at most the cost he obtains in the unique symmetric equilibrium, p^k. Under very modest assumptions every player is strictly better off.

The above results are applicable to a mechanism design setup in which the organizer knows the number of active players, and the players do not know this number. If the goal of the organizer is to maximize revenue then he is better off revealing his private information.[7] If his goal is to maximize social surplus then he should not reveal the information. In order to estimate the gain of the players resulting from their ignorance we investigate in the last section the function $c^k(p^n)$ for $n \geq k$, where $c^k(p^n)$ is the cost for a player in a k-player setup when all players play the mixed-action associated with the symmetric equilibrium of the corresponding n-player setup.

2. BACKGROUND

We remark that games can be analyzed with either payoff functions or cost functions. Most of the general theory has been developed with payoff functions. However, congestion games have been mainly analyzed using cost functions. Translating results proved in one of the setups to the other setup is obvious in most cases.[8] We follow the tradition of previous literature in the sense that the general theory is discussed with payoff functions, while resource selection games are discussed with cost functions.

A game in strategic form is a tuple, $\Gamma = (I, (X_i)_{i\in I}, (u_i)_{i\in I})$. I is a nonempty set of players, X_i is a nonempty set of actions for player i, and $u_i : X \to \Re$ is the payoff function of i, where $X = \times_{i\in I} X_i$ is the set of action profiles. Hence $u_i(x)$ is the payoff of player i when the profile of actions $x \in X$ is played. Γ is a *finite* game if I and X are finite sets.

Let $x \in X$ denote a profile of actions. For each $i \in I$ we let $x_{-i} = (x_j)_{j\in I\setminus\{i\}}$ denote the actions played by everyone but i. Thus $x = (x_i, x_{-i})$. An action profile $x \in X$ is in *equilibrium* if $u_i(x_i, x_{-i}) \geq u_i(y_i, x_{-i})$ for every player $i \in I$ and for every $y_i \in X_i$.

A *permutation* of the set of players is a one-to-one function from I onto I. For every permutation π and for every action profile $x \in X$ we denote by πx the permutation of x by π. That is, $(\pi x)_i = x_{\pi(i)}$ for every player i. Γ is a *symmetric game* if $X_i = X_s$ for all $i, s \in I$, and

$$u_i(\pi x) = u_{\pi(i)}(x)$$

for every player i, for every action profile x, and for every permutation π. A *symmetric action profile* is an action profile x such that $x_i = x_s$ for every $i, s \in I$. x is *a symmetric equilibrium* if it is both an equilibrium profile and a symmetric action profile .

For any finite set C, $\Delta(C)$ denotes the set of probability distributions over C. Let $\Gamma = (I, (X_i)_{i\in I}, (u_i)_{i\in I})$ be a fi-

[5]We note that an equilibrium concept for specific types of pre-Bayesian games were already defined in [26, 25, 24] in the context of work on artificial social systems, and in [13], where another equilibrium concept is defined for particular pre-Bayesian auctions. Both groups of authors used versions of safety-level equilibrium.

[6]The competitive ratio approach is relatively common in computer science in the context of single agent decision problems (see e.g., [3]. A recent paper of [5] applies the notion of competitive equilibrium to a particular problem of online algorithms.

[7]This is indirectly related to the Linkage Principle, in auction theory [17].

[8]An exception is the price of anarchy theory.

nite game in strategic form. Every $p_i \in \Delta(X_i)$ is called a *mixed action* for i. $p_i(x_i)$ is the probability that player i plays action x_i. Every vector $p \in \Delta = \times_{i\in I}\Delta(X_i)$ defines a probability distribution over X; The probability, $p(x)$ of $x \in X$ is $\prod_{i\in I} p_i(x_i)$.

Let u_i^m be the expected payoff function defined on Δ by u_i. That is, $u_i^m(p) = E_p(u_i)$.

The game $\Gamma^m = (I, (\Delta(X_i))_{i\in I}, (u_i^m)_{i\in I})$ is called the *mixed extension* of Γ. A mixed action for player i in the game Γ is an action for player i in the game Γ^m.

A *mixed action equilibrium* in a finite game Γ is defined to be an equilibrium in Γ^m. It is well-known (see e.g, [4]) that every finite symmetric game in strategic form possesses a symmetric mixed action equilibrium.

3. RESOURCE SELECTION GAMES WITH KNOWN NUMBER OF PLAYERS

In a *resource selection system*, $\Gamma = (M, (w_j)_{j=1}^m)$ there is a set of resources, $M = \{1, \cdots, m\}$, $m \geq 1$. Every resource j is associated with a cost function $w_j : \{1, 2, \cdots\} \to \Re$. $w_j(k)$ is the cost for every user of resource j if there are k users. Together with the set of players $I_n = \{1, \cdots, n\}$ a resource selection system defines a game in strategic form– *a resource selection game* $\Gamma(I)$. In this paper only the number of players will be relevant (and not the "names" of the players) and therefore we will denote a resource selection game by $\Gamma(n)$. The action set of every player i in $\Gamma(n)$ is the set of resources M, and the cost of i depends on the resource she chooses and on the number of other players that choose this resource via the resource-cost functions. That is, $X_i^n = M$ for every $1 \leq i \leq n$, and $c_i^n(x) = w_{x_i}(\sigma_{x_i}(x))$, where for every resource j and for every action profile $x \in \times_{i=1}^n X_i^n = M^n$, $\sigma_j(x)$ is the number of all players s for which $x_s = j$. Obviously every resource selection game is a finite symmetric game.

Let $p \in \Delta(M)$ be a mixed action of an arbitrary player. That is, $p = (p_1, \cdots, p_m)$, where p_j is the probability that a player who uses the mixed action p will select resource j. We denote the support of p by $supp(p)$. That is $supp(p) = \{j \in M | p_j > 0\}$. Denote by $c^n(p, j)$ the expected cost of a player that chooses resource j when each of the other $n-1$ players in $\Gamma(n)$ is using p. Let $c^n(p)$ be the expected cost of every player when each of the n players in $\Gamma(n)$ is choosing p.

For every $n \geq 1$, and for every $0 \leq \alpha \leq 1$. Let $Y_\alpha^n \sim Bin(n, \alpha)$ be a binomial random variable. That is, $f_\alpha^n(k) = P(Y_\alpha^n = k) = \binom{n}{k}\alpha^k(1-\alpha)^{n-k}$ for every $0 \leq k \leq n$. Let $F_\alpha^n(k) = P(Y_\alpha^n \leq k)$ be the distribution function of Y_α^n. Obviously

$$c^n(p, j) = E(w_j(1 + Y_{p_j}^{n-1})), \quad (1)$$

where E stands for the expectation operator. That is,

$$c^n(p, j) = \sum_{s=0}^{n-1} w_j(s+1) f_{p_j}^{n-1}(s). \quad (2)$$

Let $(q, \cdots, q) \in \Delta(M)^n$ be a symmetric mixed-action equilibrium profile in $\Gamma(n)$. We will refer to q as a *symmetric-equilibrium action.*

THEOREM 1. *Every resource selection game with at least two players ($n \geq 2$) with increasing* [9] *resource cost functions possesses a unique symmetric mixed-action equilibrium.*

[9]That is, $w_j(k) < w_j(k+1)$ for all j and k.

In order to prove Theorem 1 we need some preparations. The proof of the following lemma is given in the full version.

LEMMA 1. *Let $n \geq 1$. $F_\alpha^n(k)$ is a strictly decreasing function of α for every $0 \leq k \leq n-1$.*

LEMMA 2. *Let $\Gamma(n)$, $n \geq 2$ be a resource selection game. Let $q, p \in \Delta(M)$ be mixed actions, and let $j \in M$ be a resource such that w_j is increasing in $\{1, 2, \cdots, n\}$. If $p_j > q_j$ then $c^n(p, j) > c^n(q, j)$.*

PROOF. We have to show that $c^n(p, j)$ is increasing in p_j. By manipulating (2)

$$c^n(p, j) =$$

$$\sum_{k=1}^{n-1}\left((w_j(k) - w_j(k+1))\sum_{l=0}^{k-1} f_{p_j}^{n-1}(l)\right) +$$

$$w_j(n)\sum_{l=0}^{n-1} f_{p_j}^{n-1}(l) =$$

$$w_j(n) - [\sum_{k=1}^{n-1}(w_j(k+1) - w_j(k))F_{p_j}^{n-1}(k-1)],$$

where the last equality follows from the fact that $\sum_{k=0}^{n-1} f_{p_j}^{n-1}(k) = 1$.

By lemma 1, $F_{p_j}^{n-1}(k)$ is strictly decreasing in p_j for every $k = 0, ..., n-2$.In addition, w_j is strictly increasing, and therefore $c^n(p, j)$ is strictly increasing in p_j. □

Proof of Theorem 1

Suppose in negation that there is more than one mixed-action symmetric equilibrium in $\Gamma(n)$. Let q and p be two symmetric equilibrium actions with $p \neq q$. Since $p \neq q$ there exists $j \in M$ with $q_j \neq p_j$. W.l.o.g $q_j > p_j$. Therefore there exist a resource $r \in M$ such that $r \neq j$ and $q_r < p_r$. We get a contradiction from the following sequence of inequalities: $c^n(q, j) > c^n(p, j) \geq c^n(p, r) > c^n(q, r) \geq c^n(q, j)$, where the strict inequalities hold hold by Lemma 2 and the other inequalities hold because q and p are equilibrium actions. □

For every $n \geq 1$ we will denote the unique symmetric equilibrium in $\Gamma(n)$ by p^n, and we denote by $c^n = c^n(p^n)$ the equilibrium cost of a player in $\Gamma(n)$.

We say that a resource cost function w_j is *convex* if it can be extended to a convex function on $[1, \infty)$.

The following lemma will be useful later.

LEMMA 3. *Let $\Gamma = (m, (w_j)_{j=1}^m)$ be a resource selection system, with increasing and convex cost functions. There exists an integer $N \geq 2$, $N = N(\Gamma)$ such that for every $n \geq N$, the unique symmetric-equilibrium action in the game $\Gamma(n)$, $p^n \in \Delta(M)$ has a full support. That is, $p_r^n > 0$ for every $1 \leq r \leq m$.*

PROOF. Recall that p^n is the unique symmetric-equilibrium action in $\Gamma(n)$, and that $c^n = c^n(p^n)$ is the symmetric-equilibrium cost of every player. As p^n is in equilibrium, $c^n(p^n, j) = c^n$ for every $j \in supp(p^n)$. For every resource j we denote by w_j the convex extension of w_j to $[0, \infty)$. As w_j is convex,

$$c^n(p^n, j) = E(w_j(1 + Y_{p_j^n}^{n-1})) \geq w_j(1 + E(Y_{p_j^n}^{n-1})) =$$

$$w_j(1 + p_j^n(n-1)),$$

where the first equality follows from (1), the inequality follows from the convexity of w_j, and the last equality follows from the well-known fact that

$$E(Y_\alpha^n) = \alpha n. \quad (3)$$

Obviously, there exists $j \in supp(p)$ for which $p_j^n \geq \frac{1}{m}$. For this resource j

$$c^n = c^n(p^n, j) \geq w_j(1 + \frac{1}{m}(n-1)) \geq$$

$$\min_{r=1}^{m} w_r(1 + \frac{1}{m}(n-1)).$$

Since w_j is increasing and convex, $\lim_{n\to\infty} w_j(n) = \infty$ for every resource j. Therefore $\lim_{n\to\infty} c^n = \infty$. Hence, there exists N such that for every $n \geq N$ $c^n > \max_{j=1}^m w_j(1)$. We claim that for every $n \geq N$, $p_r^n > 0$ for every $1 \leq r \leq m$. Indeed, if $p_r^n = 0$ for some r then because $c^n > w_r(1)$, a player will decreases her cost by deviating from p^n to r (assuming every other player is using p^n). This contradicts p^n being a symmetric-equilibrium action. □

4. EQUILIBRIUM IN PRE-BAYESIAN GAMES

In this section we define a general model of pre-Bayesian games, and present and prove existence results for safety-level, and competitive-ratio equilibria in such games. We also give the definition of minimax-regret equilibrium (existence proved by Hyafil and Boutilier [10]).

A *pre-Bayesian game* is a tuple $H = (\Omega, I, (Z_i)_{i\in I}, J, (X_i)_{i\in I}, (u_i(\omega, *)_{\omega\in\Omega, i\in I}, (T_i)_{i\in I})$, where,

- Ω is a set of *states*.
- I is a finite set whose elements are called *potential players*.
- $J : \Omega \to 2^I \setminus \{\emptyset\}$ is the function determining the set of active players. That is, i is *active* at ω if $i \in J(w)$.

  Let Ω_i be the subset of states at which i is active. That is, $\Omega_i = \{\omega \in \Omega | i \in J(w)\}$.
- Z_i is the set of potential actions of i.

  Only a subset of Z_i will be available to i at a given state.
- For every potential player i, $X_i : \Omega_i \to 2^{Z_i} \setminus \{\emptyset\}$ is the variable determining the set of actions that are available for i at ω.

  Let $X(\omega) = \times_{i\in J(\omega)} X_i(w)$ be the set of action profiles that can be generated at ω.
- For every potential player i, and for every $\omega \in \Omega_i$, $u_i(\omega, *) : X(\omega) \to \Re$ is the *payoff function* of i at the state ω.
- T_i is the set of possible signals that i may receive.

  We will sometimes follow the traditional approach in economics and refer to $t_i \in T_i$ as a *type* of i.
- $\tilde{t}_i : \Omega_i \to T_i$ is the *signaling function of* i.

  That is, whenever i is active at ω she receives the signal $\tilde{t}_i(\omega)$.

  Without loss of generality we assume that every type is possible. That is, $\tilde{t}_i(\Omega_i) = T_i$.

  Let $\Omega_i(t_i)$ be the set of all states ω that generate the type t_i. That is, $\Omega_i(t_i) = \{\omega \in \Omega_i | \tilde{t}_i(\omega) = t_i\}$.
- $\tilde{t}_i(\omega) = \tilde{t}_i(\omega')$ implies $X_i(\omega) = X_i(\omega')$.

  That is, players know their set of actions; In other words, X_i is a constant function over $\Omega_i(t_i)$ for every $t_i \in T_i$.

  This assumption allows us to define the set of available actions for i when his type is t_i. Indeed we define $X_i(t_i) = X_i(\omega)$ for any arbitrary $\omega \in \Omega_i(t_i)$.

The pre-Bayesian game proceeds as follows. Nature chooses $\omega \in \Omega$, and the game in strategic form $\Gamma(\omega) = (J(w), (X_i(\omega))_{i\in J(\omega)}, (u_i(\omega, *))_{i\in J(\omega)})$ is played. Every active player in the game, $i \in J(\omega)$ receives the signal $\tilde{t}_i(\omega)$, which reveals part of the information about the game. The minimal information is the set of available actions at ω. Thus, every $i \in J(\omega)$ chooses $x_i \in X_i(\omega)$ and his payoff is $u_i(\omega, x)$, where $x = (x_i)_{i\in J(\omega)}$.

A *strategy* for a potential player i in the pre-Bayesian game H is a function $s_i : T_i \to Z_i$ that satisfies: $s_i(t_i) \in X_i(t_i)$ for every $t_i \in T_i$. Hence, i follows the strategy s_i if whenever he is active and receives the signal t_i he chooses the action $s_i(t_i)$. The set of strategies of i is denoted by $\Sigma_i = \Sigma_i(H)$, and the set of strategy profiles is denoted by $\Sigma = \Sigma(H)$, that is $\Sigma = \times_{i\in I}\Sigma_i$.

Let H be a pre-Bayesian game. We say that H is *finite* if the set of states, and the sets of potential actions are finite.

We say that H is a *compact-continuous pre-Bayesian game* if the set of states are finite, Z_i is a compact subset of some Euclidean space[10], $X_i(t_i)$ is a compact subset of Z_i for every type t_i, and $u_i(\omega, *)$ is continuous on $X(\omega)$ for every $\omega \in \Omega_i$.

A compact continuous pre-Bayesian game is *(quasi) concave* if Z_i is a convex set, $X_i(t_i)$ is a convex subset of Z_i for every type t_i, and $u_i(\omega, *, x_{-i})$ is (quasi) concave on $X_i(\omega)$ for every $\omega \in \Omega_i$ and every $x_{-i} \in X_{-i}(\omega)$.

Let $H = (\Omega, I, (Z_i)_{i\in I}, J, (X_i)_{i\in I}, (u_i(\omega, *)_{\omega\in\Omega, i\in I}, (T_i)_{i\in I})$ be a finite pre-Bayesian game. We are about to define the mixed extension, H^m of H by allowing every active player at $\omega \in \Omega$ to choose a mixed action $\mu_i \in \Delta(X_i(\omega))$. However we need the following definition.

For every $\omega \in \Omega_i$ let $\Delta_i(\omega)$ be the set of all probability distributions $\mu_i \in \Delta(Z_i)$ that vanishes outside $X_i(\omega)$. Obviously, $\Delta_i(\omega)$ can be identified with $\Delta(X_i(\omega))$.

The pre-Bayesian game $H^m = (\Omega, I, (\Delta(Z_i))_{i\in I}, J, (\Delta_i)_{i\in I}, (u_i^m(\omega, *)_{\omega\in\Omega, i\in I}, (T_i)_{i\in I})$ is called the *mixed extension* of H, where $u_i^m(\omega, *)$ is the expected-payoff function defined by u_i. Obviously, H^m is a concave pre-Bayesian game. Every strategy of i in H^m is called a *mixed-strategy for i in H*.

4.1 Safety-level Equilibrium

Let H be a compact-continuous pre-Bayesian game. For every profile, $s \in \Sigma$ of strategies in H, and for every state ω we denote by $s[\omega]$ the profile of actions chosen in $X(w)$ when

[10]Or of some linear topological space.

every player i uses s_i. That is, $s[\omega] = (s_j(\tilde{t}_j(\omega))_{j\in J(\omega)}$. As usual, $s_{-i}[\omega]$ is obtained from $s[\omega]$ by removing the action chosen by i.

Let $i \in I$, $t_i \in T_i$, $x_i \in X_i(t_i)$, and let $s_{-i} = (s_j)_{j\in I\setminus i}$ be a profile of strategies of all players but i. The worst case cost of i is

$$W_i(t_i, s_{-i}, x_i) = \min_{\omega\in\Omega_i(t_i)} u_i(\omega, x_i, s_{-i}[\omega]).$$

Obviously $W_i(t_i, s_{-i}, *)$ is continuous on $X_i(t_i)$. We say that $x_i^* \in X_i(t_i)$ is *optimal* for type t_i given s_{-i} if the maximal value of $W_i(t_i, s_{-i}, x_i)$ over $x_i \in X_i(t_i)$ is attained at x_i^*. A strategy of player i, s_i, is a *safety-level best-response to* s_{-i} if for every type t_i, $s_i(t_i)$ is optimal for t_i given s_{-i}. A strategy profile $s = (s_i)_{i\in I}$ is called a *safety-level equilibrium* if for every i, s_i is a safety-level best-response to s_{-i}.

Hence, s is a safety-level equilibrium if and only if for every ω, and for every player i, which is active at ω, $s_i(\tilde{t}_i(\omega))$ is optimal for $\tilde{t}_i(\omega)$ given s_{-i}.

A safety-level equilibrium in a pre-Bayesian game with exactly one state is simply a Nash equilibrium in this game. We next show that safety-level equilibria exist in every quasi concave game.

THEOREM 2. *Every quasi concave pre-Bayesian game possesses a safety-level equilibrium.*

PROOF. Note that for every i Σ_i is a closed convex and compact subset of $Z_i^{T_i}$. Therefore Σ is a closed convex and compact set because it is a cartesian products of such sets. For every $s \in \Sigma$ and for every $i \in I$ let $B_i(s) \subseteq \Sigma_i$ be the set of all $d_i \in \Sigma_i$, which are best response to s_{-i}. Let $B(s) = \times_{i\in I} B_i(s) \subseteq \Sigma$. It is standard to check that the correspondence $s \to B(s)$ satisfies the conditions of Kakutani's fixed point theorem. That is, it is upper hemicontinuous, and $B(s)$ is a nonempty compact convex subset of Σ for every $s \in \Sigma$. Therefore there exists a fixed point s^*, that is, $s_i^* \in B_i(s^*)$ for every $i \in I$. Obviously such a fixed point is a safety-level equilibrium. □

Hence, if H is a finite game, H^m possesses a safety-level equilibrium. Every such an equilibrium is called a *mixed-strategy safety-level equilibrium* in H.

4.2 Minimax-regret Equilibrium

Minimax-regret equilibrium was defined by Hyafil and Boutilier in [10]. We use their definition for our general model of pre-Bayesian games.

Let H be a compact-continuous pre-Bayesian game. Let $i \in I$, $t_i \in T_i$ and let $s_{-i} = (s_j)_{j\in I\setminus i}$ be a profile of strategies of all players but i. Let $\omega \in \Omega_i(t_i)$. The *regret* of $x_i \in X_i(t_i)$ at w is defined as:

$$R(x_i, w, t_i, s_{-i}) =$$

$$\max_{z_i\in X_i(t_i)} [u_i(w, z_i, s_{-i}[\omega]) - u_i(w, x_i, s_{-i}[\omega]]].$$

The *maximal regret* of $x_i \in X_i(t_i)$ over all $\omega \in \Omega_i(t_i)$ is denoted by $MR(x_i, t_i, s_{-i})$. That is:

$$MR(x_i, t_i, s_{-i}) = \max_{\omega\in\Omega_i(t_i)} R(x_i, w, t_i, s_{-i}).$$

We say that $y_i \in X_i(t_i)$ is a minimax regret strategy at t_i given s_{-i} if the minimal value of $MR(x_i, t_i, s_{-i})$ over $x_i \in X_i(t_i)$ is attained at y_i. A strategy s_i is a minimax regret best response to s_{-i} if for every type t_i, $s_i(t_i)$ is a minimax regret strategy at t_i given s_{-i}. s is a *minimax regret equilibrium* if for every player i s_i is a minimax regret best response to s_{-i}. In [10] the authors show:

THEOREM 3 (HYAFIL AND BOUTILIER). *Every quasi concave pre-Bayesian game possesses a minimax-regret equilibrium.*

4.3 Competitive Ratio Equilibrium

Competitive ratio equilibrium resembles the minimax-regret equilibrium. They differ only in the definition of regret.

Let H be a compact-continuous pre-Bayesian game, where all payoff functions are positive. Let $s_{-i} = (s_j)_{j\in I\setminus i}$ be a profile of strategies of all players but i, let t_i be an active type of i, and let $\omega \in \Omega(t_i)$. Replace the definition of $R(x_i, w, t_i, s_{-i})$ in the previous section with the following:

$$\hat{R}(x_i, w, t_i, b_{-i}) = \max_{z_i\in X_i(t_i)} \frac{u_i(w, z_i, s_{-i}[\omega])}{u_i(w, x_i, s_{-i}[\omega])}.$$

Note that $\hat{R}$ is well defined since all payoff functions are positive. A strategy profile s is a competitive-ratio equilibrium if for every player i s_i is a minimax-regret best response to s_{-i} with respect to the regret function $\hat{R}$.

THEOREM 4. *Every quasi concave game in pre-Bayesian game with positive payoffs functions possesses a competitive ratio equilibrium.*

The proof follows from Theorem 3 by applying the logarithmic function to the payoff functions.

5. RESOURCE SELECTION GAMES WITH UNKNOWN NUMBER OF PLAYERS

Consider a fixed resource selection system, Γ with the set of resources $M = \{1, \cdots, m\}$, $m \geq 1$, and resource cost functions $(w_j)_{j=1}^m$.

We proceed to describe our model of resource selection games with unknown number of players. Let $I = \{1, 2, \cdots, n\}$, $n \geq 1$. be the set of potential players. The set of states, Ω is the set $2^I \setminus \{\emptyset\}$ of all nonempty subsets of I. The set of active players at state K is K itself. That is $J(K) = K$ for every $K \in \Omega$. The set of actions of player i is the set of resources. That is, $Z_i = M$ for every player i. The set of types of $i \in I$ is a singleton, $T_i = \{active\}$. That is, an active player knows that he is active. The non-active players do not receive any signal. For every player $i \in I$ and every $\omega \in \Omega_i$ $X_i(\omega) = M$. For every $i \in I$ and for every $K \in \Omega$ such that $i \in K$ the cost function of i $c_i(K, *) : Z \to \Re$ is defined by $c_i(K, z) = w_{z_i}(\sigma_{z_i}^K(z))$, where $\sigma_{z_i}^K(z)$ is the number of all players $l \in K$ for which $z_l = z_i$. The above pre-Bayesian game is finite. We denote its mixed extension by $H_\Gamma(n)$, and we referred to $H_\Gamma(n)$ as a *resource selection game with unknown number of players*. A strategy of player i in $H_\Gamma(n)$ can be described by a mixed action $q[i] \in \Delta(M)$. That is, when receiving the signal $\{active\}$, i uses $q[i]$. Since we deal with costs and not with payoffs we use minimax rather than maximin in the definition of safety-level equilibrium. let $\mu = (q[1], \cdots, q[n])$ be a strategy profile in $H_\Gamma(n)$, and let i be a player. Let $\mu[-i] = (q[l])_{l\in I\setminus\{i\}}$ be the profile of strategies of the other players. Observe that Ω_i is the set of all nonempty subsets of I that contain i. If all cost functions are non-decreasing, and if i believes that all other players

are using the profile $q[-i]$, then it is obvious that the worst case scenario for i is obtained in the state I. Thus we have:

LEMMA 4. *Let Γ be a resource selection system in which the resource cost functions are non-decreasing. Let $\mu \in \Delta(M)^n$. μ is a safety-level equilibrium in $H_\Gamma(n)$ if and only if μ is a mixed-action equilibrium in $\Gamma(n)$.*

PROOF. Assume μ is a mixed-action equilibrium in $\Gamma(n)$. Let i be an active player. By the comment we made before the statement of the lemma,

$$\min_{p[i]\in\Delta(M)} \max_{K\in\Omega_i} c_i(K, p[i], \mu[-i]) =$$

$$\min_{p[i]\in\Delta(M)} c_i(I, p[i], \mu[-i]).$$

Because μ is a mixed-action equilibrium in $\Gamma(n)$, the min in the right hand-side of the above formula is attained at $q[i]$. Therefore μ is a safety-level equilibrium in $H_\Gamma(n)$. An analogous argument proves the if part of the lemma. □

THEOREM 5. *Let Γ be a resource selection system in which the resource cost functions are non-decreasing. $H_\Gamma(n)$ has a unique symmetric safety-level equilibrium. In this symmetric safety-level equilibrium every player is using the strategy p^n, where p^n is the unique symmetric-equilibrium action in $\Gamma(n)$.*

PROOF. The proof follows directly from Theorem 1 and Lemma 4. □

By Theorem 5, each of the players in $H_\Gamma(n)$ is using the strategy p^n, where p^n is the unique symmetric-equilibrium mixed action in $\Gamma(n)$. However, the cost of each active player in $H_\Gamma(n)$ is not $c^n = c^n(p^n)$, it depends on the true state. If the true state is K, that is K is the set of active players, and $|K| = k$, the cost of each active player i is $c^k(p^n)$. It is worthy to compare this cost with the cost $c^k = c^k(p^k)$ that every player in K would have paid had the players in K known the state. We make these comparison in linear models. We say that a resource selection system is *linear* if for every resource j there exists a constant d_j such that $w_j(k) = w_j(1)+(k-1)d_j$ for every $k \geq 1$. For every number of players, n, the associated resource selection game, $\Gamma(n)$, as well as the associated resource selection game with unknown player set, $H_\Gamma(n)$ will be called *linear* too. Note that in a linear system, w_j is increasing if and only if $d_j > 0$, and w_j is non-decreasing if and only if $d_j \geq 0$.

THEOREM 6. *Let Γ be a linear resource selection system with increasing resource cost functions. For every $k \geq 2$ let p^k be the unique symmetric equilibrium in $\Gamma(k)$. There exist an integer $N = N(\Gamma)$, $N \geq 2$ such that for all $n > k \geq N$:*

1. *$c^k(p^k) \geq c^k(p^n)$.*
2. *All inequalities above are strict if and only if there exists $j_1, j_2 \in M$ such that $w_{j_2}(1) \neq w_{j_1}(1)$*

PROOF. 1. Let $j \in M$. By lemma 3 there exist an integer N such that for every $n \geq N$ the unique symmetric equilibrium of $\Gamma(n)$ has full support. By (1) and (3), $c^k = c^k(p^k) = w_j(1) + (k-1)d_j p_j^k$ for every $k \geq N$. Let n, k be integers such that $n > k \geq N$. We begin by showing that $c^k(p^k) \geq c^k(p^n)$. Let $c^k = c^k(p)$.

$$c^k(p^n) = \sum_{j=1}^m p_j^n c^k(p^n, j) = \sum_{j=1}^m p_j^n [c^n - (n-k)d_j p_j^n] =$$

$$c^n - (n-k)\sum_{j=1}^m d_j (p_j^n)^2. \quad (1)$$

It remains to show that

$$c^n - c^k \leq (n-k)\sum_{j=1}^m d_j (p_j^n)^2 \quad (2)$$

We have

$$p_j^n = \frac{c^n - w_j(1)}{d_j(n-1)}, \quad p_j^k = \frac{c^k - w_j(1)}{d_j(k-1)}.$$

Let $A = \sum_{j=1}^m \frac{1}{d_j}$ and $B = \sum_{j=1}^m \frac{w_j(1)}{d_j}$. Since

$$\sum_{j=1}^m p_j^k = \sum_{j=1}^m p_j^n = 1$$

we have that $c^n = \frac{(n-1)+B}{A}$ and $c^k = \frac{(k-1)+B}{A}$. Hence

$$c^n - c^k = \frac{n-k}{A}.$$

Together with (2) it remains to show that

$$A\sum_{j=1}^m d_j (p_j^n)^2 \geq 1.$$

Let $L = \sum_{j=1}^m \frac{(w_j(1))^2}{d_j}$. We have

$$A\sum_{j=1}^m d_j (p_j^n)^2 = A\sum_{j=1}^m \frac{(c^n - w_j(1))^2}{d_j(n-1)^2} =$$

$$\frac{A}{(n-1)^2}[(c^n)^2 A - 2c^n B + L] =$$

$$\frac{1}{(n-1)^2}[((n-1)+B)^2 - 2((n-1)+B)B + LA] =$$

$$\frac{1}{(n-1)^2}[(n-1)^2 - B^2 + LA] = 1 - \frac{B^2 - LA}{(n-1)^2}. \quad (3)$$

It remains to show that $LA - B^2 \geq 0$. This is immediate since for every couple of resources $j, r \in M$ such that $j \neq r$, $(w_j(1))^2 + (w_r(1))^2 \geq 2w_j(1)w_r(1)$.

2. Observe that equality holds if and only if $w_j(1) = w_r(1)$ for every $j, r \in M$.

□

Theorem 6 is applicable to a mechanism design setup in which the organizer knows the number of active players, and the players do not know this number. If the goal of the organizer is to maximize revenue then he is better off revealing his private information. If his goal is to maximize social surplus, then he should not reveal that information. In order to estimate the gain of the players resulting from their ignorance we analyze the function $c^k(p^n)$. The proof of the following theorem is given in the full version.

THEOREM 7. *Let Γ be a linear resource selection system with increasing resource cost functions.There exist N such that for every $n \geq N$ the following assertions hold:*

1. $p_j^n = \frac{n-1+B-w_j(1)A}{Ad_j(n-1)}$, *where* $A = \sum_{j=1}^{m} \frac{1}{d_j}$, *and* $B = \sum_{j=1}^{m} \frac{w_j(1)}{d_j}$.

2. *The minimal social cost in* $\Gamma(k)$ *attained with symmetric mixed-action profiles is attained at* p^{2k-1}. *Consequently,* $c^k(p^n)$ *is minimized at* $n = 2k - 1$.

6. CONCLUSIONS

This paper tackles two fundamental issues in the study of multi-agent systems:

1. Providing solution concepts for multi-agent interactions with incomplete information, where exact probabilistic information is unavailable.

2. Incorporating uncertainty about the number of participants into the context of resource selection systems, one of the most fundamental settings in multi-agent systems.

Our results turned out to be both general and illuminating. On one hand, we provided general existence results for safety-level/competitive ratio equilibria. On the other hand, we were able to apply them to the context of resource selection games. Most importantly, our study led to highly surprising results, showing the positive effect of ignorance about the number of participants on the agents' costs and the system surplus.

Together, our work provides a foundational rigorous study of congestion games with incomplete information, while presenting general tools for the analysis of multi-agent systems where exact probabilistic information is not available.

ABSTRACT

A major challenge in efficiently solving distributed resource allocation problems is to cope with the dynamic state changes that characterise such systems. An effective solution to this problem should be able to detect state changes and determine why they occur (diagnosing the cause) in order to adapt to the prevailing situation. Now, since agents typically have localised views and communication constraints that prohibit global instantaneous synchronisation, we argue that cooperative information-sharing can provide them with the necessary adaptiveness and diagnostics ability. To this end, we develop a novel information-sharing algorithm for resource allocation tasks by building upon the most effective algorithm currently available in this domain. Then, using empirical analyses on a resource allocation application with dynamic state changes, network call routing with network failures, we show that, compared to the benchmark, our new algorithm achieves up to a 20% increase in call throughput, up to 3.5 times faster throughput recovery after failures, and provides a novel mechanism for distributed failure diagnosis without false positives and false negatives.

Keywords

Resource allocation, state diagnosis, information-sharing

1. INTRODUCTION

Resource allocation is a core functionality of many distributed systems [5, 8]. In such systems, multiple agents typically allocate resources under a decentralised regime using their individual localised views of the system, in order to complete their tasks. To do so, they use estimates of system states to ensure their individual actions are coordinated [2]. Now, to do this effectively in complex environments (where states change dynamically), such estimation necessarily involves detecting where, when, and why changes occur. Thus, to maintain these estimates and to perform such diagnostics, the agents need to share information. In particular, they need to communicate their individual views of the system to one another. Such information can then be used to generate robust local estimates and allow the agents to adapt these when states change. To this end, we develop and empirically evaluate a novel information-sharing algorithm that allows distributed agents to adapt dynamically to state changes and to perform distributed state diagnostics.

Given its importance, several strands of work on cooperative MAS have focused on analysing how communication can generate better solutions to distributed coordination [1, 6, 7]. However, in these, several limitations exist. For example, in [7], the authors develop a theoretical model for optimising information-sharing with the assumption that the agents need to synchronise their views periodically. In a typical distributed application, however, the agents should be able to act in a decentralised fashion without requiring to synchronise. The work in [6] considers how communication can improve the expected utility of an individual agent. We argue, however, that in cooperative systems, communication should be targeted towards improving overall system performance. Finally, the partial global planning algorithm in [1] allows the agents to communicate partial plans, representing their individual views of the system, to ensure consistent global solutions. Nevertheless, this work uses a set of pre-determined coordination mechanisms which can be inadequate for the agents to adapt to all possible environment dynamics that cannot be predicted a priori.

In our previous work, we addressed these limitations by developing an information-sharing protocol (the *post task-completion* (PTC) protocol) for distributed resource allocation [3]. Specifically, we showed that such cooperative information-sharing can generate highly effective distributed resource allocation. Our algorithm outperformed a range of state-of-the-art algorithms (including Littman's Q-routing, Stone's TPOT-RL, and a broadcast protocol) that have previously been shown to perform highly effective distributed task processing in dynamic systems. In [3], we chose an exemplar resource allocation application, that of call routing in resource-constrained mesh networks, to verify the performance advantage of our solution in a real application and demonstrated that our solution is more generally applicable to all such problems using a formal analysis. However, PTC did not produce the adaptiveness required in highly dynamic resource allocation problems by ensuring effective state diagnostics. Thus, in this paper, we extend PTC (to e-PTC) to remove these limitations. This necessarily implies an improvement over the benchmarks used in [3].

In more detail, e-PTC allows the agents to share information both when they successfully complete tasks and fail to do so. In contrast, PTC only allows agents communicate state information after they successfully complete tasks. In so doing, they are able to communicate their local states and build state estimates when the system is functioning under "steady state". However, unpredictable incidents such as process failures, network node saturation, and hardware crashes, can lead to subsequent failures in task processing. To adapt under these conditions, which are common in many distributed systems [10], the agents need to maintain estimates of the dynamic state changes and diagnose states for efficient recovery. Accordingly, we argue that such capabilities can be incorporated by allowing information-sharing after task failures. Indeed, by developing e-PTC, this paper extends the current state-of-the-art in the following significant ways: (1) It provides a simple but effective means of providing highly adaptive behaviour among distributed agents in dynamic environments. (2) It establishes, using empirical analyses, the advantage of e-PTC in providing effective resource allocation in a real application: call routing in mesh networks. Specifically, e-PTC generates up to 20% higher call throughput than PTC when network failures occur and allows up to 3.5 times faster recovery of throughput after failures. (3) A novel state-diagnosis algorithm is developed, based on e-PTC, that allows distributed agents with localised views to diagnose network failures correctly (no false positives) and only when failures occur (no false negatives).

In the rest of this paper, section 2 briefly describes the distributed resource allocation task in the context of our application domain and reviews how information-sharing aids state estimation. Then, section 3 describes e-PTC and how it generates effective adaptiveness in highly dynamic systems. The experimental setup is described in section 4 and the results in section 5. Section 6 develops the state-diagnosis algorithm using e-PTC and presents empirical results on its performance. Section 7 concludes.

2. INFORMATION-SHARING IN RESOURCE ALLOCATION TASKS

The task of decentralised routing in mesh networks requires individual agents to allocate node bandwidth (representing the resources in the system) and forward a call to a neighbouring node (the next hop along the call route) such that the call reaches the destination when a set of end-to-end bandwidth is allocated. To forward a call, an agent chooses that neighbour for which it estimates that the call would be placed via the most efficient overall route. Thus, each agent maintains an estimate of the bandwidth availability along paths to any other node. This reflects its partial view of the overall network. It attempts to keep these estimates up-to-date as much as possible by using the information exchanged between agents. The more up-to-date the estimates with respect to the actual network states, the higher the quality of routing and, thus, the better the network performance.

More specifically, each node i in a network of A nodes, maintains a routing table RT_i, where each element $RT_i(d,n)$ ($d \in A$ is the destination node, and $n \in A$ is a neighbour of i) represents i's estimate of the best end-to-end bandwidth availability in going from n to d. Node i chooses a neighbour j using a Boltzmann distribution over its neighbours based on the RT_i values: $e^{\frac{-RT_i(d,j)}{\tau}} / \sum_n e^{\frac{-RT_i(d,n)}{\tau}}$, where τ is the "temperature" parameter used to set the skewness of the distribution. When a call forward request reaches the destination, the latter sends "upstream" along the call route an `ack` message indicating a successful call connection. Otherwise, if a call forwarding fails before reaching the destination, the node at which it fails sends a `drop` message "upstream". As each node i transmits the `ack` or `drop`, it appends its state value s_i to the message. In this application, a node's state is the bandwidth available at that time expressed as a fraction of the maximum available bandwidth.[1] Therefore, a node (say, k) receiving an `ack` or `drop` from the immediate "downstream" node (say, l) gets the set of state values that were appended by all "downstream" nodes on this call route. These state values are then used by k to update its RT as: $RT_k(d,l) \leftarrow (1-\alpha)RT_k(d,l) + \alpha\Gamma(s_l, ..., s_d)$.[2] Here, $\Gamma()$ is an aggregation function on a set of node state values, and α is a discount factor ($0 < \alpha < 1$) that puts different weights on previous and current information. In particular, we choose Γ as the *minimum* of the set of node states since the node with the minimum available bandwidth determines the maximum number of calls that can be accommodated along a given route. Figure 1 presents a schematic of the above description.

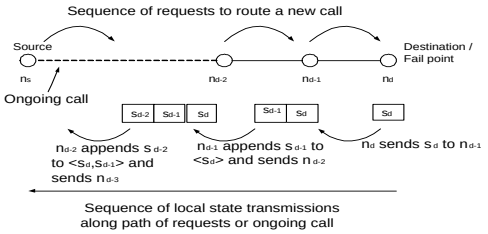

Figure 1: Call setup and information exchange

In this system, state information is exchanged between nodes *after every call connection and failure*. This is the definition of e-PTC (see [2] for more details of the design of e-PTC on this application). Note, the original PTC allowed information-sharing only after a call connection. Thus, e-PTC expands the set of events that PTC uses for sharing information.

3. ADAPTIVENESS IN HIGHLY DYNAMIC SYSTEMS

The e-PTC algorithm dictates that agents should share information after both successful task completions and task failures. Sharing information after task completion provides e-PTC with the same advantage as that of PTC: effective resource allocation when the system states are steady. However, when unforeseen events such as network failures cause task processing to fail, e-PTC allows the agents to share state information and thus allows for the estimation of the state changes caused by such events and diagnosis of the events. These capabilities cannot be achieved using PTC alone. Thus, the e-PTC algorithm, together with the estimate-generation mechanism discussed in section 2, provide effective adaptive behaviour in dynamic systems which is a significant improvement over the current state-of-the-art. In the rest of this section, we first describe the model we adopt to define network failures that cause dynamic state changes and, then, describe the design of e-PTC in the context of call routing with failures.

3.1 Model of Dynamic State Changes

Network failures cause dynamic state changes in our application. In the failure model, there are the following components:

[1] As nodes route new calls or existing calls terminate, available bandwidth (hence, node state) varies dynamically.

[2] This mechanism of computing a discounted running average is used to learn estimates in environments where the dynamics are not known a priori [11].

Failure Characterisation: Only **stop** failures are considered because these are the most commonly studied in distributed systems [9] and, hence, form a good testbed for measuring the performance of e-PTC. We assume that a failed node (1) cannot run any processes, (2) cannot communicate with other nodes, and (3) once failed, continues to remain so. Thus, after a failure, all ongoing calls on a node will be lost and it will not be able to detect or acknowledge new call forward requests. A failure would cause both bandwidth availability (by removing existing calls) and the topology to change, thereby, changing the network state.

Detection Characterisation: After a node fails, one of its neighbours actually detects that it has failed after the latter makes a forwarding request. The requesting node detects the failure status since it does not receive any response to its request. It then generates `drop` messages to inform its neighbouring nodes to deallocate the reserved bandwidth for the calls that were ongoing along this affected route.

3.2 Adaptiveness and Diagnostics with e-PTC

As identified in section 3.1, a failure causes network states to change dynamically. The e-PTC algorithm, by distributing state information after failures, allows the agents to assess these state changes. This, in turn, lets the agents adapt their task processing to best respond to state changes and to diagnose where in the system the failure has occurred.

In more detail, figure 2 shows the schematic of a node failure and the subsequent transmission of state information by its neighbour. In this figure, node f is shown to have failed. One of its neighbours, i, detects that f has failed after it attempts to forward a call request to f and does not get a response. Thus, it deallocates its bandwidth for all calls that were being routed through both i and f, and that for the new call it was trying to set up. Also, it informs each j (a neighbour of i that is also on the path of calls via i and f) by sending a `drop` message to de-allocate bandwidth. Each such j continues to propagate the `drop` message until the terminal node on that path is reached. Note that, a similar process is undertaken by each neighbour of f whenever they detect that f has failed. In the above process, after receiving a `drop` message, a node updates its estimate (see section 2 for the estimate-update mechanism) about the affected network path from the node state values appended to the message by each agent transmitting it. In this manner, the nodes learn that the bandwidth availability along the affected path has changed. Such information, therefore, allows them to adapt their routing behaviour to best respond to the state dynamics.

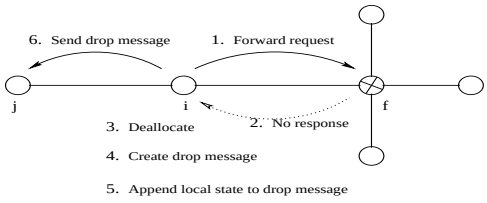

Figure 2: Network failure detection schematic

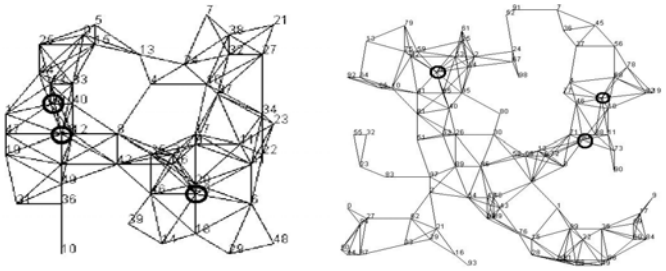
Importantly, using this information, a node can diagnose if a certain node in the network has failed. Note, when i transmits state information with a `drop` message, it assigns a value of zero for f's state. Alternatively, when a node has no available bandwidth, it rejects a forwarding request and, therefore, the call attempt fails. Similar to a node failure, the state value transmitted with a `drop` message in this case is also zero. Therefore, for correct failure diagnosis, an agent should be able to distinguish between the information (zero) received from a node that has failed and that is saturated (also zero). The key to do this is to observe a *sequence* of state values. Note, to indicate a failure, a separate message (e.g., `fail`) could be used instead of a zero state. However, the state values are used to update the routing tables. Hence, a separate message to explicitly indicate failure would not be useful for state estimation. In fact, as shown in section 6, the zero state values can be used for diagnosing failures in addition to state estimation. In section 6, we develop an algorithm that computes the *number of consecutive state values* an agent needs to monitor from another node to achieve correct diagnosis. It is shown that this algorithm is both (i) without false positives — a failure is diagnosed only if one has occurred, and (ii) without false negatives — once a failure occurs, a positive diagnosis is guaranteed.

4. EXPERIMENTAL SETUP



This section first outlines the simulation of a limited-bandwidth mesh network application used for call routing with failures. This system effectively emulates distributed resource allocation tasks under highly dynamic environments (see [2] for additional justification). Then, we go on to present the criteria used to evaluate the performance of e-PTC.

4.1 The Simulation Environment

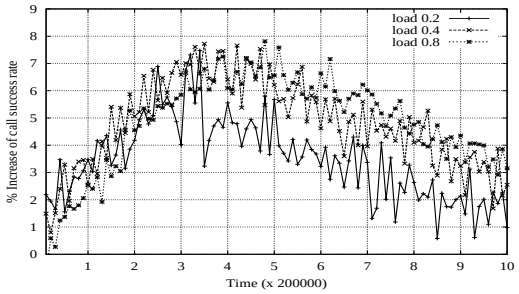
Each node has a fixed maximum bandwidth (C units). This captures the limited bandwidth of mesh networks. Each call takes one bandwidth unit. The probability (p_c) of a call originating at any node is termed the "load". Call destinations are selected uniformly. A node reserves one bandwidth unit for a call after forwarding it to a neighbour. The reservation is removed if the call fails to connect or terminates after the duration t_l, for which the call lasts, measured since it is routed to its destination. Before forwarding, an agent inserts its id to the call so that a call has a sequence of ids used to transmit state information after a connection or failure. If connected, an acknowledgement (`ack`) message is transmitted from the destination up to the source. In case of a failure, the failed node's neighbour transmits a `drop` message along the call path and bandwidth reserved for this call is de-allocated. Nodes share state information by appending state values to an `ack` or `drop` message: only `ack` is used by PTC, while e-PTC uses both. Numerically, a node state is the bandwidth units available expressed as a fraction of the maximum state estimate (C). Thus, if it has x units available, its state is $\frac{x}{C}$. The routing tables are initialised to 1.0, the maximum availability. One simulation run consists of 2×10^6 simulated time steps (time is measured on a global clock) where in one step any agent can send one message to one of its neighbours. Experiments are run for a sufficient number of runs to ensure statistical significance at the 95% confidence level. The following parameter values are chosen: a network with a total of $N = 50$ nodes (figure 3(a)), and $N = 100$ nodes (figure 3(b)), $C = 10$, $\alpha = 0.03$, $\tau = 0.1$, $p_c = \{0.1, 0.2, 0.4, 0.6, 0.8\}$ (to test the effect of different loads), and $t_l = 50$ for the 50-node network and $t_l = 100$ for the 100-node network. Experiments have been conducted on several other topologies and similar trends are observed in the results [2]. Here, therefore, we report results from these sample topologies. Also, the same general observations hold for other values of α and τ.

4.2 Performance Evaluation Criteria

The following criteria are used to compare the performance of e-PTC against that of PTC to determine its adaptiveness in dynamic resource allocation tasks.

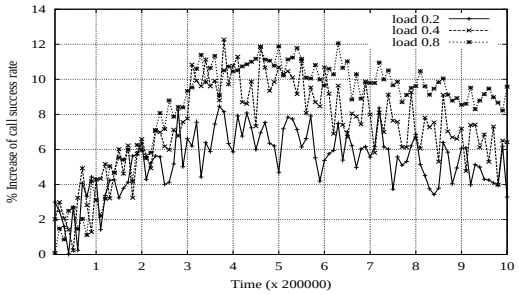
(a) 50-node topology (b) 100-node topology

Figure 3: Network topologies



Call Success Rate (CSR): The advantage of having a highly adaptive solution in dynamic systems is to have a high rate of successful task processing. In the call routing application, this is measured in terms of the call success rate. Specifically, if, in a given time interval, K calls originate out of which k are successfully connected, the CSR within that period is: k/K. The higher the CSR in a given system, the better the performance of the information-sharing algorithm by maintaining high-quality routing tables.

Recovery of Call Success Rate: Good adaptiveness in dynamic systems should allow quick recovery of performance after state changes occur. Now, in our application, after a failure, the CSR will necessarily drop since a set of network paths become unavailable. However, as the agents adapt their estimates and find alternative routes, the CSR should recover from the initial drop. The efficiencies of e-PTC and PTC are compared by measuring how fast the CSR recovers following failures. Thus, we compare the CSR (denoted as r_{fail}) when a node fails in the simulation (termed the "test" case) to the CSR (r_{miss}) when the corresponding node is removed from the topology from the start of the simulation (termed the "baseline" case) keeping all other parameters identical. In the baseline, the agents learn the routing tables based on the topology that results after failure in the test simulation. Now, if all agents had global information, then, after failure, r_{fail} could recover and become equal to r_{miss}. But, since the agents do not have this, r_{fail} is unlikely to be able to recover to exactly r_{miss}. Nevertheless, the closer and faster it can get to r_{miss}, the more efficient the system.

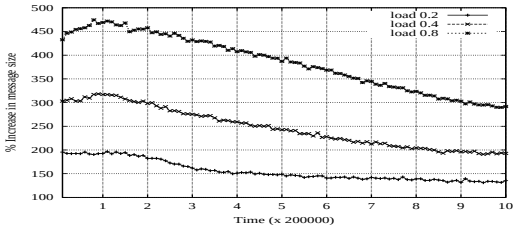


Message Size (MS): Any advantage of e-PTC over PTC in CSR or CSR recovery is due to sharing more information. Although one message is transmitted for a call success (`ack`) and one for a call failure (`drop`) in both e-PTC and PTC, these may not be of the same size. In both cases, the message size is determined by the number of state values appended. Thus, the average size of k messages is $\sum_{i=1}^{k}(l_i)/k$, where l_i is the size of the ith message. To assess if e-PTC has an overhead over PTC, we compare the average size of messages generated in both.

5. RESULTS AND ANALYSIS

In this section, first, the CSR and MS of e-PTC and PTC are compared in the absence of failures to test if e-PTC has any inherent advantage (a higher CSR) or overhead (higher MS). The second set of experiments then measure their performances when dynamic state changes occur due to failures. Since it has already been shown that PTC performs better than a range of benchmark algorithms widely used for adaptive distributed resource allocation tasks [3], any improvement in e-PTC over PTC necessarily indicates an improvement over the current state-of-the-art.

(a) % CSR increase in 50-node topology



(b) % CSR increase in 100-node topology

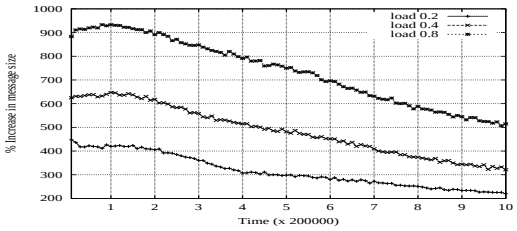


Figure 4: CSR increase in e-PTC over PTC without failures

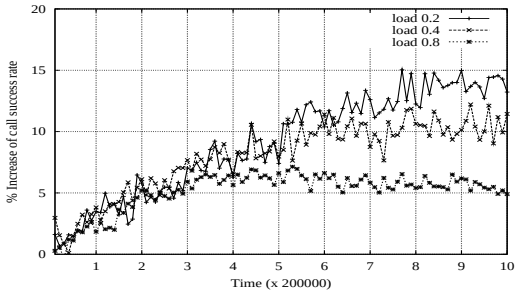
5.1 No State Change Dynamics (No Failures)

The time-variation of the network call success rates for e-PTC and PTC are compared by calculating the percentage deviation of the e-PTC CSR from that of PTC: $(\texttt{CSR(ePTC)} - \texttt{CSR(PTC)})/\texttt{CSR(PTC)}$. These values are plotted for different network load values in figure 4. Now, the motivation for designing e-PTC is to generate effective adaptation of the system in response to dynamic state changes. However, the results in figure 4 show that *even without such dynamic state changes, e-PTC has an advantage over PTC in terms of generating higher CSR*: in figure 4(b), at load 0.8, e-PTC achieves a peak 11% increase in CSR compared to PTC. When no failures occur in the network, the source of state-change dynamics is due to network saturation when some nodes are unable to transmit further calls. Now, this obviously happens more at higher loads. Thus, the call success rates of both PTC and e-PTC decrease with increasing load. Note, in e-PTC, nodes share information after call failures. Thus, with increasing load and, hence, more call failures due to network saturation, e-PTC allows more information-sharing and ensures that the routing table estimates remain more up-to-date with the actual bandwidth availability. This allows e-PTC to adapt to the dynamics caused due to saturation better than PTC. The CSR of e-PTC does not decrease as much as that of PTC with increasing load; in figure 4, we observe the relative improvement of e-PTC CSR over PTC CSR to increase with increasing load.

(a) % MS increase in 50-node topology

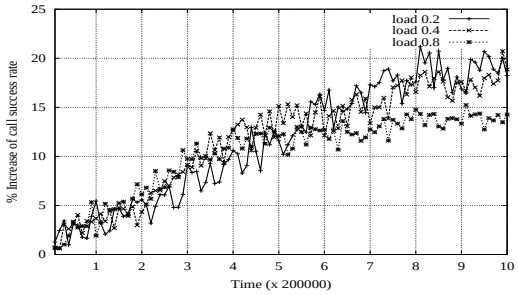
(b) % MS increase in 100-node topology

Figure 5: MS increase in e-PTC over PTC without failures



The average message size of e-PTC and PTC are compared in an analogous manner in figure 5. These results show that e-PTC incurs more message overhead than PTC and it increases with load. So, in figure 5(a), the e-PTC MS is about 2.3 times of PTC MS at load 0.2, and it is about 3.9 times at load 0.8. Now, e-PTC communicates state information when calls fail to keep the routing tables updated. However, this causes the MS (of the `drop` messages) to increase. This effect becomes more pronounced at higher loads when more calls fail (as explained before). Therefore, e-PTC attains a higher CSR at a cost of larger MS compared to PTC.

5.2 With Dynamic State Changes (Failures)

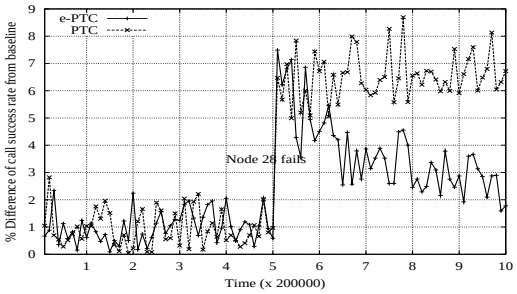


State-change dynamics are incorporated in our simulator by way of network failures. We allow one node to fail at a given time and different failures to occur at equidistant points in an experiment. More arbitrary failure patters (e.g., several failures occurring at close intervals) have been used in our ongoing work that show similar broad trends. The nodes that fail are pre-selected. However, different combinations of nodes are selected to fail in different experiments. Note, the failures are initiated by the simulator and no agent knows when and where one would occur. The results reported here use failures of (i) 3 nodes with the highest edge connectivity (encircled in figure 3), and (ii) 3 randomly chosen nodes with average edge connectivity. The motivation for choosing (i) is that the nodes with the most connectivity are critical points and heavily used for routing. Thus, their failures cause a major disruption in the network state which provides a "hard" test for the advantage, if any, that e-PTC has over PTC. However, (ii) provides a more typical scenario. We report results using (i) since the results from (ii) show identical trends.

5.2.1 Call Success Rate.

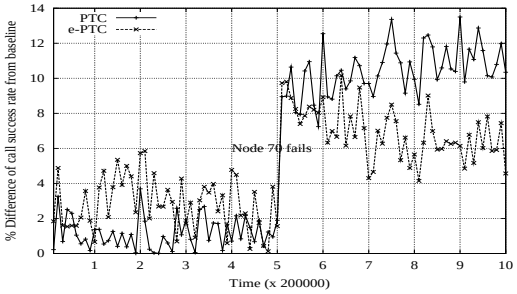
The percentage increase of call success rate of e-PTC over PTC with the three most-connected nodes failing are shown in figure 6. As explained in section 5.1, the CSRs of both e-PTC and PTC decrease with increasing load. There is an additional drop due to node

(a) % CSR increase in 50-node topology



(b) % CSR increase in 100-node topology

Figure 6: CSR increase in e-PTC over PTC with 3 most-connected nodes failing

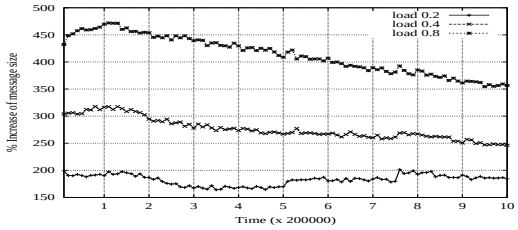


failure since it results in less bandwidth being available. However, *the CSR for e-PTC is always higher than that for PTC, confirming the effectiveness of e-PTC over PTC*. The difference in their performances is, however, more pronounced at lighter loads because at high loads the effects of both saturation and failures offset the advantage achieved by e-PTC over PTC (unlike section 5.1 where a higher relative improvement was observed at higher loads). Thus, in figure 6(b), after all 3 nodes fail, the CSR of e-PTC is about 20% higher than PTC at load 0.2 and about 14% at load 0.8. Moreover, *at a given load, the relative improvement in CSR of e-PTC over PTC increases with the number of failures*. Hence, although the CSRs decrease with failures, *the rate of deterioration in e-PTC is lower than in PTC*. These results indicate that our e-PTC algorithm generates better adaptiveness in response to state changes caused by failures. This is the reason for the networks to achieve higher call success rates with e-PTC compared to PTC in such dynamic conditions.

5.2.2 Recovery Rate.

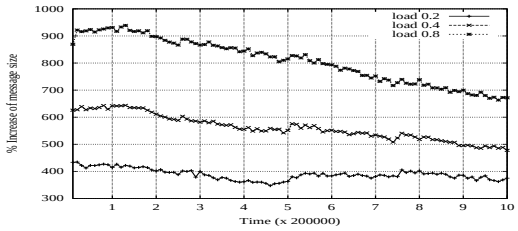
To evaluate the efficiency with which e-PTC and PTC allow the network call success rate to recover after failures occur, we compare the CSRs of the e-PTC(test) and PTC(test) strategies against that of the baseline strategy (see section 4.2 for the definitions of these). Specifically, the percentage difference between the CSRs of e-PTC(test) and the baseline, and that between the CSRs of PTC(test) and the baseline are computed as: $|\ CSR_{base} - CSR_{test}\ | / CSR_{base}$. Figure 7 shows these results, generated when the highest-connected node in the corresponding networks fail halfway through the simulation and a load of 0.1 is used. Similar trends have been observed with all other load values. Now, before the failure, e-

(a) CSR recovery in 50-node topology



(b) CSR recovery in 100-node topology

Figure 7: Recovery of CSR after failure



PTC(test) has the highest CSR (similar to section 5.1). However, after the failure in the test cases, the CSRs of both e-PTC(test) and PTC(test) drop. However, in figure 7, the CSR of e-PTC(test) recovers at a faster rate towards the baseline than PTC(test). The percentage deviation of the CSRs in both sets of graphs of figure 7 are observed to decrease faster for e-PTC than PTC. For example, in figure 7(a), at the end of a simulation run, e-PTC(test) CSR reaches within about 2.0% of the baseline CSR which is 3.5 times (350%) better than that of PTC(test) which reaches within 7% of the baseline. These results, therefore, confirm that e-PTC ensures a *superior efficiency in the recovery of system performance after state-changes occur.* Thus, better adaptiveness to dynamic environments is indeed achieved by e-PTC than PTC.

5.2.3 Message Size.

Sections 5.2.1 and 5.2.2 have confirmed that using e-PTC, distributed agents with localised views can achieve significantly better adaptiveness when states change dynamically. This advantage of e-PTC is generated by sharing information about the state changes, a feature lacking in PTC. Thus, the message overhead of e-PTC exceeds that of PTC. Specifically, figure 8 shows the percentage increase in message size of e-PTC compared with that of PTC, computed in a way analogous to the results in figure 5. However, the results in figure 8 are generated when the three highest-connected nodes in the corresponding topologies fail. These results show that MS *of e-PTC is significantly higher than PTC.* Also, they show that the higher the load, the greater is the increase in the MS of e-PTC relative to PTC: in figure 8(a), at the end of a simulation run, e-PTC MS is about 2.8 times that of PTC at load 0.2, whereas it is about 4.6 times at load 0.8. As mentioned earlier, e-PTC incurs the extra overhead in message size since it uses `drop` messages

(a) % MS increase in 50-node topology

(b) % MS increase in 100-node topology

Figure 8: MS increase with 3 most-connected nodes failing

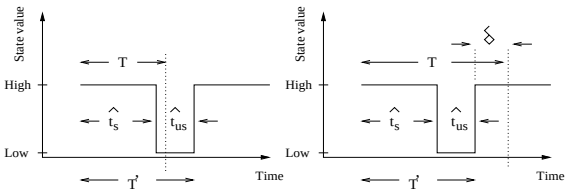
to communicate the state-change information. Such information-sharing, while allowing the routing tables to be more up-to-date compared to PTC, leads to larger messages in e-PTC. As the number of call failures increase with load and network failures, so does the number of state-value transmissions in `drop` messages. One way of reducing the message overhead of e-PTC is to selectively communicate information. We are developing such a mechanism in our ongoing work, where agents use their communication histories to judge how useful a certain information would be to a recipient. Significant savings in message overhead are observed while maintaining the advantages of e-PTC.

6. STATE DIAGNOSIS USING E-PTC

The results of section 5 indicate how e-PTC ensures that agents *adapt* effectively to dynamic state changes caused by failures. In this section, we elaborate on the additional benefit of e-PTC in *diagnosing* such state changes. In particular, we develop an algorithm, based on the shared information generated by e-PTC, that distributed agents can use to detect if a certain node has failed. Such a capability would then be useful for automating distributed diagnosis and recovery.

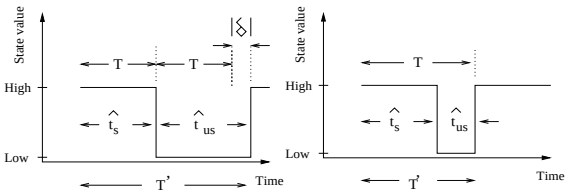
Here, failure diagnosis means that a node raises an alert when it interprets, from the state values it receives along `drop` messages, a fail condition of another node. The detecting node is termed the "monitoring" node and the one interpreted is the "monitored" node. Note, any node can take either of these roles because information is distributed between all nodes in the network. This is because calls can originate from and terminate at all nodes and, thus, e-PTC would distribute information along call paths between all node pairs. Our aim in this context is to ensure that failure diagnosis using e-PTC is both truly indicative of a failure (no false positives), and that all failures will be detected (no false negatives). To ensure the first property, the monitoring node needs to observe a series of state values of the monitored node (explained shortly). The second property guarantees a detection.

To explain the diagnosis process, a node n_a is considered to do the monitoring of another node n_b (the monitored node). Let T be the average interval at which n_a receives the state values of n_b, distributed by e-PTC. The state values of n_b can be transmitted along `ack` and/or `drop` messages either when n_b is saturated or unsaturated, or when the latter has failed. Now, the state values of a node that is saturated and that is failed are both zeros (section 3.2). However, the difference is that a saturated node becomes unsaturated when bandwidth becomes available, whereas a failed node continues to remain so. Therefore, after receiving the first zero state value of a saturated (not failed) n_b, if n_a continues to observe the state values, then it will receive a non-zero state value after a *certain number of observations*. This will happen when n_b becomes unsaturated. Against this background, note that if n_a has the information about the average durations for which n_b remains alternately saturated and unsaturated, then it can compute the number of such observations using its knowledge of T. We assume that n_b remains alternately saturated for an average period of $\hat{t}_s$ and unsaturated for $\hat{t}_{us}$. To summarise, when n_a receives a zero state value of n_b, it assumes n_b is saturated. Then, using the knowledge of T, $\hat{t}_s$, and $\hat{t}_{us}$, n_a computes *the minimum number of observations* (termed as m) *after which it would receive a non-zero state value* of n_b. If the actual number of zero-state values of n_b received exceeds the computed value, then n_a interprets a failure by rejecting its previous assumption of a saturated n_b. The algorithm to compute m is detailed in the following section. Now, out of T, $\hat{t}_s$, and $\hat{t}_{us}$, n_a can estimate online the average interval (T) at which it receives information from n_b. However, it cannot estimate online $\hat{t}_s$ and $\hat{t}_{us}$ of n_b since it does not have information about the overall network load. But, n_a can acquire these estimates from node traffic statistics that are usually available for most networks [4].



6.1 The Failure Diagnosis Algorithm

After receiving the first zero state of n_b, n_a invokes the algorithm assuming the state value to be from a $\hat{t}_s$ interval of n_b (i.e., from a saturated n_b; it may of course be from a failed n_b). Now, knowing that it would receive state values from n_b after every T units and that n_b would remain alternately saturated for $\hat{t}_s$ and unsaturated for $\hat{t}_{us}$, n_a determines whether the next reception should be from a $\hat{t}_s$ or a $\hat{t}_{us}$ interval of n_b. This is done by comparing T against the sum of $\hat{t}_s$ and $\hat{t}_{us}$. This process is repeated until the next projected reception is from a $\hat{t}_{us}$ interval; the total number of receptions before this happens is equal to m. In more detail, figure 9 shows the algorithm. The algorithm's inputs are T, $\hat{t}_s$, and $\hat{t}_{us}$ and the output is m, the minimum number of zero state values n_a would observe from n_b. In figure 9, T' is the sum of $\hat{t}_s$ and $\hat{t}_{us}$. The algorithm identifies the various possible relationships between T and $\hat{t}_s$ and $\hat{t}_{us}$ to decide how to compute m.



Input: T, $\hat{t}_s$, $\hat{t}_{us}$; Output: m.

0. $T' \leftarrow \hat{t}_s + \hat{t}_{us}$; $m \leftarrow 1$;
1. if($T < T'$ and $T > \hat{t}_s$)
2. $m \leftarrow 2$; //2nd msg in unsaturation
3. else if ($T > T'$) //next msg in a subsequent T' zone
4. $\delta \leftarrow T \% T'$; //modulus
5. while($(\delta - \hat{t}_s) < 0$)
6. $m \leftarrow m + 1$;
7. $\delta \leftarrow (T - (T' - \delta)) \% T'$; //offset from start of next interval
8. else if($T \leq \hat{t}_s$) //next msg in a saturation zone
9. $\delta \leftarrow 0$;
10. do
11. $m \leftarrow m + \frac{\hat{t}_s - \delta}{T} + 1$; //integer division
12. $\delta \leftarrow T(\frac{\hat{t}_s - \delta}{T} + 1) - (T' - \delta)$; //offset from end of current interval
13. while($\delta > 0$);
14else
15. $m \leftarrow \infty$; //to observe infinite zero-state messages; diagnosis inconclusive

Figure 9: Failure diagnosis algorithm

(a) Condition: $T < T'$ and $T > \hat{t}_s$ (b) Condition: $T > T'$

(c) Condition: $T \leq \hat{t}_{us}$ (d) Condition: $T = T'$

Figure 10: Relationships between T, $\hat{t}_s$, and $\hat{t}_{us}$ of figure 9

First, if $T < T'$ and $T > \hat{t}_s$ (line 1), the next state value of n_b (after an interval of T since the first reception) would be from its $\hat{t}_{us}$ interval and, hence, $m = 2$. Figure 10(a) shows this condition in schematic. Here, the saturated and unsaturated states of n_b are shown as a pulse wave: the "high" value represents the $\hat{t}_s$ interval and "low" the $\hat{t}_{us}$ interval. Along the x-axis is time and the y-axis represents state value. Thus, from the start of the first $\hat{t}_s$ interval (corresponding to the first zero state value n_a received from n_b), the end of a period equal to T (which is when n_a would receive the next message from n_b) falls within the $\hat{t}_{us}$ interval; which is when n_a will receive a non-zero state value. Thus, n_a would receive a non-zero state value on the message after the first zero it received from n_b. Hence, $m = 2$.

Second, if $T > T'$ (line 3), first, it is computed by how much (δ) the next reception is within the next T' of n_b (line 4). Then, this offset is recomputed (line 7) for successive observations (the loop at line 5) until it is greater than $\hat{t}_s$ of the next T' (line 5), which indicates a non-zero state. Until this happens, in each iteration one more zero state value needs to be observed by n_a (line 6). Figure 10(b) shows the schematic.

Third, if $T \leq \hat{t}_s$ (line 8), a similar calculation is done as above. Specifically, in line 12, $T(\frac{\hat{t}_s - \delta}{T} + 1)$ gives the total duration of the consecutive observations made within an offset-adjusted $\hat{t}_s$ interval, and $(T' - \delta)$ gives the effective (offset-adjusted) T' in which the above calculation is done. Thus, the new offset from the end of the current T' is the difference of the above two values (line 12). The process is repeated until the next observation is in the $\hat{t}_{us}$ of the current T' which is when the offset is less than zero (line 13) and indicates a non-zero state. As an example, consider $T = \hat{t}_s$. Then, δ at the end of iteration 1 is (line 12): $\delta = T(\frac{\hat{t}_s - 0}{T} + 1) - (T' - 0)$, $= 2T - T'$. If $2T < T'$, then $\delta < 0$ (line 13 violated) and, thus, the third message after the first zero state that n_a received will be from a $\hat{t}_{us}$ interval of n_b; so, in this example, $m = 3$. Figure 10(c) shows this example in schematic. If $2T > T'$, then line 13 holds. So, in the next iteration, an offset-adjusted $\hat{t}_s$ and T' are used (where the offset is the δ of the previous iteration) to re-compute a new δ.

Lastly, when $T = T'$ (line 14), the next state from n_b always co-

incides with a $\hat{t}_s$ interval (see the schematic of figure 10(d)). Therefore, n_a receives an endless sequence of zero states from n_b and, hence, cannot distinguish between a saturated and a failed n_b.

The above algorithm can be invoked when n_a receives a zero state of a *saturated* n_b. However, assuming n_a has the correct estimates of T, $\hat{t}_s$, and $\hat{t}_{us}$, it will eventually receive a non-zero state of n_b on the mth instance since the first zero. This is when n_b has become unsaturated. So, n_a would not signal a failure which is the correct diagnosis. Hence, the diagnosis has no false positive. Alternatively, if n_b had indeed failed when n_a received the first zero, it would continue to be failed indefinitely. Therefore, n_a would eventually receive more than m zero state values from n_b and then signal a failure — the correct diagnosis (no false negatives).

6.2 Empirical Evaluation

The algorithm of figure 9 is evaluated empirically using the same experimental setup as in section 5. In a given network, one node (n_a) is selected as the monitoring node and then, in turn, all other nodes are selected to fail (n_b), each in a differect simulation with all parameters the same as before. Selecting one node to fail does not limit our conclusions about our diagnosis algorithm which is theoretically capable of detecting arbitrary number of failures. However, multiple failures can cause a practical difficulty of state information not reaching the monitoring node due to a disconnected network. Now, for every other node, n_a estimates T and the simulator estimates $\hat{t}_s$ and $\hat{t}_{us}$, which are fed to n_a using which, it can invoke the algorithm of figure 9 to compute m as described before. In these experiments, node 8 in figure 3(a) and node 13 in figure 3(b) are used as the monitoring nodes. With a different node (the monitored node) failing in each experiment, the average values of m and T over the monitored nodes that are at a given distance from n_a, are computed. Hence, a summary assessment of how many consecutive observations n_a requires to diagnose failure at a given distance is obtained.

To this end, tables 1 and 2 show the average estimates of m, T, and the delay between the time a node fails and n_a actually making a diagnosis for figure 3(a) and 3(b), respectively. *In each experiment, n_a has diagnosed only after the chosen n_b has failed. Thus, the properties of no false positives and no false negatives of the diagnosis algorithm are corroborated by these empirical results.* Thus, not only does e-PTC yield highly effective adaptive response in distributed dynamic environments, but also using the information exchanged by e-PTC, accurate state diagnosis can be achieved.

Note the diagnosis delay increases with increasing distance of the failures because of the increasing delay (T) in receiving information from distant nodes. The value of T is determined by the topology, load, call pattern, and the information-sharing protocol used. By reducing T, such as by distributing information more frequently and along multiple paths, the detection delay can be reduced; this is part of our future work. The delay is also due to using a single monitoring node. By choosing multiple such nodes, the maximum distance of any node and at least one monitoring node can be restricted such that the delay is within tolerable limits. Nevertheless, we verified the theoretical properties of the diagnosis algorithm using a single monitoring node which actually provides a "harder" test than using multiple ones.

Table 1: Diagnosis performance on the topology of figure 3(a)

Min dist of target	T		m		Detection delay
	avg	stdev	avg	stdev	
1	420	50.7	2.8	1.2	756

7. CONCLUSIONS AND FUTURE WORK

In this paper, we develop a new information-sharing algorithm, e-PTC, for distributed resource allocation problems that can generate highly effective adaptive behaviour in dynamic environments and achieve distributed diagnosis of state changes. Empirical evaluation of e-PTC in a simulated call routing application confirms its advantages over the previous state-of-the-art in this area. Specifically, with dynamic state changes caused by network failures, e-PTC achieves up to 20% higher call throughput, up to 3.5 times faster recovery of throughput after failures, and provides a novel algorithm for diagnosing failures without false positives and false negatives. These improvements are earned by e-PTC at the cost of sending more messages than PTC. However, to address this, we plan to investigate ways of limiting the message overhead of e-PTC by using selective communication in which the agents can use a notion of information redundancy to decide when to communicate.

ABSTRACT

In this paper we produce complexity and impossibility results and develop algorithms for a task allocation problem that needs to be solved by a group of autonomous agents working together. In particular, each task is assumed to be composed of several subtasks and involves an associated predetermined and known overall payment (set by the task's owner) for its completion. However, the division of this payment among the corresponding contributors is not predefined. Now to accomplish a particular task, all its subtasks need to be allocated to agents with the necessary capabilities and the agents' corresponding costs need to fall within the preset overall task payment. For this scenario, we first provide a cooperative agent system designer with a practical solution that achieves an efficient allocation. However, this solution is not applicable for non-cooperative settings. Consequently, we go on to provide a detailed analysis where we prove that certain design goals cannot be achieved if the agents are self interested. Specifically, we prove that for the general case, no protocol achieving the efficient solution can exist that is individually rational and budget balanced. We show that although efficient protocols may exist in some settings, these will inevitably be setting-specific.

1. INTRODUCTION

Many task allocation problems require a number of autonomous agents to form groups in order to execute complex activities they can't perform individually [16]. In this work, we specifically consider the case in which tasks: (1) are composed of several subtasks and (2) have predetermined and known overall payments, set by the tasks' owners (i.e., a fixed price contract) [6]. To accomplish a particular task in this case, all its relevant subtasks need to be completed by agents with the necessary capabilities, and the agents' costs need to fall within the preset task payment. Therefore, in this scenario, allocated agents are likely to receive payments which are higher than their reported costs, to meet the requirement that the overall task payment need to be fully paid out.

This task allocation problem is common in a wide range of contexts, including both cooperative and non-cooperative systems. By means of illustration, for the former case consider a large organization composed of several departments, each with its own set of capabilities. Such organizations may receive offers to carry out multiple projects with known payments. In order to accomplish the specific goals of each project, several departments need to work together. In such cases, the role of the organization manager is to allocate the projects to the departments and to decide on the division of the complete available payments to the contributing departments, in order to maximize the organization's efficiency. Here it is assumed the departments cooperate by revealing their actual costs and are prepared to execute any given subtask within their capabilities. Similar scenarios also occur in Grid resource allocation problems where a controller faces demands to allocate an appropriate set of computational resources for the completion of a set of tasks within the fixed payments constraints of the tasks' owners. However, in contrast to the first example, here the controller neither owns the computation resources that may be deployed nor does it have full information about them. Therefore, this must be a non-cooperative designation. Each such resource has to explicitly declare which activities it is willing to perform and its corresponding costs. Only with this information can the controller make the allocation.

Given the ubiquity of this problem, it is surprising that it has received no significant attention to date. Specifically, the main work in this area is due to Kraus et al. [7, 6] who consider a non-cooperative agent system for executing such tasks. In particular they provide a protocol that achieves 80% efficiency, but which does not scale to a large number of subtasks and agents. In addition, they benchmark their protocol's efficiency against a solution achieved by a heuristic and not against the the most efficient solution (which makes their results even more fragile). To rectify these shortcomings, in this paper we first provide a cooperative agent system designer with a practical solution that achieves the efficient allocation. We do so by developing

an algorithm which is exponential in the number of tasks, but polynomial in the number of agents and the number of subtasks. Since in many real world situations, the number of tasks is relatively small and can be bounded by a small constant number, the algorithm's complexity can be considered polynomial in the size of the input. We also prove that no polynomial algorithm exists when the number of tasks is unbounded (unless P=NP). This is therefore the best result that can be achieved.

Unfortunately, this solution is not applicable for non-cooperative settings, where more difficulties are raised (e.g., uncertainties about agent's cost, self interested nature). Consequently, in the second part of the paper we analyze what can and cannot be achieved when we consider self interested agents. Specifically, for the general problem we prove that no individually rational and budget balanced protocol can exist which achieves an efficient solution. However, there are some non-cooperative settings for which an efficient protocol does exist. The drawback is that such an efficient protocol for one such setting is likely to be inefficient for another. This result can then be used by the designers of agent systems, who are faced with this task allocation scenario, to direct them to develop appropriate protocols and strategies for particular settings of the problem, and to ensure they know what can and cannot be achieved. Moreover, the performance of any proposed protocol for the non-cooperative setting can in the future be benchmarked against our solution for the cooperative case. This will give more accurate results than benchmarking against heuristics as has been done in previous work.

The rest of the paper is organized as follows. Section 2 introduces our problem definition. In section 3 a cooperative setting for the problem is considered for which we develop an algorithm resulting in an efficient solution. Section 4 focuses on the non-cooperative setting where we show what can and cannot be achieved. In section 5 related work is described and, finally, we conclude in section 6.

2. PROBLEM FORMALIZATION

The general description of our task allocation problem assumes there are M candidate tasks $\Im = \{T_1, ..., T_M\}$, where each T_i is composed of several subtasks $\left\{ST_{i_1}, ..., ST_{i_{k_i}}\right\}$. The overall payment of a task, $p(T_i)$, is predefined and known to all and no inter-task payments transfer is allowed. Moreover, by definition, the task payments need to be fully paid out for their completion. However, the partitioning of the task payment among its subtasks is not predetermined, but will be set as part of the task allocation process. Here a task is considered to have been completed if all its subtasks have been executed.

For the completion of these tasks, a set of agents, $A = \{A_1, ..., A_N\}$, is given. Each of these agents has capabilities to perform multiple subtasks (where some overlapping among different agents' capabilities is assumed). Here, we assume these capabilities to be known to all participating agents and the controller. However, as the subtasks should be carried out simultaneously, we assume that each agent is capable of performing only one subtask at a time.[1] Note that given the dependency on the resource constraints and the reward structures, not all of the tasks may get executed.

In this paper we consider both cooperative and non-cooperative settings. For both cases we assume a central controller is responsible for the task allocation. In the cooperative case we assume the controller has full information about the agents' costs (as the capabilities are known to all) either because of the system's characteristics or because the agents are assumed to report their costs truthfully (since they have no incentive to manipulate this information). In addition, here an agent's cooperation also signals its agreement to complete any assigned subtask which it is capable of performing. Now in the non-cooperative setting, the agents' capabilities are still known to all including the controller, but in this case the controller can only assign subtasks to those agents that indicated their willingness to perform them. Therefore, an agent may strategize by choosing which of the subtasks it is willing to undertake and by manipulating their corresponding declared costs. Note that in doing so agents may use the information they have about the other agents' capabilities and their cost distributions as we define below.

Formally, a knowledge capability function (φ) that is known to all agents and the controller is assumed, where $\varphi(A_j, ST_{i_l})$ equals one if agent A_j is capable of performing subtask ST_{i_l} and otherwise zero. Using this function, we summarize each agent's capabilities by $\Psi_j = \{ST_{i_l} | \varphi(A_j, ST_{i_l}) = 1\}$. Conversely, for any subtask ST_{i_l} there is a set of agents capable of completing it, $\Omega_{i_l} = \{A_j | \varphi(A_j, ST_{i_l}) = 1\}$. Moreover, each agent A_j has a private cost for performing a given subtask ST_{i_l}, $c^j_{i_l}$, taken from a common distribution F_{i_l} in the range of $\left[\underline{\theta}_{i_l}, \overline{\theta}_{i_l}\right]$.

An *allocation* Φ is defined as a match between some of the agents and some of the subtasks, $\Phi = \left\{(A_{i_1}, ST_{i_{1_{l_1}}}), ..., (A_{i_n}, ST_{i_{n_{l_n}}})\right\}$. Here Φ_T indicates the set of tasks allocated by Φ ($\Phi_T \subseteq \Phi$) and an allocation Φ is *feasible*, if and only if it satisfies three conditions:

C1 Each agent in Φ is allocated to at most one subtask.

C2 Any task is either fully allocated (one agent per subtask) or it is unallocated.

C3 For each task $T_i \in \Phi_T$, the total cost for the agents to perform its constituent subtasks does not exceed the task's total payment $p(T_i)$.

As discussed in the introduction, we seek to find an efficient allocation. To this end, we define the **value of an allocation** Φ, $V(\Phi)$, to be the difference between the total payments of the allocated tasks and the total cost for the assigned agents to perform the corresponding subtasks, $V(\Phi) = \sum_{T \in \Phi_T} p(T) - \sum_{(A_j, ST_{i_l}) \in \Phi} c^j_{i_l}$. The feasible allocation with the highest value is considered to be the ***efficient allocation*** Φ_{eff}. Consequently, the efficiency of any proposed allocation Φ is measured relative to Φ_{eff} as: $efficiency(\Phi) = \frac{V(\Phi)}{V(\Phi_{eff})}$.

Next we present a formal description of our problem using an integer program. The variables y_i and $x^j_{i_l}$ are decision variables where $y_i = 1$ if task T_i is chosen to be allocated and otherwise zero, and $x^j_{i_l} = 1$ if agent A_j is chosen to perform subtask ST_{i_l} and otherwise zero:

$$\Phi_{eff} = \max_{y_i, x^j_{i_l}} \left(\sum_{i=1}^{M} (y_i \cdot p(T_i)) - \sum_{j=1}^{N} \sum_{ST_{i_l} \in \Psi_j} (x^j_{i_l} \cdot c^j_{i_l})\right) \quad (1)$$

[1]This is for simplicity of exposition and our results can be easily extended to the case where an agent is capable of performing any constant number of subtasks at a time.

such that:

$$\sum_{ST_{i_l} \in \Psi_j} (x_{i_l}^j) \leq 1, \forall j \in 1, ..., N \quad (2)$$

$$\sum_{j \in \Omega_{i_l}} (x_{i_l}^j) = y_i, \forall i \in 1, ..., M, \text{ and } l \in 1, ..., k_i \quad (3)$$

$$x_{i_l}^j, y_i \in \{0, 1\} \forall i \in 1, ..., M, \forall l \in 1, ..., k_i, \forall j \in \Omega_{i_l} \quad (4)$$

where equations 2 and 3 correspond to C1 and C2, respectively. Note that condition C3 is implicitly achieved by the definition of Φ_{eff}.[2]

3. THE COOPERATIVE SETTING

In this section, we develop a practical algorithm that can be used by the system's controller to achieve an efficient solution in a cooperative setting. Specifically, we analyze the problem's complexity, then develop an algorithm to find an efficient solution, and finally explore the algorithm's properties.

3.1 Problem Complexity

The complexity of our task allocation problem is given by the following lemma:

LEMMA 1. *Given the task allocation problem defined in the integer program (1-4), the computational complexity of finding an efficient solution is NP-hard. Moreover, it is hard to approximate within a factor of* $M^{1-\epsilon}$.

PROOF. We show this using a reduction from the winner determination problem in combinatorial auctions. In a winner determination problem, there is a set of n items and a set of M bids $B_j(S_j, p_j)$, where S_j may be any bundle of items and p_j is the price offered for S_j. The goal of winner determination is to find the subset of bids that maximizes the revenue with no conflicts (in the sense that the same item would not be included in more than one bid). Given an instance of the winner determination problem we present the items as the agents in our problem (we define a one to one correspondence, so that any item i is associated with an agent A_i). Each bid $B_j(S_j, p_j)$ is viewed as a task T_j for which its payment is p_j. T_j is composed of $|S_j|$ subtasks, where the agents that are associated with the items in S_j are the only agents that are capable of performing the subtasks in T_j. We assume that an agent can perform any of the subtasks of the task it is associated with. In addition, we assume that the cost of the agents performing any subtask is zero. Given this mapping, it is easy to see that there is a solution to the winner determination problem in combinatorial auctions that will achieve a certain profit P for the auctioneer, if and only if an allocation to our task allocation problem exists in which its value is P. Building on this, [14] proves that no polynomial time algorithm can guarantee a bound $k \leq M^{1-\epsilon}$ for any $\epsilon > 0$ for the winner determination problem and thus based on reduction preserving approximability, our task allocation problem is also hard to approximate within a factor of $M^{1-\epsilon}$. □

Having shown our task allocation problem is NP hard, we now go on to present an algorithm which is exponential solely in the number of tasks, but polynomial in the numbers of subtasks and agents. This is a significant improvement over the brute-force algorithm which exhaustively goes through all possible assignments and searches for the minimum cost one. Such an algorithm is also exponential in the number of subtasks.

[2]Assume, by way of contradiction, that an Φ_{eff} exists that doesn't satisfy C3 (i.e., some tasks exist for which the agent's costs exceed the tasks' payments). Omitting these tasks from the allocation results in a higher value allocation, which is a contradiction.

Agents	ST_{1_1}	ST_{1_2}	ST_{2_1}	ST_{2_2}
A_1	5	-	5	-
A_2	-	5	-	5
A_3	30	-	10	-
A_4	-	30	-	10

Table 1: Costs and capabilities for example 1

3.2 Finding an Efficient Allocation

Our solution is based on the algorithm for finding the minimum weighted perfect matching in a bipartite graph [1]. Before describing the algorithm, we first provide an interpretation of our problem in terms of a bipartite graph $G = (V, E)$. Each of the agents and subtasks are represented by a vertex in V, such that a capability of an agent to perform some subtask is indicated by an edge (in E) between the corresponding vertices. A graph G is considered a **bipartite** graph if its vertices, V, can be partitioned into two groups, V_1 and V_2, such that no edge in E exists between members of the same group. In our case, this partition can be viewed as the agents and the subtasks groups. Given a bipartite graph G, a **perfect matching** $M \subset E$ is defined to be a subset of edges that cover all vertices and for which no common vertex exists for any pair of edges in M. In terms of our problem, a perfect matching is an assignment of agents to subtasks such that all the agents and the subtasks in V are allocated. By representing an agent's cost to complete some subtask as a weight of the edge connecting the two corresponding vertices, we obtain a weighted graph. Thus a **minimum weighted** perfect matching is a perfect matching, such that the sum of its edges' weights is the minimum (which in our case is an efficient solution if it satisfies the feasibility conditions). However, in our problem, some of the tasks may not be completed, as explained in section 2, thus in order to find the efficient solution one must go through all the subsets of tasks as we formally describe below.

Given a set of M candidate tasks $\Im = \{T_1, ..., T_M\}$, we define the power set of $\Im$ to be $\Lambda = \{\lambda | \lambda \subseteq \Im\}$). For each λ in Λ, we construct a bipartite graph $G_\lambda = (V_1, V_2, E)$, where V_1 represents all the subtasks, ST, associated with one of the tasks in λ, and V_2 corresponds to the agents in A (if the number of vertices in V_2 is larger than the number of vertices in V_1, the algorithm extends V_1 to the size of V_2 by adding $|V_2| - |V_1|$ vertices that are connected to all vertices in V_2 with a weight of 0). An edge between ST in V_1 and A_j in V_2 exists in E if A_j is capable of performing ST and the edge's weight is A_j's cost to perform ST. Given this construction, the problem of finding the ***minimum cost assignment*** that allocates all tasks in λ to agents in A is equivalent to the problem of finding the ***minimum weighted perfect matching*** M_λ in G_λ. An additional step of the feasibility test is required to validate the solution. The Algorithm is described in figure 1.

To illustrate the proposed algorithm consider the following example:

EXAMPLE 1. *Assume there are four agents* $\{A_1, A_2, A_3, A_4\}$ *and two tasks, each of which includes two subtasks* $T_1 = \{ST_{1_1}, ST_{1_2}\}$, $T_2 = \{ST_{2_1}, ST_{2_2}\}$, *where the task payments*

1. For each λ in Λ do:
   (a) Build a bipartite graph, $G_\lambda = (V_1, V_2, E)$.
   (b) Find the minimum weighted perfect matching M_λ in G_λ (if no perfect matching exists go to 1).
   (c) Check whether M_λ is a feasible allocation.
   (d) If M_λ is feasible, compute its allocation value $V(M_\lambda)$, otherwise go to 1.
2. Return the most efficient allocation, M_λ, which is a feasible allocation with the highest value $V(M_\lambda)$.

Figure 1: Algorithm for finding an efficient allocation

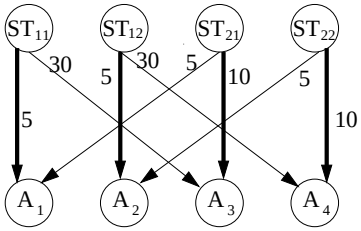

Figure 2: Graph for $\lambda_1 = \{T_1, T_2\}$

are $p(T_1) = 500$ and $p(T_2) = 12$. The agents' costs and capabilities are given in Table 1. The power set of the tasks includes three nonempty sets: $\lambda_1 = \{T_1, T_2\}$, $\lambda_2 = \{T_1\}$ and $\lambda_3 = \{T_2\}$. For each of them, the algorithm constructs the corresponding graph and computes the minimum cost allocation. Figure 2 shows the graph built for $\lambda_1 = \{T_1, T_2\}$.

Here the bold edges indicate the minimum cost allocation generated by the algorithm
$\Phi_{eff} = \{(A_1, ST_{1_1}), (A_2, ST_{1_2}), (A_3, ST_{2_1}), (A_4, ST_{2_2})\}$ for λ_1 whose value is 482. As this allocation is infeasible (since the total cost for T_2 is 20 whilst T_2's payment is 12) the algorithm ignores it and continues by considering λ_2. The efficient allocation of this example is to allocate only task T_1 to agents A_1 and A_2 for which the value is 490 (the highest possible).

According to the algorithm, given a certain subset of tasks, λ, first, a minimum weighted perfect matching is generated. Next its feasibility is verified[3]. Once it fails to satisfy the feasibility requirement, all other possible allocations of λ are ignored. It may seem possible that the efficient solution is not necessarily the minimum perfect matching for some λ, but, instead, is the minimum of all the *feasible weighted perfect matching*. For instance, in example 1, a feasible allocation exists where
$\Phi' = \{(A_1, ST_{2_1}), (A_2, ST_{2_2}), (A_3, ST_{1_1}), (A_4, ST_{1_2})\}$ that might have been the efficient allocation, but the algorithm ignores it. However, as we will prove in section 3.3.2, such a scenario cannot occur.

[3]Note that for each set of tasks $\lambda \in \Lambda$, the algorithm checks for the allocation that includes all tasks in λ, regardless of its feasibility, and computes the minimum allocation if such an allocation exists. However, if we change the algorithm to forbid infeasible allocations, the problem of checking for the *existence* of a *feasible* allocation that allocates all tasks in λ will become NP complete (a reduction can be made from the subset sum problem [2]).

3.3 The Algorithm's Properties

Here, we consider the time complexity and the correctness of our algorithm.

3.3.1 Time Complexity

The complexity of step 1 is exponential in the number of tasks in $\Im$, simply because it goes through all the $\Im$'s subsets. However, the complexity of the internal steps 1a-1d is polynomial, as the complexity of the matching problem is polynomial [1]. Therefore the total complexity of the algorithm is exponential in the number of tasks $|\Im|$ and polynomial in the numbers of subtasks and agents.

3.3.2 Correctness

Here, we prove that if the set of tasks allocated by an efficient allocation Φ is λ, then for G_λ the algorithm will return a feasible perfect minimum matching with the same value as Φ. This implies that the algorithm always returns an efficient allocation. Note that the algorithm can return an allocation different from Φ, but since it has the same value as Φ it is also considered an efficient allocation.

LEMMA 2. *Assume Φ_{eff} is an efficient allocation that allocates the set of tasks in λ_{eff}. Then the algorithm: (i) finds the minimum weighted perfect matching $M_{\lambda_{eff}}$ in graph $G_{\lambda_{eff}}$, (ii) $M_{\lambda_{eff}}$ is a feasible allocation, and (iii) $M_{\lambda_{eff}}$ has the same value as Φ_{eff}'s value.*

PROOF. Assume λ_{eff} is the set of tasks that are allocated by the efficient allocation Φ_{eff}. We begin by proving that a minimum weighted perfect matching $M_{\lambda_{eff}}$ exists for the corresponding graph $G_{\lambda_{eff}}$. As Φ_{eff} is feasible, by definition, it satisfies C1 and C2. That is, Φ_{eff} defines a perfect matching for $G_{\lambda_{eff}}$ which, in turn, means that a *minimum weighted* perfect matching exists. Therefore the algorithm returns $M_{\lambda_{eff}}$ (in the worst case it will be Φ_{eff}). Next, we prove that $M_{\lambda_{eff}}$ is a feasible allocation. Assume, by way of contradiction, that $M_{\lambda_{eff}}$ is an infeasible allocation. By definition $M_{\lambda_{eff}}$ satisfies C1 and C2. This implies that C3 is not satisfied. Let $\lambda_{infeasible}$ be the set of tasks in $M_{\lambda_{eff}}$ that do not satisfy C3 (i.e., $\lambda_{infeasible} = \left\{T_i | T_i \in \lambda_{eff} \text{ and } \sum_{(A_j, ST_{i_l}) \in M_{\lambda_{eff}}} c^j_{i_l} > p(T_i)\right\}$). Now let λ_{new} be the set of tasks that are allocated by $M_{\lambda_{eff}}$ that satisfy C3. That is, $\lambda_{new} = \lambda_{eff} - \lambda_{infeasible}$. As we assume $M_{\lambda_{eff}}$ is an infeasible allocation, $\lambda_{infeasible}$ must not be empty (therefore $\lambda_{eff} \neq \lambda_{new}$). Let $M_{\lambda_{new}} = \left\{(A_j, ST_{i_l}) | (A_j, ST_{i_l}) \in M_{\lambda_{eff}} \text{ and } T_i \in \lambda_{new}\right\}$. $M_{\lambda_{new}}$ is a perfect matching for the set λ_{new}. Consequently, $M_{\lambda_{new}}$ is a feasible allocation for λ_{new} and thus, from the feasibility definition, $M_{\lambda_{new}}$ is a feasible allocation for the entire set of tasks $\Im$. In conclusion, at this point, we have two feasible allocations for $\Im$, Φ_{eff} and $M_{\lambda_{new}}$. Next, we will calculate their efficiency values.

$V(\Phi_{eff}) = \sum_{T \in \lambda_{eff}} p(T) - \sum_{(A_j, ST_{l_i}) \in \Phi_{eff}} c^j_{i_l}$
$\leq$ [4] $\sum_{T \in \lambda_{eff}} P(T) - \sum_{(A_j, ST_{l_i}) \in M_{\lambda_{eff}}} c^j_{i_l} = V(M_{\lambda_{eff}})$
$= \sum_{T \in \lambda_{infeasible}} P(T) - \sum_{(A_j, ST_{i_l}) \in M_{\lambda_{eff}} - M_{\lambda_{new}}} c^j_{i_l} +$
$\sum_{T \in \lambda_{new}} P(T) - \sum_{(A_j, ST_{i_l}) \in M_{\lambda_{new}}} c^j_{i_l}$

[4]As the minimum perfect matching finds the lowest weight matching but not necessarily a feasible one, the efficiency value of $V(M_{\lambda_{eff}})$ is greater or equal to $V(\Phi_{eff})$.

$< \sum_{T \in \lambda_{new}} P(T) - \sum_{(A_j, ST_{i_l}) \in M_{\lambda_{new}}} c^j_{i_l} = V(M_{new})$.

To conclude, we prove that $V(\Phi_{eff}) < V(M_{new})$, which contradicts the fact that Φ_{eff} is the allocation with the maximum efficiency value. Therefore the efficiency value of $V(M_{\lambda_{eff}})$ is equal to $V(\Phi_{eff})$. Previously we proved that $M_{\lambda_{eff}}$ is a feasible allocation. That is, the value $V(M_{\lambda_{eff}})$ cannot be greater than $V(\Phi_{eff})$ since Φ_{eff} is *the* efficient allocation. On the other hand, $V(M_{\lambda_{eff}})$ cannot be less than $V(\Phi_{eff})$ as both allocate all tasks in λ_{eff} and $M_{\lambda_{eff}}$ is the minimum matching cost . □

Up to this point, we have dealt with a cooperative setting. Unfortunately, however, the algorithm developed for this setting cannot be simply applied to the non-cooperative case for the following reasons: (1) the controller in a non-cooperative setting cannot assign a subtask to an agent that has not indicated its willingness to take on the activity and (2) the agents in a non-cooperative case may manipulate their reported costs in order to increase their individual benefit. Moreover, while in a cooperative setting the division of a task's payment does not have any impact on the allocation outcome, in the non-cooperative case the payment division may well play an important role (as it directly affects the agents' behavior). Therefore, as part of any proposed protocol, a rule by which the task's payment is divided among the contributing agents needs to be designed. As a consequence, no guarantees about the proposed algorithm's efficiency exist when applied to the non-cooperative settings. Thus next we examine the non-cooperative setting in terms of desiderata, impossibility results, and potential solutions.

4. THE NON-COOPERATIVE SETTING

In a non-cooperative system, agents have the freedom to decide which subtasks they wish to carry out and which costs to report (since the controller has no information on the agents' actual costs). Thus the controller can only allocate the subtasks based on the agents' requests. Therefore, in order to achieve an efficient solution, the simple approach of asking agents to report their private information (as assumed by the algorithm for the cooperative case) needs to be replaced by a more sophisticated protocol. That protocol should still seek to maximize the overall efficiency, while taking into consideration that each individual agent may strategise (on the subset of its capabilities and their costs to report) in order to maximize its own utility.

In most task allocation scenarios, the strategy space for a buyer considers values that are lower than its actual valuation. Similarly, the strategy space for a seller considers values that are higher than its cost. In our case, the agents are selling their services to perform some subtasks. Given this, one might think that as part of our agents' strategies in the task allocation problem we need to consider only those costs that are higher than their actual costs. In contrast, however, we show that this is not the case in our setting and an agent designer needs to consider values that are both higher and lower than the actual agents' costs[5]. Consequently, given that in non-cooperative settings the agents may make strategy-based declarations, we would like to develop protocols for which dominant strategies (i.e., the best strategy for an agent regardless of the strategies chosen by other players), or at least Bayesian Nash equilibria [11] exist to free agents from the need to strategize.

In particular, we would like to find one general protocol for which agents will have equilibrium strategies (for the strongest concept possible) that achieves the ***efficient*** solution for all instances of our problem and, in addition, will satisfy the following desirable properties. First, as we have self interested agents, a primary desiderata of any proposed protocol is to be ***individually rational*** (i.e., the expected revenue for each agent from participating should be higher than or equal to the revenue achieved by not participating). This is essential to guarantee that no agent loses by participating in the allocation process. Second, the protocol should also be ***budget balanced*** to match the definition of our task allocation problem (i.e., any task's payment should be fully paid out to its contributing agents and no transfer is allowed between tasks). The motivation for such a requirement is the fact that the preset overall payment is known and that it has been allocated solely for the completion of the task. Third, we would like our protocol to be ***undiscriminating*** (i.e. it should not discriminate among the agents by utilizing the knowledge of the agents' capabilities. In this model the protocol is required to give the same expected payment to any two agents with the same declared capabilities and the same costs, regardless of the difference in their actual capabilities). Such a requirement is vital to ensure that the maximum number of agents are willing to engage in the pool of providers.

For the analysis that follows, we consider two classes of environment: one in which the agents may strategize about their costs and another in which they cannot. We term the latter a ***real cost environment*** and we consider it a means of factoring out any issues that follow from the information uncertainty, rather than the self-interested nature of the agents.

4.1 No Efficient, Individually Rational, and Budget Balanced Mechanism Exists

Here we prove that no protocol can exist that is efficient, individually rational and budget balanced, for which there is a dominant strategy or at least a Bayesian Nash equilibrium.

To prove this, we use a reduction to the bilateral trading problem. In the bilateral trading problem, a single buyer wants to buy a single item from a single seller. Both the seller and the buyer have private values for the item v_s and v_b, respectively. Both values are independently drawn from the same uniform distribution between 0 and 1. In such problems there are cases in which trading is possible ($v_s \leq v_b$), but due to the buyer's and seller's strategies, trading might not be achieved. Myerson and Satterthwaite prove that for this problem no efficient protocol exists which is individually rational and budget balanced even in a Bayesian Nash equilibrium [10].

LEMMA 3. *Given the general task allocation problem defined in the integer program (1-4) even for only one task $|\Im| = 1$, no efficient protocol exists that is individually ra-*

[5]As an illustration, consider the task allocation described in Example 1 with a protocol, that given the agents' declaration, calculates the efficient solution (using the algorithm presented in figure 1) and distributes the surplus of each task equally among its contributing agents. In this case, A_3 is incentivised to declare a cost lower than the real one for subtask ST_{1_1} (for which $p(T_1) = 500$); by doing this it increases its chance to win this subtask.

tional, and budget balanced, even in a Bayesian Nash equilibrium.

PROOF. Assume, by way of contradiction, that there is an efficient, budget balanced and individually rational protocol PR_{task} for our task allocation problem. We can then use PR_{task} in order to design a protocol $PR_{BiTrading}$ that solves the bilateral trading problem.

Given an instance of the bilateral trading problem, the protocol $PR_{BiTrading}$ is defined as follows:

- Both the seller and the buyer bid their values for the item b_s and b_b, to the controller, respectively.
- The controller builds the following instance I_{task} of our task allocation problem that considers two agents, $\{A_1, A_2\}$, and one task including two subtasks, $T_1 = \{ST_{1_1}, ST_{1_2}\}$ where $p(T_1) = 1$. The agents' costs for both subtasks are uniformly distributed over $[0, 1]$. Agent A_1 is capable of performing only subtask ST_{1_1} and its cost is b_s. Agent A_2 is capable of performing only subtask ST_{1_2} and its cost is $1 - b_b$.
- Run PR_{task} to solve the instance of our task allocation problem I_{task}.
- If T_1 is allocated and the payments p_1 and p_2 are made to A_1 and A_2 respectively, (since the fixed payment constraint is $p_1 = 1 - p_2$) the seller sells the item to the buyer and the buyer pays p_1 to the seller, otherwise no trade occurs.

Since we assume that PR_{task} is efficient, budget balanced and individually rational, $PR_{BiTrading}$ is as well. This is a contradiction to Myerson and Satterthwaite's work which proved that there is no efficient, individually rational and budget balanced protocol that exists for the bilateral trading problem which is in Bayesian Nash equilibrium [10]. □

Hence, as the property of being strategy proof (i.e. truth telling is a dominant strategy) is a strictly stronger concept than the Bayesian Nash equilibrium, from Lemma 3 we can conclude that no efficient, individually rational and budget balanced protocol which is strategy proof exists for our general problem.

In the next section, we consider real cost environments, removing the agents' ability to falsely report their costs for their own benefit and demonstrate that there is still no efficient protocol meeting our requirements.

4.2 No Efficient Protocol Exists for Real Cost Environments

There are some situations in which the real costs of the agents may be verified. One example is a scenario where service providers do not directly receive payment for the costs of their raw materials, but payments are given against original receipts. Notice that in this case, in addition to the cost reimbursement, the agents expect a supplementary payment from the surplus of the task overall payments, and this is their motivation for participating in the allocation.

In such cases an agent's strategy reduces to one dimension: its willingness to perform certain subtasks (it no longer incorporates the subtask cost dimension). Therefore, a truth telling agent in this case is one that declares all the subtasks it is able to perform. If in this scenario an agent is forced to declare all the subtasks it can perform, we are reduced to the problem which is solved in section 2. However, we wish to consider the case where the agent is free to choose the subtasks it declares.

Agents	ST_{1_1}	ST_{1_2}	ST_{2_1}	ST_{2_2}
A_1	1	1	-	-
A_2	1	1	-	-
A_3	1	1	2	-
A_4	-	-	-	3

Table 2: Agents' capabilities and costs of example 4.2

Against this background, we will now go on to prove that even for real cost environments, no protocol achieving the efficient solution can exist that is individually rational and budget balanced (except where the allocation problem consists of a single task).

LEMMA 4. *Given the general task allocation problem defined in the integer program (1-4) and assuming there are at least two tasks, no protocol achieving the efficient solution can exist for real cost environments that is individually rational and budget balanced, not even in a Bayesian Nash equilibrium.*[6]

PROOF. We demonstrate that there is no general protocol by exhibiting a particular setting for which no protocol can exist. Assume there are four agents $\{A_1, A_2, A_3, A_4\}$ and two tasks, each of which includes two subtasks $T_1 = \{ST_{1_1}, ST_{1_2}\}$, $T_2 = \{ST_{2_1}, ST_{2_2}\}$, where the task payments are $p(T_1) = 100$ and $p(T_2) = 8$. The costs of subtasks ST_{1_1} and ST_{1_2} are 1 for all agents, and the costs for ST_{2_1} and ST_{2_2} are uniformly taken from [1,4]. The specific agents' costs and capabilities are given in table 2.

By the revelation principle[11] it is sufficient to prove that no efficient protocol exists where an agent's best strategy is to agree to perform all the subtasks it is able to perform and declare its real costs assuming all other agents will do the same. If agent $A3$ declares its willingness to perform all the subtasks it is capable of performing $\{ST_{1_1}, ST_{1_2}, ST_{2_1}\}$, it will be assigned to ST_{2_1} and its utility will be less than 8 (as any payment can not exceed the task payment). However, if A_3 agrees to perform only $\{ST_{1_1}, ST_{1_2}\}$, it becomes similar to A_1 and A_2 [7]. Consequently, its expected utility is $\frac{98}{3}$ (as the expected payment for agents with identical costs and the same declared subtasks should be the same). Therefore, for every protocol, A_3 won't declare subtask ST_{2_1}, resulting

[6]Note that this lemma cannot be derived from lemma 3 since here we assume a real cost environment (whilst in lemma 3 the agents can lie about their costs). On the other hand, lemma 3 cannot also be derived from this lemma (since there we proved that no desired solution can be achieved for one task and, for real cost environments a desired solution does exist for one task).

[7]Note that since A_3 knows the other agents' capabilities and subtask's costs distribution it knows both A_1 and A_2's costs and capabilities (the costs of ST_{1_1} and ST_{1_2} are equal to 1 for all agents). By assuming that all other agents declare all their subtasks, A_3 knows that by agreeing to perform only subtasks $\{ST_{1_1}, ST_{1_2}\}$ and declaring the costs of 1, it agrees to perform the same subtasks and declare the same costs as A_1 and A_2. Therefore the protocol should yield A_3 the same expected payment.

in an inefficient allocation as only one of the tasks can be allocated. □

However, in contrast to our results in section 4.1, next we prove that in the case where there is only one task to allocate, an efficient protocol exists for real cost environments.

LEMMA 5. *Given a real cost environment, an efficient protocol exists for the task allocation problem defined in the integer program (1-4) where* ***there is only one task****.*

PROOF. Consider a protocol in which each agent is requested to declare the subtasks it is interested in and its costs for them. Based on this information, the controller calculates the efficient allocation using the perfect minimum weighted matching algorithm (section 3). According to this efficient allocation, the protocol pays the cost of each allocated agent and an extra equal share of the surplus from the task payment. Given this protocol and the fact that there is only one task to allocate, it is easy to see that a dominant strategy exists where each agent is motivated to declare all the subtasks it is able to perform with their real costs (as we assume the real cost environment). By assuming that all agents use this dominant strategy, we can deduce that this protocol inevitably derives the real efficient solution as it does in the full information case. □

So far, we have shown that no single efficient protocol exists for the general case that achieves the desirable properties. However, there are settings for which such efficient protocols exist. The next section explores these settings.

4.3 Only Setting-Specific Efficient Protocols Exist

In order to show that efficient solutions can be generated for specific settings, but the ensuing solutions are specific to these settings, we consider two reasonably common environments. Specifically, we consider a Different Capabilities Setting (DCS) in which the agents have different capabilities and all the tasks are associated with the same overall payment, and a Different Task Payment Setting (DTPS) in which all agents are capable of performing all the subtasks and the tasks are associated with different payments. Then, for each setting, we provide an efficient protocol, and prove that this protocol is not efficient for the other one. In both settings we consider that the number of subtasks is equal to the number of agents and that each task includes K subtasks (the same number for all the tasks). Finally, we assume the agents' cost for any subtask is equal to c.

Given these settings, we consider two protocols: (1) the sequential protocol ***SEQP*** and (2) the simultaneous protocol ***SIMP***. According to both protocols, the task's payments are divided equally among the contributing agents. Then as it is assumed that each agent's cost to perform any of the candidate subtasks is c, each agent has to declare which subtasks it wants to perform but not their costs.

In detail, Protocol **SIMP** allocates all tasks simultaneously. Therefore, each agent has to declare at once all the subtasks (of all the tasks) it wants to perform. Based on these declarations, the protocol finds the most efficient allocation (using the algorithm described in figure 1). In contrast, the **SEQP** protocol allocates the tasks sequentially according to a decreasing order of the tasks' payments (a random order is used to break ties). In each round the controller announces a task, T_i, and the agents declare which of its subtasks they wish to perform. Based on these declarations, in each round, the SEQP protocol finds the most efficient allocation for the considered task. Next we show that for each setting, only one of the protocols achieves an efficient solution.

We begin by considering the efficient protocol for the DCS setting. In this case all subtasks' payments are equal; thus any agent is indifferent to which subtask it is allocated. Accordingly, under the SIMP protocol, a rational agent will declare all the subtasks it can perform. Moreover, as the SIMP protocol searches for the overall efficient allocation, based on the reported capabilities, it achieves the same result as in the cooperative system case. However, using SEQP in this setting does not achieve an efficient solution. This is because the allocation is made separately for each task in a greedy manner (i.e. finding the most efficient allocation for a given task at a time while ignoring the rest of the tasks). For example, consider the case where two agents, A_1 and A_2, are capable of performing subtask ST of task T, while A_1 is the only agent capable of performing subtask $ST^{'}$ of task $T^{'}$. For this case, if the allocation is made simultaneously for all tasks, A_1 will be allocated to $ST^{'}$ and A_2 will be allocated to ST so that both tasks may be completed. However, for SEQP protocol, T can be allocated first (as a random order is used to break ties). Therefore in this case, A_1 may be chosen to perform ST and consequently, $T^{'}$ won't be allocated.

For the DTPS setting, SEQP achieves an efficient solution. This is because when it allocates a certain task, it is the currently most attractive one (as all tasks with higher payments have already been allocated). Thus, each agent is motivated to declare all subtasks of the announced tasks. As all agents are capable of performing any of the tasks, the concern that some particular agent will be needed for a later allocation does not exist. By contrast, in this case SIMP does not achieve an efficient solution. This is because there may be a case where some subtasks may not be declared by any agent. To understand why SIMP fails in this setting, consider the case of an agent that declares all the subtasks. This agent might be assigned to the lowest payment subtask, while the highest payment one is allocated to another agent who declared only the subtasks with the highest payments.

In conclusion, we have demonstrated that in the non-cooperative case, there is no general protocol which fulfils all our desiderata. Moreover we have proved that there exist settings for which protocols can be developed. However, each such settings requires individual treatment and a tailored protocol. Consequently, any further attempt to develop a protocol for this task allocation problem in the non-cooperative setting, will have to commence by clearly defining the setting in which it is to operate.

5. RELATED WORK

Task allocation and coalition formation in multi-agent environments have been widely studied in recent years. However, to date most of the works including classical solutions for coalition formation (such as Shaply value and Kernal [5, 4]) assume complete information about the agents is available and that they are self interested. Therefore these solutions are not applicable to our cooperative and non-cooperative settings, where, respectively, cooperative agents and incomplete information are assumed.

However, the coalition formation work by Li and Zhang does consider a cooperative setting for a task allocation problem that is similar to ours [8]. However, the authors assume that the agents may use all their resources simultaneously (i.e using one resource type doesn't prevent the agent from using its other available resource types). This contradicts our assumption that agents have finite capabilities and can perform only a constant number of subtasks simultaneously. Thus their results cannot be applied to our problem. Other works on coalition formation in a cooperative setting are [15, 3] in which the authors looked for the optimal coalition structure. However, in their works they considered environments in which only one value is associated with each coalition. This contrasts with our case, where a coalition may have different values for each task it can perform depending on the subtask allocation.

In our algorithm for the cooperative setting we use matching in order to find an efficient solution, similar to other works like [13] that use matching in order to solve various allocation and assignment problems. However none of these works have the same constraints as we have (e.g., constraints C1-C3 in section 2) . Therefore their solutions are inapplicable to our case. The only work that considers the same problem constraints as ours is [6, 7]. However, as explained in section 1, they use heuristics (e.g., hill climbing), while we find the exact efficient solution.

Another related research area is the cost sharing mechanism problem [9]. According to this work, incomplete information, and, typically, a fixed known cost per coalition (similar to our task's payment) is assumed. But, in contrast to our work, they consider a much simpler structure of the problem. Specifically, the allocator is responsible for forming only one coalition, while in our case the allocator faces the more complex decision as of which group of agents to assign a certain task to and how to allocate the subtasks to its coalition members.

Our problem also has similarities to a combinatorial market problem [12]. Each subtask can be treated as an item, each task as a bundle of complementary items, and each agent as a seller with substitutable valuations, since an agent can perform only one sub-task simultaneously (see section 2). However, in the combinatorial market the payment for each bundle is determined by the auction. By contrast, in our problem the payment for each task is predefined and known. In addition, in most work on combinatorial markets the surplus of the overall buyers' values and the overall sellers' values is divided among all participants. This is not appropriate in our model, where the task payment is divided only among the agents that perform the task.

6. CONCLUSIONS

In this paper we have considered a complex task allocation problem that needs to be solved by a group of autonomous agents working together. Given the ubiquity of this problem, it is surprising that to date it has not received significant attention. To rectify this omission, we consider both cooperative and non-cooperative settings of the problem. For the former setting we provide a practical algorithm for finding an efficient solution. The time complexity of this algorithm is polynomial in case the number of tasks is bounded by a small constant number (which is often the case in real world situations). In contrast, for the non-cooperative setting we prove that no general protocol achieving the efficient solution exists for our problem that satisfies our desired properties. However, we show that there exist some non-cooperative settings scenarios for which an efficient protocol does exist. Unfortunately, each such setting requires the design of a bespoke protocol, since the solution for one setting is likely to be inappropriate for another. In so doing, this study hopes to assist system designers confronting this problem to understand what can and cannot be achieved.

ABSTRACT

Assigning tasks to agents is complex, especially in highly dynamic environments. Typical protocol-based approaches for task assignment such as Contract Net have proven their value, however, they may not be flexible enough to cope with continuously changing circumstances. In this paper we study and validate the feasibility of a field-based approach for task assignment in a complex problem domain.

In particular, we apply the field-based approach for task assignment in an AGV transportation system. In this approach, transports emit fields into the environment that attract idle AGVs. To avoid multiple AGVs driving towards the same transport, AGVs emit repulsive fields. AGVs combine received fields and follow the gradient of the combined fields, that guide them towards pick locations of transports. The AGVs continuously reconsider the situation of the environment and task assignment is delayed until the load is picked, improves the flexibility of the system.

Extensive experiments indicate that the field-based approach outperforms the standard Contract Net approach on various performance measures, such as the average wait time of transports and throughput. Limitations of the field-based approach are an unequal distribution of wait times across different transports and a small increase of bandwidth occupation.

General Terms

Design

1. INTRODUCTION

Multiagent systems (MASs) are generally considered as an approach to build complex software systems. Adopting an agent-oriented approach means decomposing a system into multiple, autonomous entities that can act and interact in a shared environment to achieve the system goals. A MAS provides a decentralized architectural solution to a software problem that aims for qualities such as robustness and flexibility.

The application that is central in this paper is an Automatic Guided Vehicle (AGV) transportation system. An AGV system is a fully automated industrial transport system that makes use of multiple AGVs that have to transport loads in an industrial environment, e.g. a warehouse. One way to control an AGV system is through a central server. This server maintains all relevant information, needed to decide which AGV has to do what and which route is to be taken. In a joint research project between AgentWise taskforce and Egemin, a producer of automated logistic systems, we investigate the feasibility of applying the MAS paradigm to an AGV transportation system [5, 21]. In this approach, the control is distributed over the different AGVs, who cooperate to achieve the goals of the system. One major challenge in an AGV transportation system is task assignment, i.e. the assignment of transports to AGVs. *Transports*, which consist of picking up a *load* on a location (i.e. the pick location) and transporting it to another location (the drop location), are generated by an external system. Transports are dynamically created when needed and the transport profile (i.e. the order and pace in which transports are created) is irregular and unpredictable. Due to the highly dynamic nature of transport creation, the assignment of transports to AGVs is complex. Egemin currently applies a policy that pre-stages the AGVs based on a fixed set of rules. This approach however, lacks flexibility to cope with the continuously changing circumstances in the environment.

Typical protocol-based approaches for task assignment such as Contract Net have proven their value, however, they may not be flexible enough to cope with continuous dynamics in the environment. The main goal of the work reported here is to examine the *feasibility* of using a *field-based approach* to achieve *task assignment* in a complex domain, in casu an AGV transportation system. We aim to investigate the advantages as well as the limitations of the approach in this real world setting. In the field-based task assignment for AGVs, transports emit fields that attract idle AGVs, while competing AGVs emit repulsive fields. Each idle AGV follows the gradient of the combined fields it receives, which guide the AGV towards the pick location of a transport. To validate the field-based approach, we implemented it in an AGV simulator [1]. In the simulations, we use data of a realistic AGV system, including a real-world map and transport profiles. We have performed various performance measures, such as the average time a transport has to wait before it is executed, the throughput of the system, and the number of messages that are transmitted. The test results are compared with a reference algorithm for task assignment that uses a Contract Net protocol [19]. In this paper, we give an overview of the field-based approach for task assignment, and we discuss the main

results obtained from this study. A detailed description of additional tests not included in this paper can be consulted in [17].

Overview. The remainder of this paper is structured as follows. In Section 2 we briefly introduce the AGV application. Section 3 discusses related work on task assignment and field-based techniques applied in MAS. In Section 4 we describe the approach of field-based task assignment. Section 5 discusses test results and evaluates the approach. Finally, we draw conclusions in Section 6.

2. THE AGV APPLICATION

An AGV system is a fully automated industrial transport system, that uses multiple AGVs to transport loads (raw materials, finished products, etc.) in an industrial environment such as a warehouse. In this section we give a brief overview of the AGV application. Subsequently the map of the environment, the transports, and the AGVs are described.

2.1 Map of the Environment

The AGVs are restricted to follow predefined paths in the environment, on which they navigate by using sensors and stationary beacons. These paths are defined in a *map* of the environment. A map is logical representation of the physical layout on the factory floor, it consists of a network of stations and connecting segments that are accessible by the AGVs. A station is a predefined point on the map, stations can hold special locations, such as a pick or drop location for transports, a parking place for AGVs, or a place where AGVs can reload their battery. A segment defines in which direction(s) AGVs can drive. Additional information may be associated to segments, e.g. speed limits, mutexes that indicate that only one AGV can enter a particulate zone at a time, etc. In section 5 we give an example of a realistic map that we have used for testing.

2.2 Transports

The goal of the AGV system is to let AGVs transport loads. A transport is created by an external system, typically a warehouse management system. A transport represents an order to move a load from a pick location to a certain drop location. Each transport has a priority from 1 to 10, with 10 being the most important. A transport's life-cycle starts when it enters the system. The transport is started when an AGV picks up the load and is terminated when that AGV drops the load at the drop location. The priority of a transport may increase over time, e.g. as a result of long waiting times.

2.3 AGVs

An AGV is a computer controlled, unmanned vehicle that is capable of transporting loads in an industrial environment. An AGV is capable of picking up loads, driving them around and dropping them. AGVs can communicate by means of a wireless LAN. An AGV navigates by storing an internal map of the environment and using internal and external sensors, in combination with stationary beacons. AGVs are equipped with low-level control software that handles the physical interaction with the environment such as staying on track, turning, or determining the current position.

To allow smooth and save movement, an AGV has to make routing decisions over a certain distance in advance. This distance, called the *look-ahead*, is measured according to the logical topology of the environment map. The *look-ahead buffer* associated with an AGV is an ordered set of stations and segments that holds the routing decisions, representing the path that the AGV will follow with certainty, unless something catastrophical (such as a crash) happens.

In this paper we focus on achieving *task assignment* by applying a field-based approach. During task assignment the AGV will use a simple A* algorithm [8] to *rout* towards a transport. Besides task assignment, other important concerns are collision avoidance and deadlock prevention, however, these concerns are not further discussed.

3. RELATED WORK

In this section, we discuss a number of approaches related to our field-based task assignment approach. First we discuss a number of general approaches for task assignment. Task assignment is an extensive domain of research. Here we mainly focus on well-known Contract Net-based mechanisms. Next, we discuss a number of related field-based techniques for MAS described in literature.

3.1 Task Assignment

Efficiently assigning tasks to individual entities in a decentralized system is a common, but certainly not a simple problem [7]. A classic way to achieve task assignment is through auction-based mechanisms, e.g. the widely known and extensively used *Contract Net* protocol (CNET [19]). CNET is based on the notion of call for bids on markets, where managers request for bids and bidders bid to perform the task. In a first step, the manager sends a description of the task to perform to all the bidders. In a second step, the bidders draw up a proposal based on the description of the task and send it to the manager. In a third step, after the manager has received a proposal from all bidders or after a deadline has expired, the manager evaluates the received proposals and assigns the best bidder the task.

In the original CNET protocol, a bidder that has placed a bid for a task (step 2), cannot place a bid for a new task before the first task has ended. In [10], an improvement to CNET is proposed that allows a bidder to place bids for multiple unassigned tasks. This is achieved by giving the bidder the option to refuse the task in step 3 of the original protocol. The manager will then award the contract to the second best bidder, who can again accept it or refuse it, etc.

The CNET protocol can also be extended to allow cascading task assignment, where the receiver of a task proposal starts one or more new CNET protocols to delegate the task or parts of the task to other agents [10]. For example, a system of holonic agents can be used to improve efficiency when dealing with complex tasks that require the collaboration of several agents [11]. A holonic agent consists of several agents but interacts with agents outside the holon as a single agent.

The CNET protocol suffers from low flexibility when dealing with tasks that can not immediately be started upon the allocation (delayed commencement of tasks [3]). Consider for example the CNET protocol applied to task assignment in an AGV system. When a new transport enters the system, a suitable AGV is selected through the CNET protocol and is assigned to the transport. Suppose that while the assigned AGV is driving towards the pick location of the transport, a new transport appears that is more suitable to the AGV (e.g. it is closer or has a higher priority). The AGV will not be able to execute the second transport, since it is already assigned to the original transport. Thus, the CNET protocol achieves an *immediate* and *permanent* assignment of tasks, making it impossible for the system to react flexibly and adaptively when dealing with tasks with delayed start in a highly dynamic environment. [2] provides more flexibility by assigning tasks in two phases (first phase temporarily assignment, next phase definitive assignment) but still does not provide full flexibility in case of delayed commencement.

Another interesting approach for task allocation is described in [6] that is based on the exchange of *tokens* among agents. The authors describe an example of robots that drive around and perceive objects in the environment. These objects have to transferred from one location to another. To move an object, two robots have to col-

laborate. Therefore, two roles are associated with the task: a helper role and a collector role. The coordination among agents is based on the exchange of tokens, which are associated with the roles of a task. Tokens can be exchanged between agents and whoever owns a token can participate in the task in the associated role.

In earlier work [3], we have described an approach for flexible and decentralized task allocation that deals with the problems mentioned above. This approach consists of a continuous *negotiation* protocol where the situation and the allocation of tasks is continuously *reconsidered* until the task is actually started. The approach presented in this paper builds upon the principles developed in that research. However, here we provide a simplified and uniform model that consistently uses fields for task assignment.

3.2 Field-Based Techniques in MASs

Techniques based on *fields* have proven to be valuable in various applications that involve movement of agents in a metric space [7, 15, 12, 16, 13, 14]. In this approach, objects in the environment produce fields, which are propagated in the environment in a certain range. At each position in the metric space these fields have a certain value, forming *potential fields*. These values are typically proportional to the distance from the source of the field. Agents perceive the fields and combine them in a certain way. The behavior of an agent then simply consists of following the combined potential field downhill, that is, agents follow the direction of the *gradient* of the field. As an example, suppose an agent has to move to a goal while avoiding obstacles in the environment. The obstacles emit repulsive fields, while the goal emits an attractive field. The agent combines the fields by adding the values of the attractive and repulsive field. The combined field can be visualized as a landscape, with the goal representing a valley and the obstacles mountains. This combined field is then followed downhill, which can be viewed as a ball rolling down the slopes of the landscape towards the goal. The field-based approach readily extends to task allocation, where each task emits an attractive field and agents follow the strongest field. Competition among agents can be handled by letting the agents emit repulsive fields.

Field-based techniques have also been applied in systems that are inspired by biological phenomena and physics. For example, birds in a flock all fly in the same direction and avoid collision by keeping a fixed distance between each other. An example application for this idea are guards who have to patrol a museum, keeping a certain distance between each other to cover more ground [15]. Shehory et al. [18] describes a physics oriented model for cooperative goal-satisfaction with simple agents in a large-scale cooperative MAS. Different kinds of gradient field approaches have also been used in the context of RoboCup, a recent example is [4].

[12] discusses a variation on the field-based approach where agents construct a field in their direct neighborhood to achieve routing and deadlock avoidance in a simplified AGV systems. Another variation is described in [16], where the MMASS (Multilayered Multi Agent Situated System) model for multiagent coordination is used. In this model, the environment is represented as a multi-layered graph in which the agents can spread abstract fields. In the standard field-based approach, agents combine perceived fields and are constantly guided by the fields, while in MMASS fields are in principle considered independent from each other and are exploited only to trigger one shot reactions.

Pros versus Cons. The field-based approach is an elegant and effective way to tackle problems in a metric environment. The agents can be kept simple, relying on the environment to achieve the system objective. Since no rigorous protocols are used, robustness and openness (agents can easily be added or removed from the system) are achieved. The approach also benefits from adaptivity: the landscape of fields is readily adjusted to changes in the environment. Also, the fields can be interpreted and combined in different ways by different agents (e.g. a location may be a goal for one agent, while another agent needs to avoid it).

However, the field-based approach also suffers from some limitations. Firstly, the approach is difficult to apply when the situation cannot be represented as a metric space. Secondly, local minima can arise, agents can become stuck at a local minimum, leading to sub-optimal solutions. Another problem is that the approach is not easily to combine with cognitive decision making mechanisms. Finally, a disciplined methodology is lacking to predict the overall evolution of the system. With the field-based approach, the solution emerges from the interaction among the agents. Typically, the development of such systems requires intensive parameter tuning.

Maintaining Fields. An important issue when using the field-based approach is the distribution and maintenance of fields within the environment. A possible way to maintain fields is a storage infrastructure to store the different values of fields in different (digitized) positions in the environment. When dealing with a software environment, this requirement is automatically achieved. For example, the field-based approach has been used successfully in games such as in "Quake 3 Arena" [13] to guide the behavior of non-human characters.

When dealing with a physical environment, a distributed storage capability could be physically supported by the environment. For example in [15], the field-based approach is applied in guiding tourists in a museum. The tourists are provided with a software agent running on some wireless handheld device, giving suggestions on how and where to move. A computer network with a topology that mimics the topology of the museum plan is embedded in the museum walls. The hosts in the network are associated to each room and are capable of communicating with each other and the mobile devices in their proximity. Fields can be injected at a host, after which they will be diffused hop-by-hop across the network, modulating the values of the fields as necessary. The latter is achieved by supporting middleware, such a TOTA (Tuples On The Air) [14].

If no environmental storage infrastructure is available, fields can still be realized by broadcasting information messages, which contain the position of the source of the field and its initial strength. Agents receive these messages and calculate the value of the field on their position. In this paper we have applied this approach since a typical AGV system provides no distributed storage infrastructure external to the mobile AGV machines.

4. FIELD-BASED TASK ASSIGNMENT

In this section we explain the approach for field-based task assignment in AGV transportation systems. Similar to the approach in [3], task assignment is *delayed* until the AGV actually reaches the pick location of the transport, allowing the system to react flexibly and adaptively to new transports that enter the system. We start with a high-level explanation of the approach, followed by an overview of the software architecture.

4.1 High-Level Overview

The basic idea of field-based task assignment is to let each idle AGVs follow the gradient of a field that guides it toward a load that has to be transported. There are two types of fields in the system: (1) transports emit fields into the environment that attract idle AGVs; (2) to avoid multiple AGVs driving towards the same transport, AGVs emit repulsive fields. AGVs combine received fields and follow the gradient of the combined fields, that guide them towards pick locations of transports. The AGVs continuously reconsider the situation of the environment and task assignment is delayed

until the load is picked, which benefits the flexibility of the system. To explain the field-based approach for taks assignment, we use the scenario depicted in Fig. 1.

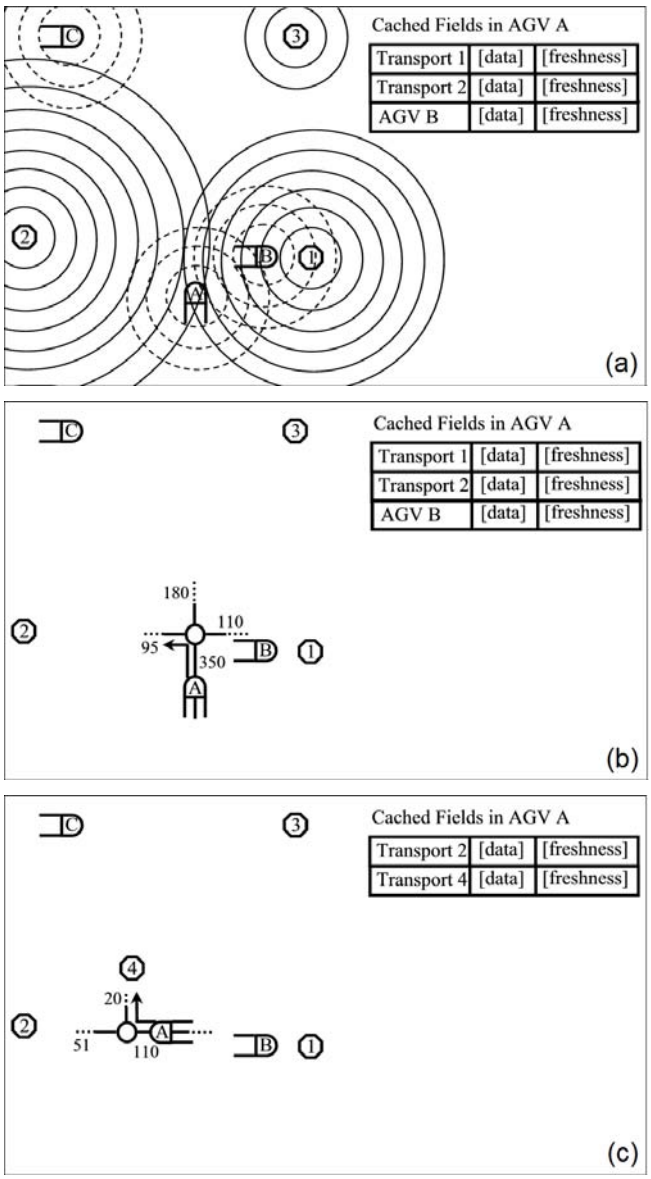

Figure 1: ***Example scenario of the developed approach. The full circles represent transport fields, the dotted circles AGV fields. For clarity, we have not drawn the fields in (b) and (c).***

- **AGV agents and transport agents.** Task assignment is achieved by the interaction between two kinds of agents: *AGV agents* and *transport agents*. The AGV agents correspond to the physical vehicles and the transport agents represent transports. Whenever a new transport enters the system, a corresponding transport agent is created. The lifetime of the transport agents ends when the associated load is delivered. *Conceptually* a transport agent resides at the pick location of the associated transport. On which physical computer system(s) the transport agents reside is not important for the discussion in this paper, the only important issue is that the agents operate independently and therefore can be distributed across several computer systems.

- **Agents emit fields.** Both AGV and transport agents emit fields, called *AGV fields* and *transport fields* respectively, see Fig. 1-a. Fields have a certain range and contain information about the source agent. AGV fields have a fixed range, while the range of transport fields is variable. Fields are refreshed at regular times, according to a predefined refresh rate.

- **AGV agents store received fields.** When an AGV agent perceives fields, it stores the data contained in these fields in a *field-cache*. The field-case consists of a number of cache-entries. Each cache entry contains the source of the received field (an ID), the most recent data contained in that field and a *freshness*. The freshness is a measure of how up-to-date the cached data is. Fig. 1 shows the field-cache of AGV A through the scenario.

- **AGV agents construct calculated-fields to decide their movement.** An AGV agent constructs a *calculated-field* to decide in which direction to drive from a station. A calculated-field is a combination of the received fields, which are stored in the field-cache. The lower the freshness of a cache-entry, the lower the influence of the associated field on the calculated-field.

  The calculated-field is constructed locally and temporarily from the last selected target station (this is the last station that is added to the look ahead buffer, we further clarify this below) and contains values for each outgoing segment. An AGV agent follows the calculated-field in the direction of the smallest value. This can be considered as following the calculated-field downhill, in the direction of the *gradient*.

  Transport fields have an *attractive* influence on the calculated-field, which results in AGVs driving towards unassigned transports. However, it is undesirable that many AGVs drive to the same transport, since they will obstruct each other and travel superfluous distance. To remedy this, AGV fields have a *repulsive* influence.

  In Fig. 1-b, AGV A constructs a calculated-field on a station. Although transport 1 is closer, the calculated-field will guide AGV A towards transport 2. This is the result of the repulsive effect of AGV B. Notice that it would have been ineffective for AGV A to drive towards transport 1, since AGV B is closer and likely will reach the transport first.

- **Task assignment occurs at pick up.** Task assignment is delayed until an AGV actually reaches the pick location and picks up the load. This results in a greater flexibility with respect to task assignment, in comparison for example to the CNET protocol, which assigns a transport as soon as it enters the system. By delaying task assignment, the field-based approach can cope with unforseen situation like transports which suddenly popup, as illustrated in Fig. 1-c. While AGV A is driving towards transport 2, a new transport (transport 4) appears close to AGV A. Since no transport has been assigned to AGV A yet, it can drive towards the closer transport 4.

4.2 Software Architecture

The software architecture of the AGV system is shown in Fig. 2. This architecture is based on a reference model for situated MAS that is described in [20, 22, 23]. Successively, we explain the different agent components. The architecture of the environment is not further discussed here.

- **Field-cache**: This module of the AGV agent stores the information of fields received from other AGV agents and transport agents in cache-entries. A freshness is associated with each cache-entry, which is a measurement of how up-to-date the entry is.

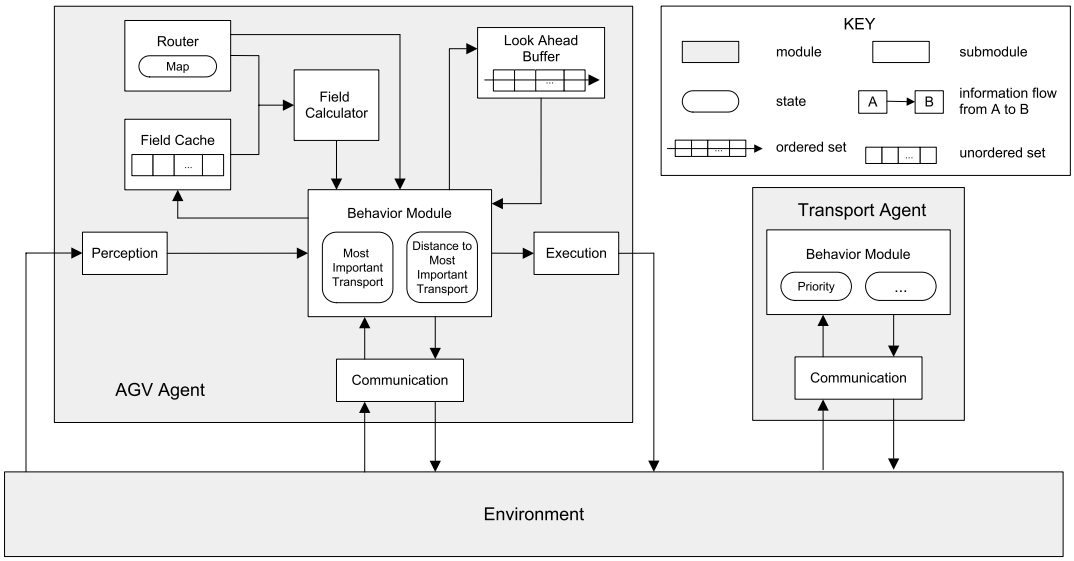

Figure 2: ***The architecture of the AGV transportation system.***

- **Router**: This module contains a global map of the stations and segments. The router is used by the AGV agent to calculate paths and distances from one station to another. We used a *static* router that uses the A* algorithm [8]. However, the approach discussed in this paper is fully compatible with a *dynamic* router that would take dynamic runtime information into account such as traffic distribution or blocked segments.

- **Look-ahead buffer**: As explained in section 2, an AGV has to make routing decisions over a certain distance in advance to allow save and smooth movement. This distance, called the *look-ahead*, is not a straight line distance, but is measured discretely, in terms of stations and segments of the environment map. The look-ahead buffer of an AGV agent is an ordered array that holds these routing decisions. It represents a path that the AGV will follow with certainty, unless something catastrophical (such as a crash) happens.

- **Field calculator**: This module constructs a calculated-field locally and temporarily from the last selected target station (i.e. the last station added to the look-ahead buffer) by combining the received fields, which are stored in the field-cache. The higher the freshness of a cache-entry, the more influence the field associated with the cache-entry will have on the construction of the calculated-field. Thus, although still used, less importance is given to outdated information. The field calculator makes use of the router to calculate the values of the calculated-field on different positions. The gradient of the calculated-field is used as driving direction on the target station.

- **Behaviour module**: The behavior module continuously reconsiders the dynamic conditions in the environment and selects appropriate actions to achieve the agent's goals. The behaviour module of an AGV agent also maintains the *current most important transport* and the *distance to the most important transport*. These values are used to achieve the repulsive influence of AGV agents, as described above. The behaviour module of a transport agent maintains, among other data, the current *priority* of the transport and the *field range*. To avoid starvation of the transport, the priority grows over time. The field-range of the transport agent is a function of time and the number of interested AGV agents. The following two high-level descriptions summarize the behavior of the agents during task assignment:

```
{Behavior procedure of the AGV agent}
while idle
 do repeat with constant frequency {
  1. Do communication
   1.1 Send out field
   1.2 Accept received fields and enter
       them in the field-cache
  2. Fill the look-ahead buffer (if needed)
  3. Perform an action
}

{Behavior procedure of the transport agent}
while not assigned
 do repeat with constant frequency {
  1. Do communication
   1.1 Send out field
   1.2 Accept received messages
  2. Calculate priority and field-range
}
```

5. TEST RESULTS

This section discusses the main test results obtained from applying the field-based task assignment approach. For a detailed discussion of the AGV simulator used in the tests we refer to [1, 17]. We start this section with explaining the test setting and subsequently we elaborate on the test results.

5.1 Setting

Map. All tests were performed on the map of a real layout that has been implemented by Egemin at EuroBaltic, see Fig. 3. The size of the physical layout is 134 m x 134 m. The map has 56 pick and 50 drop locations. The six locations at the lower side of the map are only pick locations, all other locations are pick and drop locations.

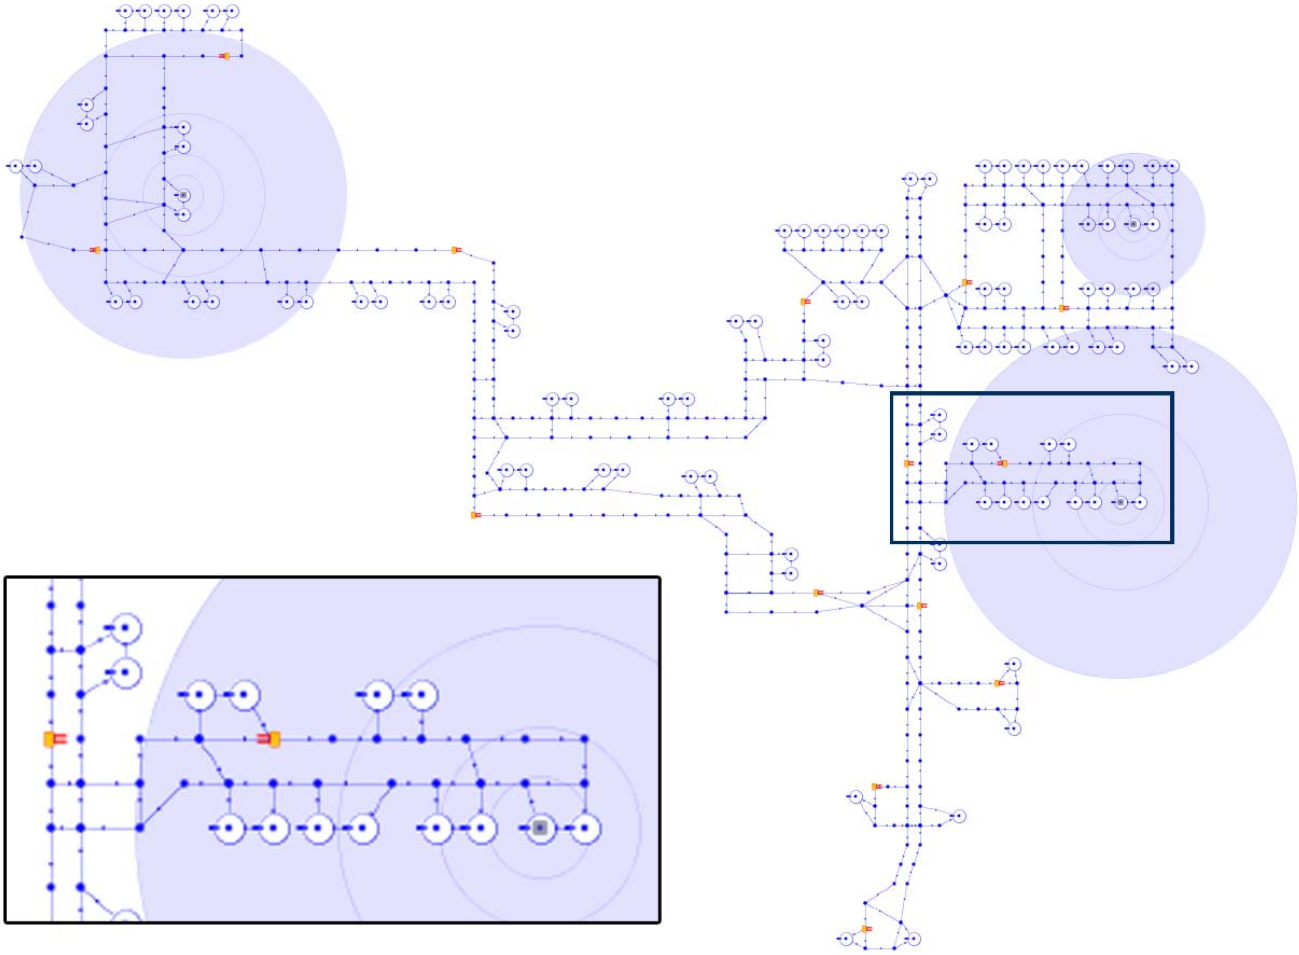

Figure 3: ***Map used in the tests.***

To allow running tests with the current implementation of the AGV simulator, we made a number of small modifications to the map, e.g., all curved segments were changed to straight lines.

Transport profile and AGVs. We used a standard transport test profile that is been used by Egemin for testing purposes. This profile generates 140 transports with a random pick location and a random drop location per simulation run, corresponding to the number of transports that are generated in 1 hour real time.

In the simulation, we used 14 AGVs just as in the real application. The average speed of driving AGVs is 0.7 m/s, while pick and drop actions take an average amount of time of 5 s.

Infrastructure. The AGV simulator and the multiagent system used for testing the field-based approach for task assignment are written in Java. An explanation of the working of the AGV simulator, the source code, as well as the tests results are available on the web [1]. The simulator uses a framework for time management [9] to make sure the simulation results are independent of performance characteristics of the execution platform, working load of the processor, or amount of memory.

To allow running the huge amount of simulations, we used a cluster of 40 machines: P4 2Ghz, 512MB RAM, Debian Stable 3.0. Testing one set of parameter values took approximately 30 hours of simulation time.

Metrics. Every simulation was run for 50000 timesteps, corresponding to approximately 1 hour real time, i.e. one time step represents 20 ms in real time. All test results displayed in the paper are average values over 20 simulation runs. Performance is measured in terms of throughput and reaction time. Additionally, the amount of communication needed is measured.

Reference algorithm: CNET. We used CNET as a reference algorithm to compare the field-based approach. With CNET each transport that enters the system is assigned as soon as possible to the most suitable AGV (i.e., an idle AGV for which the cost to reach the pick location is minimal). When transports can not be assigned immediately, they enter a waiting status. All waiting transports are ordered by priority, and this priority determines the order in which transports are assigned. The priority of transports grows over time, the same way as in the field-based approach.

5.2 Results

A number of tests have been performed to measure the performance of the field-based approach, both for tuning the parameters of the field-based approach and for comparison with CNET under varying circumstances and parameters. Due to space limitation we limit the discussion to the main test results. For a detailed discussion of the remaining test results we refer to [17].

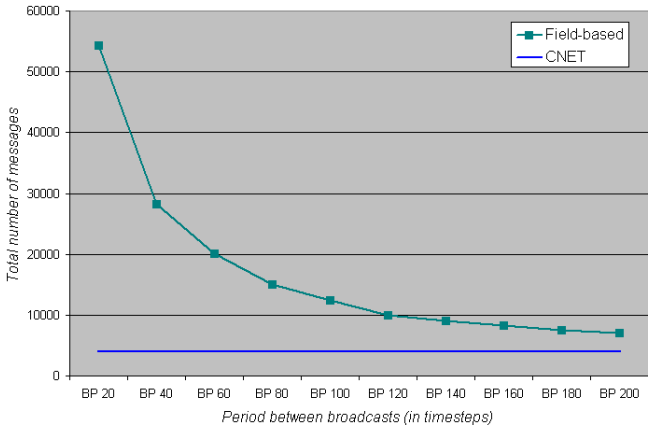

Figure 4: ***Amount of messages being sent.***

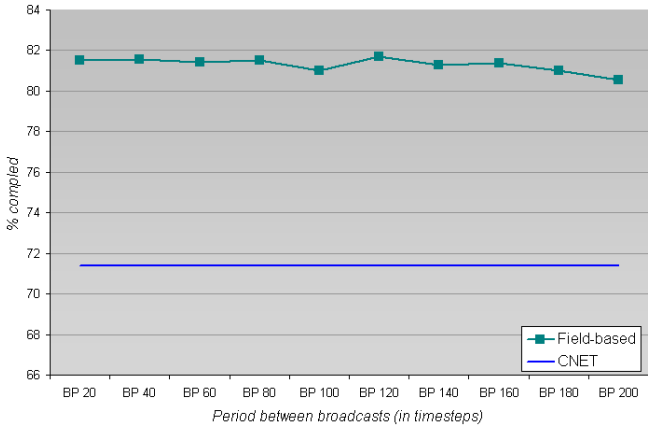

Figure 5: ***Percentage of completed transports.***

5.2.1 *Refreshment of Fields*

As stated before, maintenance of fields in our approach is achieved by periodically broadcasting the status of the fields (both position and strength). Obviously, the period between subsequent broadcasts strongly affects the amount of messages being sent. Making the period too short will produce a huge number of useless messages, but each agent in the system will have up-to-date information. On the other hand, if the broadcast period is too long, AGVs may have outdated information about the fields and probably miss some opportunities.

Fig. 4 shows the expected decrease in number of messages sent if the period between two broadcasts increases. BR20 corresponds to a field refresh each 20 time steps, i.e. each agent broadcasts its field status every second. With a field refresh each 200 time steps (BP200, i.e. every 10 s) the number of messages sent with the field-based approach is 1.7 times higher then with CNET. Of course what is interesting are the implications of reducing the field refresh on the performance of the system.

5.2.2 *Performance and Field Refresh*

Fig. 5 depicts the percentage of transports handled as a function of the field refresh rate. It can be seen that the percentage of completed tasks fluctuates around 81,5% and slowly decreases, the difference between BR20 and BR200 is only 1% but still significantly

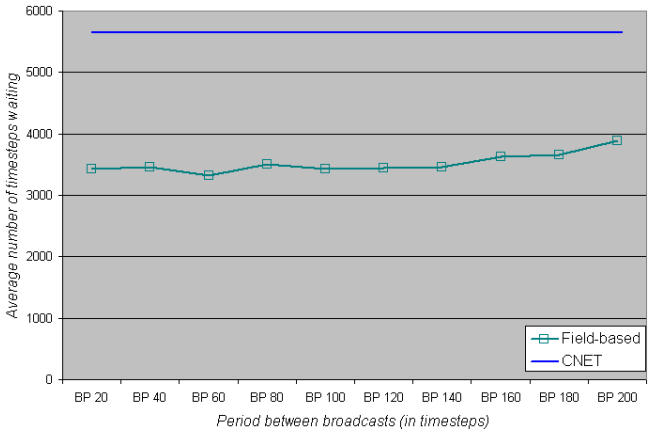

Figure 6: ***Average wait time for transports.***

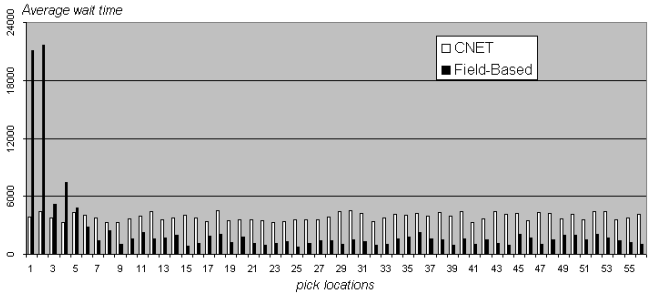

Figure 7: ***Average wait time for transports per pick location.***

better then the CNET approach. Fig. 6 illustrates that the average waiting time slowly increases with lower refresh rates, here the difference between BR20 and BR200 is 14%, which is still 31% better then the CNET approach.

These results clearly illustrate that communication overhead can be reduced by using a longer broadcast period, without significant performance loss. Overall, the throughput of the field-based approach is 10% higher than the throughput of CNET. The average waiting time of a transport is 39% lower, while the average number of transports waiting at each time step was around 20% lower for the field-based approach. [17] elaborates on the distance travelled by the AGVs. On average, the travelled distance of all AGVs with the field-based approach was 33% lower compared to CNET which is a result of a more optimal allocation of tasks.

5.2.3 *Average Waiting Time per Pick Location*

Although the average waiting time for transports is significantly better for the field-based approach compared to the reference algorithm, it is interesting to compare the average waiting time for transports per pick location.

Fig. 7 shows the average wait time for transports grouped by pick location. Clearly, the CNET reference algorithm achieves a more equal distribution. In particular, the wait times for pick locations 1 to 5 are significantly higher for the field-based approach. This drawback can be explained as follows: because the pick locations 1 to 5 are far away from the main traffic in the warehouse, the chance an AGV will be close to the pick location is significantly lower and this decreases the chance for immediately attraction an idle AGV when a new transport pops up. Starvation is prevented since the priority

of the transports on the remote locations gradually increasing when the load is not picked. It simply takes a longer time for the field to "grow" and attract AGVs compared to the immediate assignment of an AGV in the CNET protocol. A possible remedy to this problem is to increase the strength of fields of transports on isolated locations right from the moment the transport is created.

Finally, gradient field-based approaches are known to suffer from local minima. To deal with this problem agents do not use straight distances to sources of fields to construct calculated fields, but use a router that takes into account real distances along the paths on the map. As a result, we experienced little problems with local minima.

6. CONCLUSION

In this paper we presented a field-based approach for task assignment in AGV transportation systems. In this approach, each idle AGV is guided toward a load of an unassigned transport by following the gradient of a field that combines attracting fields received from transports and repulsing fields received from competing AGVs. By delaying the definitive assignment of a transport until the load is finally picked the approach achieves the required flexibility to exploit opportunities that may arise while AGVs search for transports in the highly dynamic environment.

Extensive tests show that the field-based approach outperforms standard CNET for throughput as well as for average waiting time of transports. On the other hand, the approach requires a limited amount of additional bandwidth, and the waiting time for isolated pick locations is higher compared to CNET. We experienced little problems with the traditional difficulties of field-based approaches, including parameter tuning and problems with local minima. As an overall conclusion, field-based task assignment is a promising approach in the domain of AGV transportation systems.

As future work, we aim to compare the field-based approach with other flexible approaches for task assignment. Currently we study a dynamic version of CNET in which transport agents and idle AGV agents continuously reconsider the assignment of transports until loads are picked, aiming to exploit opportunities that arise in the environment. Another interesting venue for future work, is to separate the management of fields from the agent logic by using a *virtual environment* as proposed in [21]. In this approach, agents may simply perceive fields in the virtual environment, while this latter–supported by middleware–takes the burden of managing the spreading of fields. This model improves separation of concerns by making the environment responsible for managing fields, which responsibility conceptually belongs to the environment.

Learning the Task Allocation Game *

Sherief Abdallah† and Victor Lesser

ABSTRACT

The distributed task allocation problem occurs in domains like web services, the grid, and other distributed systems. In this problem, the system consists of servers and mediators. Servers execute tasks and may differ in their capabilities, e.g. one server may take more time than the other in executing the same task. Mediators act on behalf of users, which can potentially be other mediators, and are responsible for receiving tasks from users and allocating them to servers.

This work introduces a new gradient ascent learning algorithm that outperforms state of the art multiagent learners on this problem. We experimentally show that our algorithm converges faster and is less sensitive to tuning parameters than other algorithms. We also provide an informal proof that WPL has the same convergence guarantee as the best known algorithm, GIGA-WoLF. We also show that our algorithm converges in Jordan's and Shapley's games where many other algorithms fail to converge. Finally, we verify the practicality of our algorithm in the distributed task allocation domain, comparing its performance to an optimal global solution.

1. INTRODUCTION

The distributed task allocation problem occurs in domains like web services, the grid, and other distributed systems. The problem can be illustrated by Figure 1. There are L servers and N mediators. Servers execute tasks and may differ in their capabilities, e.g. one server may take more time than another server in executing the same task. Mediators receive tasks from users, which can potentially be other mediators. Mediators are responsible for allocating tasks to servers. The goal is to find an optimal allocation that minimizes the average turn around time.[1] Turn Around Time, or TAT, is the time interval between a task arrival and its completion. It includes both the task processing time and the task waiting time at the server. Average TAT is then averaged over tasks to produce TAT.

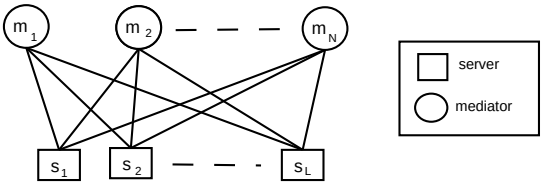

Figure 1: An example of distributed task allocation.

What makes this problem challenging is the *limited observability* of each mediator. In a large open system, a mediator will not be aware of all other mediators, their queues, their actions, or the queue length of each server. Ideally, one would like a learning algorithm that finds the optimal policy for each mediator. We identify certain characteristics that are desirable in such a learning algorithm.

- **Ability to learn a stochastic policy.** This is necessary in order to minimize TAT. For example, consider a system of two servers and three mediators. Any deterministic joint policy will overload one server more than the other, increasing the average TAT.
- **Convergence.** If the mediator policies do not converge, then oscillation between policies will occur making the system unstable.

[1]Other optimal criteria are also possible.

- **Adaptability.** This is directly related to the convergence property: not only do we need the algorithm to converge, we want it to converge quickly. This is important in a dynamic and open system that is constantly changing.

This work develops a gradient ascent learning algorithm that meets all these requirements and is better than the state-of-the-art algorithms. We analyze its performance in two-action games and prove its convergence. We also show that our algorithm converges in Jordan's and Shapley's game where many other algorithms fail to converge. Furthermore, we show that our algorithm converges faster and is less sensitive to tuning parameters when compared to previous approaches. Finally, we verify the practicality of our algorithm in the distributed task allocation domain, comparing its performance to an optimal global solution (computed using queuing theory).

This paper is organized as follows. Section 2 gives necessary definitions of game theory, which provides an elegant methodology for analyzing the performance of multiagent learners. Section 3 describes our algorithm and proves its convergence. Section 4 describes in more detail the state of the art algorithms. Section 5 verifies our claims in both simple games and distributed task allocation. Finally, we conclude in Section 6.

2. GAME THEORY

Game theory provides an elegant framework for analyzing learning in multiagent systems. It was used by previous researchers [4, 3, 2] to analyze the convergence properties of multiagent learning algorithms. This section gives an overview of the game theory framework, illustrating how it can be used to model distributed task allocation. The following section describes our algorithm and analyzes its convergence using game theory.

A game in normal form is defined by the tuple $\langle n, A_1, ..., A_n, R_1, ..., R_n \rangle$, where n is the number of players[2] in the game, A_i is the set of actions available to agent i, and $R_i : A_1 \times ... \times A_n \rightarrow \Re$ is the reward agent i will receive as a function of the joint action executed by all agents. If the game has only two players, then it is convenient to define their reward function as a payoff matrix as shown in Table 1. Each cell (i, j) in the grid represents the payoff received by the row player (Player 1) and the column player (Player 2), respectively, if the row player plays action i and the column player plays action j. The first three games in Table 1 were used in evaluating previous research [3, 1, 2].

The game in Table 1(d) represents the task allocation game at time t for two mediators and two servers. Action s_i corresponds to the row/column mediator assigning the task to server s_i. l_i^t is the expected TAT if the task is allocated to server i at time t. This is a compact representation of a set of games with constant payoff. The game the mediators play at time t depends on the status of the server queues at that time. However, due to the limited observability of each mediator, mediators can not distinguish between these games. In other words, an optimal policy would be the policy that performs best, on average, over time. While we will limit our theoretical analysis to games with payoffs that remain constant over time, Section 5 shows the effectiveness of our algorithm experimentally in the task allocation game with varying payoffs and involving more players and servers.

[2]We use the terms: agent, player, and mediator interchangeably.

Table 1: 2-action games

A policy (or a strategy) of agent i at time t is $\pi_i^t \in PD(A_i)$, where PD is the set of probability distributions over actions A_i. In case of two-player-two-action games (like the ones in Table 1) we refer to the joint policy of the two players by (p, q), where $\pi_1 = (p, 1-p)$ and $\pi_2 = (q, 1-q)$. Let the vector r_i^t be the actual reward agent i would receive at time t for each of its actions. This is the only feedback signal agent i would receive. The expected payoff agent i would get given its policy is $V_i^t(\pi_i) = \pi_i^t.r_i^t$.

2.1 Learning and Convergence

The primary goal of any rational learner would be to maximize its expected payoff by changing its policy. The problem is that r_i^t is not fixed and depends on other agents' policies. Consider for example the matching pennies game in Table 1(b). Each player can play either head (H) or tail (T). The payoff of Player 1 (row player) is $r_1^t = (2q-1, 1-2q)$, which is dependent on Player 2's policy q. Therefore, an optimal policy for Player 1 depends on the current policy of Player 2 and vice versa.

This dependence between optimal policies may prevent the convergence of a simple policy gradient algorithm. Consider the matching penny example again. Assume that initially the joint policy of the two players is $(p^0 = 1, q^0 = 0)$ (i.e. Player 1 always plays H and Player 2 always plays T), this means $r_1^t = (-1, 1)$ and $r_2^t = (-1, 1)$. Player 1 realizes it can do better by moving its policy toward action T by a small step of size δ. The new joint policy is $(p^1 = 1 - \delta, q^1 = 0)$. The process continues, until time t where the joint policy is $(p^t = 0.5 - \delta, q^t = 0)$. In this case $r_2^t = (\delta, -\delta)$. Player 1 continues moving its policy toward $p = 0$ while player 2 starts increasing q. This process continues and the two players keeps oscillating around the joint policy $(p = 0.5, q = 0.5)$ as shown in the Figure 2.

The joint policy $(p^* = 0.5, q^* = 0.5)$ that both players are oscillating around is the *Nash Equilibrium* of the matching pennies game. A joint policy is a Nash Equilibrium, NE, iff no agent can get higher expected reward by changing its policy unilaterally. A pure NE is the one where all agents policies are deterministic. Otherwise the NE is mixed. The coordination game has two pure NE, $(1, 1)$ and $(0, 0)$. The other two games have one mixed NE, $(0.5, 0.5)$.

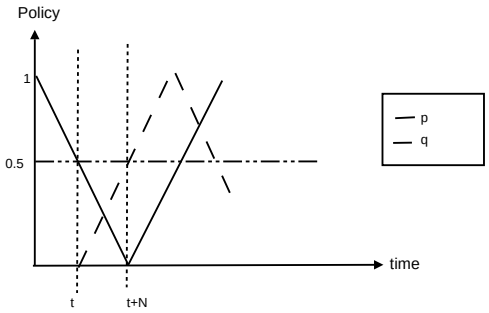

Figure 2: An illustration of policy oscillation.

The oscillation we have just described is common in policy gradient algorithms that change policies depending only on actual reward r_i^t [7, 10]. This is particularly true when the NE is mixed. The main idea behind our algorithm is to slow down learning such that this oscillation dampens until the joint policy gradually stabilizes to a NE.

3. THE WEIGHTED POLICY LEARNER ALGORITHM

Algorithm 1 illustrates our WPL algorithm. is the policy gradient which is used to update the policy π. The idea of our algorithm is to start learning fastest when changes its direction and then to gradually slow down learning if the policy gradient does not change its direction. We detect change in the direction of the gradient using the difference between action rewards (because the policy gradient follows the reward). If the reward of action a is decreasing, then the change in $\pi(a)$ is weighted by $\pi(a)$, otherwise it is weighted by $(1-\pi(a))$. Therefore, the change in $\pi(a)$, (a), is largest when either $\pi(a)$ is near 1 and $r(a)$ is lower than average reward $\bar{r}$, or $\pi(a)$ is low and $r(a)$ is higher than $\bar{r}$. The process repeats until convergence is reached and we get a damped oscillation as shown in Figure 3. The *limit* function is adopted from [10] with minor modifications to ensure fixed exploration: $limit(x) = argmin_{x':valid(x')}(x - x')$, i.e. $limit(x)$ returns a valid policy that is closest to x. A policy is valid if it sums to 1 and every action is played with miminum probability ϵ (for exploration). The following section discusses the convergence of WPL.

Algorithm 1: WPL: Weighted Policy Learner

```
begin
    Let r(a) be the (expected) reward for executing
    action a
    r̂ ← total average reward = Σ_{a∈A} r(a) / |A|.
    foreach action a ∈ A do
        (a) ← r(a) − r̂
        if (a) > 0 then (a) ← (a)(1 − π(a))
        else (a) ← (a)(π(a))
    end
    π ← limit(π + )
end
```

3.1 Convergence Proof

This section presents an informal proof that WPL converges for 2x2 games that is verified by experimental results involving 2x2 games as well as other games.[3] In the case of a pure NE, any gradient ascent player that follows the actual reward r^t will converge to the pure NE [7, 10]. The interesting case is when the NE is mixed. This is usually the case in the distributed task allocation problems, where mediators compete for servers.

Because $_1^t(a1) + _1^t(a2)$ will always sum to zero in 2x2 games, the only effect of the function *limit* is to constrain each action probability within 0 and 1. This actually helps convergence because it prevents players from moving further away from the NE (since by definition any NE is within the space of valid policies) [7]. Therefore, the limit function will be ignored for the rest of the proof.

LEMMA 1. *WPL learners stop learning iff they reached an NE.*

PROOF. From the WPL description, the change in the row agent policy, or $_1^t$ is zero only if one of the following is true: $p^t = 0, p^t = 1$, or $r_1^t(a) - \widehat{r}^t$. In practice, p is bounded by $[\epsilon, 1-\epsilon]$, where $\epsilon > 0$. This forces agents to keep exploring non-optimal actions in case the environment changes and non-optimal actions becomes optimal.[4] Therefore, ^{t} is zero iff $r_1^t(a1) = r_1^t(a2)$. The same argument goes for player 2, i.e. it stops learning iff $r_2^t(a1) = r_2^t(a2)$. This is only true in a Nash equilibrium.[5] □

LEMMA 2. *A player changes its gradient direction iff the other player crosses its NE strategy.*

PROOF. We say Player 1 *crosses the NE* at time t iff $p^{t-1} < p^* < p^{t+1}$, where p^* is Player 1's NE policy. For example, in Figure 2 Player 1 crosses the NE at time t. The lemma follows from the fact that when a player is at a NE, the values of both actions of the other player are equal. This means that the relative values of each of player 1's actions switch when player 2 crosses its NE strategy. This changes the gradient direction of player 1 because the gradients follow the action with highest expected reward. The lemma is depicted in Figure 3. □

LEMMA 3. *The two agents using WPL will continue to oscillate around the NE unless both converge to the NE.*

PROOF. Both players try to maximize their reward by moving their strategy toward the action that yields more rewards. At any time t, one agent (player 1) will be better off by moving its strategy closer to the NE strategy while the other agent (player 2) is better off by moving its strategy away from the NE strategy (because we are considering only competitive game, i.e. mixed NE). Eventually, Player 1 will cross its NE strategy. This will cause player 2 to switch its policy gradient direction toward the NE strategy, while player 1 is now moving away from the NE. This process continues, unless both players converge to an NE. □

[3]We are currently working on a more formal proof using differential equations.

[4]Even in a static environment agents need time to correctly estimate the rewards r_i^t either because of noise or other agents learning; ϵ then decreases gradually with time t such that $t \overset{lim}{\to} \infty\ (\epsilon^t) \to 0$.

[5]This is a property of two-action games (and can be generalized for larger games): if players are at a mixed NE then both actions for each player have the same expected reward.

LEMMA 4. *A WPL learner slows down (i.e. the magnitude of the policy gradient decreases) if its gradient direction does not change.*

PROOF. We will prove the lemma for Player 1 and a similar argument goes for the column player. Let $|\ _1^t| = |\ _1^t(a1) + \ _1^t(a2)| = 2|\ _1^t(a1)| = 2(1-p^t)(r_1^t(a1) - r_1^t(a2))$ be the magnitude of gradient change, assuming $r_1^t(a1) > r_1^t(a2)$. A WPL learner slows down its learning iff $|\ _1^{t+1}| < |\ _1^t|$. If the gradient direction is the same, then $r_1^{t+1}(a1) > r_1^{t+1}(a2)$, and therefore $|\ _1^{t+1}| = 2(1-p^{t+1})(r_1^{t+1}(a1) - r_1^{t+1}(a2))$. There are two cases:

- Either $r_1^{t+1}(a1) - r_1^{t+1}(a2) <= r_1^t(a1) - r_1^t(a2)$. In this case, the gradient magnitude decreases; i.e. $|\ _1^{t+1}| < |\ _1^t|$ because $1-p^{t+1} = 1-p^t - \ _1^t(a1) < 1-p^t$. If the gradient magnitude decreases then the learning slows down.

- Or $r_1^{t+1}(a1) - r_1^{t+1}(a2) > r_1^t(a1) - r_1^t(a2)$. We prove by contradiction that this case can not occur. If $r_1^{t+1}(a1) - r_1^{t+1}(a2) > r^t(a1)_1 - r_1^t(a2)$ then the only explanation is that Player 2 moved faster. However as we have just proved, Player 2 will slow down if its gradient $\ _2^{t+1}$ is moving in the same direction as $\ _2^t$. Therefore, Player 2 must have changed its gradient direction. However, if $\ _2^t$ increases $r^t(a1) - r^t(a2)$ then $\ _2^{t+1}$ must decrease this difference (because it is in the opposite direction), and therefore $|\ _1^t|$ actually decreases further.

□

LEMMA 5. *A WPL learner moves toward its NE strategy faster than it moves away from its NE strategy.*

PROOF. From the previous lemma, an agent slows down as long as it does not change its gradient direction. Therefore, after player 1 crosses its NE strategy (i.e. starts moving its policy away from the NE) player 1 does not change its gradient direction (while player 2 changes its gradient direction) and consequently player 1 moves away from its NE strategy slower than player 1 moves toward its NE strategy. □

Lemma 3 says that both players will continue to oscillate around the NE while Lemma 5 says that each player will slow down as long as it does not change its policy gradient direction. This leads to a damping effect as illustrated by Figure 3 until both players reach the NE. Our experimental results reflect this same behavior as Section 5 will show.

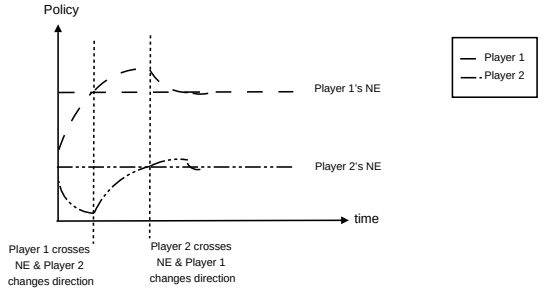

Figure 3: An illustration of WPL convergence.

4. RELATED WORK

There are many algorithms that have been proposed for multiagent learning. Unfortunately, all of them either fail to achieve all the three desired characteristics that are listed in Section 1 or assume agents can observe each other's actions. Independent Learners and Joint Learners [4] only learn a deterministic policy using the Q-Learning algorithm[8] and do not have any convergence guarantee. Joint Learners also require the knowledge of other agents' actions, an assumption that is not practical in large open systems.

Equilibrium learners such as Nash-Q [6], OAL [9], AWESOME [5] require that each agent observe other agents' actions. Each agent then computes a stable joint policy (NE). While these learners are guaranteed to converge, similar to joint learners, they are not applicable in open domains.

The gradient ascent learners are the most promising and relevant as they can learn a stochastic policy without observing other agents actions. These algorithms directly follow the expected reward. The Infinitisemal Gradient Ascent algorithm, or IGA [7] and its generalization, Generalized IGA, or GIGA [10] were the first algorithms to provide any convergence guarantees in a multiagent context. They converge to games with pure NE. However both algorithms failed to converge in games with mixed NE, and therefore are not suitable for the distributed task allocation problem.

Several modifications to IGA and GIGA were proposed to avoid divergence in games with mixed NE, including: PHC-WoLF [3], PHC-PDWoLF [1], and GIGA-WoLF [2]. They all used some form of the Win or Learn Fast heuristics [3], whose purpose is to speedup learning if the agent is moving toward its NE policy and slow down learning if the agent is moving away from the NE policy. The main problem with this heuristic is that an agent does not know what policy is an NE policy. Therefore, all the algorithms that use the WoLF heuristic use approximate methods to determine when an agent is moving toward or away from the NE. This is different from our approach, in which an agent slows down its learning as long as its policy gradient has the same direction. Except for GIGA-WoLF, none of the WoLF-based algorithms have any form of convergence guarantee. Therefore, while we will compare our algorithm to all of them, our experiments will focus on comparing our algorithm to GIGA-WoLF.

5. RESULTS

5.1 Practical Issues

5.1.1 Expected Reward vs Most Recent Reward

Our algorithm, along with all previous approaches, needs the expected reward of an action a at time t, or $r^t(a)$. However, this is not known a *priori* and needs to be computed. The common approach in reinforcement learning, which we also use, is the equation $r^{t+1}(a) \leftarrow \alpha R^t + (1-\alpha) r^t(a)$, where R^t is the sample reward received at time t and $0 \leq \alpha \leq 1$ is a learning parameter [8]. Tuning α is not an easy task when the expected reward itself is dynamically changing (because other agents are changing their policies concurrently). Smaller α means more samples contribute to computed expected reward and vice versa.

Using more samples to estimate the reward makes the estimate more accurate. However, the time required to get more samples may in fact degrade the accuracy of reward

estimate. This is because it will take more time for r^t to follow the dynamically changing expected reward. In other words, a higher α value increases the adaptability of the learning algorithm, but may affect convergence which requires r to reflect the expected reward, not a sample. We investigate this tradeoff in our experiments and show that our approach is less sensitive to the value of α than previous approaches.

5.1.2 *Fixing Learning Parameters*

In our experiments we have not used any decaying rates. The reason is that in an open system where dynamics can continuously change, one would want learning to be continuous as well. We have fixed the exploration rate ϵ to 0.1, the learning rate δ to 0.001. Two values of the learning parameter α have been used to measure the tradeoff between accuracy and responsiveness: 0.1 and 1.

5.2 Benchmark Games

To verify our theoretical result, we tested our algorithm for the three games described in 1. Figure 4 plots $\pi(r1)$ and $\pi(c1)$ against time, when the initial joint policy is $([0.1, 0.9]_r, [0.9, 0.1]_c)$ (several initial joint policies have been tested with similar results) and $\alpha = 0.1$. The algorithm converged to an NE in all the games. Note also that the plotted change of agents' policy over time in the two games with mixed equilibrium is almost identical to our theoretical prediction.

The tricky game deserves more attention as it is the most challenging among two-player-two-action games. Figure 5 shows the performance of PHC-WoLF, PHC-PDWoLF, and GIGA-WoLF in this game using the exact same settings of our approach. Only GIGA-WoLF converges but with slower rate than our approach (Figure 4(c)).[6] The performance of PHC-WoLF and GIGA-WoLF conforms to the results reported by their authors [3, 2] (actually PHC-WoLF performs here better than reported results). On the other hand, PHC-PDWoLF diverged in our experiments while it converged in the authors' experiments [1]. A possible explanation is that they used more tuned learning parameters, possibly with decaying rates. Due to the poor performance of both PHC-WoLF and PHC-PDWoLF in the rest of our experiments, the focus will be on GIGA-WoLF thereafter.

Table 2 shows two well known 3-action games used to evaluate GIGA-WoLF [2]. The NE in both games is mixed and equals $([\frac{1}{3}, \frac{1}{3}, \frac{1}{3}]_r, [\frac{1}{3}, \frac{1}{3}, \frac{1}{3}]_c)$. GIGA-WoLF is known to converge in the rock-paper-scissors game and diverge in Shapley's game as we verify ourselves.

	c1	c2	c3

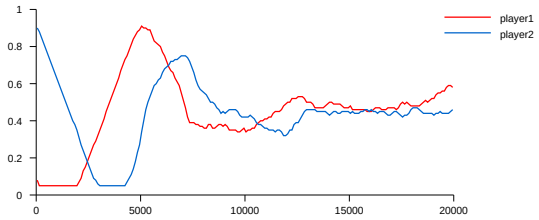
for the two games for both WPL and GIGA-WoLF when the initial joint strategy is $([0.1, 0.8, 0.1]_r, [0.8, 0.1, 0.1]_c)$, $\delta = 0.0003$, and for two values of α: 0.1 and 1. GIGA-WoLF's performance usually gets worse as α increases. GIGA-WoLF also keeps oscillating in Shapley's game regardless of the value of α. WLP on the other hand performs better as α increases and converges in Shapley's game when $\alpha = 1$. We believe the reason is that small α leads to an out of date reward estimate which in turn leads agents to continuously chase the NE without successfully reaching it. One of our future directions is to theoretically analyze this tradeoff between accuracy and recency of the reward and its effect on both convergence and optimality.

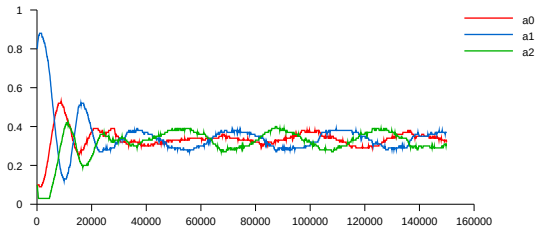
5.3 The Task Allocation Game



This section evaluates WPL in the distributed task allocation domain. Let N be the number of mediators and L

(a) PHC-WolF

(b) PHC-PdWolF



(c) GIGA-WolF

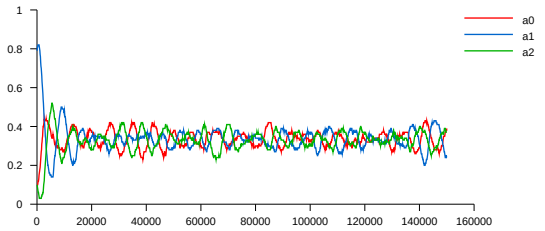


Figure 5: Convergence of the previous approaches in the tricky game. The figures plot the probability of playing the first action for each player (vertical axis) against time (horizontal axis).

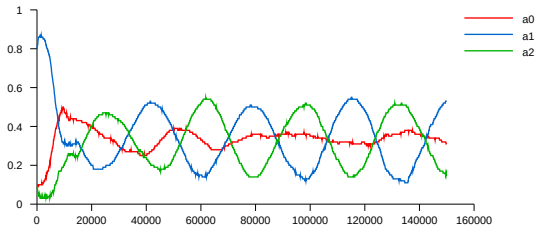
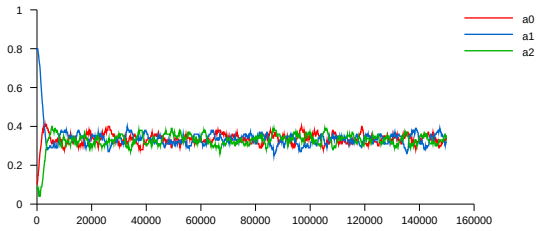
be the number of servers. The turn-around-time, or TAT, is the time interval between a task arrival and its completion. An upper bound on the TAT can be computed using queuing theory as follows. Let μ_i be rate by which tasks are serviced at server i. Let λ_j be the rate by which tasks arrive at mediator j. Then the global task arrival rate $\lambda = \sum_j \lambda_j$ and the global service rate $\mu = \sum_i \mu_i$. The global utilization $u = \lambda/\mu$. Then a lower bound on the turn around time is given by the equation $\widehat{TAT} = \frac{1}{\mu}(1 + \frac{u}{1-u})$.

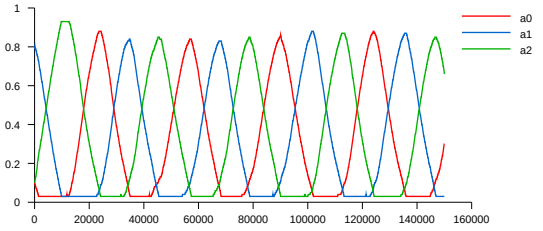


We define $\overline{TAT}$ to be the average TAT seen by each mediator when using WPL. Table 3 shows $\overline{TAT}/\widehat{TAT}$ (lower is better, where 1 is optimal) for different numbers of players N (columns) and different values of load u (rows). This data is collected from a system with 4 servers. Two servers have $\mu_i = 1$ task/time unit and the other two have $\mu = 0.5$ task/time unit. Tasks arrival rate is the same for all agents.

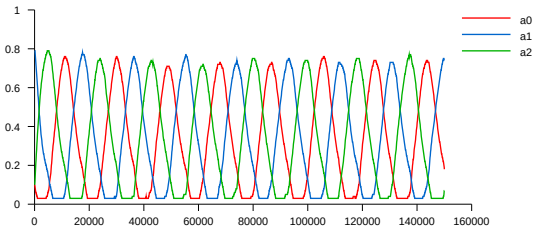


(a) GIGA-WolF, $\alpha = 0.1$

(b) WPL, $\alpha = 0.1$



(c) GIGA-WolF, $\alpha = 1$



(d) WPL, $\alpha = 1$

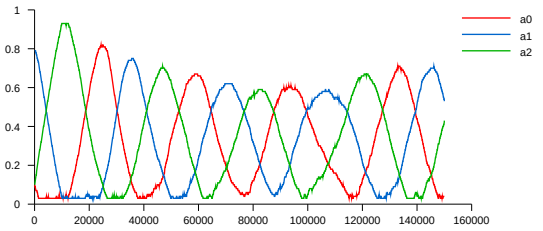


Figure 6: Convergence of GIGA-WoLF and WPL in the rock-paper-scissors game. The figures plot the probability of playing each action of the first player (vertical axis) against time (horizontal axis).

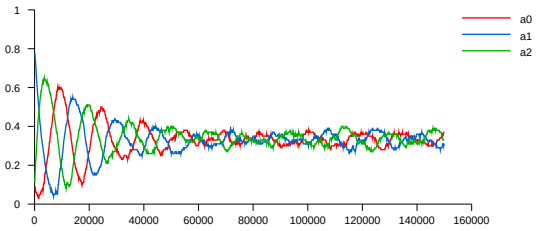

(a) GIGA-WolF, $\alpha = 0.1$

(b) WPL, $\alpha = 0.1$

(c) GIGA-WolF, $\alpha = 1$

(d) WPL, $\alpha = 1$

Figure 7: Convergence of GIGA-WoLF and WPL in Shapley's game. The figures plot the probability of playing each action of the first player (vertical axis) against time (horizontal axis).

The initial policy of all agents is to allocate all tasks to the first server. $\overline{TAT}/\widehat{TAT}$ approaches 1 as u increases. In other words, WPL is closer to optimal in high loads. This is expected because knowing the queue length of all servers is more advantageous in low loads (some servers may have an empty queue while others have nonempty queues). In high loads, all servers have on average constant queue length at all times. We can also notice that $\overline{TAT}/\widehat{TAT}$ does not change much for the same u and different N. This means that WPL scales well with the number of agents.

u \ N	3	4	5
0.3	3.13	3.34	3.44
0.6	2.27	2.3	2.3
0.9	1.68	1.875	1.9

Table 3: $\overline{TAT}/\widehat{TAT}$ for different values of N (columns) and u (rows)

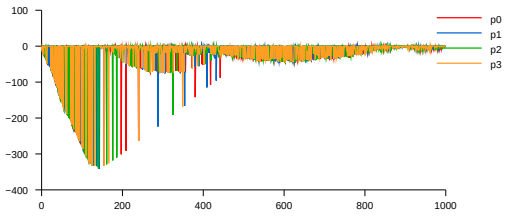

Figure 8 compares the performance of GIGA-WoLF and WPL with 5 mediators and 4 servers. The figure plots the TAT from individual mediators' perspective (TAT is plotted as a negative reward for each mediator). Note that the scale in GIGA-WoLF figure is almost double the scale in the WPL figure. There are two observations from the figures: time of convergence and maximum TAT. By 250 time steps, all mediators using the WLP algorithm witness TAT less than 50 time units. It took GIGA-WoLF more than 450 time units to achieve the same results. The maximum TAT that is ever witnessed by a WPL mediator is under 170 time units. GIGA-WoLF mediators have witnessed TAT of more than 320 time units.

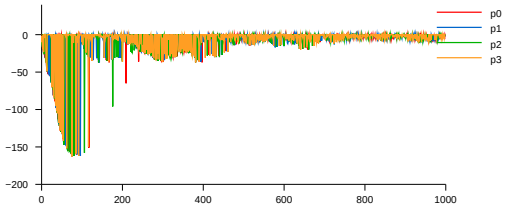
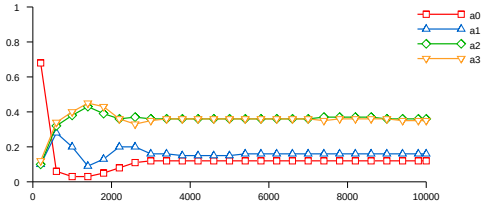
Figure 9 illustrates how the policy of one player converges over time. As expected, for both WPL and GIGA-WoLF, the probability of sending a task to one of the fast servers (a2 and a3) becomes almost double the probability of sending a task to any of the slow servers. However, WPL learns a better policy, where the probabilities of sending a task to any of slower servers are equal (while in GIGA-WoLF there is a consistent difference).



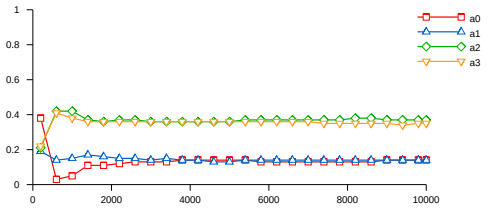
In conclusion, GIGA-WoLF converges slower than WPL and also reaches almost double the maximum TAT that WLP ever reaches. This gives WPL a clear advantage in dynamic environments where agents are continuously adapting to changes in the environment. We believe GIGA-WoLF's slow convergence is due to the way GIGA-WoLF works. GIGA-WoLF relies on learning a slowly moving policy in addition to the actual policy π to determine the direction of the gradient. This requires more time than the WPL algorithm, which changes its gradient direction according to the current expected reward.

6. CONCLUSION AND FUTURE WORK

This work presents WPL, a gradient ascent learning algorithm that outperforms state of the art multiagent learners in the task allocation. We experimentally show that our algorithm converges faster and is less sensitive to tuning parameters than other algorithms. We provide an informal proof of WPL's convergence. We also show that our algorithm converges in Shapley's game where many other algorithms fail to converge. Finally, we verify the practicality



(a) GIGA-WolF



(b) WPL

Figure 8: Convergence of GIGA-WoLF and WPL in distributed task allocation. The figures plot the reward (negative TAT) obtained by each player (vertical axis) against time (horizontal axis).

(a) GIGA-WolF

(b) WPL

of our algorithm in the distributed task allocation domain, comparing its performance to an optimal global solution.

In the future, we want to extend our convergence guarantee to more than two players and two actions. We also want to evaluate WPL in more general task allocation settings where mediators may be connected to other mediators. This work also illustrates the importance of computing the expected reward and how it affects convergence. This issue was overlooked in previous work and assumed an implementation issue. Using more samples of the immediate reward may increase the accuracy of the reward expectation but may also make the expectation out of date. Finding the right balance and theoretically analyzing how it affects convergence are interesting research questions that we plan to address.

ABSTRACT

The challenge we address is to reason about projected resource usage within a hierarchical task execution framework in order to improve agent effectiveness. Specifically, we seek to define and maintain maximally informative guaranteed bounds on projected resource requirements, in order to enable an agent to take full advantage of available resources while avoiding problems of resource conflict. Our approach is grounded in well-understood techniques for resource projection over possible paths through the plan space of an agent, but introduces three technical innovations. The first is the use of multi-fidelity models of projected resource requirements that provide increasingly more accurate projections as additional information becomes available. The second is execution-time refinement of initial bounds through pruning possible execution paths and variable domains based on the current world and execution state. The third is exploitation of additional semantic information about tasks that enables improved bounds on resource consumption. In contrast to earlier work in this area, we consider an expressive procedure language that includes complex control constructs and parameterized tasks. The approach has been implemented in the SPARK agent system and is being used to improve the performance of an operational intelligent assistant application.

1. INTRODUCTION

The challenge we address is to provide reasoning about projected resource usage within a hierarchical task execution framework to enable improved agent effectiveness. In particular, we seek to provide *guaranteed* bounds on resource consumption consisting of a lower bound that describes necessary resource requirements and an upper bound that describes possible resource requirements. The range between these bounds can stem from uncertainty about the current world, uncertainty about future actions and events, and ambiguity about the consumption requirements of actions.

Guaranteed resource bounds are essential for informing an agent's deliberations for task adoption and strategy selection because they enable it to make *conservative* commitments that eliminate the possibility of resource contention [15, 3]. With such bounds, an agent can avoid adopting tasks or performing actions that are resource infeasible given the agent's other commitments. In addition to being guaranteed, resource bounds should be *maximally informative*, meaning that they incorporate as much information as is available, in as timely a fashion as is possible. This requirement introduces the need to provide execution-time updates of bounds in response to both runtime events and the acquisition of relevant knowledge. By updating the bounds during execution, an agent can reassess its task set [11], for instance, to suspend or drop a task that consumes more of a resource than anticipated, or to adopt a task that becomes resource feasible.

Current techniques for agent resource projection are inadequate. Purely reactive agents perform no lookahead, acquiring knowledge about resource usage only as it occurs. Problems with resource contention are handled as they arise, which can be both costly and failure prone. Methods from the AI planning literature show how to derive guaranteed initial bounds on resource consumption [6, 2], but they require that estimates for all resource-consuming tasks be available before execution commences. Furthermore, they do not address the issue of updating resource projections at execution time. Previous work that combines lookahead and reactive techniques uses overly simplistic task models, reasoning about resource usage only for propositional tasks (i.e., not parameterized by variables) without branching or iteration [16].

Our approach is a middle ground focused on limited projection and runtime updates, in the spirit of [16]. The contributions are threefold. First, we adopt a *multi-fidelity* model of resource production and consumption that supports estimates whose accuracy can vary with the information available about tasks. One of the difficulties in estimating resource requirements accurately is that future tasks may depend on parameters that have not yet been instantiated. Our multi-fidelity models are valuable when bounds change significantly depending on how individual parameters are instantiated. For example, consider a task $(\mathsf{Flight}\ \langle\text{from}\rangle\langle\text{to}\rangle\langle\text{airline}\rangle\langle\text{class}\rangle)$. Without any knowledge of the starting point and destination, the bound on resource *money* would be very loose. If the $\langle\text{from}\rangle$ and $\langle\text{to}\rangle$ parameters are known, then the bound may be reduced substan-

tially; similarly, the choice of airline could limit fares (e.g., budget vs. full-service airlines), as could the class (e.g., first vs. coach). Our multi-fidelity models allow different bounds to be specified for each of these variations, at the discretion of the domain modeler.

Second, we refine our initial resource projections as execution unfolds. These updates are performed at the end of the observation phase in the observe–decide–act cycle of the agent. They include not only pruning possible execution paths based on the current world and execution state, but also reasoning over and narrowing variable domains. Thus we ensure that information about resources derivable from execution-time events is made available to the agent's deliberation at the earliest possible stage. Third, we show how certain kinds of additional semantic information about tasks can be exploited to improve resource bounds.

Our work is grounded in an expressive procedure language that can be viewed as an abstraction of two sophisticated procedural reasoning frameworks for Belief-Desire-Intention (BDI) agents [13], namely, PRS [7] and SPARK [9]. The language supports a range of parameterized task types, including condition achievement, task performance, and waiting for or testing a condition. Complex procedures can be composed from these task types through the control constructs of sequencing, parallelism, conditional branching, iteration, and subgoaling.

Our resource projection methods have been realized in the SPARK system and applied to improve the effectiveness of resource usage within an intelligent personal assistant domain [14].

2. RESOURCES: MODELS AND USAGE

Resource projection requires models of production and consumption for the tasks that can be performed within a domain. In this section, we present a model for *deterministic* resource usage; the nondeterministic case is left for future work. An important distinction is between consumption of *replaceable* resources, which are returned by a task after it completes, and *non-replaceable* resources. For example, a conference room or a transferable software license is a replaceable resource, while money is non-replaceable. However, money is a resource that can be *produced*. We assume a simple temporal model in which a task consumes resources when it commences, and releases (or produces) resources when it (successfully) completes. We do not consider scheduling of tasks in this paper. Resources may be discrete or continuous, and sharable between tasks or not.

In certain cases, resource requirements can be modeled precisely in advance: when the amount of resource consumed or produced is either a constant (e.g., $15 to download an article from ACM, $100 to change an airline reservation), or a parameterized function of the task's parameters (e.g., (RegisterForConference$\langle X \rangle$) — fees vary across conferences but are known once registration opens). We call resource requirements that can be modeled precisely in advance *knowledge pre facto*. These resource requirements can be modeled as an n-ary function of some subset of the task's parameters, with $n = 0$ in the case of a constant resource requirement.

In other cases, resource consumption or production for a task may not be predictable in advance (e.g., the cost of an airline ticket). In such cases, only loose bounds on the resource requirements may be obtained unless explicit actions are taken to determine the requirements (e.g., by checking the cost online). Further, certain types of resource consumption cannot be measured precisely until the action completes (e.g., how much petrol to drive to the airport); we label such requirements *knowledge ad facto*. For other tasks, there may be some delay in determining the precise consumption level (e.g., posting of a charge in foreign funds to your credit card); we label such requirements *knowledge post facto*. Similarly, certain types of resource production may also be knowledge post facto.

We say that a task is *knowledge pre facto* (similarly, *ad* or *post facto*) if it is so for all its resources. In this paper we avoid the complications of knowledge post facto tasks by assuming that all consumption and production are knowledge pre or ad facto.

In our approach to modeling resource requirements, each task that directly consumes (produces) a resource includes an explicit effect for that consumption (production). A *resource model* consists of a set of *approximations* that provide strict lower and upper bounds on the amount of a particular resource R required for (produced by) a given task:

$$(\ \langle R \rangle\ \langle \mathit{appr}_0 \rangle \langle \mathit{appr}_1 \rangle \ldots \langle \mathit{appr}_m \rangle\ ) \tag{1}$$

The approximations $\langle \mathit{appr}_i \rangle$ are specified in terms of functions of some subset of the task parameters that specify lower and upper bounds on the resource consumption (production):

$$[\underline{f_i}(p_1, \ldots, p_{s_i}),\ \overline{f}_i(q_1, \ldots, q_{t_i})] \tag{2}$$

In cases where $\underline{f_i} = \overline{f}_i$, we say that the bound is *precise*. For simplicity of presentation, we assume that the functions used to compute lower and upper bounds share the same set of arguments (i.e., in (2) above, $s_i = t_i$ and $\forall j.\ p_j = q_j$). Projected resource estimates, as explained later, should take into account all possible approximations as they become computable, that is, as all the parameters to the approximation functions have been instantiated.

A typical usage of the construct (1) would be something like the following for a resource *money* consumed by an ArrangeCateringExternal task: $(\mathit{money}\ [(\times\ \$\mathsf{n}\ 10),\ (\times\ \$\mathsf{n}\ 20)]\ \ [120,\ 1000])$, where $\mathsf{n} is the number of people to be catered.

3. RESOURCE PROJECTION

3.1 Overview

Our resource projection framework provides *guaranteed* bounds on the use of resources for execution of a task, where the lower bound describes *necessary* and the upper bound describes *possible* resource requirements. Given the requirement of guaranteed bounds, it is sound for the projection to derive over-estimates of these bounds. Of course, excessively broad bounds may be of little or no value to an agent when deliberating over task feasibility.

Set against this background, our approach to resource projection is one of *limited* static lookahead prior to task execution, followed by dynamic updates during execution. The static projection considers the space of possible decompositions of the task, drawing on the set of plans available to the agent. The execution-time updates refine the static projections by incorporating information about execution decisions and changes to dynamic world state.

Motivated by the tasks and processes found in the personal assistant domain [11, 14], which are dominated by the use of resources to achieve tasks delegated by the user, we focus on resource consumption. Combining production and consumption is important but beyond the scope of this paper.

In the personal assistant domain, as in many others, failures can be classified as *minor* or *major*. Whereas many minor failures can be remedied by increasing resource consumption (e.g., the flight cost more than expected), major failure entails reconsideration of the task (e.g., there are no flights available and the meeting will need to be rescheduled).

Our resource projection framework does not explicitly account for task failure, focusing instead on resource needs for failure-free execution. Our expectation is that an agent that makes use of this framework would maintain a resource reserve from which it would

Figure 1: Plans for the group visit task

draw to remedy minor failures. For a major failure, a BDI agent will reconsider its commitments and decide upon a new course of action [13], which will in turn lead to the recomputation of projected resource bounds. For this reason, our projected bounds do not include resource requirements for addressing failures.

Our approach for projecting guaranteed resource bounds for a task presumes a task and plan model described in Sect. 3.2. The first step in the projection process is to generate a *task expansion tree* that encodes the space of possible decompositions for the task with respect to the agent's plan library (Sect. 3.3). For that structure, a *variable relationship graph* is then constructed that encodes relationships and constraints among parameters of the considered plans; constraint programming techniques are used on this structure to bound possible values of task parameters (Sect. 4). The resource projection itself involves determining resource requirements for leaf nodes in the task expansion tree, drawing on information from the variable relationship graph as to possible or actual bindings for task parameters, and then aggregating those values up through the task expansion tree to produce the overall resource summary for the root task (Sect. 3.4).

3.2 Tasks and Plans

To make concrete our description, we introduce an explicit task and plan model based loosely on the SPARK framework [9].

A *task* is a parameterized activity for the agent to execute. Tasks come in two types. *Simple* tasks (`achieve`, `do`, `wait`, `conclude`, `retract`, `succeed`, `fail`) are the more basic form of task. Of these, only `achieve` and `do` can consume resources. An `achieve` task is used to achieve a designated state condition, while a `do` task is used to perform a designated action. A simple task can be *primitive*, meaning that the agent's effectors can execute it directly, or *nonprimitive*. A nonprimitive task is executed by decomposing it into lower-level subtasks.

Composite tasks (`sequence`, `parallel`, `select`, `context`, `try`, `forall`, `while`) can be used to compose aggregate tasks from a set of *component* tasks in a functional manner. For example, the composite task `[sequence:` $T_1, \ldots, T_m$`]` denotes the sequential performance of the component tasks $T_1, \ldots, T_m$. The task type `select` provides for the choice among component tasks, conditioned on the outcome of a sequence of test conditions; `try` similarly supports branching, but conditioned on the successful performance of some test task; `context` provides for the testing of predicates for the purpose of binding variables. The semantics for the remaining task types follow standard interpretations (see [9]).

A *plan*, referred to as a *procedure* in SPARK terminology, describes one of possibly many ways of decomposing a nonprimitive task. (SPARK plans can also be used to respond to a change in the agent's beliefs — a capability not considered in this paper.) Each plan has a *cue* that indicates the event that triggers the plan, an optional *precondition* that states the conditions under which the plan is applicable, and a *body* that consists of a single task (either simple or composite) to be performed in response to the plan cue.

As noted above, resource models are associated with tasks. Given the definition of a plan body as a (possibly composite) task, we can similarly associate a resource model with a plan.

EXAMPLE 1. *Figure 1 shows extracts of plans for a group visit task in this language. Variables are prefixed by* `$`*. Resource approximations annotate the plans* `apply_for_clearance` *and* `arrange_catering_external`*. For instance, the latter has a resource approximation corresponding to* (*money* $[10n,\ 20n]$ $[120,\ 1000]$)*, where* n *is the length of the list* `$everyone`*. In this example, the resources money and hours are nonreplaceable (denoted by* `consumes` *in the resource approximation), while licenses are replaceable (denoted by* `requires`*).*

3.3 Task Expansion Tree

The *task expansion (TE) tree* is the principal data structure used for resource projection. Intuitively, a TE tree for a task T describes all possible resource-related (producing and consuming) subtasks that could be performed to accomplish T. It is obtained by considering how T can be expanded into subtasks via application of plans in the agent's plan library.

The root node of a TE tree corresponds to the task T. A TE tree contains both simple and composite task nodes. Each simple task node has a child node corresponding to every possible matching plan that could achieve the task; the child node denotes the task (either simple or composite) that defines the body of the associated plan. Thus, a simple task node has *or* semantics in that its children represent alternative means of achieving the task. We call the edge linking a simple task to one of its children a *plan edge*. Each composite task node has one or more child nodes corresponding to the component tasks for the composite task; links from a composite task node to its children are called *structural edges*.

The TE tree for a given task is constructed recursively. The child nodes of a simple task node are obtained by matching the possible plans, according to the task name and parameters (as far as they are instantiated), and current constraints on possible matchings. This matching considers static predicates only. The child nodes of a composite task node are obtained by decomposing the task into its component tasks. Construction halts on a given branch when the child node is either a primitive task or a task with a resource approximation. (Note that resource models can be specified for both primitive and nonprimitive tasks, at the discretion of the modeler.)

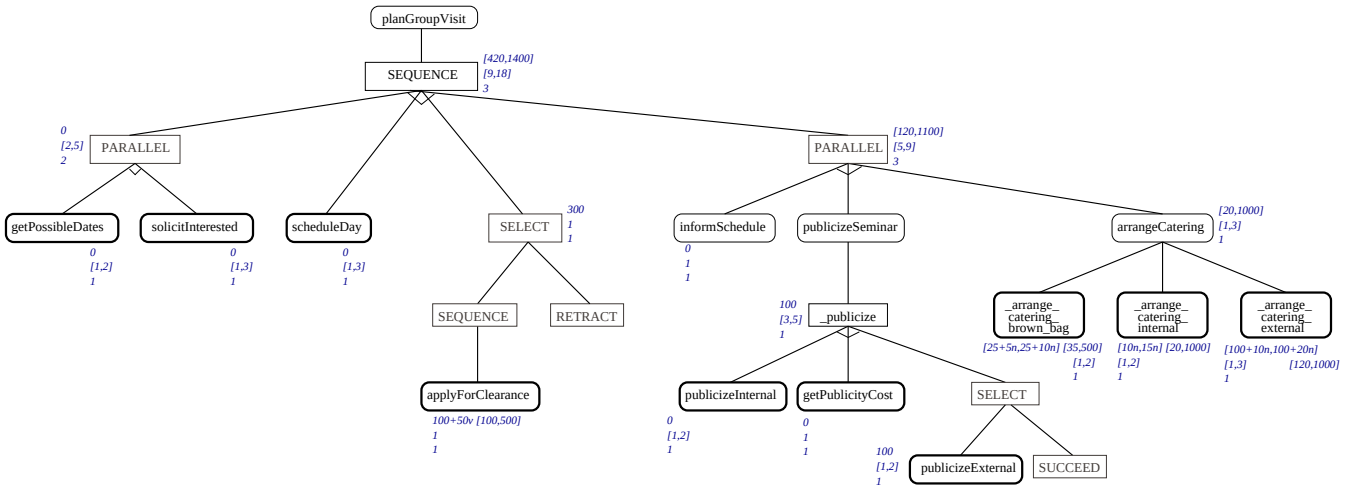

Figure 2: Task expansion tree for the task `planGroupVisit`

With the assumption of a nonrecursive library of plans, the tree and its construction are guaranteed to be finite.

Every node in a TE tree has a *resource summary* that provides for each resource the aggregate necessary and possible bounds on the consumption levels for that node and its descendants:

$$\langle\ (R_1\,[L_1,\,U_1]),\ \ldots,\ (R_m\,[L_m,\,U_m])\ \rangle \tag{3}$$

Here, L_i and U_i represent guaranteed lower and upper bounds, respectively, on the use of resource R_i for failure-free execution.

EXAMPLE 2. *The TE tree for the task* `planGroupVisit` *is displayed in Figure 2. Simple task nodes are depicted with rounded boxes and composite nodes with square boxes; bold indicates a task with a resource approximation model annotated. For simplicity, neither the parameters of tasks nor any* `conclude` *tasks are shown. Adjacent to each node is its resource approximation (for leaf nodes) or resource summary (for non-leaf nodes). These are shown as three lines for the resources money, hours, and licenses, respectively. Here, n represents the length of the list* `$everyone` *(recall Example 1), and v is the number of visitors, which is an input parameter to the root task.*

3.4 Computation of Resource Summaries

The computation of resource summaries for a TE tree involves first computing resource bounds for individual leaf nodes (Sect. 3.4.1), and then aggregating the bounds up to the root (Sect. 3.4.2). We assume that the domain model includes a *comprehensive* set of resource approximations for the domain, meaning that each primitive task that consumes resources has an associated resource approximation providing a guaranteed bound on its resource requirements.

3.4.1 Resource Bounds for Leaf Nodes

The resource summary for a leaf node T in a TE tree is determined by considering all resource approximations for the task of T (of the form (1)) whose parameters are fully instantiated. Let the bounds produced by this set of approximation functions be $\{[L_1,\,U_1],\ldots,[L_m,\,U_m]\}$. For a primitive task that does not consume resources (as reflected by the lack of a resource approximation in the domain model), this set is defined to be $\{[0,\,0]\}$. These bounds are strict, but represent different perspectives on the range of possible requirements; as such, they must be intersected as follows to produce the maximally refined bound for T:

$$\prod_{i=1,\ldots,m} [L_i,\,U_i] = [\max_{i\in\{1,\ldots,m\}} L_i,\ \min_{i\in\{1,\ldots,m\}} U_i] \tag{4}$$

It is not always necessary that a parameter to a resource approximation $[\underline{f},\,\overline{f}]$ be bound in order for the approximation to be used. Valid (but perhaps looser) bounds can be computed by inference over the variable's current domain, using techniques from constraint programming [1, 5]. In particular, in situations where the domain for the variable is restricted to a finite enumerable set $D = \{d_1,\ldots,d_k\}$, reasoning by cases can be applied to D yielding the bounds $L_i = \min_{d\in D} \underline{f}(d)$ and $U_i = \max_{d\in D} \overline{f}(d)$ on the individual approximations. The same enumeration technique applies to the Cartesian product of the domains of a set of finite domain variables, although care must be taken to consider only domains of tractable size.

3.4.2 Resource Aggregation for Non-Leaf Nodes

Resource aggregation computes the resource summary (3) for a non-leaf node T in a TE tree based on the summaries of its children. We assume no constraints between resources, that is, each resource is consumed and produced independently of others. In this case, it suffices to consider each resource in turn.

Consider first a simple task node T with child nodes $T_1,\ldots,T_m$ where T_i has resource summary $[L_i,\,U_i]$ for a given resource. As noted above, our model presumes that of the simple tasks, only `achieve` and `do` can impact resource usage. Recall that each child of a simple task node corresponds to the body of a possible plan for achieving the task. At runtime, exactly one of the T_i will be chosen for execution. Thus the resource summary for T consists of a lower bound that is the minimum of the L_i and an upper bound that is the maximum of the U_i, i.e., $[\min L_i,\,\max U_i]$.

Now consider a composite task node T with component task nodes $T_1,\ldots,T_m$; again let the child nodes have summaries $[L_i,\,U_i]$. Replaceable and non-replaceable resources differ in their aggregation. Adapting [16], we define the composition operator:

$$x \otimes y = \begin{cases} \max(x,y) & \text{for replaceable resources} \\ x+y & \text{for non-replaceable resources} \end{cases}$$

Aggregation for different types of composite nodes is defined as follows. We do not consider `context` tasks as we assume that condition testing does not impact resources.

- `[sequence:` $T_1,\ldots,T_m$`]`. T_i are tasks to be executed sequentially; the bound is $[\bigotimes L_i,\ \bigotimes U_i]$.

- `[parallel:` $T_1, \ldots, T_m$`]`. T_i are tasks to be executed in parallel; the bound is $[\sum L_i,\ \sum U_i]$.
- `[select:` $C_1T_1, \ldots, C_mT_m$`]`. The first T_i is chosen such that its condition C_i is satisfied. Since the C_i have no resource impact, the bound is $[\min L_i,\ \max U_i]$.
- `[wait:` $C\ T'$`]`. Task T' is executed once the condition C becomes true. Since we do not consider timing of tasks in this paper, and condition testing has no resource impact, the bound is simply that of T'.
- `[try:` $Q_1T_1, \ldots, Q_mT_m$`]`. The tasks Q_i are performed in order until some Q_s succeeds; the corresponding task T_s is then executed. Assuming that tasks fail at their end then a two-condition `try` statement expands to one of three sequences: $Q_1\ T_1$; $\mathbf{Q_1}\ Q_2\ T_2$; or $\mathbf{Q_1}\ \mathbf{Q_2}$, where bold denotes failure. The bound is the minimum and maximum of these possible sequences; for example, the lower bound is $\min(L_{Q_1} \otimes L_{T_1}, L_{Q_1} \otimes L_{Q_2} \otimes L_{T_2}, L_{Q_1} \otimes L_{Q_2})$.

Projection of replaceable resources through the iteration constructs `while` and `forall` is straightforward: if the projected resource estimate for a single execution of the loop body is $[L,\ U]$, then $[0,\ U]$ constitutes a guaranteed bound. Projection of non-replaceable resources for these constructs presents a challenge in that the number of iterations may depend on conditions or parameters that cannot be determined until runtime: for instance, looping over the number of people who reply to an invitation, or looping until a reply to an email request is generated.

The construct `[while:` $C\ T$`]` is particularly problematic, given the dependence on the dynamics of the termination condition C. Bounding the number of iterations requires both an upper bound d on the duration for which C is anticipated to hold, and a lower bound t on the time required to complete an iteration of T. If the projected resource estimate for a single execution of T is $[L,\ U]$, then $[0,\ U \times d/t]$ constitutes a guaranteed bound for the iteration.

Iteration based on the construct `[forall:` $x\ C(x)\ T(x)$`]` can be bounded in the following cases in which the exact number of iterations, n, can be determined. This occurs when (a) the quantification variable belongs to an enumerated type (e.g., iterate over people in the organization), (b) the iteration is defined over a concrete structure for which the number of elements can be ascertained (e.g., over a list), or (c) the scope of quantification is defined by a static predicate with bounded, known extent (e.g., purchase a flight for every member of the team). In these cases, if the projected resource estimate for a single execution of T is $[L,\ U]$, then $[L \times n,\ U \times n]$ constitutes a guaranteed bound for the iteration for a non-replaceable resource. By contrast, in the case when C is a dynamic predicate, precise determination of the number of iterations is not possible. If a bound v on the number of values for which C holds can be determined (e.g., register everyone who has a paper accepted), then $[0,\ U \times v]$ provides a guaranteed bound.

EXAMPLE 3. *Consider the task node* `arrangeCatering` *in Figure 2. Three possible plans could match the cue for this task: by brown bag, internal caterer, or external caterer. The plan for the last of these was shown in Figure 1. All three plans have resource approximations annotated as shown in Figure 2. For resource money, the approximations are functions of n, the total number of people to be catered, as before. For resource hours, the approximations are a single bound, and for licenses they are specified precisely. Since n is unknown prior to execution, the only computable approximation for money is the last, for example,* $[120,\ 1000]$ *for external catering. The resource aggregation produces the summary shown for node* `arrangeCatering` *from its three children:* $\langle$ (*money* $[20,\ 1000]$), (*hours* $[1,\ 3]$), (*licenses* 1) $\rangle$. *This information is propagated up the TE tree to its parent, the* `PARALLEL` *node. In the example, the number of visitors is a ground parameter to the root task: $v = 4$. Eventually, the resource summary derived for the root task node is* $\langle$ (*money* $[420,\ 1400]$), (*hours* $[9,\ 18]$), (*licenses* 3) $\rangle$.

By induction over the TE tree, the resource summary computed at the root node is a guaranteed enclosure of the actual resource consumption by the root task:

PROPOSITION 1. *Let T be a task and $[L,\ U]$ be the resource summary for resource R computed by the above algorithm on the TE tree rooted at T. Given that primitive tasks consume R within their resource approximations, then the amount of R consumed by T lies within $[L,\ U]$.* □

4. VARIABLE RELATIONSHIP GRAPH

Having described how to construct the TE tree and perform resource projection over it, we now describe the construction and use of the *variable relationship (VR) graph* for tracking relationships and constraints on variables. A VR graph enables both the propagation of parameter values that assist with computing resource bounds on tasks, and the pruning of impossible branches of a TE tree.

4.1 VR Graph Construction

We call the nodes of a VR graph *vertices*, to distinguish them from the nodes of a TE tree. Each vertex corresponds to a variable in a node of a TE tree. The (hyper-)edges of the VR graph correspond to relations between the variables.[1] Formally, the VR graph for a TE tree is a 4-tuple $\langle \mathcal{V}, \mathcal{D}, \mathcal{C}, \mathcal{E} \rangle$ where: $\mathcal{V}$ is a set of variables; $\mathcal{D}$ is a set of domains, one for each variable; $\mathcal{C}$ is a set of relations over $\mathcal{D}$; and $\mathcal{E}$ is a set of additional *possibility* relations, explained below. Thus $\mathcal{C}$ and $\mathcal{E}$ are two sets of constraints and $\langle \mathcal{V}, \mathcal{D}, \mathcal{C} \cup \mathcal{E} \rangle$ forms a classical *constraint satisfaction problem* (CSP) [1, 5].

The variables of a VR graph are divided into disjoint sets called *partitions*. Each partition corresponds to a different execution-time choice. These choices derive from two sources: (a) selection among alternative plan instances for a simple task (i.e., sibling plan edges in the TE tree), and (b) conditional branching via the `select` and `try` constructs. For each such choice, a partition is created to localize constraints and variables specific to that choice.

The two types of constraints, $\mathcal{C}$ and $\mathcal{E}$, represent relationships of different types between the variables. The edges in $\mathcal{C}$ encode constraints among variables *within* partitions; these constraints are derived from the predicates and functions used in the corresponding plans. In accord with terminology from the AI planning community, we say that two variables linked by an equality relation *codesignate* with each other. Second, the possibility relations in $\mathcal{E}$ link partitions. Each $\mathcal{E}$ constraint relates a variable in one partition to variables with which it may possibly codesignate in other partitions (depending upon which partition is chosen at execution time).

Consider a set of partitions created to represent selection among alternative plan edges for a simple task node T in the TE tree. For each task parameter `$x`, an edge in $\mathcal{E}$ represents the relationship from a vertex for `$x` to the vertices for the equivalent variables in the child tasks, as linked by the plan cue on the corresponding plan edge. For example, suppose T has two child nodes T_1 and T_2, with corresponding parameter variables `$x1` and `$x2`. The VR graph vertex for `$x` is related to each of `$x1` and `$x2` by a possibility relation. This describes that exactly one of `$x1` and `$x2` will codesignate with `$x` in the future, but which one is unknown at this time. This partitioning allows inference for different plan choices in the TE tree to proceed without cross-contamination from

[1] For simplicity, we assume (by introducing new variables, preconditions, and `context` tests) that the parameters in the cue of each plan and the parameters of the tasks in the body of a plan are all variables.

Algorithm 1 Pseudocode for VR graph constraint propagation (lines 1–10) and resource summary updating (lines 11–15)

```
 1: repeat
 2:    Choose a partition p such that V(p) is non-empty
 3:    Add the node N_TE(p) to Q
 4:    repeat
 5:       Pick a variable v ∈ V(p) and remove it from V(p)
 6:       for each constraint C involving v do
 7:          Update D(v') of each variable v' constrained by C
 8:          If any D(v') has changed, add v' to V(p_v)
 9:    until V(p) is empty
10: until V(p) is empty for all partitions
11: repeat
12:    Pick a node N ∈ Q and remove it from Q
13:    Update resource summary of N from the changed variable domains
14:    If resource summary of N changed, add the parent of N to Q
15: until Q is empty
```

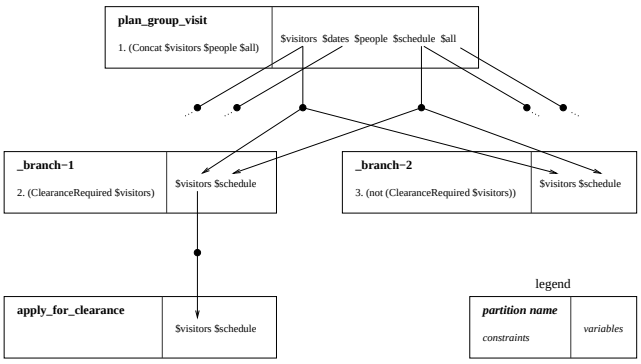

Figure 3: Variable relationship graph fragment

lower to upper levels; it also allows inferences from higher to lower levels, that is, from T to T_1 and T_2, for instance if the domain of `$x` is narrowed. If there is only one possible branch, then an equality rather than possibility relation links the variable vertices.

Similarly, each conditional branch (i.e., the `select` and `try` constructs) leads to a distinct partition with separate variables. For example, consider a plan containing the composite task `[select:` $(C_1$ `$x)` `[do:` $(T_1$ `$y)]` $(C_2$ `$x)` `[do:` $(T_2$ `$y)]]`. Separate partitions and new copies of the variables `$x` and `$y` are created for each branch. Possibility relations relate `$x` and `$y` to the corresponding branch variables $\texttt{\$x}_1$, $\texttt{\$y}_1$, $\texttt{\$x}_2$, and $\texttt{\$y}_2$. The partition for the first branch has the constraint $(C_1\ \texttt{\$x}_1)$; the partition for the second has the constraints $(C_2\ \texttt{\$x}_2)$ and $\neg(C_1\ \texttt{\$x}_1)$.

EXAMPLE 4. *Figure 3 shows part of the VR graph for the TE tree in Figure 2. The partition* `plan_group_visit` *contains the variables in the plan for the corresponding node in the TE tree, and a constraint derived from the* `context` *test in the plan. The* `select` *construct introduces two child partitions corresponding to the two branches, with constraints derived from the* `select` *conditions. Possibility relations link corresponding variables in parent and child partitions.*

The initial domain $D(v)$ of a variable v is derived from the type of v. We next describe how variable domains, and consequently resource summaries, are refined.

4.2 Propagation and TE Tree Pruning

Constraint propagation updates domains for variables in the VR graph, drawing both on information that is known when the TE tree is created, such as from variable domains and initial parameters, and information acquired during execution, such as when the domain of a variable changes or the graph is structurally modified. These updates in turn enable resource summaries to be refined as variables are instantiated or their domains are narrowed.

We perform a two-level constraint propagation that exploits the partitioned structure of the VR graph. The narrowing of a domain of a variable is propagated through the constraints of the partition containing the vertex for that variable, possibly resulting in the narrowing of other variable domains. Once a quiescent state is reached within a partition, the domain narrowings are propagated across the possibility relationships to neighboring partitions and the process is repeated. The domains are passed down to child partitions, but are merged with domains for the corresponding parameters in alternative partitions before being passed up.

Algorithm 1 gives the pseudocode for the VR graph constraint propagation and the subsequent updates to the resource summaries in the TE tree. In the pseudocode, let $V(p)$ be the set of variables in partition p that have changed and let p_v be the partition of variable v. Let $N_{\text{TE}}(p)$ be the TE tree node from which partition p is derived. Let Q be a queue of nodes in the TE tree, initially empty.

Lines 1–10 propagate domain changes through the VR graph constraints; lines 11–15 then propagate the effects in the TE tree. The loop starting at line 6 considers constraints in $\mathcal{C}$, which may affect the domains of related variables within partition p, and constraints in $\mathcal{E}$. Consider a hyperedge from variable v to variables $v_1, \ldots v_n$ representing a constraint in $\mathcal{E}$. If $D'(v)$ represents the new value of the domain of v after propagation, then $D'(v) = D(v) \cap \bigcup_i D(v_i)$ and $D'(v_i) = D(v_i) \cap D'(v)$.[2]

The narrowing of a variable domain to the empty set indicates that the containing partition is inconsistent. When propagated, this narrowing renders all descendant partitions inconsistent, and may make the parent inconsistent as well. A parent partition is made inconsistent if and only if all its child partitions are inconsistent.

Inconsistent partitions can be pruned from the VR graph; they can also be used to avoid expanding branches of the TE tree that are not viable. Moreover, if the constraints in one partition of the VR graph become inconsistent, given knowledge about possible variable bindings from the parent partition, the corresponding plan branch from the TE tree can be pruned.[3]

EXAMPLE 5. *Consider the VR graph in Figure 3. Since the top* `$visitors` *variable is bound to a specific list (in this example, of length four), the domain (not shown) associated with the variable is narrowed to a single value, that is, to that list. This narrowing is propagated to the domains of the* `$visitors` *variables in the branch partitions and then down to* `apply_for_clearance`*. The constraint associated with one of the branch partitions, say* `_branch_2`*, is now violated, leading to that branch being pruned. In that case, the unique value for* `$visitors` *allows refinement of the resource bounds on* `apply_for_clearance` *from* $[100, 500]$ *to the precise value* 300*, which is then propagated upward in the TE tree.*

Many agent and planning systems distinguish *static* predicates, which do not change over time, from *dynamic* predicates (i.e., fluents). Static predicates, such as equality and list membership, can be exploited to constrain variables in the VR graph, but because the truth value of dynamic predicates cannot be known until execution time, their usefulness for pruning the VR graph is limited. Hence, we do not reason about future values of dynamic predicates.[4]

[2] Note that for line 12 it is most efficient to handle all descendants of a node before handling the node itself. This means that Q should be partially ordered by $N_1 \prec N_2$ iff N_1 is a descendant of N_2 in the TE tree. Q can be kept sorted by inserting nodes in the correct place in lines 3 and 14.

[3] Note that this pruning may be more aggressive than in plan selection for an ordinary BDI agent: it may be possible using the VR graph to deduce that a plan must later fail due to constraint violations even if its preconditions are satisfied.

[4] Prior work in the planning community has investigated the use of the modal truth cri-

The partitioning of the CSP does not detract from the soundness or completeness of the inference, although it is worth noting that the agent's inference depends on the power of the constraint propagation techniques it has available, which we denote *Prop*. By standard results on *chaotic iteration* over the combined CSP [1]:

PROPOSITION 2. *Two-level constraint propagation over the VR graph $\langle \mathcal{V}, \mathcal{D}, \mathcal{C}, \mathcal{E} \rangle$, using Prop at each stage, achieves the identical outcome as Prop on the combined CSP $\langle \mathcal{V}, \mathcal{D}, \mathcal{C} \cup \mathcal{E} \rangle$.* □

5. RESPONDING TO EXECUTION EVENTS

A TE tree captures the anticipated resource usage for a task at a given instant in time. We have described how to construct TE trees prior to the start of task execution. In order to produce maximally informative bounds in the resource summaries, it is necessary to update the summaries at execution time as choices are made and events occur that could impact resource usage.

A typical BDI agent maintains its current intentions in data structures analogous to subtrees of the TE trees [13, 9]. As plans execute successfully, variables are bound to values, and these subtrees grow through the addition of task nodes. The VR graph tracks these changes by incorporating the variable bindings and pruning both the nodes in the TE trees and the partitions in the VR graphs that correspond to the choices *not* selected. In each of these cases, the additional information is propagated through the VR graphs and updated resource bounds are aggregated up the TE trees.

EXAMPLE 6. *Consider the point at which the* `arrangeCatering` *task of Figure 2 is to be executed. When the plan corresponding to the* `arrange_catering_external` *node is selected, the sibling nodes can be pruned, leading to a more precise resource bounds estimate. For the resource money, for instance, supposing the value of n is not yet known, the bound at the node* `arrange_catering` *becomes* $[120, 1000]$.

The effects of successful execution are *monotonic* in that they lead only to refinement, not expansion, of previously computed resource bounds. This monotonicity results because (a) the operations do not invalidate previous variable bindings or constraints, and prune only those parts of the VR graph that are certain not to impact resource consumption, and (b) elimination of options can only narrow, not expand, bounds. In contrast, task failures can lead to nonmonotonic changes to resource bounds, since an agent must reconsider its plans and may potentially prune failed subtrees in the TE tree in favor of previously rejected alternatives. Such failures require the recomputation of the resource bounds for the impacted portions of the TE tree.[5]

6. EXPLOITING SEMANTIC KNOWLEDGE

This section presents two further types of execution-time refinements to resource projections. Both leverage additional semantic knowledge about relationships among task parameters.

6.1 Active Solicitation of Requirements

In certain situations, an agent may actively gather information to provide explicit estimates for the resource requirements of a task. For example, the cost of a reception would generally be solicited as part of the process of organizing a workshop. We call a task that produces such an upper estimate a *resource estimation task*.

When a resource estimation task produces an estimate e for a given task T, the prior estimate $[l, u]$ for T can be refined to $[l, e]$. In some cases, it may even be possible to obtain precise values, as is the case when booking a hotel. We call a task that produces a precise characterization of resource consumption a *resource bid task*. When a resource bid task produces a bid b for T, the bounds for T can be set to $[b, b]$.

In certain cases, it may be appropriate for the agent to obtain multiple estimates for a resource-consuming task. If all such estimates $E = \{e_1, \ldots, e_m\}$ can be obtained together, then the resource bounds for the task can be set to $[\min E, \max E]$.[6]

6.2 Selection and Narrowing

The relationships among variables tracked in the VR graphs derive from codesignation constraints among variables both within and across plans (the latter arise from plan application to a task). Further inference can be enabled by augmenting the VR graphs to exploit additional types of inter-variable relationships. Here, we describe two common task idioms that produce such relationships, and indicate how a VR graph can be extended to reflect those relationships and support additional execution-time refinements of resource bounds.

The first idiom focuses on *selection* tasks. Consider a task (Select `$c` `$s`), where `$c` represents a set of values under consideration for some role, and where execution of the task results in the binding of the variable `$s` to a value for that role. The binding of `$c` to a list of values restricts the domain of values for `$s` to the same list. Although the binding for `$s` is not yet known, reasoning by cases can be applied over the possibilities, *before* the task (Select `$c` `$s`) is performed, to any resource approximation for a downstream resource-consuming task that depends on a parameter linked from `$s`. However, such a restriction on the domain of `$s` cannot be exploited within the VR graph as formulated, since no explicit constraint connects the variables `$c` and `$s`.

The second idiom focuses on tasks that perform some kind of *narrowing* operation that reduces the domain of a variable that is used subsequently to provide a resource approximation for a task. That is, the task reduces some *source* domain to a smaller *result* domain. For instance, in the flight purchase example given in Sect. 1, one narrowing operation would be the decision to consider only budget airlines, which precludes tickets from full-service carriers and thus refines the set of candidate flights.

To enable these forms of projective reasoning, we extend a VR graph as follows. We require semantic annotations that identify *selection* tasks along with their *candidate* and *selection* parameters, and *narrowing* tasks with their *source* and *result* parameters. Let (Member `$e` `$s`) define the constraint `$e` $\in$ `$s` and (Subset `$s1` `$s2`) define the constraint `$s1` $\subseteq$ `$s2`. We extend the constraints $\mathcal{C}$ of the VR graph as follows:

- If $T(x_1, \ldots, x_n)$ is a selection task with candidate parameter x_c and selection parameter x_s, then add (Member x_c x_s)
- If $T(x_1, \ldots, x_n)$ is a narrowing task with source parameter x_s and result parameter x_r, then add (Subset x_r x_s)

Exploitation of these additional VR graph links involves a straightforward generalization of the propagation algorithm of Sect. 4.2; in the interest of space, we forego a detailed description here.

teria for predicting the future state of dynamic predicates that model conditions under control of the system [2]. Many dynamic predicates, however, represent exogenous domain properties that lie beyond the agent's control (e.g., temperature, time of arrival of a flight) and so cannot be predicted using those methods.

[5] Thangarajah et al. [16] point out that, depending on the intended use of resource information, it may be possible to update data structures such as TE trees lazily, i.e. mark them as 'dirty' when change occurs, but not compute the new values until required.

[6] When estimates are solicited independently, there is an operational issue of knowing when the last estimate has been obtained so that the revised bound can be computed. In particular, if bounds are computed prematurely they may be overly narrow, thus violating our requirement for guaranteed bounds. Static analysis to determine the last estimation task is made difficult by the temporal unpredictability of asynchronous threads and loops, and the possibility of conditional branching.

7. DISCUSSION AND RELATED WORK

Our task expansion tree and associated aggregation of resource summaries are similar in spirit to the *goal-plan tree* of [16]. The latter is composed of alternating layers of goal nodes (analogous to our simple task nodes) and *plan nodes*; their plans are limited to sequential or parallel execution of propositional tasks. The same authors reason with a failure model whereby, if a plan T_1 fails for a task T, then every other possible plan $T_2, \ldots, T_m$ to achieve T is attempted in turn, until one succeeds or all have failed (when T is said to have failed). This failure model is reflected in their construction of the goal-plan tree, but is overly conservative and so may limit task throughput (and, hence, agent effectiveness). Last, the focus of [16] and their related work is to determine when tasks might be in potential conflict, and to resolve conflicts where possible by scheduling the task executions.

We have described a limited form of lookahead, with respect to resources. de Silva and Padgham [4] go further in deliberately incorporating full AI planning over possible plans (recipes) within an agent architecture, by the action of invoking a hierarchical planning system. Techniques for incorporating resource feasibility testing into hierarchical planning have been investigated previously [6, 2]. These approaches perform a kind of static analysis similar to that performed by our aggregation over the task expansion tree, although they support replaceable resources and resource production through the incorporation of a modal truth criteria analysis. The work assumes a single known value or single bound for the resource requirements of individual tasks, in contrast to our multi-fidelity approach. Furthermore, they do not address the issue of execution-time refinement of aggregate resource bounds.

Resource estimation is well studied in scheduling and temporal reasoning. For instance, Laborie [8] describes propagation of resource constraints in constraint-based scheduling, while Muscettola [10] computes an *envelope* encompassing the predicted evolution of resource levels over time. The emphasis in scheduling is to compute ahead of execution a feasible schedule that guarantees no resource conflicts. In contrast, detecting plan failure and recovering from it is an integral part of a reactive agent. Thus our projection of resources need not be complete; it has value even when partial since any sound inference is informative to the agent. Nonetheless, techniques particularly from constraint-based scheduling hold potential for extending our work to consider predicting resource evolution over time. Such work also points to the scheduling of tasks to avoid possible resource conflicts, as also considered by [16].

8. CONCLUSION

The framework for resource projection presented here provides a pragmatic middle ground, combining the static computation and dynamic refinement of guaranteed bounds on projected resource usage by a BDI agent. Our framework is distinguished by its use of parameterized multi-fidelity models of expected resource consumption, its focus on maximally informative resource bounds, and an expressive plan language that includes parameterized task types.

We have implemented our resource projection framework in the SPARK system, and are applying it to real-world domains derived from the CALO cognitive assistant project [14]. These domains include a full version of the group visit example in this paper, domains describing purchase of office equipment, and registration and travel to a conference. Construction of the TE trees and associate VR graphs, constraint propagation on the variables, and initial pruning of the trees are all performed with a few hundred milliseconds of runtime; the overhead is in line with required performance of CALO as a mixed-initiative task execution assistant. In addition to the minimal overhead of the static resource projection, the dynamic updates employ CSP propagation techniques of low-order polynomial complexity [5], and thus scale effectively.

Our work enables improved task throughput and execution quality, with reduced failure. It is straightforward to construct scenarios in which our approach will substantially outperform existing techniques. However, a truly meaningful evaluation of benefits will require analysis of extended agent operations within a real (or realistic simulated) environment. We will be collecting such data as our system is deployed within the CALO user community.

The work presented here focuses on guaranteed bounds for resource consumption. An interesting next step would be to develop a probabilistic counterpart to this framework that establishes the *likelihood* of resource contention by incorporating stochastic models of event likelihood and task success, building on a framework such as the probabilistic representation for process models of [12].

As noted earlier, future work is to consider a broader range of task resource consequences, including knowledge post facto costs and nondeterministic resource consumption. In addition, while much of the work described in this paper applies to production as well as consumption (on which we have focused), resource production and its interaction with consumption requires a model with temporal extent, by which the agent can reason on the relative timing and interleaving of production and consumption, including the return of replaceable resources.

ABSTRACT

Notions of fairness have recently received increased attention in the context of resource allocation problems, pushed by diverse applications where not only pure utilitarian efficiency is sought. In this paper, we study a framework where allocations of goods result from distributed negotiation conducted by autonomous agents implementing very simple deals. Assuming that these agents are strictly self-interested, we investigate how equitable the outcomes of such negotiation processes are. We first discuss a number of methodological issues raised by this study, pertaining in particular to the design of suitable payment functions as a means of distributing the social surplus generated by a deal amongst the participating agents. By running different experiments, we finally identify conditions favouring equitable outcomes.

1. INTRODUCTION

In many applications of multiagent systems it is important to achieve a *fair*, or *equitable*, allocation of the available resources amongst the agents in the system. However, this fairness requirement will often compete with the *rational* interests of individual agents. If agents are allowed to freely negotiate their preferred allocations of resources, the emerging allocations will typically be good on average, but give a rather low payoff to an unfortunate minority. In this paper, we investigate to what degree it is possible to reconcile rationality and equitability requirements. We do this by running a number of simulations where agents negotiate in a rational manner and where we track the evolution of allocations in view of their equitability.

Negotiation Problems

Take a set of (indivisible) goods $\mathcal{R}$ and a set of agents $\mathcal{A}$. A resource *allocation* is a partitioning of the resources of the set $\mathcal{R}$ amongst the n agents in $\mathcal{A}$ (that is, every resource has to be allocated to a unique agent). As an example, allocation A, defined through $A(i) = \{r_1\}$ and $A(j) = \{r_2, r_3\}$, would allocate resource r_1 to agent i, while resources r_2 and r_3 would be owned by agent j. Each agent has individual preferences regarding the bundles of resources it may hold. We are going to model the preferences of agents by means of *utility functions* mapping bundles of resources to real numbers. Assuming that agents are only concerned with resources they personally own, we will use the abbreviation $u_i(A)$ for $u_i(A(i))$, representing the utility value assigned by i to the bundle it holds for allocation A.

Definition 1 (Negotiation problems). *A negotiation problem is a tuple $\mathcal{P} = \langle \mathcal{R}, \mathcal{A}, \mathcal{U}, A_0 \rangle$, where*

- *$\mathcal{R}$ is a finite set of indivisible resources;*
- *$\mathcal{A} = \{1, \ldots, n\}$ is a finite set of agents ($n \geq 2$);*
- *$\mathcal{U} = \langle u_1, \ldots, u_n \rangle$ is a vector of utility functions, such that for all $i \in \mathcal{A}$, u_i is a mapping from $2^{\mathcal{R}}$ to $\mathbb{R}$;*
- *$A_0 : \mathcal{A} \to 2^{\mathcal{R}}$ is an initial allocation.*

From a designer's perspective, we will be interested in assessing the well-being of the whole society, or its *social welfare* [1], which is often defined as the sum of utilities of all the agents:

$$sw_u(A) = \sum_{i \in \mathcal{A}} u_i(A) \quad (1)$$

This is the *utilitarian* definition of social welfare (sw_u), but other criteria of assessment exist as well. In the next section, for instance, we are going to introduce the notion of *egalitarian social welfare*, which is a measure for the equitability of a given allocation. In this paper, we focus in general on equitability criteria. To decide how to (best) allocate the resources amongst the agents in a system is to solve a resource allocation problem.

Resource allocation problems are typically addressed from a centralized point of view (this is the case for instance in combinatorial auctions [4]). When no central authority is available, or when the computational burden would overwhelm a single agent, this approach is not well suited. A different approach, advocated by several authors [15, 7, 5], consists of distributing this process.

Distributed Approach

In the distributed perspective, instead of trying to centrally compute the optimal allocation, we shall progress in a stepwise manner towards an optimum. To do so, agents may agree on a *deal* to exchange some of the resources they possess. It transforms the current allocation of resources A into a new allocation A'; that is, we can define a deal as a pair $\delta = (A, A')$ of allocations (with $A \neq A'$). When such a deal improves the utilitarian social welfare (*i.e.* when $sw_u(A') > sw_u(A)$), we say that it is *socially beneficial*. Note that a single deal may involve the displacement of any number of resources between any number of agents. This level of generality is hardly realistic in practice. Sandholm [15] has proposed a typology of different types of deals, such as *swap deals* involving an exchange of single resources between two agents or *cluster deals* involving the transfer of a set of items from one agent to another. In this paper, we shall only consider the simplest type of deals (1-deals), *i.e.* those involving only a single resource (and thereby only two agents). The set of agents involved in the deal δ will be denoted as $\mathcal{A}^\delta$.

The above is a condition on the *structure* of a deal. Other conditions relate to the *acceptability* of a deal to a given agent. We assume that agents are *rational* in the sense of aiming to maximise their individual welfare. Furthermore, agents are assumed to be *myopic*. This means that agents will not accept deals that would reduce their level of welfare, not even temporarily, because they are either not sufficiently able to plan ahead or not willing to take the associated risk (see also [15] for a justification of such an agent model). Also agents will not behave strategically by, for instance, postponing a rational deal in the hope of finding an even better opportunity. We will, however, permit agents to enhance deals with *monetary side payments*, in order to compensate for a possible loss a utility. This is modelled using a so-called *payment function* $p : \mathcal{A} \to \mathbb{R}$ satisfying $\sum_{i \in \mathcal{A}} p(i) = 0$. A positive value $p(i)$ indicates that agent i *pays* money, while a negative value means that that agent *receives money*. In summary, the following rationality criterion will define the acceptability of deals:

DEFINITION 2 (RATIONALITY). *A deal $\delta = (A, A')$ is individually rational iff there exists a payment function p such that $u_i(A') - u_i(A) > p(i)$ for all $i \in \mathcal{A}$, except possibly $p(i) = 0$ for agents i with $A(i) = A'(i)$.*

The following result, due to Endriss et al. [7], makes the connection between the local decisions of agents and the global behaviour of the system explicit:

LEMMA 1. *A deal $\delta = (A, A')$ is individually rational iff $sw_u(A) < sw_u(A')$.*

A corollary of Lemma 1, originally due to Sandholm [15], is that *any* sequence of rational deals will eventually result in an allocation of resources with maximal social welfare. However, deals involving any number of agents and resources may be required to do so [15, 7]. In particular, 1-deals alone are certainly *not* sufficient for negotiation between agents that are not only rational but also myopic. Of course, for some particular negotiation problems, rational 1-deals *will* be sufficient. This is, for instance, the case when all agents are using *modular* utility functions [7].[1]

Paper Overview

The remainder of this paper is structured as follows. Section 2 presents the challenges posed by the study of egalitarian outcomes of distributed negotiation. Different types of payment functions are then introduced (Section 3), and we discuss how the choice of a particular function would affect the egalitarian nature of negotiation outcomes. Our experimental setup is introduced in Section 4. We then report results on different series of tests, both in modular (Section 5) and non-modular domains (Section 6). Section 7 concludes.

2. EGALITARIAN FRAMEWORK

While the utilitarian interpretation of the concept of social welfare is the definition usually adopted in the multiagent systems literature [16, 17], there are also several other formal tools for assessing the level of welfare of a society of agents that have been developed in the socio-economic sciences [1, 3, 12] and that have potential applications in the context of multiagent resource allocation as well [7].

Efficiency and Fairness

The well-known Pareto condition and the utilitarian social welfare ordering address the *efficiency* of an allocation of resources. In many situations, however, the efficiency of an outcome alone is not sufficiently accurate a criterion to assess the quality of an allocation of goods. Rather, the quest for efficiency needs to be balanced with certain *fairness* requirements.

This is, for instance, the case when a multiagent resource allocation system is used to automatically allocate airport slots to different airlines [9]: we want to minimise the overall delay of all flights (efficiency), without risking to completely ignore the requests of a particular flight that may be difficult to integrate into the current schedule (fairness). Another example are reverse combinatorial auctions for industrial procurement, where a single buyer solicits offers for, say, the parts required to assemble 500 cars [8]. Here it may be in the interest of the buyer to try to contract deals with more than one seller, even when that agreement does not entail the lowest possible price, in order to avoid being dependent on the good will of a single provider. This kind of safety constraint (from the viewpoint of the buyer) may also be interpreted as a fairness requirement (from the viewpoint of the competing sellers). The case of earth observation satellites discussed by Lemaître et al. [10] offers a particularly interesting and original example. In this application, several stakeholder (e.g. countries) are jointly funding a satellite that is circling the earth and can take photos, subject to various technical constraints. Different stakeholders request different (and often incompatible) photos, and a solution needs to be found that is both efficient (in the sense of

[1] A utility function is modular iff the utility assigned to a set of resources is always the sum of utilities assigned to its members.

exploiting the satellite as well as possible) and fair (in the sense of honouring an appropriate share of the requests of each of the stakeholders). Finally, Porter et al. [13] justify their study of fairness by invoking the following application: In many countries, in crisis situations, the state can commandeer diverse resources (e.g. aircrafts) from companies to cope with the emergency. However, this should be done in such a way that it minimizes the total true cost incurred by airline carriers (and by the state), and distribute this cost fairly amongst all carriers (so as not to penalize a carrier).

What these examples show is the relevance of notions such as *fairness*, *equitability*, or *envy-freeness* in many (diverse) applications. This paper will focus on what may be considered the most "basic" measure of the equitability of given allocations of goods, known as the *egalitarian social welfare*. The egalitarian social welfare is given by the utility of the agent that is currently worst off [1, 12]. That is, maximising egalitarian social welfare amounts to maximising the minimum utility in the system. This *maxmin principle* is also called 1-efficiency in the work of Porter et al. [13].

Optimal Outcomes and Local Deals

We are going to be interested in mechanisms that allow agents to reach an allocation with high (and ideally, maximal) egalitarian social welfare by means of a sequence of locally agreed deals. These deals should be *local* also and particularly in the sense that the agents should be able to decide locally within the group of agents about to agree on a given deal whether or not that deal should be deemed acceptable. In other words, we are not looking for just any algorithm to optimise with respect to egalitarian social welfare, but for a distributed negotiation scheme.

The first kind of deal we are going to consider are the *individually rational* deals introduced earlier. It is easy to show that individually rational deals alone are not sufficient to allow agents to find an allocation with maximal egalitarian social welfare in all cases (while, on the contrary, this is possible in the case of utilitarian social welfare [15, 7]). This can be seen in the following example. Assume there are two agents and two possible allocations (*i.e.* there may be just a single resource):

$$u_1(A) = 5 \quad u_1(A') = 2$$
$$u_2(A) = 1 \quad u_2(A') = 3$$

Then A' has maximal egalitarian social welfare, but in case A is the initial allocation there is no individually rational deal leading from A to A' (because the amount of utility lost by agent 1 would be greater than the utility gained by agent 2).

Another approach would be to change the notion of individual rationality and to require agents to use a different criterion when deciding on the acceptability of a given deal. This idea has been followed in previous work where the class of so-called *equitable deals* has been proposed [7]. This criterion, which requires the minimum utility within the group of agents contracting a deal to increase, can guarantee convergence to an egalitarian optimum. However, as also pointed out in [7], this is not a precise criterion in the sense that it is still possible to contract further equitable deals after an allocation with maximal egalitarian social welfare has been found. In fact, it is *impossible* to design a deal acceptability criterion that would be precise in this sense. This is related to the fact that the egalitarian social welfare ordering is not *separable* [12], which means that it is not possible to decide whether or not egalitarian social welfare has increased simply by looking at the utility levels of the agents that have experienced a change in utility after a deal. Hence, it is also not possible for the agents involved in a deal to locally verify whether the deal they are about to implement would affect egalitarian social welfare in a positive manner.

Besides such technical considerations, of course, the individual rationality criterion is also much more realistic than the idealised concept of equitable deals. Therefore, in the present paper, we are going to follow a different approach. Rather than designing agents that are "good" for egalitarian social welfare, we are going to study just how "bad" the standard utility-maximising agents are from an egalitarian point of view. To put it differently, we are going to analyse how egalitarian social welfare develops in a society where agents negotiate a sequence of individually rational deals.

Egalitarian Social Welfare and Money

Before getting further in that direction, we need to address the first challenge this approach poses. Typically, a social welfare measure does *not* take a monetary component into account. There is an obvious reason for that when utilitarian social welfare is concerned: the payment function p has been defined in such a way that the sum of payments is always zero. Hence, side payments can never change the sum of utilities, *i.e.* they can never affect utilitarian social welfare. Things are different for egalitarian social welfare. Not taking into account monetary payments would amount to assessing buyers as being more satisfied than sellers, whatever the price they pay to get the resource(s) may be. In the most extreme case, an agent selling all its goods for very good (high) prices (and thereby certainly being "happy") would still provoke a very low egalitarian social welfare (because its utility function defined over bundles of resources alone would return a zero value).

To circumvent this problem, payments have to be included into agents' utility functions. Let the *balance* of agent i be defined as the sum of all the payments $p(i)$ of that agent paid out (or received, in the case of negative payments) during all previous deals. By Lemma 1, if agents only negotiate individually rational deals, no allocation can be visited more than once. So we can index an agent's balance with the name of the allocation in question: $bal^A(i)$ is the balance of agent i once allocation A has been reached. Then we define for each agent i a second utility function u_i' that combines the utility derived from the bundle of resources it currently holds and its monetary balance:

$$u_i'(A) \quad = \quad u_i(A) - bal^A(i) \tag{2}$$

In the literature, such utilities are often called *quasi-linear* utilities, in which case u would be referred to as a valuation and u' as the actual utility [4]. The egalitarian social welfare of an allocation with money is now simply defined as the egalitarian social welfare with respect to the utilities u_i':

$$sw_e(A) \quad = \quad min\{u_i'(A) \mid i \in \mathcal{A}\} \tag{3}$$

3. PAYMENT FUNCTIONS

For any given deal that is individually rational, there will be a range of possible payment functions (in theory, there are infinitely many, in practice the number will depend on the granularity of the currency used). This raises the question

what payments to implement in a simulation context, where agents do not actually negotiate prices with each other. Choosing a payment function p for an individually rational deal $\delta = (A, A')$ means deciding how to distribute the social surplus $sw_u(A') - sw_u(A)$ amongst the agents in the system. The only condition that the payment function has to meet is to ensure that side payments add up to zero.

Amongst these payment functions, some will ensure that any socially beneficial deal is indeed individually rational (and vice versa), that is that for each agent i involved in the deal, we indeed have $u_i(A') - u(A) > p(i)$: we shall call these *rational-compatible payment functions*.

Locally Uniform Payment Function

We begin with what we call the *locally uniform payment function*, which ensures an equal payoff amongst all the agents involved in the deal (and gives no payment to any of the non-involved agents):

$$p(i) = \begin{cases} u_i(A') - u_i(A) - \frac{sw_u(A') - sw_u(A)}{|\mathcal{A}^\delta|} & \text{if } i \in \mathcal{A}^\delta \\ 0 & \text{otherwise} \end{cases}$$

Note that these payments do indeed add up to 0 as required, and that each agent $i \in \mathcal{A}^\delta$ receives the same positive payoff $u_i(A') - u_i(A) - p(i) = \frac{sw_u(A') - sw_u(A)}{|\mathcal{A}^\delta|}$.

The uniform payment function is not an arbitrary choice, but intended to be a reasonable approximation of actual payments that agents would agree upon in a real negotiation context (rather than a simulation). Equally dividing the social surplus amongst all the agents concerned also means maximising the product of individual payoffs. In the case of deals between just two agents, this corresponds to the result we would get if agents were to adopt the well-known Zeuthen strategy to negotiate the payments for a given deal [14]. This is true, at least, if we assume that agents calculate their "willingness to risk conflict" with respect to the payoff for the deal at hand (which is a reasonable assumption if agents have comparable levels of utility to begin with).

Globally Uniform Payment Function

The next type of payment that we introduce is one which ensures an equal payoff amongst *all* the agents within the society:

$$p(i) = u_i(A') - u_i(A) - \frac{sw_u(A') - sw_u(A)}{|\mathcal{A}|}$$

Observe that this function is also rational-compatible (for the same reason that the locally uniform one is), although agents involved in deals will typically receive a much more modest share of the social surplus. Note that this payment function is not inequality reducing, but not inequality increasing either. By distributing the social surplus equally amongst all agents of the society, everyone simply benefits with any deal and enjoys the same welfare increase.

It is easy to see that with such a payment function, the egalitarian social welfare depends both on the gain of utilitarian social welfare during the entire negotiation, and on the initial satisfaction of the agents. More precisely, consider a sequence $[A_0, A_1, \ldots, A_f]$ of allocations visited during a negotiation process. For all $t \in \{0..f-1\}$, we have (where $p_t(i)$ denotes the payment of agent i at time t):

$$u_i(A_{t+1}) - u_i(A_t) - p_{t+1}(i) = \frac{sw_u(A_{t+1}) - sw_u(A_t)}{|\mathcal{A}|}$$

Observe that:

$$u_i(A_f) - bal^{A_f}(i) = u_i(A_0) + \frac{sw_u(A_f) - sw_u(A_0)}{|\mathcal{A}|}$$

Thus, we finally have:

$$sw_e(A_f) = min_i \left\{ \frac{sw_u(A_f) - sw_u(A_0)}{|\mathcal{A}|} + u_i(A_0) \right\}$$

It is interesting to note that:

$$sw_e(A_f) - sw_e(A_0) = \frac{sw_u(A_f) - sw_u(A_0)}{|\mathcal{A}|}$$

This has two important consequences: first, the gain of egalitarian social welfare is proportional to the gain of utilitarian social welfare. Also, the optimal allocation(s) w.r.t. utilitarian social welfare is/are the *same* as the optimal allocation(s) w.r.t. egalitarian social welfare.

It should also be pointed out that in the case of two agents, locally uniform payment functions are of course equivalent to globally ones. As reported later on in this paper, we carried out experiments to find out from what number of agents on do locally uniform payment functions give rise to negotiations exhibiting significantly different outcomes (see Fig. 3).

Fully Locally Equitable Payment Function

In theory, it is possible to conceive an equitable payment function which would, at each step, compute a payment such that each agent (involved in the deal) would enjoy the same utility level after the deal has been achieved. This idea is very similar to that of *fair imposition* proposed in [13]. Such a payment would take the following form:

$$p(i) = \begin{cases} u_i(A') - bal^A(i) - \frac{\sum_{j \in \mathcal{A}^\delta} (u_j(A') - bal^A(j))}{|\mathcal{A}^\delta|} & \text{if } i \in \mathcal{A}^\delta \\ 0 & \text{otherwise} \end{cases}$$

Note that here, the balance $bal^A(i)$ refers to the balance of the previous allocation (A). The above must be read as follows: compute the restricted social welfare divided it by the number of agents involved (that would be the optimal repartition), then subtract the payment such that each agent reaches exactly that level of satisfaction. This is exemplified on the following example (assuming this is the first deal taking place, hence a balance of 0 for each agent):

$$\begin{array}{ll} u_1(A) = 3 & u_1(A') = 2 \\ u_2(A) = 1 & u_2(A') = 6 \end{array}$$

The final allocation exhibits a restricted (utilitarian) social welfare of 8, hence 4 for each agent would be the optimal situation. This is obtained by computing the payment function which pays +2 to agent 1 and -2 to agent 2. However, such a payment would not always be rational: in many situations, the payment would be such that at least a self-interested agent would have no interest in implementing the deal. This is for instance the case on the following example:

$$\begin{array}{ll} u_1(A) = 3 & u_1(A') = 2 \\ u_2(A) = 1 & u_2(A') = 3 \end{array}$$

In this case, the computed payment is +/- 0.5, and it is easy to see that agent 1 would not rationally accept such a deal. In general, a deal is only rational if every agent enjoys before the deal takes place a utility that is strictly lower than the mean of the restricted social welfare after the deal. This is then an example where a socially beneficial deal would not be individually rational for agents if they were to use this payment function, *i.e.* this proves that this payment function is not rational-compatible. The consequence is that it will change the structural properties of the framework: by restricting the number of feasible deals, certain sequences of deals (that could be rational with a different payment function) would not be explored. Clearly, this can be a good thing in some situations, as exemplified below:

$$\begin{array}{lll} u_1(\{r_1\}) = 2 & u_1(\{r_2\}) = 2 & u_1(\{r_1, r_2\}) = 104 \\ u_2(\{r_1\}) = 100 & u_2(\{r_2\}) = 0 & u_2(\{r_1, r_2\}) = 100 \\ u_3(\{r_1\}) = 0 & u_3(\{r_2\}) = 101 & u_3(\{r_1, r_2\}) = 101 \end{array}$$

We first suppose that agents use *any* rational-compatible payment function, and that a_2 initially holds the bundle $\{r_1, r_2\}$ (initial social welfare is 100). Now the following deal sequence takes place: (i) a_2 gives r_2 to a_1 (leading to a social welfare of 102), (ii) a_2 gives r_1 to a_1 (leading to a social welfare of 104). No more rational deal is possible (giving any resource would result in a loss of 102).

Of course, a social welfare of 201 would have been attainable, by simply offering r_2 to a_3 as a first deal. Equitable deals (payment 0.5) would indeed have discarded the deals implemented in the suboptimal sequence, leaving only this deal possible. Whether this is a good thing or not in general, *i.e* whether this payment function behaves as a good heuristic in this context will be experimentally evaluated later on in this paper (see Fig. 2 and 4).

Rational Locally Equitable Payment Function

What would be the "most equitable" payment function that would still be rational-compatible? A slight modification of the previous payment function would in fact suffice to make it rational-compatible: compute the payment function such that it makes every agent marginally better off, then allocate the remaining payments induced by the deal so as to reduce inequalities as much as possible (that is, give the remaining social surplus to the agent currently worse off).

For a deal $\delta = (A, A')$, formally, this payment can be defined as the function p maximizing

$$min_{i \in \mathcal{A}^\delta} \left\{ u_i(A') - bal^A(i) - p(i) \right\}$$

where $bal^A(i)$ is the balance of agent i before the deal, and under the two following constraints: p has to be a payment function ($\sum_{i \in \mathcal{A}} p(i) = 0$) and the deal must be rational ($\forall i \in \mathcal{A}^\delta, u_i(A') - u_i(A) > p(i)$). Obtaining an analytic formulation for p in the general case is difficult. However, in the case of bilateral negotiation, the solution to the above constraint equation for any socially beneficial deal $\delta = (A, A')$ involving agents i and j, can easily be computed. First note that in case the deal is rational with the fully locally equitable payment, this defines our payment function. Otherwise, observe that there is necessarily a single agent, say i, such that $u_i(A) \geq (u_i(A') + u_j(A'))/2$. This is so, because if both agents met this condition, then the deal would be fully equitable, while if neither of them met the condition, the deal would clearly not be be individually rational. Now we fix the payment for that agent i, in such a way that this agent is just marginally better off, in order to make the deal rational. That is, $p(i) = u_i(A') - u_i(A) - \epsilon$ for some suitably small constant $\epsilon > 0$. Note that $p(i)$ could be a positive or negative value; the payoff for i will be $+\epsilon$ either way. Then we define the other payment as $p(j) = -p(i)$.

We take again our previous example (that proved fully equitable payment functions not to be rational-compatible), to show how this works. Agent 1 has been better off before the deal than the average utility after the deal. Its payment will $p(1) = 2 - 3 - \epsilon$, *i.e.* it *receives* an amount of $1 + \epsilon$ from agent 2. After the deal, we have the following utilities (assuming there have been no earlier payments):

$$\begin{array}{l} u'_1(A') = 3 + \epsilon \\ u'_2(A') = 2 - \epsilon \end{array}$$

Whether this payment function outperforms other functions (as far as egalitarian social welfare is concerned) will be evaluated experimentally in this paper (see Fig. 1 and 5).

4. EXPERIMENTAL METHODOLOGY

Our experimental results are based on the following methodology: we first *create the system* (agents' utility functions and the initial allocation of goods), we then *compute the optimal utilitarian social welfare*, and we finally *run negotiations* (that is, let agents negotiate until no more deals are possible). Agents typically desire to hold several bundles (the details of how these utility functions are generated depends on the domain studied, and will be given later on). To avoid favouring a specific agent, the negotiation protocol is randomized: we pick an agent at random, and try to identify one rational deal involving this agent. Remember that as soon as one such rational deal meets the rationality constraints of the seller and the buyer, the deal is implemented and the allocation is updated. The results are averaged over 500 negotiation runs.

The reason why we compute the optimal utilitarian social welfare is that it serves to derive a (very generous) upper bound on optimal egalitarian social welfare: The best you can do is to optimize overall utility ($=sw_u$) and then use payments to distribute the overall wealth as evenly as possible (it is then simply $1/n$ times the maximal utilitarian social welfare). In the restricted negotiation framework that we investigate here, this optimal value will seldom be attained. What will be highly significant will be the value of the final utilitarian social welfare, which would represent an upper bound under the constraints of the negotiation framework (*e.g.* restrictions to 1-deals, rationality constraints). Note that affecting the class of acceptable deals by employing a non-rational-compatible payment function falls into that category. Again, distributing the overall wealth as evenly as possible would be the optimal egalitarian outcome (recall that a *theoretical* equitable payment function would allow to attain this value).

To sum up, the experimental results reported in this paper will typically mention the following outcome values:

(1) the value of the *optimal utilitarian welfare* (sw_u^{opt}/n), upper bound in unrestricted negotiation frameworks;

(2) the value of the *final utilitarian welfare* (sw_u/n), upper bound under the constraints imposed during this negotiation;

(3) the value of the *final egalitarian welfare* (sw_e), after negotiation took place.

The difference between (1) and (2) is an indicator for what we shall call the *protocol bias*. The difference between (2) and (3), more interesting to us, permits to appreciate the *payment function bias*. Comparison with the initial value of the egalitarian welfare proved to present very little interest in our experiments: it has been omitted for the sake of readability.

Figures presented in the next two sections exhibit curves defined by the following parameters: (1) the type of social welfare measured (`SWe` or `SWu/n`); (2) whether the social welfare shown is the `optimal` value or the `final` value; (3) the payment function used; and (4) the type of distribution used.

5. MODULAR DOMAINS

We start with very simple domains of negotiation, where no synergies can occur between different items of the bundles agents hold. In this case agents' utility functions are said to be *modular*. We generate these functions by simply picking 50 resources for each agent, and assigning random coefficients between 0 and 100. Note that in this case the optimal utilitarian social welfare can be easily computed: It suffices to assign each item to the agent who values it the most. (This allows in particular to run experiments with a large number of items). A recent (somewhat surprising) complexity result, due to Bouveret and Lang [2], shows that the difficulty of the corresponding problem largely differs for egalitarian frameworks *without money:* Optimising the egalitarian social welfare is an NP-hard problem, even when agents use modular functions (this is even true when they all use the same utility function). This is *not* the case in our setting though, because of the use of money (which allows us to separate the process of maximising overall utility and then distributing that utility evenly amongst the agents). A final important point to note is that the complexity of the overall negotiation process remains polynomial in this case, because the length (number of deals) of rational negotiations in modular domains is known to be linear [6].

Locally Uniform vs. Rational Locally Equitable

The first set of experiments has been run with 5 agents using modular utility functions, deals enhanced with rational-compatible payment functions. The number of resources varies between 50 and 150. Recall that in this case, we know that the optimal utilitarian social welfare will be reached (*i.e.* there is no "protocol bias"): the experiment will really measure the "payment function bias". To put it another way, if there were such a thing as a rational-compatible fully equitable payment function, both curves would be equivalent.

Fig. 1 shows the final egalitarian social welfare attained when locally uniform or rational equitable payments are used. It is striking that, first, both payment functions perform reasonably well (the ratio (sw_e/sw_u^{opt}) is constantly higher than 70% and improves when the number of resources increases). The rational equitable payment is, as expected, significantly above the locally uniform one (84% vs. 70% for 60 resources, 93% vs. 80% for 120 resources, 96% vs. 83% for 150 resources). However, given that this latter payment is, as argued before, the "most equitable" conceivable

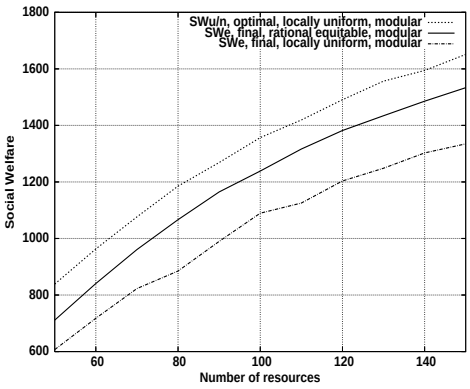

Figure 1: Modular Domains (I)

rational-compatible payment function, it is still surprising to see how close the "strategically justified" locally uniform payment stands.

Fully Locally Equitable

The second series of experiments (Fig. 2) carried out in modular domains tests the assumption that fully equitable deals can be a good heuristic in our negotiation setting, despite reducing the number of feasible deals. The results are unambiguous: in modular domains, this is far from being the case. The protocol bias (which exists in this case), is illustrated by the ratio between the optimal value and the final sw_u/n reached when allowing only fully equitable deals. For 50 resources already, the figure is around 75%, and drops to 50% for 150 resources. This really measures the loss due to the restriction put on the framework. Worse than that, the final sw_e exhibits a figure (sw_e/sw_u^{opt}) of 45% for 50 resources, shrinking down to 16% for 150 goods. Actually, the final egalitarian social welfare hardly increases in this setting. This really proves that this restriction is simply too hard to be met, and almost freezes the negotiation process.

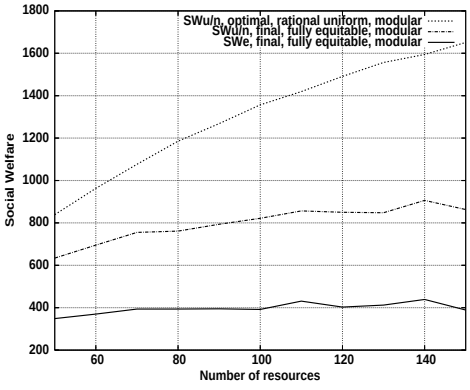

Figure 2: Modular Domains (II)

6. NON-MODULAR DOMAINS

In many situations, the assumption that resources have no synergies between them will be highly unrealistic. It is then very important to investigate the outcome of negotiation in such (non-modular) domains. The first experiments that we

envisaged were produced using a uniform distribution for the generation of the structure of utility functions. The results (not reported here), regarding the final egalitarian welfare, turned out to be very good. This simply reflected the fact that uniform distributions tended to distribute evenly the participants' needs: agents were seldom in conflict.

Realistic Distributions

In order to get realistic agent preferences we decided to make use of the CATS bid generator [11], primarily designed for the use with combinatorial auctions. The output of the CATS software is a set of bids, taking the form of XOR demands $\langle b_1, p_1\rangle \ldots, \langle b_n, p_n\rangle$, where b_i stands for the bundle of resources, and p_i stands for the value the agent assigns to this bundle. One problem that we faced when using CATS is the fact the output file contains only anonymous bids. This is perfectly suited for the case of studies of algorithms for the Winner Determination Problem in combinatorial auctions [4], because then you are not really concerned with associating resources with agents who claimed them, but only with computing the optimal solution. What we did to deal with this was to generate a (large) number of bids in a single shot (interacting in the same domain, it is likely that agents share a common dependency structure between goods). However, by allowing dominated bids to be generated, we permit agents to express different degree of preferences over the same bundles of goods. And finally, by picking (at random) only a subset of these generated bids, we allow agents to demand different bundles and admit that they may only partially share this common structure. The experiments reported in this section have been conducted using the CATS *arbitrary* distribution.

Locally Uniform vs. Globally Uniform

Fig. 3 shows the egalitarian social welfare reached when an increasing number of agents negotiate over 15 resources using locally uniform payments. Each agents claims 10 bundles. Recall that, as mentioned in the previous section, when there are no more than two agents, the locally uniform payment and the globally uniform payment coincide.

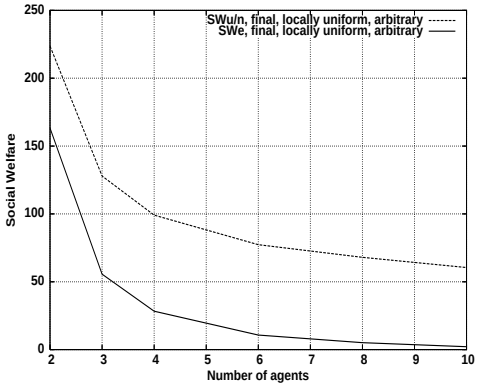

Figure 3: Non-Modular Domains (I)

First notice that, as expected, the final sw_u/n decreases exactly as a $1/n$ curve. Intuitively, we could have expected the final sw_e to decrease at the same speed. This turns out not to be the case: from 2 to 3 agents, sw_e decreases by 65%, whereas a $1/n$ decrease rate would have been of 33%. This observation can be explained in the light of the locally uniform payment function singularity: when there are no more than two agents, the locally and globally uniform payment are identical, in which case the inequalities between both agents will not increase during the negotiation. In other words, as explained in the previous section, the gain of sw_e between the beginning and the end of the negotiation will be equal to the gain of sw_u divided by n. This explains why the final sw_e for two agents is close to the final sw_u.

On the contrary, for more than 2 agents, each bilateral deal will only favor the two agents involved in it, and will thus potentially increase inequalities between agents contracting many deals, and others. This allows us to explain the rapid decrease of sw_e at the beginning of the curve.

Fully Locally Equitable vs. Locally Uniform

Next we compare fully locally equitable payment functions and locally uniform payment functions (Fig. 4). The results show that negotiation using fully equitable payments is notably less equitable than negotiation with uniform payments. This is so because the criterion is, again, too restrictive and prevents agents from contracting deals that could be rational (and hence improve social welfare). The fact that this function helps to select highly beneficial deals does not compensate for the loss incurred by these missed opportunities. This completes the answer to the question we left pending in Section 5: this payment function does not behave as a good heuristic, in this type of domains neither. The reason why the difference is far less important with uniform payment functions in these domains lies mainly in the fact that, typically, much fewer deals are contracted, and that values assigned to bundles are typically higher than those assigned to single resources (augmenting the probability to contract a fully equitable deal).

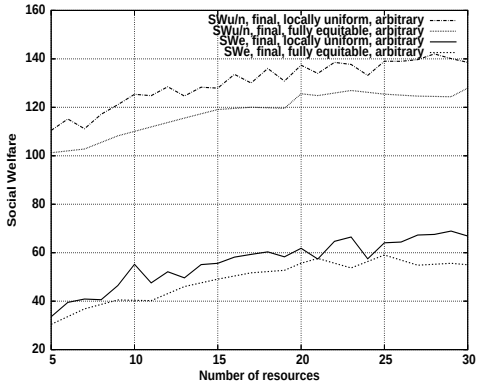

Figure 4: Non-Modular Domains (II)

Rational Locally Equitable vs. Locally Uniform

In this last series of experiments, we show that rational equitable payments slightly outperform uniform payments as far as the satisfaction of the poorest agent is concerned. (Remember that feasible deals being the same for these two types of payments, and payment functions adding up to zero at the end of a given negotiation, the fact that final values of averaged utilitarian welfare are similar should come as no surprise.) In Fig. 5, we observe that the difference with uniform payments is marginal for small number of resources,

but becomes slightly larger when this number increases. This is explained as follows: when there are few resources to be distributed, the number of deals that will take place during a negotiation will typically be very small. Each contracted deal increases the probability of redistributing some wealth to the poorest agent, the more deals contracted the happier that agent should get (on average).

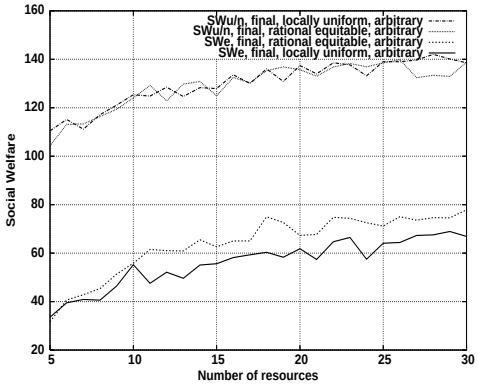

Figure 5: Non-Modular Domains (III)

7. CONCLUSION

This paper has investigated the egalitarian properties of some distributed resource allocation processes. An important aspect of the framework, that has radical consequences on egalitarian outcomes, is the choice of a specific payment function (*i.e.* the way to redistribute the social surplus induced by any given deal). We have discussed a variety of payment functions, and shown in particular that a perfectly equitable payment function is not rational-compatible. Our study has been complemented with several experiments, that have allowed us to identify conditions favourable to egalitarian outcomes. In particular, we should stress that:

- In modular domains, we observed that locally uniform payments give rise to reasonably equitable outcomes, which becomes comparatively more equitable as the number of resources grows. This remains significantly below (but closer than expected) to what could be achieved at best within the class of rational-compatible payments.
- It is typically not beneficial to enforce agents to obey to implement a fully equitable payment function, because this would conflict with rationality principles and prevent agents from conducting socially beneficial deals. This is striking in modular domains, less obvious in non-modular domains where there are typically fewer deals taking place during the negotiation.
- Locally uniform payment functions significantly differ from globally uniform payment functions for more than 2 agents. More generally, as the number of agents grows, we cannot expect any local payment to compensate for the inequalities.

A possible extension of this work will be to investigate how the conclusions drawn here will vary for other "standard" CATS distributions. A longer-term issue will be the study of other equitability measures: the *maximin* egalitarian principle is but one (admittedly rough, because it only takes into account the poorest agent) equitability measure. To refine our study, we plan to investigate other measures, such as Gini-like indexes for instance [12], which give a more global measure of a society's wealth distribution.

ABSTRACT

Deliberation scheduling is the process of scheduling decision procedures to maximize overall performance. In this paper, we present novel mathematical programming algorithms for scheduling deliberations, and illustrate them through several increasingly complex classes of deliberation scheduling problems. In comparison to previous work, our algorithms are able to optimally or near-optimally solve deliberation scheduling problems for decision procedures that have more general performance profiles, and are applicable in complex domains with uncertainty. We also illustrate that, thanks to the mathematical programming formulation, our algorithms can be easily extended to model additional system aspects.

1. MOTIVATION AND INTRODUCTION

Many complex problems are too difficult for autonomous agents to solve within deadlines. For example, an autonomous aircraft flying a prolonged mission might not have time to prepare a plan that specifies actions and reactions for all possible contingencies over the entire mission before it starts to execute the plan. In this situation, if the problem can be divided into multiple independent sub-problems (such as takeoff, ingress, rescue, egress, and landing), which we call *phases*, then the agent might do better to focus only on near-term phases. Then, while executing the plan for earlier phases, the agent could use available computational time during execution to reconsider aspects of the problem and improve its solutions for current and future phases. This assertion is not surprising. The challenge, though, is in automating the process of allocating computational time to appropriate phases given the uncertainty and complexity of the problem domain.

Deliberation scheduling is the process of scheduling decision procedures to maximize overall performance. Boddy and Dean proposed an optimal deliberation scheduling algorithm for a subclass of problems with piecewise linear concave value functions [2, 1]. Horvitz considered likelihood of future instances, and explored policies for proactive allocation of idle time for these potential problems in several settings [6]. Goldman, Musliner, and Krebsbach proposed a greedy deliberation scheduling algorithm and compared its performance with the optimal algorithm using Markov Decision Process models [5, 7]. However, these approaches are either only applicable in restricted subclasses of deliberation scheduling problems (e.g., for limited types of performance profiles for decision procedures), or ignore some aspects of systems (e.g., uncertainty, or deliberation cost).

Our work is directed at addressing these shortcomings. Our formulation of the deliberation scheduling problem as a mathematical program—as a linear program (LP) or mixed-integer linear program (MILP)—makes it much easier to work with a wide variety of performance profiles. It also allows us to explicitly model the costs of deliberation both before mission execution (where more deliberation allows an agent to prepare for more contingencies but delays the start of the mission) and during mission execution (where reconsidering plans can improve performance but can also distract when responding to emergent situations). Our mathematical programming approach is unique among proposed solutions to deliberation scheduling in its ability to work with a richer set of performance profiles, and to simultaneously solve the coupled problems of deciding both when to deliberate given its cost, and which decision procedures to execute during deliberation intervals.

Furthermore, our mathematical programming approach provides a domain-independent framework on which we can easily make simplifying transformations or impose additional constraints. For example, as we will show, a deliberation scheduling problem where the mission quality is the multiplication of individual phase qualities (i.e., a nonlinear ob-

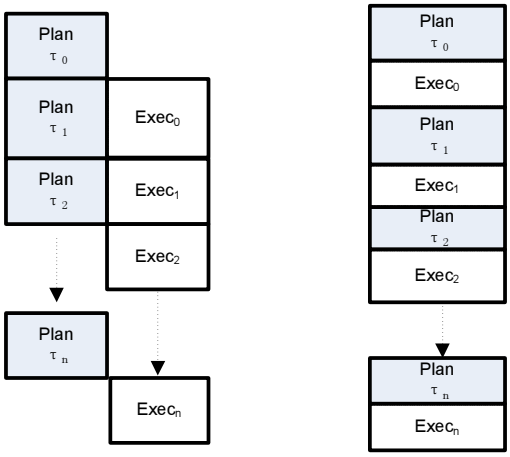

Figure 1: Deterministic phase transitions in two situations: simultaneous planning and execution (left) and interleaved planning and execution (right).

jective function) can be easily transformed into a problem where the mission quality can be represented as the sum of individual phase qualities (i.e., a linear objective function). A mathematical programming formulation also makes it possible to model additional system features. In this paper, we demonstrate this capability by modeling the fact that an autonomous agent should control which phases it will face in the future while scheduling deliberation.

The rest of the paper is organized as follows. Section 2 describes a basic mathematical programming formulation and introduces transformation and approximation techniques. Section 3 extends the formulation to suit domains involving uncertainty, and Section 4 makes further extensions by assuming that phase transitions are controllable by the autonomous agent. We present empirical results in Section 5, where we evaluate the efficiency and optimality of our approach. Finally, Section 6 summarizes the contributions of the work presented and outlines future directions.

2. DETERMINISTIC PHASE TRANSITIONS

We begin our examination of deliberation scheduling techniques by assuming that transitions among phases are deterministic —a mission can be represented as a chain of phases as shown in Figure 1. The left side of the figure depicts the case where deliberation and execution can occur simultaneously, such that deliberation about future phases can be done during execution of the current phase. The right side of the figure shows interleaved planning and execution, where an interval for deliberation is followed by an interval for execution, which in turn is followed by time for deliberation, and so on. In this paper, we describe and illustrate our algorithms on interleaved planning and execution. However, our algorithms, with slight modification, can also be applied for agents that simultaneously plan and execute.

Let τ_0 be the computational time that the autonomous agent initially has when the problem is presented, and τ_i ($i \geq 1$) be additional computational time that the agent can have after finishing the previous phase and before beginning the execution of $phase_i$. Let us temporarily assume that τ_i is specified *a priori*; we will relax this assumption shortly. The deliberation scheduling problem is then to schedule decision procedures within these available computational time intervals so that the expected quality of mission solution is maximized. A straightforward strategy is to allocate τ_i to $decision_i$ (where $decision_i$ represents the decision procedure for $phase_i$), but this myopic approach is usually suboptimal since it might be fruitful to use some of the time to get a head start on decision procedures for future phases.

In deliberation scheduling, a common construct is the expected value of computation (EVC) function (also called performance profile) [1, 2, 5, 6, 7]. An EVC (performance profile) of an anytime algorithm is the expected quality of the solution as a function of the algorithm's run time. In this paper, we use this construct as well.

Let t_i denote the total amount of computational time scheduled for decision procedure $decision_i$, and let $V_i(t)$ denote the EVC function of $decision_i$. The deliberation scheduling problem with deterministic phase transitions can then be represented in the following mathematical formulation:

$$\max f(v_0, v_1, \ldots, v_n) \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \leq \sum_{i=0}^{k} \tau_i \\ v_i = V_i(t_i) \\ t_i \geq 0 \end{array} \right. \tag{1}$$

where $\forall k \in \{0, 1, \ldots, n\} : \sum_{i=0}^{k} t_i \leq \sum_{i=0}^{k} \tau_i$ indicates the fact that the amount of scheduled computational time can never exceed the amount of available computational time. v_i is the expected quality of the solution to $phase_i$, and the objective function $f(v_0, v_1, \ldots, v_n)$ specifies how the expected qualities of individual phase solutions determine the overall quality of the mission.

In this paper, we concentrate on the linear objective function $f(v_0, v_1, \ldots, v_n) = \sum_i v_i$, which fits many real-world domains where the quality of a mission is the accumulative quality through all its phases. An intuitive example is that of an autonomous delivery robot making several rounds of deliveries: its total quality is the sum of the qualities of individual package deliveries.

Notice that many nonlinear objective functions can be linearized (but not necessarily as $\sum_i v_i$) through mathematical reformulation, and thus the techniques presented in this paper are also applicable in those domains. We now introduce linearization methods for two typical prototypes of nonlinear objective functions.

- **Objective function** $f(v_0, v_1, \ldots, v_n) = \min v_i$

  A popular objective function in real-world domains is that the quality of a mission is the minimum quality of individual phases. This nonlinear objective function $\min v_i$ can be reformulated as a linear objective function v with additional linear constraints $\forall i : v \leq v_i$. That is, Eq.1 becomes

$$\max v \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \leq \sum_{i=0}^{k} \tau_i \\ v_i = V_i(t_i) \\ v \leq v_i \\ t_i \geq 0 \end{array} \right.$$

- **Objective function** $f(v_0, v_1, \ldots, v_n) = \prod_i v_i$

  This objective function is usually used for domains where the probability of successfully completing a mission is the multiplication of the probabilities of successfully completing each phase. By using a logarithmic

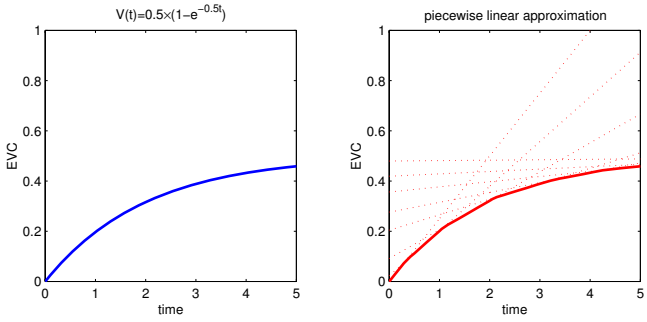

Figure 2: A continuous concave function (left), and its piecewise linear approximation (right).

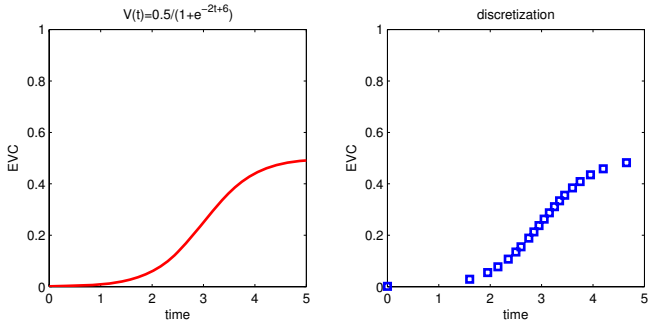

Figure 3: A general nonlinear function (left), and its discrete function (right).

transformation ($\varepsilon_i = \ln v_i$), Eq.1 can be transformed to:

$$\max e^{\sum_i \varepsilon_i} \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \le \sum_{i=0}^{k} \tau_i \\ \varepsilon_i = V_i'(t_i) \\ t_i \ge 0 \end{array} \right.$$

where $V_i'(t) \equiv \ln V_i(t)$.

Notice that e^x is a monotonically increasing function, maximizing $e^{\sum_i \varepsilon_i}$ is equivalent to maximizing $\sum_i \varepsilon_i$, and so the objective function is linearized (while nonlinearity is moved to EVC functions).

We have introduced linearization methods for some nonlinear objective functions, but we have not fully addressed the difficulty in solving Eq.1, in which the constraint $v_i = V_i(t_i)$ might be nonlinear. Nonlinear optimization problems are generally intractable; in the following discussion, we present approximation techniques used for linearization in several settings.

- **Linear EVC function**

  If $V_i(t)$ are linear functions of t for any i, then $v_i = V_i(t_i)$ are trivial linear constraints, and deliberation scheduling problems can be formulated as linear programs which are solvable in polynomial time.

- **Continuous concave EVC function**

  For many anytime algorithms, the rate of refinement of the solution slows down with increasing computational activity, i.e., $V_i(t)$ is a continuous concave function. It is well established that a continuous concave function can be approximated as a piecewise linear concave function [8]. Using a sufficiently large number of pieces, such approximation usually performs well. Figure 2 shows an example of approximating function $V(t) = 0.5\times(1-e^{-0.5t})$ with a piecewise linear concave function that is composed of eight linear pieces.

  Considering that deliberation scheduling often occurs online, we adopt a simple but fast algorithm to construct piecewise linear functions, which, at each time step, myopically adds a linear piece that will reduce approximation error most. Our empirical results show that this myopic algorithm can, in general, approximate a function within several milliseconds, and thus is well suited for online applications.

Let $V_{i,j}(t) = a^v_{i,j} \times t + b^v_{i,j}$ be the linear function used to represent the jth segment of the piecewise linear concave curve, then function $V_i(t)$ can be approximated as $V_i(t) = \min_j a^v_{i,j} \times t + b^v_{i,j}$. That is, the constraint $v_i = V_i(t_i)$ in Eq.1 becomes $v_i = \min_j a^v_{i,j} \times t_i + b^v_{i,j}$, and the deliberation scheduling problem can be formulated into the following linear program:

$$\max \sum_i v_i \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \le \sum_{i=0}^{k} \tau_i \\ v_i \le a^v_{i,j} \times t_i + b^v_{i,j} \\ t_i \ge 0 \end{array} \right. \qquad (2)$$

A linear program can be solved fast (i.e., in polynomial time), which explains why much previous work focused on continuous concave EVC functions and there exist fast algorithms for such problems [2].

- **General nonlinear EVC function**

  In the previous discussion, we have approximated deliberation scheduling problems with decreasing return rate EVC functions into linear programs. Now, we consider more general nonlinear EVC functions, and use discretization to remove nonlinearity in such functions [8]. Figure 3 shows an example of discretization.

  Let $T^v_{i,j}$ and $V_{i,j}$ represent the jth time point and its corresponding value on the discretized function of $V_i(t)$, and let binary variable $\delta^v_{i,j}$ represent whether time point $T^v_{i,j}$ is selected. The problem can then be formulated as:

$$\max \sum_i v_i \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \le \sum_{i=0}^{k} \tau_i \\ t_i = \sum_j T^v_{i,j} \times \delta^v_{i,j} \\ v_i = \sum_j V_{i,j} \times \delta^v_{i,j} \\ \sum_j \delta^v_{i,j} = 1 \\ t_i \ge 0 \\ \delta^v_{i,j} \in \{0,1\} \end{array} \right. \qquad (3)$$

$\sum_j \delta^v_{i,j} = 1$ says that a certain amount of computational time is scheduled for decision procedure $decision_i$. The constraints $t_i = \sum_j T^v_{i,j} \times \delta^v_{i,j}$ and $v_i = \sum_j V_{i,j} \times \delta^v_{i,j}$ model the EVC function $V_i(t)$ through binary variable $\delta^v_{i,j}$.

Recall that for the phases with continuous concave EVC functions, we can approximate them into piecewise linear functions. That is, we only need to discretize non-concave EVC functions, which reduces the

number of binary variables used in mixed integer linear programs and thus improves the computational efficiency.

In the discussion so far, it is assumed that τ_i is known *a priori*, but in many real-world domains, τ_i is associated with a cost function $C_i(\tau_i)$ rather than being pre-specified. An autonomous agent thus also needs to determine the intervals of computational time it should use for improving solutions of its decision procedures.

Using our mathematical programming formulation, it is easy to make this extension. That is,

$$\max \sum_i (v_i - c_i) \quad \left| \begin{array}{l} \sum_{i=0}^{k} t_i \leq \sum_{i=0}^{k} \tau_i \\ v_i = V_i(t_i) \\ c_i = C_i(\tau_i) \\ \tau_i \geq 0 \\ t_i \geq 0 \end{array} \right. \quad (4)$$

Notice that the deliberation cost functions $C_i(\tau)$ are analogous to the EVC functions $V_i(t)$; we can use the approximation techniques described previously to linearize the constraint $c_i = C_i(\tau_i)$ as well. That is, when $C_i(\tau)$ is a continuous convex function (i.e., increasing cost rate), we can approximate it as a piecewise linear convex function. When $C_i(\tau)$ is a general nonlinear function, we can discretize it and build a mixed integer linear program.

We conclude this section by illustrating our algorithm on a simple (randomly generated) example, and more empirical results will be shown in Section 5. In this example, there are four phases $phase_{i\in\{0,1,2,3\}}$. The EVC functions are continuous concave functions:

$$V_0(t) = 3.1319 \times (1 - e^{-0.8233t})$$
$$V_1(t) = 4.0886 \times (1 - e^{-0.3603t})$$
$$V_2(t) = 0.2965 \times (1 - e^{-0.8393t})$$
$$V_3(t) = 2.3293 \times (1 - e^{-0.3057t})$$

The deliberation cost functions are continuous convex functions:

$$\begin{array}{ll} C_0(\tau) = 0.2037 \times (\tau - 1)^{1.5115} & \text{when } \tau \geq 1 \\ C_1(\tau) = 0.4808 \times \tau^{1.1843} & \text{when } \tau \geq 0 \\ C_2(\tau) = 0.4038 \times (\tau - 3)^{1.8348} & \text{when } \tau \geq 3 \\ C_3(\tau) = 0.2129 \times (\tau - 1)^{1.9415} & \text{when } \tau \geq 1 \\ \text{and} \quad C_i(\tau) = 0 & \text{otherwise} \end{array}$$

Approximating each $V_i(t)$ and $C_i(\tau)$ as a piecewise linear function with 20 pieces, this deliberation scheduling problem can then be formulated as a linear program. With the LP solver *cplex* (www.ilog.com), the mission's expected quality is 5.40 and solving the LP takes 0.021 seconds.

The deliberation schedule is shown in Figure 4. In detail, the agent spends 4.068 time units on its decision procedures

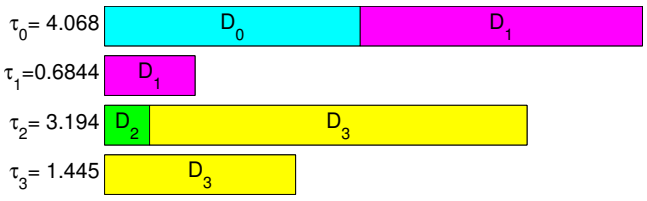

Figure 4: Deliberation schedule where D_i represents the decision procedure for $phase_i$.

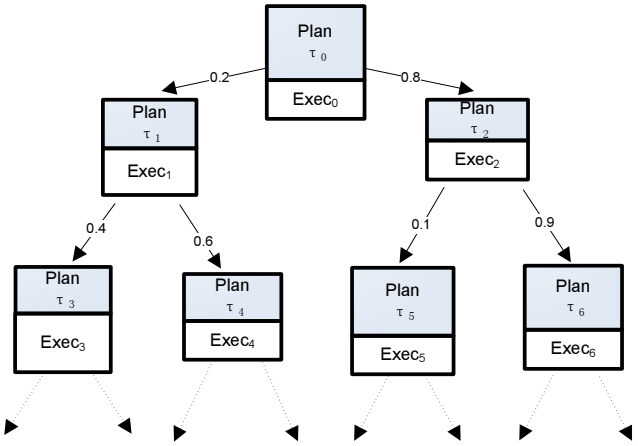

Figure 5: Uncertain phase transitions.

of $phase_0$ and $phase_1$ before it starts to execute the mission. After $phase_0$ is completed, it uses 0.6844 additional time units to improve the solution to $phase_1$. Since $phase_2$ has a much lower expected quality than $phase_3$, most of the available computational time before executing $phase_2$ is used for the decision procedure of $phase_3$. The resulting schedule achieves 20% higher expected quality than using a myopic algorithm that only runs the decision procedure of $phase_i$ right before that phase.

3. UNCERTAIN PHASE TRANSITIONS

We now consider more general deliberation scheduling problems where phase transitions are uncertain. In this paper, we focus on situations where phase transitions can be represented as a tree. Figure 5 shows one such problem. When the agent leaves a phase, it will reach one of the subsequent phases with some probability. The study of uncertain phase transitions is similar to Horvitz's previous work [6], in which future instances are nondeterministic. Our algorithms explore further by explicitly taking into account deliberation costs and more general EVC functions.

Let $p_{i,j}$ represent the transition probability from $phase_i$ to $phase_j$, and then the probability of reaching $phase_j$ in the mission, denoted as P_j, can be computed from $p_{i,j} \times P_i$ where $P_0 = 1$.

Let $\mathcal{A}_i$ denote the set composed of $phase_i$ and its ancestor phases, and let $\mathcal{D}_i$ denote the set composed of $phase_i$ and its descendant phases. Since computational time scheduled for decision procedure $decision_i$ can be from any phase in $\mathcal{A}_i$, $t_i = \sum_{k\in\mathcal{A}_i} \psi_{k,i}$ where $\psi_{k,i}$ is the period of computational time that is located at $phase_k$ and will be used for $phase_i$'s decision procedure. The deliberation scheduling problem with uncertain phase transitions then becomes

$$\max \sum_i P_i \times (v_i - c_i) \quad \left| \begin{array}{l} t_i = \sum_{k\in\mathcal{A}_i} \psi_{k,i} \\ \tau_k \geq \sum_{i\in\mathcal{D}_k} \psi_{k,i} \\ v_i = V_i(t_i) \\ c_i = C_i(\tau_i) \\ \tau_i \geq 0 \\ t_i \geq 0 \\ \psi_{k,i} \geq 0 \end{array} \right. \quad (5)$$

where the constraints $\forall k : \tau_k \geq \sum_{i\in\mathcal{D}_k} \psi_{k,i}$ guarantee that

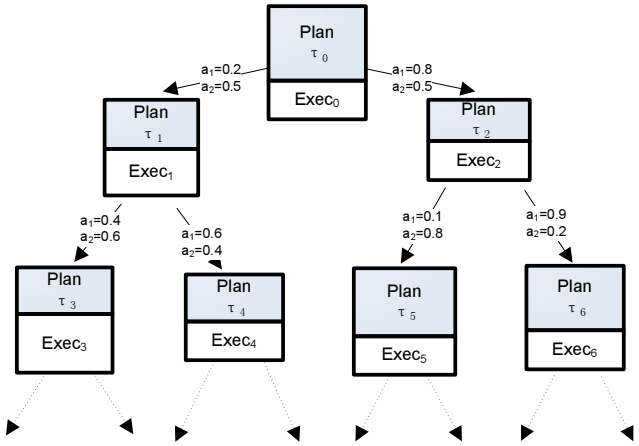

Figure 6: Controllable phase transitions.

the amount of scheduled computational time cannot exceed the amount of available computational time at any point within the mission.

The constraints $t_i = \sum_{k \in \mathcal{A}_i} \psi_{k,i}$ and $\tau_k \geq \sum_{i \in \mathcal{D}_k} \psi_{k,i}$ do not introduce nonlinearities. That is, using the techniques described in Section 2, Eq.5 can be approximated into a linear program whenever, for any $phase_i$, $V_i(t)$ is a continuous concave function and $C_i(\tau)$ is a continuous convex function. Eq.5 can be approximated into a mixed integer linear program whenever some phases have general nonlinear functions $V_i(t)$ or $C_i(\tau)$. Then, it is trivial to derive deliberation schedules from $\psi_{k,i}$ after solving the linear program or mixed integer linear program.

4. CONTROLLABLE PHASE TRANSITIONS

In this section, we further extend our mathematical programming formulation to model another important aspect of deliberation scheduling problems. Recall that in the previous sections it is assumed that transition probabilities (either deterministic or uncertain) among phases are specified *a priori*. However, in many situations, phase transitions might be controllable by agents themselves. For example, an autonomous aircraft needs to determine which route it wants to take when there exist multiple options for reaching a destination. That is, action choices of the agent determine (possibly stochastically) which phases will be reached next. Figure 6 shows one such problem.

With this extension, deliberation scheduling problems become more complex because an agent not only needs to control its reasoning, but also needs to find a policy that maps each phase to its action. A straightforward strategy for solving such problems is to enumerate all possible policies and then, for each policy, use the algorithms presented in the previous sections. However, when the number of policies is large, this simple strategy might become infeasible. In this section, we propose an alternative approach based upon a mathematical programming formulation.

Let $p_{i,a,j}$ represent the probability that the agent reaches $phase_j$ if it executes action a in $phase_i$, let α_i represent the probability that the agent is initially in $phase_i$ (i.e., $\alpha_0 = 1$, $\alpha_{i \geq 1} = 0$), and let $x_{i,a}$ represent the expected number of times that action a is executed at $phase_i$. We can then formulate deliberation scheduling problems with controllable phase transitions into:

$$\max \sum_i x_i \times (v_i - c_i) \quad \left| \begin{array}{l} \sum_a x_{j,a} = \alpha_j + \sum_i \sum_a p_{i,a,j} \times x_{i,a} \\ x_i = \sum_a x_{i,a} \\ t_i = \sum_{k \in \mathcal{A}_i} \psi_{k,i} \\ \tau_k \geq \sum_{i \in \mathcal{D}_k} \psi_{k,i} \\ v_i = V_i(t_i) \\ c_i = C_i(\tau_i) \\ \tau_i \geq 0 \\ t_i \geq 0 \\ \psi_{k,i} \geq 0 \\ x_{i,a} \geq 0 \end{array} \right. \tag{6}$$

where $x_i = \sum_a x_{i,a}$ is the total expected number of times $phase_i$ is visited. In this paper, it is assumed that the structure of phase transitions can be represented as a tree (and thus a phase cannot be visited more than once during the mission), and so x_i also represents the probability of visiting $phase_i$.

The constraint $\sum_a x_{j,a} = \alpha_j + \sum_i \sum_a p_{i,a,j} \times x_{i,a}$ indicates that the expected number of times $phase_j$ is visited must equal the initial probability distribution at $phase_j$ plus the expected number of times $phase_j$ is entered via all possible transitions [4, 10].

The objective function $\sum_i x_i \times (v_i - c_i)$ in Eq.6, which represents the total expected quality, is a quadratic function (since x_i, v_i and c_i are all variables). In general, quadratic optimization problems are difficult to solve. In the rest of this section, we will show how to reformulate Eq.6 into a mixed integer linear program with the discretization approximation technique.

EVC function-related parameters $T^v_{i,j}$, $V_{i,j}$ and $\delta^v_{i,j}$ were defined in Section 2. We now define deliberation cost function-related parameters $T^c_{i,j}$, $C_{i,j}$ and $\delta^c_{i,j}$ similarly, i.e., $T^c_{i,j}$ and $C_{i,j}$ represent the jth time point and its corresponding value on the discretized function of $C_i(\tau)$ respectively, and binary variable $\delta^c_{i,j}$ represents whether time point $T^c_{i,j}$ is selected, and so Eq.6 can be approximated as the following mixed integer linear program.

$$\max \sum_i \sum_j (\chi^v_{i,j} \times V_{i,j} - \chi^c_{i,j} \times C_{i,j}) \quad \left| \begin{array}{l} \sum_a x_{j,a} = \alpha_j + \sum_i \sum_a p_{i,a,j} \times x_{i,a} \\ x_i = \sum_a x_{i,a} \\ t_i = \sum_{k \in \mathcal{A}_i} \psi_{k,i} \\ \tau_k \geq \sum_{i \in \mathcal{D}_k} \psi_{k,i} \\ t_i = \sum_j T^v_{i,j} \times \delta^v_{i,j} \\ \sum_j \delta^v_{i,j} = 1 \\ \sum_j \chi^v_{i,j} = x_i \\ \chi^v_{i,j} \leq \delta^v_{i,j} \\ \tau_i = \sum_j T^c_{i,j} \times \delta^c_{i,j} \\ \sum_j \delta^c_{i,j} = 1 \\ \sum_j \chi^c_{i,j} = x_i \\ \chi^c_{i,j} \leq \delta^c_{i,j} \\ \psi_{k,i} \geq 0 \\ \tau_i \geq 0, \ t_i \geq 0 \\ x_{i,a} \geq 0 \\ \chi^v_{i,j} \geq 0, \ \chi^c_{i,j} \geq 0 \\ \delta^v_{i,j} \in \{0,1\}, \ \delta^c_{i,j} \in \{0,1\} \end{array} \right. \tag{7}$$

The constraints $\sum_j \delta^v_{i,j} = 1$ (where $\delta^v_{i,j}$ are binary vari-

ables) and $\chi^v_{i,j} \leq \delta^v_{i,j}$ ($\chi^v_{i,j} \geq 0$) indicate that, for each $phase_i$, there exists at most one nonzero variable $\chi^v_{i,j}$, and the constraint $\sum_j \chi^v_{i,j} = x_i$ says that this nonzero variable must equal x_i. All these constraints work together to guarantee $\chi^v_{i,j} = x_i \times \delta^v_{i,j}$. In a similar way, we can have $\chi^c_{i,j} = x_i \times \delta^c_{i,j}$.

Now, we can linearize the quadratic objective function in Eq.6. That is,

$$\begin{array}{rl} & \sum_i x_i \times (v_i - c_i) \\ \simeq & \sum_i \sum_j (x_i \times V_{i,j} \times \delta^v_{i,j} - x_i \times C_{i,j} \times \delta^c_{i,j}) \\ = & \sum_i \sum_j (\chi^v_{i,j} \times V_{i,j} - \chi^c_{i,j} \times C_{i,j}) \end{array}$$

which is the linear objective function (where $V_{i,j}$ and $C_{i,j}$ are constants) used in Eq.7.

$\psi_{k,i}$ in the solution of Eq.7 represents the deliberation schedule, and the policy that maps each phase to its action can be derived from $x_{i,a}$: at $phase_i$, action a is executed with probability $\pi_{i,a} = \frac{x_{i,a}}{\sum_a x_{i,a}}$.

5. EMPIRICAL RESULTS

It is important to remember that the run time of the deliberation scheduling algorithm itself consumes computational time that could otherwise be used for deliberation. In other words, if an agent spends too much time scheduling deliberations, then it might have too little time to actually deliberate. In this section, we give a preliminary empirical evaluation of the efficiency and optimality of our algorithms.

In our simulation, we use continuous concave functions $V_i(t) = M \times (1 - e^{-K \times t})$ to evaluate the LP-based algorithm, and use general nonlinear functions $V_i(t) = \frac{Q}{1+e^{-J \times (t-D)}}$ to evaluate the MILP-based algorithm. In both cases, continuous convex functions $C_i(\tau) = C \times \tau^N$ are used as our deliberation cost functions. The results shown in this paper are based upon the following parameters: $M \sim [0.5, 5.0]$, $K \sim [0.05, 0.5]$, $Q \sim [0.5, 5.0]$, $J \sim [1.0, 2.0]$, $D \sim [1.0, 3.0]$, $C \sim [0.05, 0.5]$, and $N \sim [1.3, 1.6]$, where $x \sim [L, U]$ represents that x is uniformly distributed in the range $[L, U]$. These parameter distributions are chosen to avoid overly-simple problems, such as the problem where the deliberation costs are so high that it is obvious that none of deliberations should be done. We run our simulation with *cplex* 9.1 LP/MILP solver (www.ilog.com) on a Pentium IV machine. Each data point is the average value from 100 runs, and curves are smoothed to improve readability.

Figure 7 shows the scalability of our algorithms in solving deliberation scheduling problems with deterministic phase transitions, where m in the figure denotes the number of pieces for each function if using piecewise linear approximation, and denotes the number of points for each function if using discretization. The y-axis of the figure specifies the total amount of runtime, including the time for making piecewise linear approximation or discretization, and the time for constructing and solving an LP/MILP. We can see that, although slower than the myopic algorithm that attempts to maximize $V_i(t) - C_i(t)$ at each individual phase without worrying about future phases, our algorithms compute near-optimal solutions reasonably fast, especially when m is small, and their solutions significantly outperform that of the myopic algorithm as shown in Figure 8.

Not surprisingly, using a small m will reduce the approximation accuracy, and thus impair optimality. In Figure 8, we evaluate the optimality of our algorithms with various

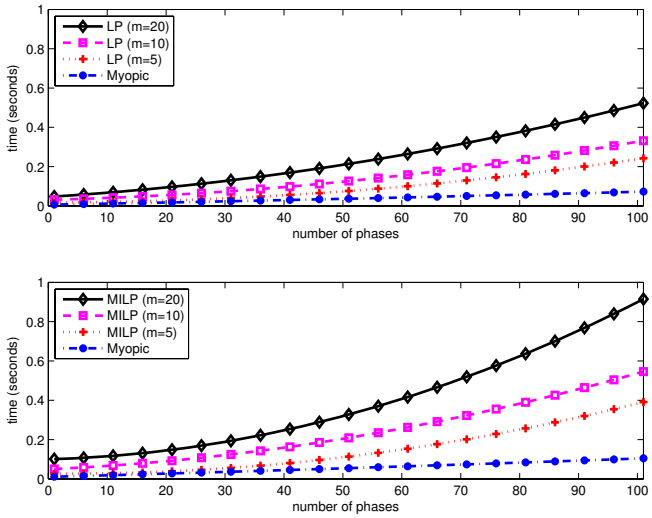

Figure 7: Scalability of the LP-based algorithm (top) and the MILP-based algorithm (bottom) for deterministic phase transitions.

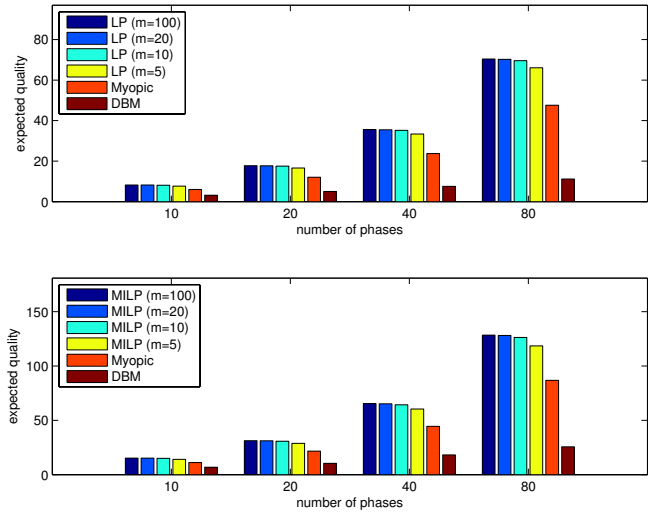

Figure 8: Optimality of the LP-based algorithm (top) and the MILP-based algorithm (bottom) for deterministic phase transitions.

m, the myopic algorithm, and a simple deliberation-before-mission (DBM) algorithm where all deliberations are done before starting the mission (i.e., $\tau_0 \geq 0$ and $\tau_{i \in \{1,2,...\}} \equiv 0$). Since, to the best of our knowledge, there are no existing algorithms that are able to compute optimal deliberation schedules in our experimental settings, we use the solution of our algorithms with a large m (i.e., $m = 100$, which usually makes the approximation error less than 1%) as the baseline. These empirical results show that, with $m = 20$, our algorithms are close to optimal. It is also shown that our algorithms, even with a small m (such as m=5), outperform the myopic algorithm and the DBM algorithm.

When testing our algorithms in problems with uncertain

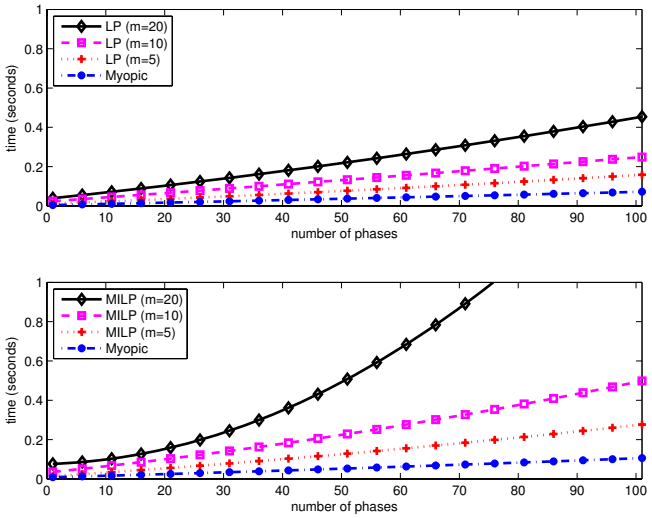

Figure 9: Scalability of the LP-based algorithm (top) and the MILP-based algorithm (bottom) for uncertain phase transitions.

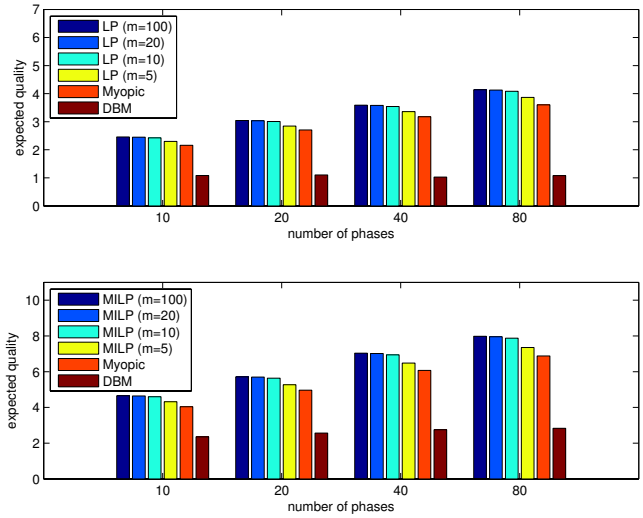

Figure 10: Optimality of the LP-based algorithm (top) and the MILP-based algorithm (bottom) for uncertain phase transitions.

phase transitions, we assume that the phase transitions can be represented as a complete binary tree. When the agent leaves a phase with 2 children, it will reach its left child and its right child with probability ρ and $1-\rho$, respectively, where ρ is uniformly distributed in the range [0, 1.0]. Figure 9 shows the scalability of our algorithms, which is similar to Figure 7.[1]

It might be interesting to see that the myopic algorithm also performs pretty well in Figure 10. This is because, for uncertain phase transitions, the time spent on a future phase is less valuable since it is possible that the agent will never reach that future phase. In other words, in such cases, the agent is more intent to act myopically. However, it is important to emphasize that the myopic algorithm does not provide any quality guarantee. In Figure 11, we can see that the myopic algorithm might return unsatisfactory results sometimes (e.g., less than 60% of the optimal quality). In contrast, the performance of our algorithms is much more stable.

Finally, we evaluate our algorithm in solving problems with controllable phase transitions. It is again assumed that the phase transitions can be represented as a complete binary tree. At each phase with two children, there are two possible actions a_1 and a_2. a_1 moves the agent to the left child with probability 0.9 and to the right child with probability 0.1, and a_2 achieves the opposite effect. Note that problems with controllable phase transitions are in general much more complex than those with deterministic or uncertain phase transitions. When the number of phases is large, the MILP-based algorithm might need a pretty long time to compute an optimal deliberation schedule. However, state-of-the-art MILP solvers (such as cplex) are usually able to return a good solution using much less time. Thus, for online applications, we can adopt a two-step algorithm. That is, we first derive a policy by solving Eq.7 with limited time. With the policy, the problem is reduced to an easier one with deterministic/uncertain phase transitions, and then we can solve the reduced problem again and return a deliberation schedule. As shown in Figure 12, this two-step algorithm is usually able to compute a good schedule within a short time, which makes it applicable in computational-time limited domains.

[1]It should be noted that, for uncertain phase transitions, if neither EVC functions nor deliberation cost functions can be approximated into piecewise linear constraints, it might take a pretty long time to compute an optimal schedule. However, state-of-the-art MILP solvers are usually able to find a good result within limited time.

6. CONCLUSION AND FUTURE WORK

In this paper, we have presented mathematical programming formulations for deliberation scheduling problems in computational time-limited domains, and have illustrated them through several increasingly complex classes of deliberation scheduling problems. In comparison with previous work, our algorithms are able to solve deliberation scheduling problems in more general settings, and are applicable in complex domains with uncertainty.

The key contribution of this work has been to integrate a variety of established ideas in mathematical programming into a novel approach for solving deliberation scheduling problems. Because most interesting deliberation scheduling problems involve nonlinear constraints, a fundamental technical hurdle that had to be overcome in this work has been to identify transformations that approximate these nonlinear constraints with linear constraints. The deliberation scheduling problems are then solved with existing highly-optimized LP/MILP techniques, rather than building algorithms from scratch that work on the original formulation. By linking deliberation scheduling with LP/MILP, this work lays the foundation for further efforts of exploiting sophisticated techniques in state-of-art LP/MILP solvers [3, 9] for deliberation scheduling problems.

The deliberation scheduling framework studied in this work can be extended to suit more general problems. First, in real-time domains with a large number of phases, a complete mathematical formulation might be too complex to be solvable under time constraints. Considering the fact that probabilities of reaching phases in the far future are often low due to uncertainties, we can restrict the number of phases to be put into the mathematical formulation. As time passes, deliberation scheduling can be repeated if necessary. Second, recall that this work makes a simplifying assumption that the quality of a phase is only determined by the computational time scheduled for it. This is not always true in real-world problems. For example, $phase_i$ might also gain utility when allocating time on another (relevant) $phase_j$ because $phase_i$ and $phase_j$ might have some similar subproblems. Thanks to the mathematical formulation, it is often easy to model such relations (e.g., $v_i = V_i(t_i + t_j)$). Finally, with techniques of limiting look-ahead and modeling inter-influence between phases, we might be able to solve deliberation scheduling problems with loops in phase transitions by *unrolling* the graph to make it acyclic (such that a phase can be repeated in the graph). In the future, we will dig deeper in these directions.

This work, like much previous research, assumes that the agent has required knowledge (such as performance profiles) *a priori*. We will look into the problem where an agent needs to acquire such information in practice, and study how the accuracy of the information affects the system performance. Additionally, in recent years, multi-agent deliberation scheduling problems have been of increasing interest, in which an agent can compute ways to improve solutions to its own problems, or joint problems with other agents. Extending our algorithm to multi-agent domains is thus another promising future direction.

Optimal Decision-Making With Minimal Waste: Strategyproof Redistribution of VCG Payments

ABSTRACT

Mechanisms for coordinating group decision-making among self-interested agents often employ a trusted center, capable of enforcing the prescribed outcome. Typically such mechanisms, including the ubiquitous Vickrey Clarke Groves (VCG), require significant transfer payments from agents to the center. While this is sought after in some settings, it is often an unwanted cost of implementation. We propose a modification of the VCG framework that—by using domain information regarding agent valuation spaces—is often able to achieve redistribution of much of the required transfer payments back among the agents, thus coming closer to budget-balance. The proposed mechanism is strategyproof, ex post individual rational, no-deficit, and leads to an efficient outcome; we prove that among all mechanisms with these qualities and an anonymity property it is *optimally balanced*, in that no mechanism ever yields greater payoff to the agents. We provide a general characterization of when strategyproof redistribution is possible, and demonstrate specifically that substantial redistribution can be achieved in allocation problems.

1. INTRODUCTION

This paper is concerned with decision-making problems that involve a group of self-interested parties, when each party may be in competition with other members of the group. Instances of this problem abound in everyday life. Consider, to name just a few examples: a group of housemates that jointly own a car and must decide who should get to use it on a Friday night; a set of city neighborhoods competing for a grant to build a new playground; a group of astronomers competing for the rights to use a publicly-owned space telescope; or companies competing for government allocation of wireless spectrum.

How would one formulate a general framework for decision-making in domains such as these? One natural objective is that the decision process lead to the choice that maximizes the total value that is realized. Moreover, and to that end, it is highly desirable that the mechanism not encourage manipulation by dishonest agents—we want *truthfulness* to be in each agent's best-interest; this will allow us to reasonably predict the actual effects of whatever outcome is selected, and will simplify the task of the agents by taking strategic behavior out of the equation that maximizes expected reward.

The well-known Groves family of social choice mechanisms, by requiring specific payments to each agent, reaches outcomes with the desirable properties described above. However, implementing the payments specified in the most basic Groves mechanism requires a large external budget, making it infeasible in typical decision-making scenarios where there is no outside funding.

The Vickrey Clarke Groves (VCG) mechanism counteracts this potential budget imbalance by imposing "charges" on the agents, to be delivered to a "center" capable of enforcing the specified outcome. For typical decision-making problems,[1] VCG results in net transfers being delivered only in the direction of agents to the center. While there are some scenarios in which revenue to a center is sought after (e.g., some auctions), often it is preferable to maintain as much wealth as possible within the group of agents, and the transfer payment can be viewed as an undesirable "cost of implementation." In other words, *budget-balance* is frequently a sought after mechanism property, and though it doesn't run a deficit, the VCG mechanism fails in this regard by producing a surplus of agent charges (hence called the "VCG surplus").

[1]Specifically, when there are no positive externalities.

The ideal social choice mechanism would have the desirable properties of VCG (truthfulness; social welfare maximization; non-negative payoff guarantee), and at the same time run neither a budget surplus nor deficit. As we will see, this *exact* budget-balance is usually not attainable. However, while it has often been stated that no improvement over VCG is possible, we demonstrate that this *is not the case* in a broad class of domains (e.g., allocation problems) where valuations have some basic structure.

We propose a modification of the VCG framework that incorporates redistribution of as much of the VCG surplus as possible back among the agents. We prove that—among all truthful, social welfare maximizing, and no-deficit mechanisms that meet basic anonymity and participation constraints—this "redistribution mechanism" is *optimally balanced*, in that no mechanism ever comes closer to budget-balance. We describe why in the case of completely unconstrained valuation functions no redistribution is possible, and characterize the domains in which it is.

We start by focusing our analysis on the special setting of "all-or-nothing" (AON) domains, those in which each outcome yields non-zero reward for just a single agent (every agent gets either all the reward or none). Here the redistribution mechanism has a particularly simple and elegant form, and the most redistribution is possible. In fact, in AON domains the mechanism is *completely* budget-balanced (i.e., redistributes all surplus) in the limit as the number of agents goes to infinity, for arbitrary valuations in an AON context. We demonstrate the applicability of the mechanism to general allocation problems, and describe empirical results that indicate the extent to which redistribution is possible for different degrees of dependency between agent valuations. Finally, we discuss implementation of the mechanism in the absence of a central enforcer.

2. BACKGROUND AND RELATED WORK

2.1 Notation

- Let I be the set of agents participating in a mechanism.
- Let $n = |I|$, the number of agents.
- Let O be the set of possible outcomes.
- Let $v_i(o)$ denote the *true* value to i of outcome $o \in O$.
- Let $\hat{v}_i(o)$ denote the *reported* value to agent i of outcome o.
- Let o^* denote the socially optimal outcome, according to reported valuations, i.e.:

$$o^* = \arg\max_{o \in O} \sum_{i \in I} \hat{v}_i(o)$$

- Let o^*_{-i} denote the outcome that maximizes payoff among agents other than i, according to reports, i.e.:

$$o^*_{-i} = \arg\max_{o \in O} \sum_{j \in I \setminus \{i\}} \hat{v}_j(o)$$

2.2 Mechanism design background

The field of mechanism design is concerned with reaching outcomes that meet certain system-level criteria, despite the assumption that individuals will pursue only their self-interest. A *mechanism* amounts to a specification of a decision rule, potentially accompanied by a set of requirements (typically monetary transfers) placed on participants. A mechanism that maximizes social welfare is termed *socially optimal* or *efficient*. When no agent can ever benefit from lying, i.e., when being truthful is a dominant strategy, a mechanism is called *strategyproof*. A somewhat weaker property is *incentive-compatibility* (IC); in an IC mechanism truthfulness is a Nash equilibrium: no agent can benefit from being dishonest when all other agents are truthful.

The Groves class of mechanisms is *efficient* and *strategyproof* [Groves, 1973]. A Groves mechanism chooses the outcome that maximizes reported reward across all agents, and makes a transfer payment to each agent equal to the reward received by all other agents. In the most basic version, each agent's payoff is equal to the reward received by the entire system; clearly such a mechanism would require a massive budget to implement. Fortunately, the Groves framework allows for the imposition of a charge on each agent, which does nothing to diminish the mechanism's desirable incentive properties so long as each agent's charge is completely beyond their control. Formally, a Groves mechanism chooses the outcome o^* that maximizes social welfare according to reported rewards, and defines the following transfer payment T_i to each agent i:

$$T_i = \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*) - C_{-i}$$

where C_{-i} can be *any quantity independent of agent i*.

In order to ensure that all agents want to participate in a mechanism, it is desirable that none ever be worse for having done so. A mechanism that provides this guarantee to every agent, for any possible set of agent valuation functions, is referred to as *ex post individual rational (IR)*. A mechanism that yields non-negative payoff in expectation is termed *ex ante IR*. To obtain ex post IR in the Groves framework, we should ensure that for each i:

$$v_i(o^*) + \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*) \geq C_{-i}$$

An important special case of the Groves class is the VCG mechanism [Vickrey, 1961; Clarke, 1971; Groves, 1973]. VCG defines C_{-i} above to be $\sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*_{-i})$, the reported reward that all other agents would have received if i were not a participant.[2] Thus VCG yields the following payoff, π_i, for each agent i:

$$\begin{aligned} \pi_i &= v_i(o^*) + T_i \\ &= v_i(o^*) + \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*) - \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*_{-i}) \end{aligned}$$

VCG is ex post IR, and is also *no-deficit*: the sum of payments made from agents to the center is never less than 0. But it is often greater—each agent's net payment to the center is always between 0 and the reward it reported for the selected outcome, depending on the reported valuations of the other agents. In the case of AON domains, VCG is known simply as the Vickrey or second-price auction, and there is only one payment made—the winning agent must pay the second highest "price".

Consider the following 4-agent AON example, where outcome o_i corresponds to the decision that yields value for agent i:

[2]Note that since all Groves mechanisms are strategyproof, $\hat{v}_j$ will equal v_j in dominant strategy equilibrium.

	v_1	v_2	v_3	v_4
o_1	10	0	0	0
o_2	0	8	0	0
o_3	0	0	5	0
o_4	0	0	0	4

Table 1: 4-agent AON decision problem.

VCG chooses outcome o_1, as agent 1's value (10) is highest, and the following payoffs result:

$$\pi_i = v_i(o^*) + \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*) - \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*_{-i})$$

$$\pi_1 = 10 + 0 - 8 = 2$$

$$\pi_2 = 0 + 10 - 10 = 0$$

$$\pi_3 = 0 + 10 - 10 = 0$$

$$\pi_4 = 0 + 10 - 10 = 0$$

$$\text{total payment to center} = 8$$

In the case of an auction, this rather large payment of 8 may be desirable—it can go to the seller that is providing the item. But for a general social choice or decision problem, it may merely be an unwanted side-effect of choosing to implement VCG, the most famous strategyproof and efficient mechanism. In this work we explore the possibility of returning the surplus to the agents.

DEFINITION 1. **(Redistribution mechanism)** *An efficient social choice procedure that seeks to minimize net transfers from agents to an external body by return of VCG surplus to the agents.*

Our characterization of efforts to achieve minimal surplus in terms of redistribution is motivated by the centrality (and ubiquity) of VCG. In seeking to redistribute as much of the VCG surplus as possible (without violating truthfulness), we are effectively searching among all IR and no-deficit instances of the Groves class of mechanisms for the one that maximizes payoff to the agents. Green & Laffont [1977] showed that for general valuations, the only efficient and strategyproof mechanisms are the members of the Groves class. Holmstrom [1979] strengthened this result significantly, proving that Groves is also unique in any restricted domain in which each agent's space of potential valuations is *smoothly connected*, i.e., when for any two valuations an agent could report, one can be differentiably deformed into the other. As Holmstrom notes, this result shows that "for all practical purposes" one must be content with Groves. Thus, our approach is comprehensive and will yield uniqueness properties for the mechanism we propose.

2.3 Related work

Work in the area of designing budget-balanced mechanisms is relatively scarce, presumably due to the primacy of the goal of social efficiency in combination with the strong negative result of the *Myerson-Satterthwaite impossibility theorem*: that no mechanism is capable of achieving individual rationality, efficiency, and budget balance at the same time for general valuation functions, even if we loosen our solution concept to Bayes-Nash equilibrium [Myerson and Satterthwaite, 1983]. This is an extension of the Hurwicz impossibility theorem [Hurwicz, 1975], which proves the result for dominant-strategy equilibria.

One proposal for achieving budget-balance is the d'AGVA mechanism [d'Aspremont and Gerard-Varet, 2002]. d'AGVA selects the efficient outcome according to reported types, but determines transfer payments based on a model of agent valuations that the center maintains. This mechanism is interesting primarily because it leads to exact budget-balance; however, it is implementable only in Bayes-Nash (rather than dominant-strategy) equilibrium, and if the center's model is produced via iterative execution, serious problems regarding incentive compatibility can arise. Moreover, d'AGVA is only ex ante IR—instances in which an agent is worse off for participating are possible.

Parkes et al. [2001] describe a payment rule that approximates VCG and achieves perfect budget-balance in exchange settings where VCG runs a deficit, though truthfulness (and thus efficiency) is sacrificed. Faltings [2004] formulates the problem more closely to the way we do in this work, though his approach also attains exact budget-balance at the expense of efficiency. His mechanism chooses the outcome that is socially efficient among a subset of agents, and distributes the VCG surplus among agents that are not part of that subset. In a similar vein, Feigenbaum et al. [2001] analyze the Shapley-value mechanism for sharing multicast transmission costs, which comes closest to the efficient outcome among all budget-balanced mechanisms for that domain, though their results suggest its implementation is computationally intractable. Most similar to our proposal is that of Bailey [1997]. He specifies an efficient mechanism that refunds surplus to participants, but he forfeits the no-deficit guarantee in order to achieve a mechanism that is budget-balanced in expectation.

Our approach is significantly different than those described above—we characterize the extent to which budget-balance can be approximated (and sometimes reached) in dominant strategies, without sacrificing individual-rationality, efficiency, or no-deficit guarantees. Rather than giving up one or another of these properties, we are able to achieve budget-balance superiority over VCG *by using domain information that constrains the space of possible valuations.*

3. REDISTRIBUTION IN AON DOMAINS

It is instructive to start with the special case of AON domains, for which our solution is especially simple and elegant, as it provides good intuition for the general case. Formally, we define an AON domain as one in which the number of outcomes is equal to the number of agents, and each agent i's valuation function v_i is known to be constrained in the following way: $v_i(o_j) = 0, \forall j \neq i$. We identify o_i with the unique outcome that may yield positive value to agent i, and use the following short-hand notation:

- Let a_c denote the agent with the cth highest reported value. (So in a welfare-maximizing mechanism a_1 is the "winning" agent—the one that receives positive value from the selected outcome.)
- Let $\mathbb{V}_{a_c}$ denote the *true* value to a_c of the outcome he favors (i.e., $v_{a_c}(o_{a_c})$), and $\hat{\mathbb{V}}_{a_c}$ the *reported* value (i.e., $\hat{v}_{a_c}(o_{a_c})$).

We propose the following redistribution mechanism for AON domains that maintains much of the VCG surplus among the agents:

DEFINITION 2. **(Redistribution mechanism RM)**

1. Each agent i communicates to the center $\mathbb{v}_i$, the value he places on the outcome under which he obtains non-zero reward.
2. The center implements the outcome that maximizes social welfare.
3. The winner (a_1) pays each agent (including himself) a VCG surplus redistribution of Z_i, and pays the center $\hat{\mathbb{v}}_{a_2} - \sum_{i \in I} Z_i$, where

$$Z_i = \begin{cases} \frac{\hat{\mathbb{v}}_{a_3}}{n} & \text{for } i = a_1, a_2 \\ \frac{\hat{\mathbb{v}}_{a_2}}{n} & \text{for } i = a_3, ..., a_n \end{cases}$$

THEOREM 1. **RM** *is ex post individual-rational in AON domains.*

PROOF. The payoff to each agent for the implemented outcome in **RM** is:

$$\pi_{a_1} = \mathbb{v}_{a_1} - \hat{\mathbb{v}}_{a_2} + Z_{a_1}$$
$$\pi_{j \neq a_1} = Z_j$$

The payoff to any "non-winner" j is always the non-negative Z_j payment term. When the mechanism is followed, $\mathbb{v}_{a_1} = \hat{\mathbb{v}}_{a_1}$; then since $\hat{\mathbb{v}}_{a_1} \geq \hat{\mathbb{v}}_{a_2}$ by definition, and since $Z_{a_i} \geq 0$, a_1's payoff is also always non-negative. □

THEOREM 2. **RM** *is strategyproof in AON domains.*

PROOF. **RM** differs from the VCG mechanism only in the Z payment term—each agent receives the standard VCG payoff plus a non-negative Z payment. Since we know VCG is strategyproof, it suffices to show that no agent i can increase its Z_i payment term by misreporting its reward. a_k below denotes the agent with the kth highest bid under truthful reporting.

Agent a_1 receives redistribution payment (from himself) $\hat{\mathbb{v}}_{a_3}/n$. Over-reporting $\hat{\mathbb{v}}_{a_1}$ changes nothing. Under-reporting could put a_1 in the second or third position (beyond the third it's obvious that nothing could change). In the second position, he would still receive $\hat{\mathbb{v}}_{a_3}/n$. In the third he would receive $\hat{\mathbb{v}}_{a_3}/n$ as well, since the second position would then be held by the actual a_3.

Agent a_2 receives redistribution payment $\hat{\mathbb{v}}_{a_3}/n$. Over-reporting could move him to the first position, in which case his payment would be the same. Under-reporting could put him in the third position or beyond, but then the second position would be held by the actual a_3, so a_2's payoff would be the same.

Agent a_3 receives redistribution payment $\hat{\mathbb{v}}_{a_2}/n$. Under-reporting changes nothing. Over-reporting could put him in the first or second position. In both cases he receives the same Z payment, since the third position would then be held by the actual a_2. The same holds for all $a_{j>3}$. □

Theorems 1 and 2 together show that **RM** for AON domains always achieves the efficient outcome in dominant strategy equilibrium.

THEOREM 3. *As the number of participating agents n goes to ∞, the amount of extracted wealth that cannot be redistributed among the agents under* **RM** *goes to 0. That is,* **RM** *is asymptotically budget-balanced for AON domains.*

PROOF. The amount of wealth redistributed among the agents is:

$$\sum_{i \in I} Z_i = \frac{n-2}{n} \cdot \hat{\mathbb{v}}_{a_2} + \frac{2}{n} \cdot \hat{\mathbb{v}}_{a_3}$$

The amount not redistributed is the payment to the center:

$$\begin{aligned} Z_c &= \hat{\mathbb{v}}_{a_2} - \sum_{i \in I} Z_i \\ &= \hat{\mathbb{v}}_{a_2} - \frac{n-2}{n} \cdot \hat{\mathbb{v}}_{a_2} - \frac{2}{n} \cdot \hat{\mathbb{v}}_{a_3} \\ &= \frac{2}{n} \cdot (\hat{\mathbb{v}}_{a_2} - \hat{\mathbb{v}}_{a_3}) \end{aligned}$$

We assume existence of some finite bound on valuations, and thus on $\hat{\mathbb{v}}_{a_2}$. □

As n increases, we may expect Z_c to be pushed down by a convergence of $\mathbb{v}_{a_2}$ and $\mathbb{v}_{a_3}$, but regardless of this **RM** achieves perfect budget balance in the limit. *VCG will always lose $\hat{\mathbb{v}}_{a_2}$, no matter the number of agents.*

Consider once more the example illustrated in Table 1. The following payoffs are obtained under **RM**:

$$\pi_1 = 10 - 8 + \frac{5}{4} = \frac{13}{4}$$
$$\pi_2 = \frac{5}{4}\,, \quad \pi_3 = \frac{8}{4}\,, \quad \pi_4 = \frac{8}{4}$$
$$Z_c = 8 - \left(\frac{5}{4} + \frac{5}{4} + \frac{8}{4} + \frac{8}{4}\right) = \frac{3}{2}$$

Even in this example with just 4 agents, the vast majority (81%) of the VCG surplus has been redistributed. If $\mathbb{v}_{a_3}$ were 8 rather than 5, 100% would be redistributed.

3.1 Optimality of RM

We will now characterize the relationship between **RM** and all other possible redistribution mechanisms through a series of incremental observations. We seek the optimal way of redistributing the VCG payment back among agents in AON domains. More specifically, we wish to achieve the following:

DEFINITION 3. **(Optimally balanced mechanism)** *A mechanism is optimally balanced for domain D if—among all efficient, no-deficit, and ex post IR mechanisms that can be implemented in dominant strategy equilibrium—it maintains the most wealth within the set of agents, for every instance $d \in D$.*

A domain D specifies a space of possible valuations for every agent, and an instance $d \in D$ may be any realization of actual valuations consistent with D.

LEMMA 1. *In any strategyproof redistribution mechanism for smoothly connected valuation spaces, for every agent i, the amount of surplus redistributed to i, Z_i, must be independent of the valuation function i reports.*

PROOF. The Lemma follows from uniqueness of the Groves class. For intuition, consider an agent i with arbitrary valuation $v_i = \{v_i(o_1), ..., v_i(o_n)\}$ yielding payment Z_i. If there is some outcome o_k and $\epsilon \in \Re$ such that reporting $\hat{v}_i(o_k) = v_i(o_k) + \epsilon$ yields $Z_i + \gamma$ for some $\gamma > 0$ without changing the selected outcome, agent i will misreport to maximize payment. □

To achieve efficiency in dominant strategy equilibrium, a redistribution mechanism must be an instantiation of the Groves class, so the redistribution can be considered part of the necessarily agent-independent Groves "charge" function.

Given Lemma 1, it will be useful now to consider each agent's redistribution payment as a function of the reported rewards of all other agents in the system. So we have, $\forall_{i \in I}$:

$$Z_i = f_i(\hat{\mathbb{V}}_0, \hat{\mathbb{V}}_1, ..., \hat{\mathbb{V}}_{i-1}, \hat{\mathbb{V}}_{i+1}, ..., \hat{\mathbb{V}}_n)$$

for some f_i. The task of constructing a redistribution mechanism can then be viewed as the specification of n functions, each of which is defined over a distinct set of $n-1$ of the valuation reports. It's important to note that the above characterization is comprehensive, as each f_i is defined over all variables in the system save i's report, which it can't depend on by Lemma 1.

But it is often preferred (or even required) that we do not discriminate amongst agents based on personal identity; we often want to implement mechanisms that are *anonymous*:

DEFINITION 4. **(Anonymous mechanism)** *A mechanism that chooses an outcome and defines transfer payments (including redistribution) according to a single deterministic function that is invariant to domain information that does not apply identically to every agent.*

In other words, anonymity requires that transfer payments be computed independent of "personal identity". To construct an anonymous redistribution mechanism, then, in fact we define only a single function f that is used universally, but applied to a distinct set of $n-1$ parameters for each agent. We know that an *optimally balanced* anonymous redistribution mechanism exists, since to define it amounts to specifying the value of f, for every possible set of $n-1$ values, that is greatest while still ensuring that no deficit could result for any possible instantiation of the excluded n^{th} value.

Let $p_i^{(k)}$ denote the kth largest parameter to the function that defines Z_i. $p_i^{(2)}$ is then the second highest bid among all agents other than i, and is also the greatest lower-bound (*guarantee*) on the VCG surplus that will exist, independent of the valuation i reports.

LEMMA 2. *The optimally balanced anonymous redistribution mechanism for AON domains must define redistribution payments Z_i, $\forall_{i \in I}$, that are monotonically increasing in $p_i^{(2)}$.*

PROOF. Suppose the Lemma didn't hold. Then there would be reported reward profiles A and $B \in \Re^n$ with $\hat{\mathbb{V}}_{a_2}(A) \leq \hat{\mathbb{V}}_{a_2}(B)$, yet with $Z(A) > Z(B)$. In such a case the mechanism could not be optimal, as implementing $Z(A)$ in case B would keep more wealth among the agents. □

THEOREM 4. **RM** *is the optimally balanced anonymous mechanism for AON domains.*

PROOF. Any anonymous, efficient, no-deficit, and ex post IR redistribution mechanism defines payments $Z_i \leq \frac{p_i^{(2)}}{n}$, $\forall_{i \in I}$. Consider the parameters of f_i that would lead to Z_i being $> \frac{p_i^{(2)}}{n}$. Simply note that there exists a problem instance such that all $p_j^{(2)}$, $\forall_{j \in I}$ are identical. This, when viewed in light of Lemma 2, shows that if Z_i were $> \frac{p_i^{(2)}}{n}$, the mechanism would not be guaranteed IR and no-deficit, as $\sum_j Z_j$ could then be $> \hat{\mathbb{V}}_{a_2}$.

Now observe that another way of describing **RM** is as follows: redistribute a portion of $\hat{\mathbb{V}}_{a_2}$ to each agent i equal to $\frac{1}{n}$ times the value of the second highest reported reward of agents other than i. □

4. REDISTRIBUTION IN THE GENERAL CASE

We have thus far only considered redistribution of VCG payments in AON domains. In this section we explore the general conditions under which strategyproof redistribution is possible, and characterize how to redistribute surplus optimally.

We first show that in the case of domains in which value functions are completely unrestricted, redistributing any of the transfer payments while maintaining the desirable properties of VCG is impossible. One way of understanding this is to consider the problem of finding a lower-bound on the total amount of VCG surplus that is guaranteed to exist, independent of any given agent's reported valuation.

LEMMA 3. *In any efficient, strategyproof, ex post IR and no-deficit mechanism, an upper-bound on the redistribution payment to any agent i is the minimum VCG surplus that could be realized, taken over all possible instantiations of $\hat{v}_i$.*

PROOF. Among all efficient, strategyproof, and ex post IR mechanisms, VCG yields the greatest surplus [Krishna and Perry, 1998]. Thus a mechanism with these properties that redistributes a quantity greater than the VCG surplus will run a deficit, since charging any agent more would violate ex post IR.

Let $\underline{\hat{v}}_i$ be the instantiation of $\hat{v}_i$ that results in minimum VCG surplus, S_i. Suppose for contradiction that i receives redistribution payment $Z_i > S_i$. By Lemma 1, Z_i must be the same regardless of the valuation i reports; thus when i reports $\underline{\hat{v}}_i$ he will have been redistributed a quantity greater than the total VCG surplus, and the system will have run a deficit. □

Lemma 3 points to a way of generally characterizing when redistribution is and is not possible. Whether or not a VCG surplus will result is intimately connected to the *similarity* of agents' valuations. In the extreme, all agents may favor the same outcome, in which case there will be no surplus. In some domains, e.g., AON, we know a priori that agents' valuations are distinct; such distinctions are in fact what enables redistribution. We now formalize these intuitions.

DEFINITION 5. **(Potential for Universal Relevance Nullification [PURN])** *An agent i has the potential for universal relevance nullification, given the valuation reports of the other agents, if i could report a valuation $\hat{v}_i$ that would yield $o^* = o^*_{-j}$, $\forall_{j \in I}$ (including i).*

The *PURN* property indicates that an agent could potentially report a value that renders null the influence on the outcome of any single agent's report alone, even his own. *PURN* is often dependent on the values other agents have reported, and is then a property of one agent's valuation domain combined with the other agents' actual reports.

THEOREM 5. *No efficient, strategyproof, ex-post IR, and no-deficit mechanism redistributes any surplus to an agent in an instance in which* PURN *holds for that agent.*

PROOF. The total VCG surplus is:

$$\sum_{j\in I}\Big(\sum_{k\in I\setminus\{j\}}\hat{v}_k(o^*_{-j})-\sum_{k\in I\setminus\{j\}}\hat{v}_k(o^*)\Big)$$

Here we sum over all agents $j \in I$ the VCG surplus j creates: the difference between j's VCG "charge" delivered to the center and the Groves payment he receives. By definition, any agent i with *PURN* may report a $\hat{v}_i$ that would lead to this quantity being zero. The theorem follows directly from this and Lemma 3. □

LEMMA 4. *Any agent with an unconstrained valuation always has PURN, regardless of the other agents' valuations.*

PROOF. Let i be an agent with an unconstrained valuation. Consider the outcome o^*_{-i} that maximizes utility among the $n-1$ other agents. Let i's valuation be as follows: $\hat{v}_i(o^*_{-i}) = \max_{j\in I\setminus\{i\}}\hat{v}_j(o^*_{-i})$, and $\hat{v}_i(o) = 0,\ \forall_{o\neq o^*_{-i}}$. Considering this full set of n valuations, the overall efficient outcome o^* will be identical to $o^*_{-j},\ \forall_{j\in I}$; this is precisely the condition for *PURN*. □

PROPOSITION 1. *The VCG mechanism with no redistribution is optimally balanced for unconstrained valuations.*

PROOF. When valuations are unconstrained, by Lemma 4 each agent has *PURN*. By Theorem 5, then, no agent can receive any redistribution payment. □

While this is a strong negative result, its applicability is hardly universal; in practice no valuation function is *entirely* unconstrained. Specifically, in determining the payment Z_i for any agent i, v_i need not be treated as a complete unknown. The AON case, for instance, is not caught by Proposition 1 because we need only consider valuations that are non-zero for just a single outcome.

In any given domain there may be several ways in which valuations are known to be restricted. Even the mere existence (and knowledge) of distinct finite bounds on each agent's valuation for any outcome can be enough to enable redistribution. *PURN* can be seen as one extreme in a spectrum of possible relationships between agent valuation spaces—rather than having the capacity to *completely* nullify the relevance of other agents in determining the outcome, an agent may have the potential to diminish others' impact only partially, or perhaps not at all. This capacity is of interest to us here because of the bearing it has on the amount of VCG surplus that will result. *Our ability to redistribute VCG surplus to an agent is directly tied to the extent to which we can know surplus will exist independent of that agent's reported valuation.*

DEFINITION 6. **(Surplus-guarantee S_i)** *The lower-bound on VCG surplus computed over all possible instantiations of $\hat{v}_i$, i.e., the greatest surplus guarantee that is independent of agent i.*

$$S_i = \min_{\hat{v}_i}\Big[\sum_{j\in I}\Big(\max_{o'\in O}\Big\{\sum_{k\in I\setminus\{j\}}\hat{v}_k(o')\Big\}-\sum_{k\in I\setminus\{j\}}\hat{v}_k(o^\dagger)\Big)\Big] \quad (1)$$

$$= \min_{\hat{v}_i}\Big[\sum_{j\in I}\Big(\max_{o'\in O}\sum_{k\in I\setminus\{j\}}\hat{v}_k(o')\Big)-(n-1)\Big(\sum_{j\in I}\hat{v}_j(o^\dagger)\Big)\Big]$$

subject to the constraint that the $o^\dagger$ and $\hat{v}_i$ in the above minimization must satisfy the following:

$$o^\dagger = \arg\max_{o\in O}\sum_{j\in I}\hat{v}_j(o) \quad (2)$$

Breaking down equation (1), within brackets is an expression representing the net payment—summed over all agents—to the center under VCG; this is the surplus we'll have to redistribute. For each agent i, we take the minimum of this expression over all possible valuations i could report.

Now note that a payment based on S_i will not always be *completely* anonymous, since we're using information about valuation constraints that are potentially unique to each agent. Specifically, it will not be anonymous in domains that are not *symmetric*.[3] But interestingly, it turns out that a generalization of mechanism **RM** is optimal not only across the space of completely anonymous mechanisms, but also among mechanisms that meet just the following weaker requirement:

DEFINITION 7. **(Surplus-anonymous redistribution mechanism)** *A mechanism that chooses an outcome and maps agent-specific VCG surplus lower-bounds (S_i) to redistribution payments (Z_i) according to a single deterministic function that is invariant to domain information that does not apply identically to every agent.*

In a *surplus-anonymous* redistribution mechanism, then, for any two agents i and j: if $S_i = S_j$, then $Z_i = Z_j$.

THEOREM 6. *For all domains with smoothly connected valuation spaces, the redistribution mechanism* $\mathbf{RM_g}$ *that modifies the VCG mechanism by paying each agent i a quantity equal to $\frac{S_i}{n}$ is strategyproof, and is optimally balanced across all surplus-anonymous mechanisms.*

PROOF SKETCH. Strategyproofness follows immediately from strategyproofness of VCG plus the fact that S_i is independent of i's reported valuation. The argument for optimality is omitted here for lack of space. □

Any *completely-anonymous* mechanism is also *surplus-anonymous*, and the conditions for *complete-anonymity* and *surplus-anonymity* coincide in symmetric domains (e.g., AON). $\mathbf{RM_g}$ is thus *completely-anonymous* when applied to symmetric domains, and *surplus-anonymous* otherwise. It is easy to verify that the AON mechanism **RM** is a special case of $\mathbf{RM_g}$—S_i in an AON domain is equal to the second highest of the bids placed by agents other than i.

It can be shown that no mechanism, including $\mathbf{RM_g}$, is *optimally-balanced* when anonymity considerations are completely dropped. For instance, a mechanism that redistributes S_i to a randomly selected agent i, and none to other agents, will in some cases redistribute more surplus than $\mathbf{RM_g}$; however, such a mechanism is clearly not *optimally-balanced*.

4.1 Redistribution in Allocation Problems

We've been discussing redistribution in the context of general social choice or decision-making problems. An important subclass of social choice problems consists of those in which a decision must be made on how to allocate goods amongst a group of competing agents. The most basic allocation problem is that in which a single item is available; this limited case (usually) falls within the AON class.[4] Generally, an allocation problem consists of a number of sellers

[3]A *symmetric domain* is one in which the space of possible valuation reports is identical for each agent.

[4]The exception is when there are externalities, e.g., when agent i is happy if his friend agent j is allocated the item.

who bring goods to the system, and a number of interested buyers, each with preferences over the goods that are potentially combinatorial in nature.

Sometimes in such domains allocation mechanisms are selected to maximize revenue to the seller(s), but there are many significant cases in which it is preferable to keep as much wealth as possible in the hands of the agents. For example, consider the allocation of job time on a publicly owned super-computer among a community of researchers. Resources like this are often established with the mandate of maximizing benefit to the public good (efficiency); if a VCG-based allocation were implemented a surplus would result, fair redistribution of which would go further toward satisfying this mandate.

In the vast majority of allocation problems, the following are generally accepted to hold: agents receive no value if they aren't allocated anything (normalization); agents' values monotonically increase as they receive more goods (free disposal); and agents have no preferences over allocations to other agents (no externalities). These intrinsic elements of the allocation domain map directly to constraints on valuation functions that can allow for significant strategyproof redistribution of VCG surplus. Formally, let G be the set of goods to be allocated, and for any bundle of goods $b \subset G$ let $v_i(b)$ be agent i's value for obtaining b. Each agent i's valuation conforms to the following:

$$v_i(\emptyset) = 0$$
$$v_i(b) \leq v_i(b \cup \{g\}), \quad \forall_{b \subset G,\, g \in G}$$

Consider the following valuations of three agents in an allocation problem with two goods, A and B, where $\{X_1, X_2, X_3\}$ represents the outcome in which bundles X_1, X_2, and X_3 are allocated to agents 1, 2, and 3 respectively.

	v_1	v_2	v_3
$\{AB, \emptyset, \emptyset\}$	12	0	0
$\{\emptyset, AB, \emptyset\}$	0	10	0
$\{\emptyset, \emptyset, AB\}$	0	0	11
$\{A, B, \emptyset\}$	4	6	0
$\{A, \emptyset, B\}$	4	0	5
$\{B, A, \emptyset\}$	5	7	0
$\{B, \emptyset, A\}$	5	0	7
$\{\emptyset, A, B\}$	0	7	5
$\{\emptyset, B, A\}$	0	6	7

Table 2: 2-good, 3-agent allocation problem.

The efficient outcome is to allocate A to agent 3 and B to agent 2. Applying $\mathbf{RM_g}$, agent payoffs are as follows:

$$\pi_i = v_i(o^*) + \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*) - \sum_{j \in I \setminus \{i\}} \hat{v}_j(o^*_{-i}) + Z_i$$
$$\pi_1 = 0 + 13 - 13 + \frac{8}{3} = \frac{8}{3}$$
$$\pi_2 = 6 + 7 - 12 + \frac{11}{3} = \frac{14}{3}$$
$$\pi_3 = 7 + 6 - 12 + \frac{10}{3} = \frac{13}{3}$$

Using VCG with no redistribution, total social utility is 2 and payment to the center is 11. 9.67 of this (88% of surplus) can be redistributed to the agents under $\mathbf{RM_g}$, yielding a social utility of 11.67, a nearly 5-fold improvement.

5. SIMULATIONS

5.1 Computing redistribution payments

Determining redistribution payments under $\mathbf{RM_g}$ amounts to computing surplus guarantee S_i for each agent i, and then merely dividing by n. In a broad range of domains, a simple algorithm for computing S_i exists. For example, in AON and in fact any typical[5] allocation domain, S_i can be computed as follows: consider v_i to be as high as possible for outcome o^*, and 0 for all other outcomes; then compute the VCG surplus with this v_i and all other agents' reported valuations. This simple algorithm does not hold in general (i.e., not for *all* possible sets of value constraints); however, we can *always* compute S_i through a mixed-integer programming (MIP) specification of equation (1). We briefly outline the formulation here.

The objective in the MIP for agent i's payment is to minimize VCG surplus, and the primary variables are $v_i(o)$ for each $o \in O$. Representing the program constraints is relatively straightforward, but some care must be taken in handling equation (2) and the inner maximization in (1). In both cases there are non-linearities. In (2), for instance, we must specify $c_o \cdot v_i(o)$ for each outcome o, where c_o is a boolean variable representing whether or not o is chosen as the outcome that maximizes social welfare. We can get around this issue by representing $c_o \cdot v_i(o)$ with a new variable $v'_i(o)$, and including the following constraints:

$$v'_i(o) \leq v_i(o)$$
$$v'_i(o) \leq c_o \cdot M$$

where M is a value larger than the maximum possible value an agent could have for any outcome. $v'_i(o)$ will then be $v_i(o)$ if $o^* = o$, and 0 otherwise, as desired.

While solving a mixed-integer program has exponential worst-case running time, in practice we were able to quickly find solutions to very large problems. Determining redistribution payments in a 100 agent, 100 outcome problem took 24 seconds for each agent.[6] Note that the MIPs for calculating agent payments (one for each agent) are independent of each other, and thus all can be solved in parallel.

5.2 Numerical results

In order to understand how much redistribution can be achieved for valuations under different levels of mutual constraint, we performed an empirical analysis on large sets of randomly generated problem instances (sets of valuations), each with the same number of outcomes as agents. We generated valuations according to the following process, where e is an "exclusivity" (between agent valuations) parameter representing the extent to which a domain has "all-or-nothing properties." We chose a maximum value for each agent i's valuation function uniformly at random between 0 and 100. We then chose each $v_i(o_i)$ uniformly at random between 0 and $maxval_i$, and $v_i(o_{j \neq i})$ uniformly at random between 0 and $(1 - e) \cdot maxval_i$. So when $e = 1$, we have a completely AON domain; when $e = 0$ there are no exclusivity constraints between agent valuations. The graph

[5]One without valuation space constraints beyond the standard normalization, free disposal, and no externalities assumptions.

[6]Solutions were obtained using the commercial solver CPLEX, run on a 1.6 GHz Pentium 4 PC.

below plots the percentage of VCG surplus that could be redistributed as a function of the parameter e, for problems with various numbers of agents. For each number of agents, 100 samples were computed for each value of e between 0 and 1 in increments of 0.05.

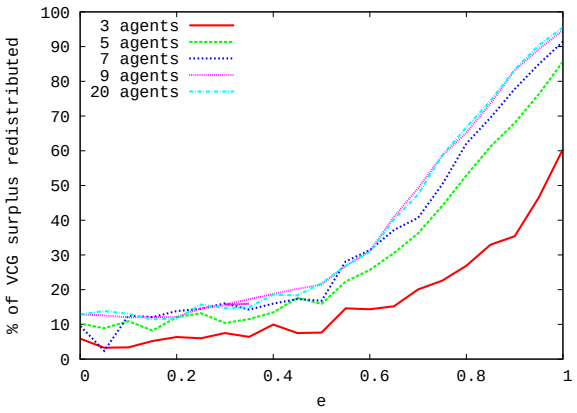

Figure 1: Percent of surplus redistributed as a function of mutual "exclusivity" between agent valuations.

Notably, redistribution remains nearly constant for values of e between 0 and 0.5, and then increases roughly linearly with e from 0.5 to 1. As expected, the possibility for redistribution grows with the number of agents.

6. A CENTER-LESS IMPLEMENTATION

Consider the problem of building a decision-making mechanism that doesn't require a center. This is intuitively desirable, as it's easy to imagine scenarios in which a group of agents must determine an allocation or decide on an action to take without the benefit of a trusted central authority.[7]

THEOREM 7. **RM$_\mathbf{g}$** *can be implemented in Nash equilibrium without the facilitation of a center when the following conditions hold:*

i) no agent acting alone has the power to obstruct realization of a specified outcome or transfer payments, while $n-1$ agents acting together do.
ii) agents can simultaneously "broadcast" valuations to all other agents, and can compute and perform transfers.
iii) agents have the capacity to publicly destroy money.

PROOF SKETCH. The first condition brings abiding by the mechanism into Nash equilibrium—unilaterally deviating cannot be beneficial. The second and third conditions ensure that agents will be able to execute what the mechanism prescribes. With (ii), all agents can recognize the efficient outcome, and deliver the appropriate redistribution payment to each "receiving" agent. (iii) allows the "paying" agents (just a_1 in AON domains) to demonstrably receive the appropriate payoff. The quantity Z_c that cannot stay within the group of agents would normally be transfered to a center, but its destruction is a satisfactory substitute. □

In AON domains, at least, where communicating a valuation amounts merely to a public announcement of a single (value, outcome) pair, satisfaction of these conditions is quite plausible. Then using **RM**, it is possible in equilibrium for a large group of self-interested agents to independently reach the socially optimal outcome, and jointly reap nearly all fruits of the chosen action via redistribution.

[7]See [Shneidman and Parkes, 2004; Petcu *et al.*, 2006] for further discussion of distributed implementations that seek to minimize the role of a center.

7. CONCLUSION

In this paper we argued for the desirability of redistributing VCG payments back among participants in a mechanism, and showed it is feasible in a broad range of settings, including allocation problems. We presented the *optimally balanced* redistribution mechanism, that which always redistributes the maximal amount that any strategyproof, efficient, IR, and no-deficit mechanism could. In "all-or-nothing" domains, a class which encompasses all typical single-item allocation problems, the mechanism is perfectly budget-balanced in the limit.

The VCG mechanism maximizes transfers *from* the group of agents, which is sometimes appealing because transfers amount to revenue for a center. But in many decision problems the transfers are, in a sense, actually waste; in this paper we specified the mechanism that minimizes that waste.

Acknowledgments

I'd like to thank David C. Parkes for inspiration, as well as very helpful suggestions and comments on a draft.

ABSTRACT

We present a new formulation of distributed task assignment, *Generalized Mutual Assignment Problem* (GMAP), which is derived from a typical NP-hard combinatorial optimization problem that has been studied for many years mainly in the operations research community. Then, to solve the GMAP, we introduce a novel distributed solution protocol using *Lagrangean decomposition* and *distributed constraint satisfaction*, where the agents solve their individual optimization problems and coordinate their locally optimized solutions through a distributed constraint satisfaction technique. Next, to produce quick agreement between the agents on a feasible solution with reasonably good quality, we provide a parameter that controls the range of "noise" mixed with increment/decrement in a Lagrangean multiplier and report our experimental results indicating that the parameter may allow us to control tradeoffs between the quality of a solution and the cost of finding it.

distributed combinatorial optimization

1. INTRODUCTION

The distributed task assignment problem, which concerns assigning a set of jobs to multiple agents, has been one of the main research issues from the early days of distributed problem solving [9]. Recently, several studies have been reported in which they formalize the problem as the optimization problem to be solved by some general solution protocol. [3, 6, 7].

In this paper, we present a new formulation of distributed task assignment which is derived from the *Generalized Assignment Problem* (GAP). The GAP is a typical NP-hard combinatorial optimization problem that has been studied for many years mainly in the operations research community [1, 8]. The goal of the GAP is to find an optimal assignment of jobs to agents such that a job is assigned to exactly one agent and the assignment satisfies all of the resource constraints imposed on individual agents.

To adapt the GAP for a distributed context, we first introduce the *Generalized Mutual Assignment Problem* (GMAP). The GMAP is the distributed problem in which each agent in the GAP has a set of jobs and tries to achieve the goal of the GAP. To put it another way, the agents themselves try to generate an optimal solution of the GAP from a non-optimal (and sometimes infeasible) solution of it. Then, to solve the GMAP, we introduce a novel distributed solution protocol using *Lagrangean decomposition* [4] and *distributed constraint satisfaction* [10]. In this protocol, the agents solve their individual optimization problems and coordinate their locally optimized solutions through a distributed constraint satisfaction technique. One important feature of this protocol is that, unlike other optimization protocols for distributed task assignment, it is a pure distributed protocol where neither the server nor the coordinator exists.

2. FORMALIZATION

A GMAP instance consists of multiple agents each having a finite set of jobs that are to be assigned. The agents as a whole solves the following *integer programming problem* denoted as $\mathcal{GAP}$.

$$
\begin{aligned}
\mathcal{GAP} \quad & (\text{decide } x_{kj},\ \forall k \in A,\ \forall j \in J) : \\
\text{max.} \quad & \sum_{k \in A} \sum_{j \in J} p_{kj} x_{kj} \\
\text{s. t.} \quad & \sum_{k \in A} x_{kj} = 1, \ \ \forall j \in J, && (1) \\
& \sum_{j \in J} w_{kj} x_{kj} \leq c_k, \ \ \forall k \in A, && (2) \\
& x_{kj} \in \{0, 1\},\ \forall k \in A,\ \forall j \in J, && (3)
\end{aligned}
$$

where $A = \{1, ..., m\}$ is a set of agents; $J = \{1, ..., n\}$ is a set of jobs; p_{kj} and w_{kj} are a profit and an amount of resource required, respectively, when agent k selects job j;

c_k is a capacity, an amount of available resource, of agent k. Also, x_{kj} is a decision variable whose value is set to 1 when agent k selects job j and 0 otherwise. A goal of the agents is to find a job assignment that maximizes a total sum of profits such that (1) each job is assigned to exactly one agent (denoted as *assignment constraints*), (2) a total amount of resource required for each agent does not exceed its capacity (denoted as *knapsack constraints*), and (3) each job is assigned or not assigned to an agent (denoted as *01 constraints*). We refer to the maximal total sum of profits as the *optimal value* and the assignment that provides the optimal value as an *optimal solution*.

We can obtain the following Lagrangean relaxation problem $\mathcal{LGAP}(\mu)$ by dualizing assignment constraints of $\mathcal{GAP}$ [2].

$$\begin{aligned}
\mathcal{LGAP}(\mu) \quad & (\text{decide } x_{kj},\ \forall k \in A,\ \forall j \in J) : \\
\text{max.} \quad & \sum_{k\in A}\sum_{j\in J} p_{kj}x_{kj} + \sum_{j\in J}\mu_j\left(1 - \sum_{k\in A} x_{kj}\right) \\
\text{s. t.} \quad & \sum_{j\in J} w_{kj}x_{kj} \le c_k,\ \forall k \in A, \\
& x_{kj} \in \{0,1\},\ \forall k \in A,\ \forall j \in J,
\end{aligned}$$

where μ_j is a real-valued parameter and generally called a *Lagrangean multiplier* for (the assignment constraint of) job j. Note that a vector $\mu = (\mu_1, \mu_2, \ldots, \mu_n)$ is called a *Lagrangean multiplier vector*. Based on the idea of *Lagrangean decomposition* [4], we can divide this problem to produce a set of subproblems $\{\mathcal{LGMP}_k(\mu) | k \in A\}$, where each subproblem $\mathcal{LGMP}_k(\mu)$ of agent k is as follows.

$$\begin{aligned}
\mathcal{LGMP}_k(\mu) \quad & (\text{decide } x_{kj}, \forall j \in R_k) : \\
\text{max.} \quad & \sum_{j\in R_k} p_{kj}x_{kj} + \sum_{j\in R_k}\mu_j\left(\frac{1}{|S_j|} - x_{kj}\right) \\
\text{s. t.} \quad & \sum_{j\in R_k} w_{kj}x_{kj} \le c_k, \\
& x_{kj} \in \{0,1\},\ \forall j \in R_k,
\end{aligned}$$

where R_k is a set of jobs that may be assigned to agent k and S_j is a set of agents to whom job j may be assigned. We can assume $S_j \neq \emptyset$ because the job with an empty S_j does not have to be considered in the problem. When we consider that agent k decides the value of x_{kj} for $\forall j \in R_k$ (in other words, the agent that may be assigned job j has a right to decide whether it will undertake the job or not), agent k is able to solve $\mathcal{LGMP}_k(\mu)$ completely by itself since $\mathcal{LGMP}_k(\mu)$ includes only k's decision variables.

On the relation between the entire problem and a set of subproblems, there exist the following properties which are very useful in designing a distributed solution protocol for the GMAP.

PROPERTY 1. *For any values for μ, a total sum of the optimal values of $\{\mathcal{LGMP}_k(\mu)|k \in A\}$ provides an upper bound of the optimal value of $\mathcal{GAP}$.*

PROPERTY 2. *For any values for μ, if all of the optimal solutions to $\{\mathcal{LGMP}_k(\mu)|k \in A\}$ satisfy the assignment constraints, $\sum_{i\in A} x_{ij} = 1$, $\forall j \in J$, then these optimal solutions constitute an optimal solution to $\mathcal{GAP}$.*

3. PROTOCOL

Property 2 prompted the development of a distributed solution protocol, which is called the *distributed Lagrangean relaxation protocol*, where the agents start with $t = 0$ and $\mu^{(0)} = (0, \ldots, 0)$; then, they alternate the following series of actions (called a *round*) in parallel until all of the assignment constraints are satisfied.

1. Each agent k finds an optimal solution to $\mathcal{LGMP}_k(\mu^{(t)})$ (solves the *primal problem*).
2. Agents exchange these solutions with their neighboring agents.
3. Each agent k updates the Lagrangean multiplier vector from $\mu^{(t)}$ to $\mu^{(t+1)}$ (solves the *dual problem*) and increases t by one.

It must be noted that the overall behavior of this protocol is similar to the *distributed breakout algorithm* for solving the DisCSP [5]. We describe the key ideas of the protocol in this section.

3.1 Neighborhood and Communication Model

In order to solve primal and dual problems, agent k needs, for each job j in R_k, the values of Lagrangean multiplier $\mu_j^{(t)}$, the size of set S_j, and the decision variables of the related agents (i.e., $\{x_{ij} \,|\, i \in S_j, i \neq k\}$). The value of $\mu_j^{(t)}$ is locally computed as we will explain later, and the size of set S_j is given to agent k as prior knowledge. On the other hand, the values of the decision variables are obtained through communication with a set of agents denoted as $\bigcup_{j\in R_k} S_j \setminus \{k\}$. We refer to this set of agents as agent k's *neighbors* and allow an agent to communicate only with its neighbors. Thus, the protocol assumes a peer-to-peer message exchange model, in which a message is never lost and, for any pair of agents, messages are received in the order in which they were sent.

3.2 Primal Problem

Once agent k determines the values of the associated Lagrangean multipliers, agent k searches for an optimal solution to $\mathcal{LGMP}_k(\mu^{(t)})$ to determine the values of its own decision variables $\{x_{kj} \,|\, j \in R_k\}$. This search problem is equivalent to the *knapsack problem* whose goal is to select the most profitable subset of R_k such that the total resource requirement of the subset does not exceed c_k. In the problem, for each job j in R_k, the profit is $p_{kj} - \mu_j^{(t)}$, and the resource requirement is w_{kj}.

After finding an optimal solution, agent k sends the solution to its neighbors via an *assign* message.

3.3 Dual Problem

After receiving all of the current solutions of neighbors, agent k solves the dual problem by updating the related Lagrangean multipliers. In this work we use a *subgradient optimization method*, a well-known technique for systematically updating a Lagrangean multiplier vector [2]. In the method, under the current values of the related decision variables, agent k first computes *subgradient* g_j for an assignment constraint of each job $j \in R_k$ as follows:

$$g_j = 1 - \sum_{i\in S_j} x_{ij}.$$

Then, using $|S_j|$ and *step length* $l^{(t)}$, which may decay at rate r $(0 < r \leq 1)$ as the number of rounds t proceeds (i.e., $l^{(t+1)} \leftarrow r l^{(t)}$), agent k updates the multiplier of job j as

$$\mu_j^{(t+1)} \leftarrow \mu_j^{(t)} - l^{(t)} \frac{g_j}{|S_j|}. \quad (4)$$

Notice that since multiplier μ_j is attached to job j all of the agents in S_j must agree on a common value for it. If the agents in S_j assign different values to μ_j, then neither property 1 nor 2 holds any more. To set such a common value, we give all of the agents a common initial value for μ, a common value for initial step length $l^{(0)}$, and a common value for decay rate r as their prior knowledge, and prohibit each agent from working at round $t+1$ until it receives all of the assign messages issued from its neighbors at round t. By doing this, instead of implementing explicit communication among S_j, we can force agents to automatically set a common value to a Lagrangean multiplier.

3.4 Convergence Detection

The protocol should be terminated when all of the optimal solutions to $\{\mathcal{LGMP}_k(\mu^{(t)}) \,|\, k \in A\}$ satisfy all of the assignment constraints, but it is not so simplistic to detect this fact because no agent knows the entire solving processes. In this protocol we use a termination detection procedure of the distributed breakout algorithm [5] to detect this fact.

3.5 Convergence to Feasible Solution

Unfortunately, the protocol may be trapped in an infinite loop depending on the parameter values in rule (4). If that case, the protocol must be forced to terminate after a certain number of rounds, but it has not yet discovered any feasible solution on the way to an optimal solution. Therefore, we make rule (4) stochastic so that the protocol can break an infinite loop and produce quick agreement between the agents on a feasible solution with reasonably good quality. More specifically, we let the agents in S_j assign slightly different values to μ_j by introducing a parameter δ $(0 \leq \delta \leq 1)$ that controls the range of "noise" mixed with increment/decrement in a Lagrangean multiplier. The noise, denoted as N_δ, is a random variable whose value is uniformly distributed over $[-\delta, \delta]$. Multiplier updating rule (4) is thus replaced by

$$\mu_j^{(t+1)} \leftarrow \mu_j^{(t)} - (1 + N_\delta) l^{(t)} \frac{g_j}{|S_j|}. \quad (5)$$

This rule diversifies agents' views on the value of μ_j and thus the protocol can break an infinite loop. On the other hand, since properties 1 and 2 do not hold anymore under this rule, the protocol may converge to a non-optimal (but feasible) solution. Note that rule (5) is equal to rule (4) if δ is set to zero.

4. EXPERIMENTS

Through experiments, we observed the actual performance of the protocol when varying the values of δ and the *assignment topologies*. We adopted two problem suites, one is hand-made but has various assignment topologies and the other is from the GAP benchmark instances of OR-Library but has a specific assignment topology.

Consequently, we observed that the performance of the protocol dramatically changed when δ was set to one of the non-zero values. The results showed that the cost got lower while the solution quality was kept at a reasonable level, suggesting that by using the protocol with those settings, the agents can quickly agree on a feasible solution with reasonably good quality.

It is also true that the protocol with those settings may fail to find an optimal solution. In the experiments, it failed to find an optimal solution at every non-zero value of δ for 3 complete topology instances of the hand-made problem suite and 5 instances of the benchmark problem suite.

For almost all of the instances, we observed that when δ increased both the cost and the solution quality were reduced. This means that increasing δ may generally influence the agents to rush to reach a compromise of lower quality. This indicates that parameter δ may allow us to control tradeoffs between the quality of a solution and the cost of finding it.

5. CONCLUSION

We presented a new formulation of distributed task assignment and a novel distributed solution protocol, where the agents solve their individual optimization problems and coordinate their locally optimized solutions. Furthermore, we introduce a parameter of the protocol that may allow us to control tradeoffs between the quality of a solution and the cost of finding it.

ABSTRACT

In this paper we explore whether an auctioneer/buyer may benefit from introducing his transformability relationships (some goods can be transformed into others at a transformation cost) into multi-unit combinatorial reverse auctions. Thus, we quantitatively assess the potential savings the auctioneer/buyer may obtain with respect to combinatorial reverse auctions that do not consider tranformability relationships.

1. INTRODUCTION

Consider a company devoted to sell manufactured goods. It can either buy raw goods from providers, transform them into some other goods via some manufacturing process, and sell them to customers; or it can buy already-transformed products and resell them to customers. Thus, either the company buys raw goods to transform via an in-house process at a certain cost, or it buys already-transformed goods. Figure 1 graphically represents an example of a company's inner manufacturing process, more formally *Transformability Network Structure* (TNS), fully described in [1]. This graphical description largely borrows from the representation of Place/Transition Nets (PTN), a particular type of Petri Net [2]. Each circle (corresponding to a PTN *place*) represents a good. Horizontal bars connecting goods represent manufacturing operations, likewise *transitions* in a PTN. Manufacturing operations are labeled with a numbered *t*, and shall be referred to as *transformation relationships* (*t-relationships* henceforth). An arc connecting a good to a transformation indicates that the good is an *input* to the transformation, whereas an arc connecting a transformation to a good indicates that the good is an *output* from the transformation. In our example, g_2 is an *input good* to t_2, whereas g_6, g_7, and g_8 are *output goods* of t_2. Thus, t_2 represents the way g_2 is transformed. The labels on the arcs connecting *input goods* to transitions, and the labels on the arcs connecting *output goods* to transitions indicate the units required of each *input good* to perform a transformation and the units generated per *output good* respectively. In figure 1, the labels on the arcs connected to t_2 indicate that 1 unit of g_6, 7 units of g_7, and 1 unit of g_8 are obtained after processing 1 unit of g_2. Each transformation has an associated cost every time it is carried out. In our example, transformation t_2 costs €7.

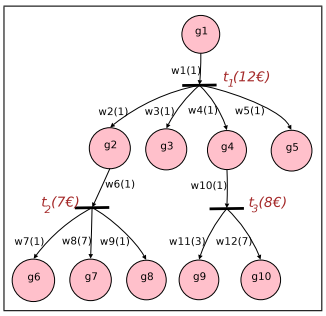

Figure 1: Example of a Transformability Network Structure.

Say that a buying agent requires to purchase a certain amount of goods g_3, g_5, g_6, g_7, g_8, g_9, and g_{10}. For this purpose, it may opt for running a combinatorial reverse auction with qualified providers. But before that, a buying agent may realise that he faces a decision problem: shall he buy g_1 and transform it via an in-house process, or buy already-transformed goods, or opt for a *mixed-purchase* solution and buy some already-transformed goods and some to transform in-house? This concern is reasonable since the cost of g_1 plus transformation costs may eventually be higher than the cost of already-transformed goods.

The work in [1] addresses the possibility of expressing transformability relationships among the different assets to sell/buy on the bid-taker side in a multi-unit combinatorial reverse auction. The new type of combinatorial reverse auction (the Multi-Unit Combinatorial Reverse Auction with Transformability Relationships among Goods (MUCRAtR)) provides to buying agents: (a) a language to express required goods along with the relationships that hold among them; and (b) a winner determination problem (WDP) solver that not only assesses what goods to buy and to whom, but also the transformations to apply to such goods in order to obtain the initially required ones. It is shown that, if the TNS representing the relationships among goods is acyclic, the associated WDP is modeled by the following integer program:

$$min[\sum_{j=1}^{m} x_j p_j + \sum_{k=1}^{r} q_k c(t_k)] \quad (1)$$

$$\forall\, 1 \leq i \leq n \;\; \sum_{j=1}^{m} a_j^i x_j + \sum_{k=1}^{r} q_k m_k^i \geq u_i \quad (2)$$

where $x_j \in \{0,1\}\ \forall\ 1 \leq j \leq m$ stands for whether bid b_j is selected or not, p_j is the price associated to bid b_j, q_k is a decision variable taking into account how many times transformation t_k is fired, a_j^i is the number of units of good i offered in bid b_j, u_i is the number of required unit of good i, m_k^i is obtained from the *incidence matrix* [2] of the place-transition net within a TNS,

$c(t_k)$ stands for the cost associated to transformation t_k, m is the number of bids, n is the number of different negotiated goods, and r is the number of *t-relationships*. Expression (1) minimises the sum of the costs of the selected bids plus the cost of the transformations to apply, and equation (2) enforces that the selected bids plus the transformations applied at least fulfill a buyer's requirements. We will assume a finite production capacity, that is $q_k \in \{0, 1, \ldots, max_k\}, 1 \leq q_k \leq r$.

Notice that the integer program above can be clearly regarded as an extension of the integer program associated to a Multi Unit Combinatorial Reverse Auction (MUCRA) WDP as formalised in [3]. Thus, the second component of expression (1) changes the overall cost as transformations are applied, whereas the second component of expression (2) makes sure that the units of the selected bids fulfill a buyer's requirements, taking into account the units consumed and produced by transformations.

The purpose of this paper to quantitatively assess the potential savings the auctioneer/buyer may obtain with respect to combinatorial reverse auctions that do not consider tranformability relationships.

2. EMPIRICAL EVALUATION

Our experiments artificially generate different data sets. Each data set shall be composed of: (1) a TNS; (2) a Request for Quotations (RFQ) detailing the number of required units per good; and (3) a set of combinatorial bids. Then, we solve the WDP for each auction problem regarding and disregarding *t-relationships*. This is done to quantitatively assess the potential savings that a buyer/auctioneer may obtain thanks to *t-relationships*. Thus, the WDP for a MUCRA will only consider the last two components of the data set, whereas the WDP for a MUCRAtR will consider them all. In order to solve the WDP for a MUCRA we exploit its equivalence with the multi-dimensional knapsack problem [3]. The WDP for a MUCRAtR is modeled by the integer program represented by expressions (1) and (2). In what follows we describe the way to artificially generate such data set.

2.1 Data Set Generation

In order to create a data set, the most delicate task is concerned with the generation of a collection of combinatorial bids. Unfortunately, we cannot benefit from any previous methods for artificially generating auction data sets in the literature since they do not take into account the novel notion of t-relationship.

TNS generation. Firstly, we consider the creation of a TNS. As explained in the introduction, if we restrict to the case of an acyclic TNS, then the WDP for a MUCRAtR can be formulated as an integer program. Thus, we shall focus on generating acyclic TNSs for our data sets. For this purpose, we create TNSs fulfilling the following requirements: (a) each transition receives a single input arc; (b) each place can have no more than one input and one output arc; and (c) there exists a place, called *root place*, that can only have output arcs. Figure 1 depicts an example of a TNS that satisfies such requirements. A distinguishing feature of our algorithm is that, since we aim at empirically assessing the potential savings when considering *t-relationships* independently of TNSs' shapes, it is capable of constructing acyclic TNSs that may largely differ in their shapes, and in the combination of weights assigned to arcs. Our generator randomly constructs TNSs receiving as inputs: (1) a number of places n (the number of goods); (2) a number of *t-relationships* r; (3) the minimum/maximum arc weight w_{min}/w_{max} (each arc weight is chosen from a uniform discrete distribution $U[w_{min}, w_{max}]$); and (4) the minimum/maximum transformation cost c_{min}/c_{max} (a transformation cost for each *t-relationship* is drawn from a uniform distribution $U[c_{min}, c_{max}]$).

RFQ generation. An RFQ is represented as a set $U = \{u_1, \ldots, u_n\}$ where u_i stands for the number of units requested of good g_i. We generate each $u_i \in U$ from a uniform discrete distribution $U[u_{min}, u_{max}]$, where u_{min} and u_{max} stand for the minimum and maximum number of units required per item respectively.

Bid generation. Finally, we complete the artificial generation of a data set by generating a set of plausible bids. Each bid $b_j \in B$ can be represented as a pair $\langle p_j, [a_j^1, \ldots, a_j^n] \rangle$ where p_j stands for the bid price and $[a_j^1, \ldots, a_j^n]$ for the units offered per good. For each bid b_j our generator firstly obtains the number of jointly offered goods from a binomial distribution with parameters ($p_{offered\_goods}$,n), (say z goods); then it randomly selects z goods in G (the set of required goods). For each one of the z selected good g_i, the number of offered units is obtained from another binomial distribution parameterised by ($p_{offered\_units}, u_i$). We employ binomial distributions since our aim is to maintain a proportionality relationships among: (1) the number of negotiated goods and the cardinality of offers; and (2) the number of required units and the number of offered units per good. This is done since we would like to analyse separately the effects of such parameters on savings, and we want to avoid inter-dependency effects. For instance, employing a geometric distribution to describe the number of offered units would implicitly create a dependency effect among the number of required units and the number of offered units, since increasing the number of required units would have the equivalent effect of lowering the number of offered units. Instead, a binomial distribution allows to analise, *ceteris paribus*, the effect of increasing the number of required units.

After generating the units to offer per good for all bids, we must assess all bid prices. This process is rather delicate when considering *t-relationships* if we want to guarantee the generation of plausible bids. In general, it is unrealistic to think of a market scenario wherein raw goods are more expensive than transformed goods. Hence, we assume that all providing agents produce goods in a *similar* manner (they share similar TNSs). However, goods' prices and transformation costs differ from provider to provider. In practice, our providing agents use the same TNS as the buying agent, though each one has his own transformation costs. Thus, for each provider we compute the unitary price for each good in the TNS. Thereafter, for each provider, we use his unitary prices to construct his bids.

Next, we describe how to calculate the unitary prices for each good for a given provider. We depart from the value of the p_{root} parameter, standing for the average unitary price of the root good (e.g. the root good in figure 1 is g_1). The first step of our pricing algorithm calculates the unitary price of the root good for each provider under the assumption that all providers have similar values for such good. Thus, for each provider P_j, his unitary price for the root good is assessed as $\pi_{root,j} = p_{root} \cdot \lambda$, where λ is sampled from a normal distribution $N(\mu_{root\_price}, \sigma_{root\_price})$. After that, our pricing algorithm recursively proceeds as follows. Given a provider and a good whose unitary price has been already computed, this is *propagated down* the provider's TNS through the transition it is linked to towards its output goods. We compute the value to propagate by weighting the unitary price by the value labelling the arc connecting the input good to the transition, and adding the provider's particular transformation cost of the transition. The resulting value is unevenly distributed among the output goods according to a *share factor* randomly assigned to each output good. For instance, consider the TNS in figure 1 and a provider P_j such that its unitary cost for g_2 is $\pi_{g_2,j} = €50$, *his* transformation cost (different from the buying agent's one) for t_2 is €10, and $w_6 = 1$.

Table 1: Parameters characterising our experimental scenario

Parameter	*Explanation*	*Value*
n	The number of items	20
r	The number of transitions	8
u_{min}, u_{max}	The minimum/maximum number of units required per item	10/10
w_{min}, w_{max}	Minimum/Maximum arc weight	1/5
c_{min}, c_{max}	Minimum/Maximum Transformation cost	10/10
m	The number of bids to generate	1000
$p_{offered\_goods}$	Statistically sets the number of items simultaneously present in a bid	0.2 - 0.3 0.4 - 0.5
$p_{offered\_units}$	Statistically sets the number of unit offered per item	0.2 - 0.3 0.4 - 0.5
p_{root}	Average price of the $root$ good	1000
μ_{root_price} σ_{root_price}	Parameters of a Gaussian distribution weighting the $root$ price p_{root}	1 0.01
$\mu_{production\_cost}$ $\sigma_{production\_cost}$	Parameters of a Gaussian distribution setting the production costs difference between buyer and providers	0.8:0.1:1.8 0.1

In such a case, the value to split down through t_2 towards g_6, g_7, and g_8 would be $50 \cdot 1 + 10 = €60$. Say that g_7 is assigned 0.2 as share factor. Thus, $60 \cdot 0.2 = €12$ would be allocated to g_7. Finally, that amount should be split further to obtain g_7 unitary price since $w_8 = 7$. Then, the final unitary price for g_7 is $€1.7142 = \frac{12}{7}$. Hence, we can provide a general way of calculating the unitary price for any good for a given provider. Let P_j be a provider and g a good such that $a_j^g \neq 0$. Let t be a transition such that g is one of its output goods, and $father(g)$ is its single input good. Besides, we note as G' the set of output goods of t. Then, we obtain $\pi_{g,j}$, the unitary price for good g as follows:

$$\pi_{g,j} = \frac{\pi_{father(g),k} \cdot |M[father(g),t]| + c(t) \cdot \nu}{M[g,t]} \omega_g \qquad (3)$$

where $\pi_{father(g),k}$ is the unitary price for good $father(g)$ for a provider $P_k \neq P_j$; $|M[father(g),t]|$ indicates the units of good $father(g)$ that are input to transition t; ν is a value obtained from a normal distribution $N(\mu_{production\_cost}, \sigma_{production\_cost})$ that weighs transformation cost $c(t)$; $M[g,t]$ indicates the number of units of good g that are output by transition t; and ω_g is the share factor for good g. Notice that after applying our pricing algorithm we obtain Π, an $n \times m$ matrix storing all unitary prices.

Several remarks apply to equation 3. Firstly, the share factors for output goods must satisfy $\sum_{g' \in G'} \omega_{g'} = 1$. Secondly, it may surprise the reader to realise that the value to propagate down the TNS ($\pi_{father(g),k}$) is collected from a different provider. We enforce this *crossover* operation among unitary prices of different providers to avoid undesirable *cascading effects* that occur when we start out calculating unitary prices departing from either high or low unitary root prices. In this way we avoid to produce non-competitive and extremely competitive bids respectively that could be in some sense regarded as noise that could eventually lead to diverting results. Finally, from equation 3 we can readily obtain the bid price for a bid $b_j \in B$ as $p_j = \sum_{i=1}^{n} a_j^i \cdot \pi_{i,j}$.

After generating a complete data set, in a MUCRA scenario the Winner Determination Algorithm (WDA) shall solely focus on finding an optimal allocation for the required goods, whereas in a MUCRAtR scenario, the WDA shall assess whether an optimal allocation that considers the buying agent's *t-relationships* can be obtained. Therefore, the difference is that a MUCRAtR WDA does consider and exploit both the buying agent's *t-relationships* along with the implicit transformation cost within each bid, while a MUCRA WDA does not.

To summarise, the parameters we must set to create an auction data set are reported in table 1.

2.2 Experimental Settings and Results

In order to measure the benefits provided by the introduction of t-relationships among goods we compute the cost of the optimal outcome, that is, the cost of the winning bid set for MUCRA (C^{MUCRA}) and the cost of the winning bid set plus transformations for MUCRAtR ($C^{MUCRAtR}$). We define the *saving index* (SI) as: $SI = 100 \cdot \frac{C^{MUCRA} - C^{MUCRAtR}}{C^{MUCRA}}$. The larger the index, the higher the benefits that a buyer can expect to obtain by using a MUCRAtR instead of a MUCRA. Our experimental hypothesis is that the SI index will increase as the buyer's transformation costs increase wrt the providers' ones. Therefore, we will analyse how the difference in production costs between the buyer and the providers affects SI. The differences among the transformation costs of the buyer and the average transformation costs of the providers are controlled by the $\mu_{production\_cost}$ parameter. We expect that, as the average transformation costs of the providers increases with respect to the buyer's ones, so do the benefits of using a MUCRAtR instead of a MUCRA. In fact, the experimental results do strongly agree with our hypothesis. Figure 2 depicts the results when varying $\mu_{production\_cost}$ from 0.8 to 1.8. The legend reports the value of the $p_{offered\_goods}(=)p_{offered\_units}$ parameter. As $\mu_{production\_cost}$ increases, so do savings.

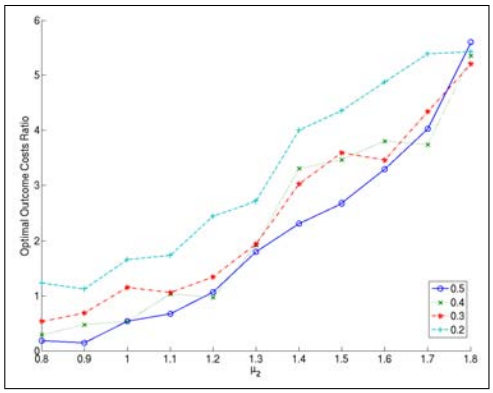

Figure 2: Varying the $\mu_{production\_cost}$ parameter

3. CONCLUSIONS AND FUTURE WORK

We have performed an experiment to empirically evaluate under which market conditions it is convenient to employ the new auction defined in [1]. We found that the best benefits in terms of savings are obtained when: (1) the manufacturing costs of a buyer/auctioneer are higher than the providers' ones; and (2) a buyer cannot access the raw materials at a price lower or equal than the providers.

ABSTRACT

Communication in open heterogeneous multi agent systems is hampered by lack of shared ontologies. To overcome these problems, we propose a layered communication protocol which incorporates techniques for ontology exchange. Using this protocol, the agents gradually build towards a semantically integrated system by establishing minimal and effective shared ontologies. We tested our approach, called ANEMONE, on a number of heterogeneous news agents. We show how these agents successfully exchange information on news articles, despite initial difficulties raised by heterogeneous ontologies.

1. INTRODUCTION

A fundamental communication problem in open multi agent systems is caused by the heterogeneity of the agent's knowledge sources, or more specifically of the underlying *ontologies*. Although ontologies are often advocated as a complete solution for knowledge sharing between agents, this is only true when all agents have knowledge about each others' ontology. The most straightforward way to establish this would be to develop one common ontology which is used by all agents. However, this scenario would be very unlikely in open multi agent systems, as those on the internet, because it would require all involved system developers to reach consensus on which ontology to use. Moreover, a common ontology forces an agent to abandon its own world view and adopt one that is not specifically designed for its task [7]. This may result in a suboptimal situation.

In an open multi agent system, communication problems that arise from heterogeneous ontologies should be *solved*, rather than avoided. In this paper, we present a suitable solution, called ANEMONE: AN Effective Minimal Ontology Negotiation Environment. We illustrate our approach with a case study that involves some semantic integration problems that are typical for open systems. We consider an open community of agents that periodically download news articles on different topics from RSS news feeds[1]. Different news providers are represented by different agents; the taxonomy of news topics supplied by a provider forms the agent's ontology. The fact that different news providers categorize their news differently gives rise to a proliferation of heterogeneous ontologies. The resulting semantic integration problems crop up once the agents start to exchange news articles with each other. For example, consider the agent Ag-M that represents the news provider *Moreover* [5], and the agent Ag-Y that represents the news provider *Yahoo* [3]. Driven by a user's request to Ag-M for more articles on the topic *Basketball*, Ag-M decides to ask Ag-Y for *Basketball* articles. Although Ag-Y has relevant articles on this topic, in Ag-Y's ontology they are classified under *NBA*[2]. Because Ag-Y does not know *Basketball* and Ag-M does not know *NBA* their communication fails.

Traditional approaches, such as standardization and *Ontology alignment* [16], are not suited for these kinds of semantic integration problems. Standardization efforts in this domain are almost doomed to fail, because the news providers deliberately distinguish themselves from others by using different ontologies. Ontology alignment has been proposed as a technique that enables agents to keep their individual ontologies by making use of *mappings* between the different ontologies. Although this is a step in the right direction, it assumes that the mappings can be pre-defined before the agents start interacting. In our case, it is not known beforehand which ontology mappings are needed due to the openness of the system and the fact that ontologies change from time to time. For example, one of Yahoo's news topics, *Asia Tsunami Disaster*, is clearly a temporary topic.

[1]RSS is a popular XML format for the syndication of news content on the internet

In ANEMONE, the agents exchange ontological information on an as-need basis. We hereby adhere to the emerging paradigm of ontology negotiation [6]. Agents first try to cope with the situation as is; when communication fails to be effective, the agents seek a minimal solution which solves their communication problem at hand. Drawing on related work on ontology negotiation and on our experiences with the news agent case, we adopt a standpoint on issues as what kind of shared ontology should be built up, and when and where this should occur. These standpoints are incorporated in ANEMONE and make it a novel approach for ontology negotiation. By implementing ANEMONE and applying it to the news agent case, we show that ANEMONE provides a solution for some semantic integration problems which, to the best of our knowledge, cannot be solved using existing techniques.

In the following section we compare our approach with related work. The third section provides a broad outline of our approach. The communication mechanisms of ANEMONE are discussed in section four. Section five describes implementation details and experimental results. We conclude and give directions for future research in section six.

2. RELATED WORK

Recently, researchers have turned their attention to more flexible solutions for semantic integration problems. An ontology agent [1] has been proposed to facilitate agent communication by registering ontologies and performing services such as translating between ontologies. This would allow agents to reconcile heterogeneous ontologies at interaction time, *on the condition* that every agent knows and trusts the ontology agent and that the ontology agent knows a mapping between every ontology in the system. In our case, such a centralized service is unsuitable as it is not known beforehand which inter-ontology mappings are needed.

Most recently, a few approaches appeared in the literature which tackled the problem in a fully *decentralized* way. W. Truszkowski and S. Bailin have coined the term *Ontology Negotiation* to refer to such approaches [6]. In their paper, the authors present a communication mechanism which enables agents to exchange parts of their ontology in a pattern of successive clarifications. The DOGGIE approach [20] makes similar assumptions, but focuses mainly on the machine learning aspects of ontology exchange, namely the problem of teaching the meaning of a concept to another agent. In this context, we also mention the approach by Soh and Chen [17], where agents exchange ontological knowledge when they believe it would improve operational efficiency. Ontology negotiation can be considered as the most ambitious approach for semantic integration [19]. Because this area is also relatively new, much work remains to be done.

The main differences between ANEMONE and the approaches mentioned above are:

- Contrary to [6], [20] and [17],ANEMONE is not restricted to equivalence mappings (mappings between two equivalent concepts in two ontologies), but deals with arbitrary mappings, such as subset mappings and disjointness mappings. For example, a mapping might state that one agent's concept *NBA* is a subset of another agent's concept *Basketball*. This has some repercussions in the overall communication mechanism regarding the prevention of overgeneralization.

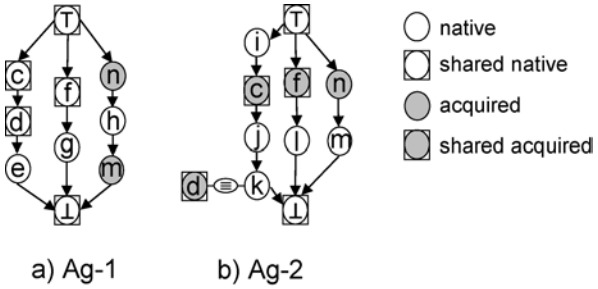

Figure 1: Example ontologies

- Before the agents use resource consuming machine learning techniques, they try to exchange a meaning of a concept by stating the relations with other concepts. This is done by defining the unknown concept in terms of other concepts. The receiver decides whether this definition sufficiently explains the concept.
- Whereas the approach by Soh and Chen uses improved operational efficiency as a main criterium to start ontology exchange, we use a formal, and thus more precise, notion of lossless communication [10]. As lossless communication depends on the ontologies of both agents, both agents are involved in assessing this property.

3. APPROACH

3.1 Ontologies

An ontology consists of a set of concepts and a set of concept relations. We avoid naming conflicts by ensuring that two concepts in different ontologies with the same name also have the same meaning. This can be easily achieved by using namespaces. A concept relation is one of the following: $\sqsubset$ (strict subconcept relation), $\sqsupset$ (strict superconcept relation), $\equiv$ (equivalence), $\perp$ (disjointness), $\oplus$ (overlap). The symbol $\perp$ is also used to denote the bottom concept. Figure 1 presents a graphical representation of two example ontologies. An arrow between two concepts represents a subconcept relation (and against the flow a superconcept relation). Two concepts in two different branches in the ontology are disjoint. Concepts that are equivalent or overlap are connected with a line with the $\equiv$ or $\oplus$ symbol in it. For readability, we have left out concept relations that are derivable from other relations.

Besides concepts and their relations, some other aspects of ontologies are important in the context of ontology negotiation. Firstly, there is a difference between a *native* concept and an *acquired* concept. In Figure 1, the former is represented as non-shaded and the latter as shaded. An agent that has not yet exchanged any ontological knowledge with other agents, has only native concepts in its ontology. The native ontology of an agent is implemented by its system developer to enable it to store and reason with operational knowledge (knowledge that is used by the agent to carry out its task). Because the operational knowledge base is defined in terms of the native ontology, this ontology is constrained to be static. During ontology negotiation, the agents occasionally teach each other new concepts. These are the agent's acquired concepts and are defined additionally to its native concepts. Acquired concepts are not used for storing knowledge but only serve as vehicles for communication.

This allows the acquired ontology to be dynamic.

Another important issue in ontology negotiation is keeping track of which concepts are shared with other agents. In Figure 1, a concept that is shared between Ag-1 and Ag-2 is represented by a box around the concept. When we speak of a concept that is shared between two agents, we actually mean that the concept is common knowledge between the agents. In ontology negotiation, a concept may also be *unknowingly shared*. In this case, both agents know the concept, but do not know this of each other. Examples of unknowingly shared concepts are n and m in Figure 1. Such a situation might arise when two agents learn the same concept from a third agent.

The following terminology is useful for discussing the communication mechanisms of ANEMONE:

- γ_1 is a *particularization* w.r.t. γ_2 iff $\gamma_1 \sqsubset \gamma_2$ or $\gamma_1 \oplus \gamma_2$
- γ_1 is an *implied concept* w.r.t. γ_2 iff $\gamma_1 \sqsupset \gamma_2$ or $\gamma_1 \equiv \gamma_2$

3.2 Communication

ANEMONE does not make any initial demands on agents with regard to their amount of shared concepts. We will discuss an initial situation which is the most difficult, i.e. the agents do not share any native concepts besides the $\top$ concept. At first, these agents lack any means to cooperate. As they participate in conversations, they build up something which enables them to reach a desired level of coordination. An overview of the communication protocol that provides for this is presented in Figure 2. The upper layer of the protocol (NCP) deals with normal agent communication, i.e. the kind of social interaction which agents normally exhibit when no ontology problems exist in the system. To deal with ontology problems, two layers are added to the protocol: a protocol for exchanging concept definitions (CDP), and a protocol for teaching concepts to each other using machine learning techniques (CEP).

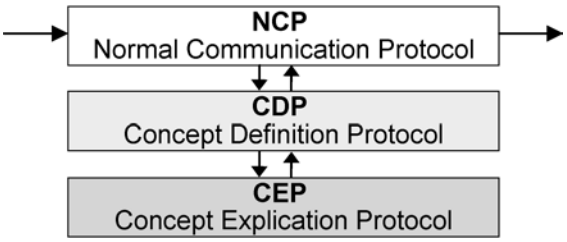

Figure 2: Layered communication protocol

This modular structure of ANEMONE's communication mechanism enables us to make alterations in one layer of the protocol without affecting the other layers. For example, in our news agent domain we have implemented CEP using text classification techniques. In another domain, which deals with individuals other than text documents, other concept learning techniques may be used in CEP.

Our focus in this section is on the domain independent design choices of the protocol, for example, on how the agents traverse through the protocol layers and on general techniques that can be used in the individual layers. These design choices are motivated by a number of standpoints on issues as: *what* should be built up during ontology negotiation and *where* and *when* is this built up?

- What: *Minimal & Effective* Agents should build up a minimal and effective shared ontology. An ontology that is minimal in size is not bulky and slowly processable due to superfluous concepts. An ontology that is minimal in use enables agents to keep their conversations short. An effective ontology is expressive enough to convey sufficient information in a sound manner. Particularly, communication should be *lossless*, meaning that no information is lost in communication that could have been avoided by spending more effort on learning each others' ontologies. A formal definition of lossless communication is presented in [10].

- When: *Lazy* Agents should build up a shared ontology only when strictly necessary. Ontology exchange is not a goal in itself; it is a means of enabling communication. The agents leave NCP when communication fails to be effective and try to return as soon as possible. Defining a concept in CDP is less resource consuming than learning a concept in CEP. Therefore an agent explicates instead of defines a concept only when strictly necessary. In other words, the agents try to stay as high up as possible in the layered communication protocol.

- Where: *Decentralized* In line with the ontology negotiation paradigm, no central location exists where a shared ontology is built up. Every agent increments its own ontology with the necessary concepts. In this way, they collectively address the semantic integration problem.

4. COMMUNICATION MECHANISM

In the following three sections we discuss and motivate the communication mechanisms that underly NCP, CDP and CEP. An overview of the messages that are exchanged while following the protocol is presented in figure 6.

4.1 Normal Communication Protocol

Normal communication protocols have been extensively studied in the agent communication literature. The focus of this section is on the adjustments that are required to deal with the partially shared ontologies described in section 3.1, and the criteria upon which the agents base their decision to resort to CDP. This confronts us with the task of finding a proper way to deal with *message composition*, *message interpretation*, and the decision of when to *switch to CDP*. To discuss these issues, we assume a simple setting in which a speaker intends to convey one of its native concepts to a hearer. *Message composition* is the speaker's task of translating the native concept it intends to convey to a concept it will actually speak to the hearer. *Message interpretation* is the hearer's task of translating the concept in the message to one of its native concepts to store the information in its knowledge base. Either the speaker or the hearer may decide to *switch to CDP* when it believes that more concepts should be shared between them. We begin our discussion with a very simple way to implement message composition, interpretation, and a switch to CDP. As we evaluate this protocol against the quality criteria of minimality, effectivity, and laziness (discussed in section 3.2), we detect shortcomings and adjust the protocol accordingly. Subsequent evaluations and refinements eventually give rise

to a communication mechanism of considerable complexity which is described in section 4.1.5.

4.1.1 Equivalence mappings

Our first proposal for NCP is a simple communication mechanism that exploits some features of partially shared ontologies introduced in section 3.1, namely the distinction between native and acquired concepts, equivalence mappings, and the notion of shared concepts. These features can be incorporated in a relatively straightforward manner. In this proposal, message composition involves translating the native concept the speaker intends to convey to an *equivalent shared concept*, and to use this in a message. Message interpretation involves translating the concept used in the message to an *equivalent native concept*. The speaker switches to CDP when no equivalent shared concept is available in its ontology. Some examples w.r.t. Figure 1: Ag-1 intends to convey d, speaks d which Ag-2 interprets as k; Ag-1 intends to convey e, can not do so, and switches to CEP to teach the concept to Ag-2. Note that in this scenario, a shared concept enables communication in *both* directions. For example, when Ag-2 intends to convey k, it may speak d which Ag-1 interprets as d. The speech act that allows the speaker to translate what it intends to convey to an equivalent shared concept is called *ExactInform*. It is clear that this communication mechanism does not give rise to information loss, i.e. it enables lossless communication.

4.1.2 Beyond equivalence mappings

The previous proposal for NCP does not describe the handling of acquired concepts that are mapped in an agent's native ontology as sub- and superconcepts. For example, Ag-2's acquired concept c is mapped between its native concepts j and i. One measure we must take to overcome this shortcoming, is to make message interpretation less strict; from now on, message interpretation involves translating the concept used in the message to *the most specific implied native concept* (instead of to an equivalent native concept). For example, Ag-1 intends to convey c, exactinforms c which Ag-2 interprets as i. Note that although this version of ExactInform may introduce some information loss, no information is lost in the communication process that could have been prevented by sharing extra concepts. Therefore, ExactInform still guarantees lossless communication.

Besides this refinement to message interpretation, the message composition part in the protocol also requires revision. This is motivated in the following example. If message composition is defined as strictly as in the previous proposal, Ag-2 would never use concept c in its message because none of Ag-2's native concepts is equivalent to c. To comply with minimality, shared concepts should allow for communication in both directions. For example, Ag-2 should be allowed to communicate j using the shared concept c. For this reason, we loosen the conditions for message composition such that the speaker can translate the native concept it intends to convey to a shared implied concept. The speech act that is associated with this version of message composition is called *Inform*. For example: Ag-2 intends to convey j, informs c which Ag-1 interprets as c; Ag-1 intends to convey e, informs d, which Ag-2 interprets as k.

4.1.3 Towards effectivity

The previous proposal for NCP threatens the effectiveness of communication by allowing the agents to become overly general. In the extreme case, an agent that intends to convey one of its native concepts, speaks the shared concept $\top$. Apparently, inform does not guarantee lossless communication. We prevent overgeneralization by enabling the hearer to recognize when communication has been lossless and when not. When the hearer is not certain that communication was lossless, it requests specification. When the speaker cannot convey more specific information due to the lack of shared concepts, the agent switches to CDP. Stated in this way, the decision to switch to CDP has to do with recognizing overgeneralization.

The hearer recognizes overgeneralization by reasoning as follows. Upon hearing that an individual belongs to some concept, it knows that the individual is a member of every implied concept and that the individual is not a member of all concepts that are disjoint with the concept. This knowledge cannot be a symptom of overgeneralization. However, the hearer remains ignorant about the particularizations of the concept. This ignorance may be a symptom of overgeneralization. The rule for recognizing overgeneralization we propose here is: if there are native particularizations of the concept used in the message, communication may not have been lossless. For example: Ag-2 intends to convey k, informs c, Ag-1 requests specification (because of concept d), Ag-2 exactinforms d and the conversation finishes; Ag-1 intends to convey e, informs d, Ag-2 interprets this as k, recognizes lossless communication and the conversation finishes; Ag-2 intends to convey l, informs f, after which Ag-1 requests specification (because of g), after which Ag-2 switches to CEP to teach l to Ag-1.

4.1.4 Towards efficiency

The proposal for NCP described in the previous section eventually guarantees lossless communication. However, the communication mechanism is not minimal in use. For example, every time that Ag-2 informs Ag-1 about j, Ag-1 requests specification (due to the presence of d), upon which Ag-2 answers that it does not know whether d holds. Especially when larger ontologies are involved, every time the speaker intends to convey a general concept, a cumbersome dialogue follows where the hearer requests for specification many times. To make communication more efficient, we make the following adjustments to the *Inform* speech act. In message composition, the agent is obliged to translate to the *most specific* shared implied concept. This not only prevents the speaker from becoming more general than necessary, it also enables the hearer to form a belief about what the speaker intended to convey and what it did not. In philosophy of language, such a derivation is known as a *conversational implicature* [12]. In ANEMONE, it works as follows: upon receiving a concept, the hearer knows that the speaker did *not* intend to convey the shared subconcepts of that concept, otherwise it would have spoken differently. It therefore considers it useless to request these particularizations. For example, when Ag-2 speaks c (with the intention to convey j), Ag-1 does not request whether d holds, because it knows that Ag-2 could not have intended to convey d. But the hearer can form an even stronger belief than that. The hearer also knows that the speaker did *not* intend to convey any non-shared subconcepts of the shared subconcept of the spoken concept. For example, when Ag-2 informs

c (with the intention to convey j), Ag-1 does not request whether e holds, because it knows that Ag-2 could not have intended to convey e, otherwise it would have informed d. This communication mechanism has been proven to yield lossless communication [8].

4.1.5 Dealing with unknown concepts

Until now, we have discussed how agents should deal with shared concepts that are common knowledge. As argued before, ontology negotiation also gives rise to unknowingly shared concepts. A minimal ontology negotiation protocol should exploit this property. Therefore, in message composition, we also allow an agent to translate to a non-shared concept (which may turn out to be an unknowingly shared concept). The rule is that an agent may still translate what it intends to convey to the most specific shared implied concept, but if there are more specific non-shared implied concepts present, it may also choose one of these. Once an agent has used an unknowingly shared concept in the message, this concept becomes shared. Because an agent is not allowed to speak non-shared implied concepts that are more general than a shared implied concept, the efficiency measures that make use of conversational implicatures are still applicable. The choice to translate to a shared concept with the risk of being too general, or to translate to a more specific non-shared concept, with the risk of being not understood, is left to the agent. Communication strategies that resolve non-determinacy in the communication protocol are investigated in [9].

The final version of NCP is summarized in Figure 3. The next example shows that it may be beneficial to speak an unknowingly shared concept rather than a more general shared concept. Ag-2 intends to convey m, exactinforms the non-shared concept m which is understood by Ag-1 as h. Ag-2 could also have informed the shared concept $\top$ with the intention to convey m, which would have been answered by Ag-1 with a request for specificity. The next example shows that it may be beneficial to speak a knowingly shared concept, rather than a more specific non-shared concept. Suppose that Ag-1 intends to convey e, exactinforms e which does not get understood by Ag-2. If Ag-1 would have informed d instead, Ag-2 would have understood the message and would have recognized lossless communication.

Composition
- The agent translates what it intends to convey to:
  - the most specific shared implied concept, or
  - an implied concept that is more specific than the most specific shared implied concept

Interpretation
- The agent translates the concept in the message to:
  - the most specific implied native concept

Switch to CDP
- The hearer switches to CDP when the speaker cannot convey what it intends to convey in a message that gets understood by the hearer and which is not overgeneralized. The hearer considers an inform message which mentions a concept γ overgeneralized if native particularizations of γ exist that are not
  - a shared subconcept of γ, or
  - a subconcept of a shared subconcept of γ

Figure 3: Normal Communication Protocol

4.2 Concept Definition Protocol

In the concept definition protocol, the speaker tries to convey the meaning of a concept by stating the relations with other concepts, i.e. it speaks a number of concept definitions. If these definitions enable the hearer to derive the *complete meaning* of the concept, the hearer switches back to NCP. An agent considers the meaning of an acquired concept complete, if it knows the relation with every other concept in its ontology. If there are not sufficient shared concepts available to convey the complete meaning, the agents switch to CEP. For example, Ag-2 intends to define k, speaks "$k \equiv d$" after which Ag-1 knows the complete meaning of k and switches back to NCP. Suppose Ag-1 intends to define h and speaks "$m \sqsubset h \sqsubset n$". This definition enables Ag-2 to derive that h is disjoint with f, l, i, c, j, k, d, that h is subset of $\top$ and n, and that h is a superset $\bot$ and m. It therefore regards the meaning of h complete and switches back to NCP. Suppose Ag-1 intends to convey the meaning of g and speaks "$\bot \sqsubset g \sqsubset f$". This definition leaves Ag-2 ignorant about the relation between g and l. It does not consider this meaning complete, and switches to CEP.

Composition
- The agent states the relations of what it intends to define with every shared concept.

Interpretation
- The agent adds the defined concept as an acquired concept to its ontology.
- The agent adds the relations in the message to its ontology, and derives relations that follow from this.

Switch to NCP
- When the hearer knows the relation of the defined concept with every concept in its ontology.

Switch to CEP
- When the speaker does not know any shared concepts to define concept relations.
- When the hearer does not know the relation of the defined concept with every concept in its ontology.

Figure 4: Concept Definition Protocol

4.3 Concept Explication Protocol

The purpose of CEP is to convey the meaning of a concept when no satisfactory definition of the concept in terms of other concepts can be given. A commonly used technique for generating a concept mapping is to invoke a dictionary or a thesaurus, such as WordNet [11]. However, this turns out to have its limitations in our domain. Firstly, the technique is incomplete, e.g. Yahoo's concept *NBA* is not defined in WordNet. Secondly, the technique may be incorrect. For example, the *International* concept of the American company Reuters is really a superset of the *UK* concept of the (British) BBC. From the perspective of the BBC agent, WordNet would suggest differently. For these reasons, we do not take the name of a concept into account while finding out its meaning.

Following Luc Steels [18], we assume that the meaning of a concept can be conveyed to another agent by pointing to instances. A basic requirement for this approach is a *classi-*

fier for each concept in an agent's ontology. The speaking agent, upon explicating a concept, communicates a number of positive and a number of negative examples of the concept. The hearer classifies these examples using the concept classifiers from its own ontology. We use the following terms that are common in machine learning [15]:

- TPR: True positive rate: the number of positively classified positive examples divided by the total number of positive examples.
- TNR: True negative rate: the number of negatively classified negative examples divided by the total number of negative examples.

For each concept, the agent calculates TPR and TNR and uses this information to assess the concept relation. In the ideal situation, when the agent's classifiers are perfect and every element in the domain of discourse is used as an example, TPR and TNR offer strict criteria for determining the correct concept relation. Consider an ideal situation, where TPR and TNR result from applying a classifier of concept γ_1 to examples of concept γ_2. The relation between concept γ_1 and γ_2 can be determined as follows: $\gamma_1 \equiv \gamma_2$ iff $\text{TPR} = 1 \wedge \text{TNR} = 1$; $\gamma_1 \bot \gamma_2$ iff $\text{TPR} = 0$; $\gamma_1 \sqsubset \gamma_2$ iff $0 < \text{TPR} < 1 \wedge \text{TNR} = 1$; $\gamma_1 \sqsupset \gamma_2$ iff $\text{TPR} = 1 \wedge \text{TNR} < 1$; $\gamma_1 \oplus \gamma_2$ iff $0 < \text{TPR} < 1 \wedge \text{TNR} < 1$. In most practical situations, the agents have noisy classifiers and the domain of discourse may be infinite (as in our case study). We deal with this by loosening the conditions for determining concept relations. There are actually many ways to do this. We follow a simple approach by introducing some threshold parameters θ_1, θ_2 and θ_3. The way the concept relation is assessed is described in Figure 5.

Composition

- The agent sends positive and negative examples. The positive examples are individuals belonging to the concept to be explicated. The negative examples are individuals that belong to concepts that are disjoint with the concept to be explicated.

Interpretation

- For every native concept γ_1 in its ontology, the agent computes TPR and TNR using the examples in the message.
- The agent assesses the relation of the explicated concept γ_2 with every native concept γ_1 as follows:
  - $\gamma_1 \equiv \gamma_2$ if $\text{TPR} \geq \theta_1 \wedge \text{TNR} \geq \theta_2$
  - $\gamma_1 \bot \gamma_2$ if $\text{TPR} \leq \theta_3$
  - $\gamma_1 \sqsubset \gamma_2$ if $\text{TPR} < \theta_1 \wedge \text{TNR} \geq \theta_2$
  - $\gamma_1 \sqsupset \gamma_2$ if $\text{TPR} \geq \theta_1 \wedge \text{TNR} < \theta_2$
  - $\gamma_1 \oplus \gamma_2$ if none of the previous conditions holds

Switch to CDP

- After the hearer has processed the examples.

Figure 5: Concept Explication Protocol

5. RESULTS

5.1 Implementation

We have implemented ANEMONE as a multi-threaded Delphi application. A single news agent corresponds to an RSS reader. It periodically checks the internet for new news articles that belong to one of the concepts in its ontology. If so, it downloads these articles and uses an XML-parser to extract the title, summary, date, and URL of the article. It stores this information in a local database. The agents actively exchange information with each other about new news articles and their topics. NCP provides for this communication. A query for news articles of a topic, is interpreted as a request to the other agent for an inform speech act, after which NCP deals with the subsequent communication. The non-determinacy in message-composition is resolved using the following simple communication strategy. If the speaker intends to convey γ and the only translation of γ to a shared concept is $\top$, the speaker prefers to speak the unshared concept γ; in all other cases, the speaker translates to the most specific shared implied concept of γ.

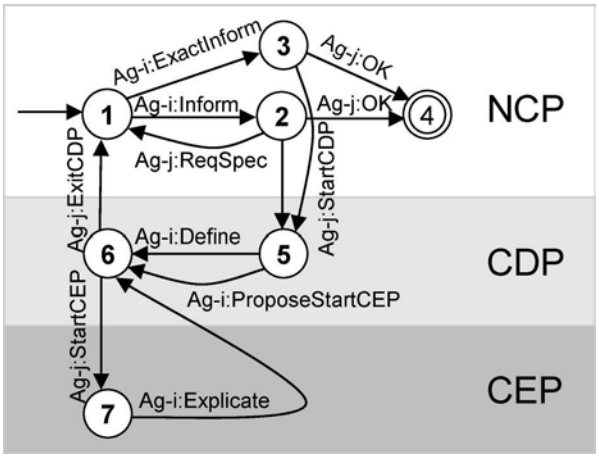

Figure 6: Message protocol of ANEMONE

The concept explication protocol incorporates some application specific design choices. Because our case deals with text documents, the classifiers are implemented using text classification techniques. We use a support vector machine [14] to classify the *description* fields of the news articles of a topic. The texts are preprocessed using common techniques in natural language processing [13], such as *stemming* and *stopword removal*; subsequently, the texts are transformed in term frequency vectors. These vectors are used for training the agent's concept classifiers. When the agent has sufficiently trained its concept classifiers on its own news articles, it is capable of learning concepts from other agents by following CEP. In CEP, the teacher sends news articles belonging to the concept to be explicated as positive examples, and news articles belonging to the concepts that are disjoint with the concept to be explicated as negative examples. As described in the previous section, the hearing agent computes TPR and TNR values for each concept in its ontology and derives the concept relations. Because in our application, a small amount of misclassifications is acceptable, we used relatively tolerant criteria to assess concept relations, i.e. $\theta_1 = 0.75$, $\theta_2 = 0.75$, $\theta_3 = 0.4$.

5.2 Case study

We demonstrate the system using the four relatively simple agents depicted in Figure 7. The agents represent news publishers BBC [2], Moreover [5], Reuters [4] and Yahoo [3]. The agent's ontologies consist of subsets of the news feeds provided by the news publishers. After the agents have col-

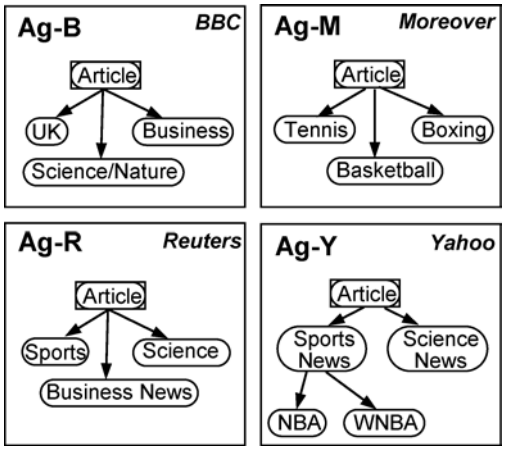

Figure 7: Initial situation

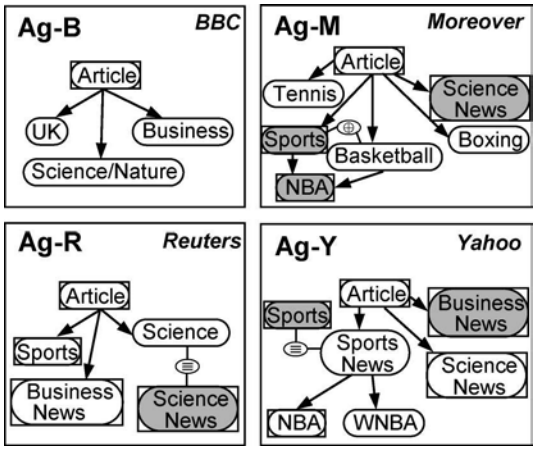

Figure 8: Situation after 9 conversations

lected news articles for a period of two months, their knowledge bases were filled with approximately 200 news articles per topic. This enabled them to train their classifiers and participate in ontology negotiation. The following examples present a series of successive dialogues which were generated by the agents. For demonstration purposes, the agents make some of their internal workings public; these are preceded by a *. Due to space limitations, we abbreviated long path names of news articles with `[]`, and summarized some of the conversations. The agents begin in a situation where they do not share any concepts with each other (Figure 7).

```

46-51 *In CEP Ag-M learns that NBA is a subset of basketball and translates to basketball*

After this conversation, the agents have built up knowledge about each others' ontologies, as shown in Figure 7. The agents have built up a shared ontology that enabled them to convey what they intended to convey (effectivity), but have not made the shared ontology larger than required (minimality). The acquired concepts are not only mapped to equivalent native concepts but also to native superconcepts (e.g. Ag-M's *NBA* and *Basketball*) and to disjoint native concepts (e.g. Ag-M's *Science News*). Because the approaches mentioned in section 2 only deal with equivalence mappings, these approaches would have failed to solve

the semantic integration problems of the news agents.

The conversation shows that many of the ontology negotiation techniques we have discussed in this paper are useful in a realistic domain. We mention the following: the use of mappings other than equivalence mappings (9-15, 42-51), the use of generalization in message composition (28-29), detecting information loss (42-43), the use of speaking in *unknowingly shared* concepts (16), using acquired concepts for communication in *both* directions (8,28), the use of communicating concept definitions (30-34), detecting inadequate concept definitions (19-20).

In this case, it took around 10 seconds (on a Pentium 4, 2.5 GHz) for the agents to finish concept explication. Although the CEP layer worked well enough for this relatively simple case, in a scenario with more complex ontologies or where the correctness of concept mappings is of critical importance, the CEP layer needs improvements. Most likely, these improved versions will be even more time consuming. This strengthens our motivation for lazy ontology negotiation to reduce the occurrence of concept explication to a minimum.

6. CONCLUSION

In this paper, we have presented the ANEMONE approach for solving semantic integration problems. Instead of trying to solve all ontology problems at one stretch at design time, ANEMONE provides agents with the tools to overcome ontology problems at agent interaction time. The layered communication mechanism tackles semantic integration problems when needed and only when needed.

We have applied ANEMONE to the domain of news articles. Despite the fact that agents used different ontologies to classify news articles, they were able to overcome their communication problems and successfully exchanged news articles with each other. The performance of ANEMONE can be improved by incorporating more sophisticated machine learning techniques in the lower layer of the protocol. For our application, where the agents use relatively simple ontologies, the concept explication layer worked sufficiently well. The focus in this paper, however, has been on the communication mechanisms which serve to embed the machine learning techniques in the overall communication architecture, i.e. the upper two layers in the protocol. Even in our relatively simple case, these communication mechanisms proved to be useful. The agents refrain from applying resource consuming machine learning techniques as much as possible. When necessary, they gradually contribute to a shared ontology which is minimal in size and enables them to convey sufficient information. There is no need for a central coordinating agent; the agents find out by themselves if their communication is not satisfactory and solve the problem between themselves. These features of ANEMONE established that the news article agents, after having participated in only a few conversations, became part of a reasonably semantically integrated system.

In the future, we plan to apply ANEMONE to more complex domains. This may require us to replace the current concept explication protocol with one that is better suited for that domain. Furthermore, the ontologies in that domain may be more complex than the concept hierarchies we have focussed on in this paper. This requires an extension of the other layers in the communication protocol to deal with, for example, the alignment of concept attributes.

ABSTRACT

Web services are increasingly utilized by organizations that want to improve responsiveness and efficiency. While they may be used in an isolated way, the need of integrating them as part of workflow processes is more and more felt. However the creation of applications composed of dynamically selected basic services entails facing two essential issues: how to efficiently discover Web services and how to allow and facilitate their composition.

In this paper, we propose an agent-based framework representing an attempt of giving an answer to such problems. Its peculiar characteristic and strength is the integration of the agent technology with other key emerging technologies, that is semantic Web, Web service, rule engine and workflow technologies. The multiagent system, which constitutes the backbone of the framework, represents the "glue" that holds these pieces together and makes them perform properly. The framework has been experimented and evaluated in the realization of a simple, but realistic, prototype of an e-travelling system. The results, though still preliminary, are quite encouraging.

Categories and Subject Descriptors

I.2.11 [**Artificial Intelligence**]: Distributed Artificial Intelligence – *multiagent systems*.

General Terms

Management, Experimentation, Security.

Keywords

Agent-mediated e-business, ontology, Web services, workflow, security, service discovery and composition.

1. INTRODUCTION

The rapid growth of the Internet, networking systems and Web technologies is stimulating an ever-increasing number of companies to use internet not only to provide e-commerce worldwide, but also to improve internal communication, to help manage supply chains, to conduct technical and market research, and to locate potential partners.

Agent technology is considered one of the most interesting technologies to successfully support these activities, which are gathered under the name of e-business. In fact, besides being an ideal mechanism for implementing complex systems, agent technology is well-suited to applications, like e-business ones, that are communication-centric, based on distributed computational and information systems, and requiring autonomous components readily adaptable to changes. In particular, the use of agent technology for realizing e-business systems provides conceptual simplicity, enhances scalability, and makes interactions in a large collection of information sources become tractable.

Considering their peculiar features and the role they should play in an e-business scenario, it is evident that agents do not necessarily offer new functionalities. To be successful, it is crucial to appropriately engineer and integrate agent technology with other technologies that have found and will find a purpose within enterprise computing. Data-mining, workflows, rule engines, just to mention a few, belong to the former group.

New interesting and promising technologies are represented by the semantic Web and Web services. The vision which is making its way into the research community is to encapsulate the organization's functionalities within appropriate interfaces and advertise them as one or more Web services, which could be integrated, when brought into play, in workflows. This innovative idea brings with it new outstanding opportunities but also new great issues, related mainly to the ability of automatically discovering and composing Web services. An answer to these problems could come from the semantic Web technology.

Recently, we have seen an explosion of interest in ontologies as artefacts to represent human knowledge and as a critical component in several applications; among these the e-business applications. Moreover the "marriage" between agents and ontologies seems to be the kind of technology that can significantly change the face of enterprise software.

On the one hand, ontologies should accomplish the task of giving a precious support to solve two tricky problems: how to efficiently discover Web services and how to make possible the interoperability of heterogeneous Web services. In order to facilitate the resolution of such a structural and semantic heterogeneity, Web services, which play the role of workflow components, will have their interfaces semantically described by ontological concepts.

On the other hand, ontologies enable agents to communicate in a semantic way, exchanging messages which convey information according to explicit domain ontologies.

In this scenario agents represent the "glue" that could hold these pieces together and make them perform properly.

Assuming to adopt an agent-based approach, a typical scenario of an e-business application would be characterized mainly by three actors: service providers, brokers and users, playing roles which would be allocated to different concrete agents. The system architecture would likely be organized in communities constituted by different kinds of agents: service providers, personal assistants and middle agents (e.g. service brokers, user profile managers, workflow managers, etc). In order to achieve their goals (semantic matching, service contracting and so on) these autonomous agents should be able to perform their tasks in cooperation or competition with other agents and to interoperate with external entities (e.g., legacy software systems). Moreover they should show reasoning capabilities and should have a support for dynamic behaviour modification based on business rules. Finally they should be able to build workflows, compose the external Web services and monitor their execution. The entire process should be supported by a distributed trust management.

Clearly the researchers are well aware that such a scenario is quite ambitious and the outlined objectives difficult to achieve in a short period. Indeed there are several overlooked technical issues and the present technology presents significant limitations. Nevertheless the realizations of prototype systems centred on the underlying infrastructure can be of great help in order to raise awareness of these issues and to delineate possible solutions.

Bearing in mind what said above, the aim of the present paper is to introduce a framework, under development at the University of Parma, for the realization of agent-based e-business applications.

In the next section we discuss the related work in the fields of the emergent and more established technologies which we aim at integrating with agent technology. Section 4 describes the framework aiming at being the basis for the realization of successful and innovative agent-based e-business applications. In this section we focus mainly on its architecture, the ontological support, the integration with a rule engine and our proposal for a distributed trust management. Section 5 shortly presents a prototype of an e-travelling system realized by using JADE and the aforementioned framework. Finally, we give some concluding remarks and present our future research directions.

2. RELATED WORK

There is evidence from several research studies [2],[33] that agents represent one of the most suitable technologies which can be used to meet the performance needs for e-business applications. Indeed, agents provide both an appropriate level of abstraction in modelling e-business applications and a natural merging of object orientation and knowledge-based technologies that can facilitate the incorporation of reasoning, learning and high-level dialogue capabilities to realize intelligent and adaptive applications. In particular the current interest in using agents for developing e-business applications is rising mostly because different works have shown how agent technology can be leveraged if used together with technologies exploited in the Internet, that is, semantic Web, Web services and workflows [8],[10],[17],[21],[28],[32],[33].

Semantic Web technologies appear to be the right means to provide the semantic integration between data and processes across systems that can be owned by different enterprises [9]. This technology is not completely mature yet; some major activities related to the definition of languages for expressing the semantics of the Web are still in progress [22],[11]. Nevertheless different works have shown how the powerful synergism between agents and semantic Web could be very promising [28],[40] and some efforts have been made in order to define ontology models and develop tools suitable for agents aiming at being truly semantic aware agents. The research community contributions have been mainly devoted to cope with three different issues:

- The formal definition of a standard language for expressing semantics on the web which has led to the Web Ontology Language,
- The development of integral software infrastructures, for writing semantic web applications, offering a variety of tools to engineer ontologies. These supports for the construction of ontology-oriented and ontology-based applications are mainly thought for applications written by using the Java language,
- The development of ontological supports specifically thought for multiagent systems.

The second and third points are strictly connected to the first one since OWL is considered the reference language; therefore the work carried out, starting from OWL, has developed tools more suitable for different contexts.

As far as the second point is concerned, an interesting approach is characterized by the definition of a meta-model that closely reflects the OWL syntax and semantics. This is the case of the modelling APIs of Jena [25], which is the most famous and widely used tool in the sphere of the semantic web (and recently also in the context of multiagent systems), and the OWL API [4] framework. The latter consists of a high-level programmatic interface for accessing and manipulating OWL ontologies. To date, it is shipped with a reference implementation which is main memory-based and not optimized.

Considering the third point, the focus is on the specific needs of multiagent systems, and the objective is to provide a communication support enabling agent to perform the proper semantic checks on a given content expression. A significant example of the efforts made in this direction is represented by the ontological support of JADE [24], designed to represent, using Java objects, a taxonomy of concepts. Such semantically aware agents should then be able to discover, invoke, compose and monitor those Web resources that provide services. In order to make agents able to use a service, they need a computer interpretable description of the service itself and furthermore to know the means by which it is accessible. To that purpose, a community of researchers is developing an ontology of services, called OWL-S, with the aim of providing a semantic orientation to the description of Web services.

To enable software systems for e-business applications, security issues have to be carefully analysed and sound solutions have to be deployed. A number of different solutions for the problems of authentication and authorization in open systems have been proposed in the scientific literature, and some standards have emerged through the years. Most of them are based on some kind of PKI and signed certificates issued by a Certification Authority.

In particular, this is the case of X.509, which is the best known and adopted standard for authentication and authorization. However, its weaknesses have been clearly demonstrated in a number of works [20], above all related to its (mainly politically motivated) effort to create a global directory of unique names. In any case, relying on an external entity as root of all certifications represents an additional, not directly controllable, point of failure for the whole system.

In contrast, different approaches have been proposed, based on local names. Both SDSI [1] and PetName Markup Language [29] allow local names to be used in a global scale by prefixing them with the public key of the principal defining them, in the form of `(key, name)` couples. This way, name conflicts are solved thanks to the uniqueness of the public keys. In [44], authors show that local names and YURLs are more robust than global names to phishing attacks, arguing the root for these attacks lie in the global namespace itself. Moreover, in [30],[31], authors shows that local names and a subset of the SDSI/SPKI standard [14] can be used to implement a distributed RBAC infrastructure, in which local names are interpreted as distributed roles, whose name is localized to their defining principal (key). In [14], delegation certificates are defined as s-expressions, to link separate namespaces and to delegate access rights among principals.

Local names and delegation certificates are the key to build systems adhering *trust management principles* [27]. These systems are completely distributed as they avoid any centralized authority. This way they can easily scale to large peer-to-peer networks, where each node is in charge of protecting its own resources and to show proper credentials when accessing resources of other nodes.

To conclude just a few remarks on JADE since it is considered the reference implementation of the FIPA specifications and one of the most used and promising agent development framework. The present release of JADE tries to provide agent developers with a support integrating almost all these technologies, even if in our opinion only partially. As a matter of fact, JADE agents can exploit an ontological model of the application domain to improve their interactions, are able to interact with external Web services [17] and finally different works have shown how the integration of a JADE agent with the Jess rule engine is feasible. But this simply represents a first step towards an effective integration with the aim of supporting real e-business applications. In fact a detailed analysis shows its weaknesses.

The idea which mostly inspired the design of the JADE content language and ontological support was to define an ontology independent abstract model of the content language that could be subsequently bound to any domain ontology representation expressed using an object-oriented data model. This ontological support has been conceived when the Semantic Web was on its very early stage of research and development and OWL was not already established as a standard. Consequently its expressive power is clearly limited with respect to OWL and basically allows expressing taxonomy of concepts, predicate and actions and therefore it is not able to represent completely the different application domains where JADE agent may be used.

JADE provides the integration with the JESS rule engine [26], which is probably the most known Java rule engine implementing the Rete algorithm [16]. This integration is realized through a so-called JessBehaviour that allows the encapsulation of a JESS rule engine inside a JADE agent and has the duty of storing and retrieving information in/from the rule engine. The main limits of this solution are: i) the rule engine is completely hidden to the other agents of the system and there is not any support for the cooperation among different rule-based agents (i.e., agents encapsulating a JESS rule engine) and ii) JESS is a commercial software and so we have additional costs if we plan to realize commercial applications by using JADE together with JESS.

At the beginning of the last year a new release of JADE was announced providing a service allowing the integration of agents with Web services. This service, called WSIGS (Web Services Integration Gateway Service), is a stand alone, encapsulated application that provides transparent, bidirectional transformations between JADE agent services and Web services [17]. To date, the WSIG supports only simple WSDL description of Web services, without taking into account emerging technologies related to the semantic Web, like OWL-S specifications. Another limit of this integration service is that it does not provide any means that agents can use to automatically compose Web services.

Finally, JADE also provides some basic facilities, to sign and/or encrypt ACL messages. But, to have a complete and usable security infrastructure, these facilities must be augmented with tools enabling the distributed management of trust relationships.

3. EXTENDING JADE FOR E-BUSINESS APPLICATIONS

To overcome the limits of the present release of JADE, we have realized GAIN (Grid Agent INfrastructure), an agent based framework that allows the automatic composition of Grid tasks and Web services through the use of workflow technologies [32]. Its architecture is based on a society of agents, mostly composed of two kinds of agents: component managers and workflow managers.

Each component manager is associated to one or more Web services and is responsible for the interaction with them. Through the use of the WSIG JADE add-on, the component managers are able to invoke a Web service, converting ACL messages into WSDL descriptions and vice versa. Moreover, a component manager allows a flexible provision of services defining "on the fly" the features of the services (prize, timing, etc.) through a set of business rules managed by a rule engine and modifiable by the operators of the service provider through a Web interface.

Workflow managers have the goal of supporting users in the process of building the workflows, composing external Web services and monitoring their execution. To accomplish this complex activity the workflow managers provide the users with two alternative automatic procedures:

i) Predefined workflow; the workflow is extracted from a repository of standard and common templates, e.g. templates used in previous computations. In this case the duty of the workflow manager is to support the user in the selection of the most appropriate Web services for the execution of the different workflow tasks. The workflow manager is able to select a matching service thanks to the exploitation of a shared ontology that gives a common knowledge background

to all the agents in the system.

ii) Dynamic workflow; the workflow manager, according to the user's requirements, creates a new workflow, composing the atomic services available in the system. This is done by applying a planner (we have realized extending the SGP planner [39]) that works on the operators extracted from the OWL-S descriptions of the Web services, provided by component managers. After the composition of the final workflow, the workflow manager is able to update it and possibly replace those Web services that are failed or no more available or cannot satisfy the execution time constraints.

Moreover, GAIN offers to the users the possibility of manually building workflows. In this case, a personal assistant (i.e. an agent, associated with each user active in the system, responsible for the interaction between the user and the other parts of the system) helps its user presenting her/him the tasks (Web services) that can be composed and possibly informing her/him when the realized workflow does not satisfy the composition rules, coming from the related OWL-S descriptions. When a complete workflow is realized, the user can ask its personal assistant to delegate the workflow execution to a workflow manager. The enactment is clearly a problematic phase. When a workflow is going to be executed, a Web service could be no more available due to the expiration of a timeout, a failure of a resource or other unpredictable problems. In this case the workflow manager helps the user finding a new solution, creating a new contract phase with all the component managers that are able to satisfy the task and suggesting to the user the replacement of the failed service with the new one.

So far we have given a concise description of the system architecture and the responsibilities of the major system components, intentionally leaving out the treatment of the issues connected to the tools needed by the agents, in order to carried out their activities. In the following subsections, we will go into details, illustrating our proposals and the implemented tools.

3.1 Ontological Support

As highlighted several times within this paper, the multi-agent systems "powered" with an ontological support seem to be the key to the success of the e-business applications. JADE already makes available an ontological support but as mentioned above it is quite limited. In order to provide a JADE agent with an adequate expressive power (i.e., equivalent to the one offered by OWL DL), it is necessary either to replace or to integrate the JADE ontological support. In the attempt of finding a suitable solution to this problem one has to choose among the proposals described above and others, each characterized by different domain knowledge modelling techniques and answering different needs. The majority of the research work in this field is thought for the semantic Web. But while in the vision of the semantic Web the increasing interest in ontologies is driven by the large volumes of information available and by the need of automating many information retrieval activities, in the agent context the focal point is slightly different and it is mainly on communicative acts - communications which implies actions. Agents would use ontologies to perform the proper semantic checks on a given content expression, and therefore ontologies should include concepts (objects of the domain of the discourse) but also predicates (assertions on properties of concepts) and actions (that agents can perform in the domain). Moreover a peculiar characteristic of the agent community is the heterogeneity of resources available and the roles played by different agents of a system. This leads us to claim that a one-level approach, based on a single ontology model and the corresponding tool, with the aim of being omni comprehensive seems to be seldom feasible. In our opinion a good compromise is represented by choosing different approaches in different contexts. Our solution was to realize a compound tool, called OWLBeans [8], that allows the use of ontologies described by using OWL DL [3]. These ontologies can be used by agents for performing their tasks in cooperation with other agents, for interoperating with external entities (e.g., legacy software systems) and for performing a semantic matching of Web services, described by using OWL-S and having inputs and outputs associated with concepts belonging to a domain ontology.

OWLBeans is based on a two-level approach with the aim of coping with both the issues of managing complex ontologies and of providing ontology management support to lightweight agents, which seldom need to deal with the whole complexity of a OWL DL ontology. Therefore, lightweight agents maintain the simple JADE ontology support whereas one or more dedicated agents, acting as ontology servers, are able to use and manage complete OWL DL ontologies and provide the service to the agents that need it.

The main functionality of OWLBeans is to extract JADE ontologies from OWL DL ontologies realizing a set of ontologies usable by JADE agents, with the obvious shortcoming that not all the information maintained in the original OWL ontologies are taken into account. Therefore, for all those systems that need a complete support for OWL DL ontologies, OWLBeans offers a set of ontology server agents implemented as JADE agents, providing a common knowledge base and reasoning facilities. These ontology servers use the Jena toolkit to load, maintain and reasoning about OWL ontologies. The other agents of the system do not need to know anything about the Jena toolkit given that these ontology servers provide them with a set of simple actions for querying and manipulating the ontologies. Furthermore, ontology servers take into account proper authorization mechanisms. In particular, the underlying trust management support (discussed in the following subsection) has been leveraged to implement a certificate-based access control. Only authenticated and authorized principals will be granted access to managed ontologies. A delegation mechanism allows the creation of communities of trusted entities, which can share a common ontology, centrally managed by the ontology server.

Finally, despite the fact that the JADE ontological support is quite simple, it could still be complex for some devices with limited resources such as smart phones. This is the reason why we have decided to improve OWLBeans adding a further feature which allows agents to import taxonomies and classifications from OWL ontologies, in the form of a hierarchy of Java classes with the purpose of providing very simple artefacts to access structured information. Given its modular architecture, based on an intermediate ontology model, OWLBeans also provides further functionalities, e.g., saving a JADE ontology into an OWL file, or generating a package of JavaBeans from the description provided by a JADE ontology.

3.2 Production Rule Management

As for the ontological support, in order to cope with the limits of the current JADE support for rule engines, we realized a software library, called D4J (Drools4JADE) [6], that integrates JADE agents with the Drools rule engine [13]. Drools is a well known, freeware implementation of the so-called Rete-OO algorithm. Apart of its open-source availability, one of the main advantages of Drools is exactly the fact that it is not just a literal implementation of the Rete algorithm, but rather an adaptation for the object-oriented world. This greatly eases the burden of integrating the rule engine and the application rules with the existing external objects. In Drools, asserted facts are simple Java objects, that can be modified through their public methods and properties. Where Jess requires hundreds of lines of code, for example to simply access an ACL message mapped into a Java object, Drools rules can obtain the same result in a dozen of easy-reading code lines.

D4J guarantees both the advantages of full rule-based agents, i.e., agent whose behaviour and/or knowledge is expressed by means of rules [23],[38], and the advantages of rule-enhanced agents, i.e., agents whose behaviour is not normally expressed by means of rules, but that use a rule engine as additional component to perform specific reasoning, learning or knowledge acquisition tasks [19]. In facts, in D4J, the Drools rule-engine is integrated into an agent as a JADE behaviour, but it also provides an API for interacting with it through ACL messages allowing both remote storing and retrieval of knowledge and the cooperation among different rule-based agents. Moreover, this API allows rules mobility, i.e., a rule-based agent can move a rule to another rule-based agent.

Given their nature, business rules often refer to domain specific concepts and, especially when dealing with data on the semantic Web, these concepts are part of a domain ontology. To better support this scenario, rule-enhanced JADE agents should be augmented with a tool for the automatic transformation of concepts, relations and individuals of an OWL ontology [5] to java classes, properties, and instances. The D4J framework can be integrated with OWLBeans, which enables the extraction of JavaBeans from an OWL ontology. The JavaBeans can then be directly asserted as facts into the working memory of Drools.

3.3 Distributed Trust Management

Out of the box e-business applications are not certainly possible if security problems are not analyzed and addressed. Our framework supports the implementation and deployment of secure systems, adhering trust management principles. For this purpose, local names, interpreted as distributed roles, and delegation certificates are made available, to build peer-to-peer networks of trusted entities.

The accurate release of authorizations is often the most critical point of security systems. Ideally, systems should respect the principle of *least privilege*, but this often contrasts with other requirements, as easiness of understanding, scalability and manageability. In this respect, the RBAC model [37] has proven to be a good abstraction to manage large and complex systems, up to corporate and virtual-organizations environments.

Following the RBAC model, each resource manager of our system (i.e. each node in the peer-to-peer network) has to deal with three main concepts: principals (i.e. authenticable entities which act as users of resources and services), permissions (i.e. rights to access resources or use services) and roles [12].

A many to many relationship binds principals and the roles they are assigned to. In the same way, a many to many relationship binds permissions and the roles they are granted to, thus creating a level of indirection between a principal and his access rights. This also leads to a better separation of duties (between the assignment of principals to roles and the definition of role permissions), to implement privilege inheritance schemes among superior and subordinate roles and to permit temporary delegations of some of the assigned roles towards other principals. The fundamental principle here is that each node is in charge of defining its own roles, and of assigning principals to them.

Dynamic delegation of access rights is made possible through the use of delegation certificates, whose structure is based on the theory of [14]. But we have avoided s-expressions, preferring XML to them, as it provides a better ground to exploit and integrate standard technologies. In particular, in recent times SAML [36] have emerged as a language to express properties of authenticable principals, encoded in the generic form of signed security assertions. SAML assertions can easily bind public keys to local names, and certify the links between two different local namespaces, as it happens in SDSI/SPKI certificates.

Both providers and consumers of services exploit this infrastructure to build a distributed P2P network of trust relationships, embodied and quantified in terms of signed delegation certificates. These certificates, attached to signed request messages, list the set of roles the requester is assigned to, and they are signed by trusted authorities according to customizable policies. The delegation certificates owned by the agents can also be used to delegate roles, and thus access rights, to other agents, to allow them to complete the requested tasks or to achieve delegated goals [7].

Delegation is particularly important to deal with the activation of intermediate agents, acting between the human user and the concrete service providers, i.e. personal agents, workflow managers and agents providing composite services. In this case, privileges must be forwarded in the form of delegation certificates from the user toward each agent in the chain, up to the final service provider, which will check them for consistency with local security policies. These policies are stored and managed locally as XACML documents [43].

It is worth noting that similar solutions are made possible in GRID environments by issuing *proxy certificates* [41]. These are essentially locally signed X.509 certificates, allowing not only to specify the identity of a subject, but also to grant only a limited set of privileges to it. But, being an extension to the X.509 standard, they end up with neither being fully compliant with existing infrastructures, nor avoiding the fundamental problem of centralized authorities. Besides, they do not even enjoy the advantages of XML-based solutions, as human readability, extensibility and interoperability.

To cope with the security problems coming from the remote utilization of the rule engine and from the mobility of rules, also D4J exploits this security layer to implement: i) the authentication of the agents, ii) the checking of permissions owned by the agents,

and iii) the delegation from an agent to another agents of its permissions. Therefore, only authenticated and authorized agents can successfully ask another to store and retrieve knowledge or to accept new rules. In D4J, the infrastructure is used to enforce security policies at two different levels: proper authorization is necessary to modify the working memory and the rule set of an agent; moreover, each rule is associated with a specific protection domain, limiting the resources made accessible when it is scheduled for execution.

4. AN E-TRAVELLING APPLICATION

The framework has been experimented in the realization of a prototype of an e-travelling system which provides both atomic services (e.g., the purchase of a flight ticket) and composite services (e.g., the reservation of various hotels and restaurants and the purchase of flight tickets for a business or holiday trip). The behaviour of this system can be described introducing three different kinds of actors: service providers, service brokers and users.

Service providers provide atomic services and make them available through a set of Web services.

Service brokers help other agents to find services and to compose them. All brokers share an ontological model to describe the provided services. Service providers that like to register to one of these brokers need to provide the mapping of their Web services to such an ontological model. Travel operators have also the opportunity of directly delegating the complete management of their services to one or more service brokers. In this case, travel operators and service brokers need to share the service status (i.e., the free/busy places of a flight, the free/busy rooms of a hotel, etc.) and travel operators need to provide their service brokers with the business rules in order to make them able to compute the prices of the services. Business rules are not static, but need to be dynamically updated by the travel operators. For this reason, service brokers provide a Web interface that allows a travel operator to list its business rules, add and remove new rules and identify dependencies among them.

A user interacts with a service broker through a Web interface too. She/he can either ask for an atomic service, receiving from the broker an ordered list of the feasible solutions that should satisfy her/his requirements, or a composite service, receiving, for example, information concerning the bookings and tickets needed for a trip or the different prices of the services necessary to organize a conference. In particular, in the case of a composed service, the Web interface assists her/him in defining the composed service through a graphical construction of a workflow in which each step corresponds to a component of the service. This is an iterative process that, for instance, initially allows a user to fix the ticket for flights and the booking for hotels, and then, after all the terms have been settled (dates, places, etc.), to add booking for special restaurants, purchasing of tickets for theatres plays, etc.

Moreover, service brokers maintain a profile of registered users and use such profiles to send them information about special offers that can be of their interest.

The core of the realized system is a multi-agent system that is deployed on the servers of the service brokers. Service providers have only the duty of maintaining the servers managing their services (the service management can also be delegated to the service brokers). Users need simply a Web browser and an Internet connection.

The multi-agent system is based on five types of agents: service providers, workflow managers, personal assistants, user profile managers and service brokers. Figure 1 shows the interactions between the different types of agents and between the agents and the software systems used by the providers to manage the services they offer.

Service providers are agents that combine the behaviour of a GAIN component manager agent powered by the D4J framework. These agents have the following responsibilities: i) to provide an interface (compliant to the ontology shared by service brokers) for the Web services offered by the providers' management systems, ii) to advertise the offered services at the service brokers (a service provider can offer services through different service brokers), and iii) to manage the business rules used to compute the features of booking and selling contracts.

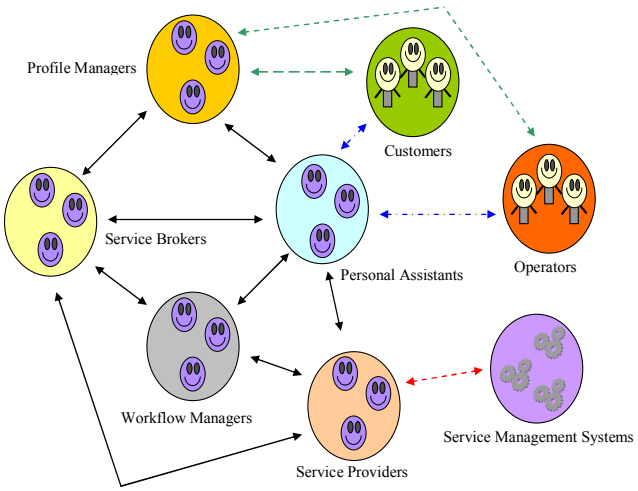

Figure 1 – Interactions between the different types of agents and between agents and service management systems.

Workflow managers are instances of the GAIN workflow manager agent and so their responsibilities concern mostly the management of workflows, strictly related to the composition of services. In particular, they are responsible for: i) checking the workflow submitted by the users, ii) building and/or completing the workflows that satisfy the requests of the users, iii) starting and monitoring the execution of the workflows, and possibly iv) updating the workflow structure if a component fails during its execution. They receive an explicit delegation from the user's personal assistant, which is responsible for providing them with all privileges needed to accomplish the task. These privileges can be further delegated to service providers, in order to enable access to crucial resources.

Personal assistants are agents that are in charge of helping service provider operators and customers of the system in their actions. In particular, they help service provider operators in the maintenance of business rules and customers in both the searching and execution of atomic services and in the construction and execution of composite services. Moreover, they have the duty of

building and updating the profile of the users of the system. Users interact with the personal assistants through Web servers. On the one hand, these Web servers provide users with the appropriate Web interfaces. On the other hand, they allow the personal assistants to push information to the users.

Personal assistants are respectively created and destroyed at the login and logoff of the users. Therefore, personal assistants need to delegate the maintenance of the user profiles to persistent agents, called profile managers. These agents are mainly responsible for exchanging the user profiles with the personal assistants when they are created and destroyed. Moreover, they have the duty of exploiting user profiles to look for new and advantageous offers (e.g., airplane tickets with reduced prize) that may be of interest and possibly to send users information about them through emails. Personal assistants are also responsible for the management of user's credentials, in the form of identity certificates submitted directly by the user at login, and other delegation certificates received by other peers in the course of business interactions.

Service brokers are the agents managing information about the services offered by the connected service providers. In fact, on the one hand, service providers register their services by the service brokers sending them an OWL-S description of their services. On the other hand, both personal assistants and workflow managers can send queries to the service brokers to look for services satisfying user requirements.

Up to now, we have not experimented the system with real users and real services, instead we have tested and evaluated the system functionalities implementing some "artificial" services and involving a group of students, acting either as service provider operators or as customers. Some of the information used by the service providers, implemented just for the experimentation of the system, comes from the Web site of some real service providers (e.g., flight companies, hotel brokers, etc.). With the view to doing it, we have realized an application able to get information from a Web site and then to make available this information through a Web service. This application is independent from the structure of the Web site because it builds queries and extracts information from the responses on the basis of an XML file containing the patterns of both queries and answers. Therefore, we are able to simulate a set of different service providers by simply defining the patterns for querying the Web site of a service.

5. CONCLUSION

In this paper, we have presented an agent-based framework for realizing e-business systems that integrates agent technology with other technologies that have found, and will find, a purpose within enterprise computing: web services, workflows, ontologies and rule engines.

We are well aware that the current multi-agent solutions, aiming at facilitating and supporting the realization of e-business applications, need to be improved since the technologies used are still not completely mature. However a lot of researchers and software developers are really interested in giving a significant contribution in this direction, driven by the motivation of providing a strengthening of the related standards and new methodologies, algorithms and implementations to realize real flexible, adaptive intelligent e-business systems [2],[15].

Our future activities will be oriented towards the aforementioned goal. In particular, we will continue working on the JADE software environment in order to both improve the integration of the JADE agents with the most interesting knowledge and internet-oriented technologies and realize real adaptive agents that will be the basis of next and future e-business applications. At present, we are working in two main directions: i) to provide a full OWL DL support through a home-made framework supplying ontology management and reasoning functionalities, with the main purpose of reducing the amount of computational resources and time required (with respect to the Jena engine), ii) to enhance the agent-based and graphical support, that users can currently use when they define their workflows or modify the set of business rules controlling their services.

ABSTRACT

We present an approach to hybrid semantic Web service matching that complements logic based reasoning with approximate matching based on syntactic IR based similarity computations. The hybrid matchmaker, called OWLS-MX, applies this approach to services and requests specified in OWL-S. Experimental results of measuring performance and scalability of different variants of OWLS-MX show that under certain constraints logic based only approaches to OWL-S service I/O matching can be significantly outperformed by hybrid ones.

1. INTRODUCTION

Key to the success of effectively retrieving relevant services in the future semantic Web is how well intelligent service agents may perform semantic matching in a way that goes far beyond of what standard service discovery protocols such as UPnP, Jini, or Salutation-Lite can deliver. Central to the majority of contemporary approaches to semantic Web service matching is that the formal semantics of services specified, for example, in OWL-S or WSMO are explicitly defined in some decidable description logic based ontology language such as OWL-DL [8] or F-Logic, respectively. This way, standard means of description logic reasoning can be exploited to automatically determine services that semantically match with a given service request based on the kind of terminological concept subsumption relations computed in the corresponding ontology. Prominent examples of such logic-based only approaches to semantic service discovery are provided by the OWLS-UDDI matchmaker [16], RACER [11], MAMA [5], and the WSMO service discovery approach [20].

These approaches do not exploit semantics that are implicit, for example, in patterns or relative frequencies of terms in service descriptions as computed by techniques from data mining, linguistics, or content-based information retrieval (IR). The objective of hybrid semantic Web service matching is to improve semantic service retrieval performance by appropriately exploiting means of both crisp logic based and approximate semantic matching where each of them alone would fail.

Consider, for example, a pair of real world concepts that are semantically synonymous or very closely related, but differing in their terminological definitions which are part of the underlying ontology. In particular, the crisp conjunctive logical concept expressions are differing with respect to a few pairs of unmatched logical constraints only. In this case, both concepts would be logically classified as disjoint siblings in a concept subsumption hierarchy such that any description logic reasoner would fail to detect the original real world semantic relationship. As a consequence, if the semantic comparison of both concepts is essential to discover services that are relevant to a given request, any logic based only matching approach would necessarily fail. The underpinning general problem is that standard logical specification of real world concept semantics is known to be inadequate. One operational way to cope with this problem would be to tolerate logical matching failures up to a specified extent by complementary approximate matching based on syntactic concept similarity computations. Of course, we acknowledge that the adaptation to the latter eventually is on the user's end.

In this paper, we present the first hybrid OWL-S service matchmaker called OWLS-MX, that exploits means of both crisp logic based and IR based approximate matching. Our experimental evaluation shows that under certain constraints this way of matching can indeed outperform logic

based only approaches.

The remainder of the paper is structured as follows. After brief background information on OWL-S in section 2, we present the hybrid matching filters, the generic algorithm of OWLS-MX together with its variants, and a simple example in section 3. Some details on the implementation of OWLS-MX version 1.1 are given in sections 4. The experimental results of measuring performance and scalability of OWLS-MX are presented in section 5, before we briefly comment on related work in section 6, and conclude in section 7.

2. OWL-S SERVICES

In the following, we briefly introduce the essentials of the semantic Web service description language OWL-S that are needed to understand the concepts of hybrid service matching. For more details, we refer the reader to, for example, [13].

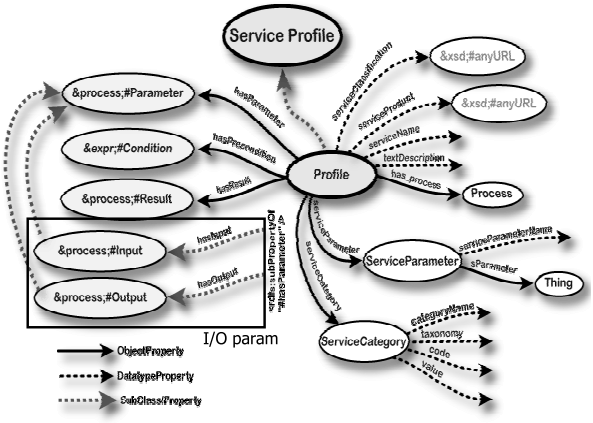

Figure 1: Parametric structure of OWL-S service profiles

OWL-S is an OWL-based Web service ontology, which supplies a core set of markup language constructs for describing the properties and capabilities of Web services in unambiguous, computer-intepretable form. The overall ontology consists of three main components: the service profile for advertising and discovering services; the process model, which gives a detailed description of a service's operation; and the grounding, which provides details on how to interoperate with a service, via messages. Specifically, it specifies the signature, that is the inputs required by the service and the outputs generated; furthermore, since a service may require external conditions to be satisfied, and it has the effect of changing such conditions, the profile describes the preconditions required by the service and the expected effects that result from the execution of the service.

To the best of our knowledge, the majority of current OWL-S matchmakers performs service I/O based profile matching that exploits defined semantics of concepts as values of service parameters hasInput and hasOutput (cf. figure 1). Exceptions include service process based approaches like in [3]. There exists no implemented matchmaker that performs an integrated service IOPE matching by means of additional reasoning on logically defined preconditions and effects. Related work on logic based semantic web rule languages such as SWRL and RuleML is ongoing.

3. HYBRID SERVICE MATCHING

Hybrid semantic service matching performed by the matchmaker OWLS-MX exploits both logic-based reasoning and content-based information retrieval techniques for OWL-S service profile I/O matching. In the following, we define the hybrid semantic filters of OWLS-MX, the generic OWLS-MX algorithm, and its five variants according to the used IR similarity metrics.

3.1 Matching filters of OWLS-MX

OWLS-MX computes the degree of semantic matching for a given pair of service advertisement and request by successively applying five different filters EXACT, PLUG IN, SUBSUMES, SUBSUMED-BY and NEAREST-NEIGHBOR. The first three are logic based only whereas the last two are hybrid due to the required additional computation of syntactic similarity values.

Let T be the terminology of the OWLS-MX matchmaker ontology specified in OWL-Lite (SHIF(D)) or OWL-DL (SHOIN(D)); CT_T the concept subsumption hierarchy of T; $LSC(C)$ the set of least specific concepts (direct children) C' of C, i.e. C' is immediate sub-concept of C in CT_T; $LGC(C)$ the set of least generic concepts (direct parents) C' of C, i.e., C' is immediate super-concept of C in CT_T; $Sim_{IR}(A,B) \in [0,1]$ the numeric degree of syntactic similarity between strings A and B according to chosen IR metric IR with used term weighting scheme and document collection, and $\alpha \in [0,1]$ given syntactic similarity threshold; $\doteq$ and $\dot{\geq}$ denote terminological concept equivalence and subsumption, respectively.

Exact match. Service S EXACTLY matches request R $\Leftrightarrow \forall$ IN_S $\exists$ IN_R: $\text{IN}_S \doteq \text{IN}_R \wedge \forall$ OUT_R $\exists$ OUT_S: $\text{OUT}_R \doteq \text{OUT}_S$. The service I/O signature perfectly matches with the request with respect to logic-based equivalence of their formal semantics.

Plug-in match. Service S PLUGS INTO request R $\Leftrightarrow \forall$ IN_S $\exists$ IN_R: $\text{IN}_S \dot{\geq} \text{IN}_R \wedge \forall$ OUT_R $\exists$ OUT_S: $\text{OUT}_S \in \text{LSC}(\text{OUT}_R)$. Relaxing the exact matching constraint, service S may require less input than it has been specified in the request R. This guarantees at a minimum that S will be executable with the provided input iff the involved OWL input concepts can be equivalently mapped to WSDL input messages and corresponding service signature data types. We assume this as a necessary constraint of each of the subsequent filters.

In addition, S is expected to return more specific output data whose logically defined semantics is exactly the same or very close to what has been requested by the user. This kind of match is borrowed from the software engineering domain, where software components are considered to plug-in match with each other as defined above but not restricting the output concepts to be direct children of those of the query.

Subsumes match. Request R SUBSUMES service S $\Leftrightarrow \forall$ IN_S $\exists$ IN_R: $\text{IN}_S \dot{\geq} \text{IN}_R \wedge \forall$ OUT_R $\exists$ OUT_S: $\text{OUT}_R \dot{\geq} \text{OUT}_S$. This filter is weaker than the plug-in filter with respect to the extent the returned output is more specific than requested by the user, since it relaxes the constraint of immediate output concept subsumption. As a consequence, the returned set of relevant services is extended in principle.

Subsumed-by match. Request R is SUBSUMED BY service $S \Leftrightarrow \forall\ \text{IN}_S\ \exists\ \text{IN}_R$: $\text{IN}_S \dot{\geq} \text{IN}_R \wedge \forall\ \text{OUT}_R\ \exists\ \text{OUT}_S$: ($\text{OUT}_S \doteq \text{OUT}_R \vee \text{OUT}_S \in \text{LGC}(\text{OUT}_R)) \wedge \text{SIM}_{IR}(\text{S, R}) \geq \alpha$. This filter selects services whose output data is more general than requested, hence, in this sense, subsumes the request. We focus on direct parent output concepts to avoid selecting services returning data which we think may be too general. Of course, it depends on the individual perspective taken by the user, the application domain, and the granularity of the underlying ontology at hand, whether a relaxation of this constraint is appropriate, or not.

Logic-based fail. Service S fails to match with request R according to the above logic-based semantic filter criteria.

Nearest-neighbor match. Service S is NEAREST NEIGHBOR of request $\text{R} \Leftrightarrow \forall\ \text{IN}_S\ \exists\ \text{IN}_R$: $\text{IN}_S \dot{\geq} \text{IN}_R \wedge \forall\ \text{OUT}_R\ \exists\ \text{OUT}_S$: $\text{OUT}_R \dot{\geq} \text{OUT}_S \vee \text{SIM}_{IR}(\text{S, R}) \geq \alpha$.

Fail. Service S does not match with request R according to any of the above filters.

The OWLS-MX matching filters are sorted according to the size of results they would return, in other words according to how relaxed the semantic matching. In this respect, we assume that service output data that are more general than requested relaxes a semantic match with a given query. As a consequence, we obtain the following total order of matching filters

EXACT < PLUG-IN < SUBSUMES < SUBSUMED-BY < LOGIC-BASED FAIL < NEAREST-NEIGHBOR < FAIL.

3.2 Generic OWLS-MX matching algorithm

The OWLS-MX matchmaker takes any OWL-S service as a query, and returns an ordered set of relevant services that match the query each of which annotated with its individual degree of matching, and syntactic similarity value. The user can specify the desired degree, and syntactic similarity threshold. OWLS-MX then first classifies the service query I/O concepts into its local service I/O concept ontology. For this purpose, it is assumed that the type of computed terminological subsumption relation determines the degree of semantic relation between pairs of input and concepts.

Auxiliary information on whether an individual concept is used as an input or output concept by any registered service is attached to this concept in the ontology. The respective lists of service identifiers are used by the matchmaker to compute the set of relevant services that I/O match the given query according to its five filters.

In particular, OWLS-MX does not only pairwisely determine the degree of logical match but syntactic similarity between the conjunctive I/O concept expressions in OWL-Lite. These expressions are built by recursively unfolding each query and service input (output) concept in the local matchmaker ontology. As a result, the unfolded concept expressions are including primitive components of a basic shared vocabulary only. Any failure of logical concept subsumption produced by the integrated description logic reasoner of OWLS-MX will be tolerated, if and only if the degree of syntactic similarity between the respective unfolded service and request concept expressions exceeds a given similarity threshold.

The pseudo-code of the generic OWLS-MX matching process is given below (cf. algorithms 1 - 3). Let $\text{INPUTS}_S = \{ \text{IN}_{S,i} | 0 \leq i \leq s \}$, $\text{INPUTS}_R = \{ \text{IN}_{R,j} | 0 \leq j \leq n \}$, $\text{OUTPUTS}_S = \{ \text{OUT}_{S,k} | 0 \leq k \leq r \}$, $\text{OUTPUTS}_R = \{ \text{OUT}_{R,t} | 0 \leq t \leq m \}$, set of input and output concepts used in the profile I/O parameters HASINPUT and HASOUTPUT of registered service S in the set *Advertisements*, and the service request R, respectively. Attached to each concept in the matchmaker ontology are auxiliary data that informs about which registered service is using this concept as an input and/or output concept.

Algorithm 1 *Match*: Find advertised services S that best hybridly match with a given request R; returns set of $(S, degreeOfMatch, SIM_{IR}(R,S))$ with maximum degree of match (*dom*) unequal FAIL (uses algs. 2 and 3 to compute *dom*), and syntactic similarity value exceeding a given threshold α.

```
1: function MATCH(Request R, α)
2:     local result, degreeOfMatch, hybridFilters = {
          SUBSUMED-BY, NEAREST NEIGHBOUR}
3:     for all (S, dom) ∈ CANDIDATES_inputset(INPUTS_R) ∧
          (S, dom') ∈ CANDIDATES_outputset(OUTPUTS_R) do
4:         degreeOfMatch ← MIN(dom, dom')
5:         if degreeOfMatch ≥ minDegree ∧ (
              degreeOfMatch ∉ hybridFilters ∨
              SIM_IR(R,S) ≥ α) then
6:             result := result ∪ { (S, degreeOfMatch,
                  SIM_IR(R,S) ) }
7:         end if
8:     end for
9:     return result
10: end function
```

In the following section, we present five variants of this generic OWLS-MX matchmaking scheme.

3.3 OWLS-MX variants

We implemented different variants of the generic OWLS-MX algorithm, called OWLS-M1 to OWLS-M4, each of which uses the same logic-based semantic filters but different IR similarity metric $\text{SIM}_{IR}(R,S)$ for content-based service I/O matching. The variant OWLS-MO performs logic based only semantic service I/O matching.

OWLS-M0. The logic-based semantic filters EXACT, PLUG-IN, and SUBSUMES are applied as defined in section 3.1, whereas the hybrid filter SUBSUMED-BY is utilized without checking the syntactic similarity constraint.

OWLS-M1 to OWLS-M4. The hybrid semantic matchmaker variants OWLS-M1, OWLS-M3, and OWLS-M4 compute the syntactic similarity value SIM_{IR} (OUT_S, OUT_R) by use of the loss-of-information measure, extended Jacquard similarity coefficient, the cosine similarity value, and the Jensen-Shannon information divergence based similarity value, respectively.

Based on the experimental results of measuring the performance of similarity metrics for text information retrieval provided by Cohen and his colleagues [4], we selected the top performing ones to build the OWLS-MX variants. These symmetric token-based string similarity measures are defined as follows.

Algorithm 2 Find services which *input* matches with that of the request; returns set of (S, dom) with minimum degree of match *dom* unequal FAIL.

function CANDIDATES$_{inputset}$(INPUTS$_R$)
  local H, dom, r
  ▷ *If a service input matches with multiple request inputs the best degree is returned*
  $H := \{ (S, \text{IN}_{S,i}, dom) \in \bigcup_{j=1..n} \text{CANDIDATES}_{input}(\text{IN}_{R_j}) \mid dom = argmax_l\{ (S, \text{IN}_{S,i}, dom_l) \mid 1 \le l \le n, 1 \le i \le s\} \}$
  ▷ *If all inputs of service S are matched by those of the request, S can be executed, and the minimum degree of its potential match is returned*
  for all $S \in Advertisement$ **do**
    if $\{ (S, \text{IN}_{S_1}, dom_1), \cdots, (S, \text{IN}_{S_s}, dom_s) \} \subseteq H$ **then**
      $r := r \cup \{ (S, \text{MIN}(dom_1, \cdots, dom_s)) \}$
    end if
  end for
  ▷ *Services with no input can always be executed and are preliminary* EXACT*-match candidates:* SERVNOIN() $= \{ (S,$ EXACT$) \mid S \in Advertisements \wedge \text{INPUTS}_S = \emptyset \}$
  ▷ *Remaining, unmatched services are at least* NEAREST NEIGHBOUR*-match candidates:* REMSERV() $= \{ (S,$ NEAREST NEIGHBOUR$) \mid S \in Advertisements \wedge \langle S, degreeOfMatch' \rangle \notin r \}$
  return $r := r \cup \text{SERVNOIN}() \cup \text{REMSERV}()$
end function

function CANDIDATES$_{input}$(IN$_{R,j}$) ▷ *Classify request input concept into ontology, and use the auxiliary concept data to collect services that at least plug-in match with respect to its input.*
  local r
  $r := r \cup \{ (S, \text{IN}_S, \text{EXACT}) \mid S \in Advertisements, \text{IN}_S \in inputs_S, \text{IN}_S \doteq \text{IN}_{R,j}, \}$
  $r := r \cup \{ (S, \text{IN}_S, \text{PLUG-IN}) \mid S \in Advertisements, \text{IN}_S \in inputs_S, \text{IN}_S \dot{\geq} \text{IN}_{R,j}, \}$
  return r
end function

Algorithm 3 Find services which *output* matches with that of the request; returns set of (S, dom) with minimum degree of match unequal FAIL.

function CANDIDATES$_{outputset}$(OUTPUTS$_R$)
  local r, dom
  if OUTPUTS$_R = \emptyset$ **then**
    return $\{ (S,$ EXACT$) \mid S \in Advertisements \}$
  end if
  for all $S \in Advertisements$ **do**
    if $(S, dom_t) \in \text{CANDIDATES}_{output}(\text{OUT}_{R,t}) \wedge dom_t \geq$ SUBSUMES **for** $t = 1..m$ **then**
      $r := r \cup \{ (S, \text{MIN}\{dom_1, \cdots, dom_m\})\}$
    else if $(S, dom_t) \in \text{CANDIDATES}_{output}(\text{OUT}_{R,t}) \wedge dom_t \in \{$ EXACT, SUBSUMES $\}$ **for** $t = 1..m$ **then**
      $r := r \cup \{ (S,$ SUBSUMED-BY $\}$
    end if
  end for
  ▷ *Any remaining, unmatched service is a potential* NEAREST NEIGHBOUR*-match:* REMSERV() $= \{ (S,$ NEAREST NEIGHBOUR$) \mid S \in Advertisements \wedge S \notin r \}$
  return $r := r \cup \text{REMSERV}()$
end function

function CANDIDATES$_{output}$(OUT$_{R,t}$) ▷ *Classify request output concept into ontology, and use the auxiliary concept data to collect services with output concepts that match with* OUT$_{R,t}$.
  local r
  $r := r \cup \{ (S,$ EXACT$) \mid \text{OUT}_S \doteq \text{OUT}_{R,t} \}$
  $r := r \cup \{ (S,$ PLUG-IN$) \mid \text{OUT}_S \in \text{LSC}(\text{OUT}_{R,t}) \wedge S \notin r \}$
  $r := r \cup \{ (S,$ SUBSUMES$) \mid \text{OUT}_S \dot{\leq} \text{OUT}_{R,t} \wedge S \notin r \}$
  $r := r \cup \{ (S,$ SUBSUMED-BY$) \mid \text{OUT}_S \in \text{LGC}(\text{OUT}_{R,t}) \}$
  return r
end function

- The *cosine* similarity metric

$$Sim_{Cos}(S,R) = \frac{\vec{R}\cdot\vec{S}}{||\vec{R}||_2^2 \cdot ||\vec{S}||_2^2} \quad (1)$$

with standard TFIDF term weighting scheme, and the unfolded concept expressions of request R and service S are represented as n-dimensional weighted index term vectors $\vec{R}$ and $\vec{S}$ respectively. $\vec{R}\cdot\vec{S} = \sum_{i=1}^{n} w_{i,R} \times w_{i,S}$, $||X||_2 = \sqrt{\sum_i^n w_{i,X}^2}$, and $w_{i,X}$ denotes the weight of the i-th index term in vector X.

- The *extended Jacquard* similarity metric $Sim_{EJ}(S,R) =$

$$\frac{\vec{R}\cdot\vec{S}}{||\vec{R}||_2^2 + ||\vec{S}||_2^2 - \vec{R}\cdot\vec{S}} \quad (2)$$

with standard TFIDF term weighting scheme.

- The intensional *loss of information* based similarity metric $Sim_{LOI}(S,R) =$

$$1 - \frac{LOI_{IN}(R,S) + LOI_{OUT}(R,S)}{2} \quad (3)$$

$$LOI_x(R,S) = \frac{|PC_{R,x} \cup PC_{S,x}| - |PC_{R,x} \cap PC_{S,x}|}{|PC_{R,x}| + |PC_{S,x}|} \quad (4)$$

with $x \in \{IN, OUT\}$, $PC_{R,x}$ and $PC_{S,x}$ set of primitive components in unfolded logical input/output concept expression of request R and service S

- The *Jensen-Shannon information divergence* based similarity measure $Sim_{JS}(S,R) = log2 - JS(S,R) =$

$$\frac{1}{2log2}\sum_{i=1}^{n} h(p_{i,R}) + h(p_{i,S}) - h(p_{i,R} + p_{i,S}) \quad (5)$$

with probability term frequency weigthing scheme, *e.g.*, $p_{i,R}$ denotes the probability of i-th index term occurrence in request R, and $h(x) = -xlogx$,

The extended Jacquard metric is a standard for measuring the degree of overlap as the ratio of the number of shared terms (primitive components) of unfolded concepts of both service and request, and the number of terms possessed by either of them. In contrast to the TFIDF/cosine similarity metric, it does not favor the document with common terms. The Jensen-Shannon measure is based on the information-theoretic, non-symmetrical Kullback-Leibler divergence measure. It measures the pairwise dissimilarity of conditional probability term distributions between service and request text rather than looking at the whole collection as it is the case for the TFIDF/cosine, or the extended Jacquard metric. The loss of (intensional) information in case some concept A is terminologically substituted by concept B, can be measured as the inverse ratio of the number of matching primitive components with those which remain unmatched in terminologically disjoint unfolded concept constraints. The symmetric LOI-based similarity value for a given pair of service and request is then computed analogously for all I/O concept definitions involved.

3.4 Example

Let us illustrate the hybrid service retrieval with OWLS-MX by means of a simple example. Suppose the concept subsumption hierarchy or taxonomy of the OWLS-MX matchmaker ontology, the service request R for physicians of hospital h that provide treatment to patient p, and relevant service advertisements S_1 and S_2 are as shown in figure 2.

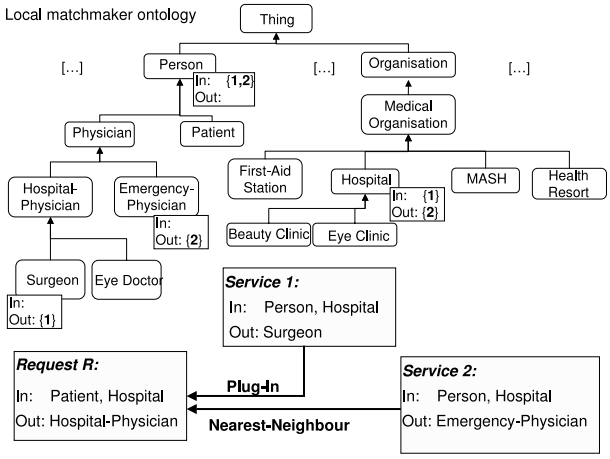

Figure 2: Example of hybrid service matching with OWLS-MX

Service S_1 is considered semantically relevant to request R, since it returns for any given person p and hospital h, the individual surgeon of h that operated on p. Likewise, service S_2 is relevant to R, since it returns those emergency physicians who provided emergency treatment to p before her transport to hospital h. Hence, both services S_1 and S_2 should be returned as matching results to the user.

However, the logic based only variant OWLS-M0 determines S_1 as plug-in matching with R but fails to return S_2, since the formal semantics of the output concept siblings "emergency physician" and "hospital physician" in the ontology are terminologically disjoint. In this example, the set of terminological constraints of unfolded concepts c correspond to the set of primitive components (c^p) of which the individual concepts are canonically defined in the matchmaker ontology T. Hence, the unfolded concept expressions are as follows.

- unfolded(Patient, T) = (and Patient^p Person^p)
- unfolded(Hospital, T) = (and Hospital^p (and MedicalOrganisation^p Organisation^p))
- unfolded(HospitalPhysician, T) = (and HospitalPhysician^p (and Physician^p Person^p))
- unfolded(Surgeon, T) = (and Surgeon^p (and HospitalPhysician^p (and Physician^p Person^p)))
- unfolded(EmergencyPhysician, T) = (and EmergencyPhysician^p (and Physician^p Person^p))

As a result, for example, OWLS-M1 would return S_1 as plug-in matching service with syntactic similarity value of Sim_{LOI} $(R, S_1) = 0.87$. In contrast to OWLS-MO, it also returns S_2, since this service is nearest-neighbor matching with the request R: Their implicit semantics exploited by the IR similarity metric LOI (cf. (5), (6)) with Sim_{LOI}

$(R, S_2) = \frac{(1-\frac{5-4}{5+4})+(1-\frac{4-2}{3+3})}{2} = 0.78 \geq \alpha = 0.7$ is sufficiently similar. Our preliminary experimental results show that this kind of matching relaxation may be useful in practice.

4. IMPLEMENTATION

We implemented the OWLS-MX matchmaker variants version 1.1 in Java using the OWL-S API 1.1 beta with the tableaux OWL-DL reasoner Pellet developed at university of Maryland (cf. `http://www.mindswap.org`). As the OWL-S API is tightly coupled with the Jena Semanic Web Framework, developed by the HP Labs Semantic Web research group (cf. `http://jena.sourceforge.net/`), the latter is also used to modify the OWLS-MX matchmaker ontology.

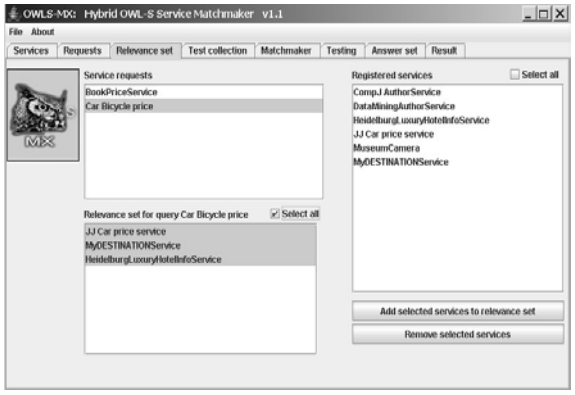

Figure 3: OWLS-MX v1.1 screenshot: Definition of service request and relevance set

Figures 3 to 5 show some screenshots of the OWLS-MX version 1.1 graphical user interface.

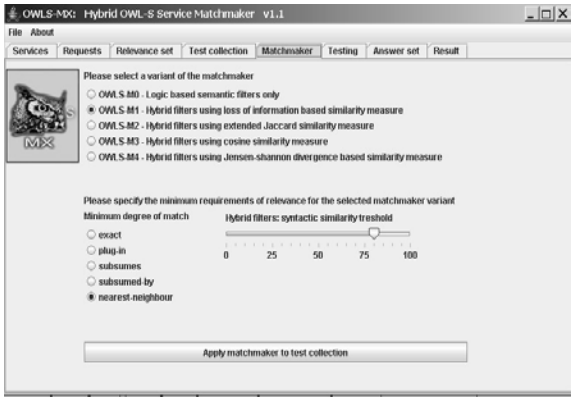

Figure 4: OWLS-MX v1.1 screenshot: Selection of OWLS-MX variant

After parsing service advertisements and requests, the respective input and output concepts are analysed and, if necessary, added to the local matchmaker ontology together with auxiliary data on their unfolding. As a consequence, the matchmaker ontology is dynamically built and growing with the number of services and underlying ontologies loaded. In addition, the matchmaker ontology is extended with auxiliary information for each concept whether it is used as an input or output concept of which service registered at the matchmaker. Service requests are treated similarly, except that they are not stored in the extended matchmaker ontology.

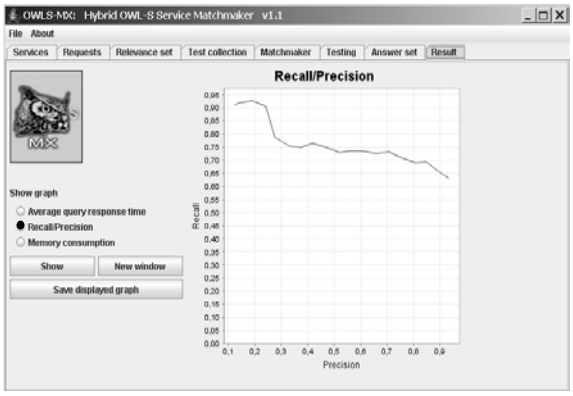

Figure 5: OWLS-MX v1.1 screenshot: Display of selected type of results (performance)

For each service request concept, the service identifiers attached to its immediate parent and child concepts of the enhanced matchmaker ontology are retrieved. The semantic degree of matching for each service is then determined by applying the semantic filters on this set of matching candidates. After this step, the syntactic similarity is computed by applying the selected IR similarity metric to the strings of unfolded concepts of the query and each registered service. Both the semantic degree of match and the syntactic similarity value determine the hybrid degree of matching of one service with the request. If this hybrid degree is better than or equal to the minimum degree specified by the user, then this service will be returned as potentially relevant.

In practice, OWLS-MX spend the largest amount of time with classifying the ontologies used by the registered services to check for new concepts not known to the matchmaker, and then to classify them into the matchmaker ontology.

5. EXPERIMENTAL EVALUATION

For measuring the service I/O retrieval performance of each OWLS-MX variant we used the OWL-S service retrieval test collection OWLS-TC v2. This collection consists of more than 570 services specified in OWL-S 1.1 covering seven application domains, that are education, medical care, food, travel, communication, economy, and weaponry. The majority of these services were retrieved from public IBM UDDI registries, and semi-automatically transformed from WSDL to OWL-S. OWLS-TC v2 provides a set of 28 test queries each of which is associated with a set of 10 to 20 services that two of the co-authors subjectively defined as relevant according to the standard TREC definition of binary relevance [17] [1]. The collection OWLS-TC v2 is available as open source at
`http://projects.semwebcentral.org/projects/owls-tc/`.

In terms of measuring the retrieval performance of each OWLS-MX variant, we adopted the evaluation strategy of

[1]Please note, that no standardized test collection for OWL-S service retrieval does exist yet. Therefore, like with any other reported results on retrieval performance of alternative OWL-S service matchmakers developed by different research groups world wide, we have to consider both our test collection and experimental results as preliminary.

micro-averaging the individual precision-recall curves [18]. Let Q be the set of test queries (service requests) in OWLS-TC, A the sum of relevant documents of all requests in Q, A_R the answer set of relevant services (service advertisements) for request $R \in Q$. For each request R, we consider $\lambda = 20$ steps up to its maximum recall value, and measure the number $B_{\lambda R}|$ of relevant documents retrieved (recall) at each of these steps. Similarly, we measure related precision with the number B_λ of retrieved documents at each step λ. The micro-averaging of recall and precision (at step λ) over all requests, as we used it for performance evaluation is then defined as

$$Rec_\lambda = \sum_{R \in Q} \frac{|A_R \cap B_{\lambda R}|}{|A|}, Prec_\lambda = \sum_{R \in Q} \frac{|A_R \cap B_{\lambda R}|}{|B_\lambda|} \quad (6)$$

The micro-averaged R-P curves of the top and worse performing IR similarity metric together with those for the OWLS-MX variants as well as the average query response time plots are displayed in figures 4 and 5, respectively.

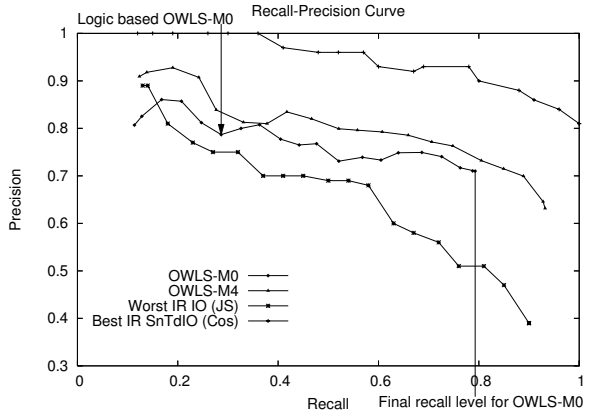

Figure 6: Recall-precision performance of logic based OWLS-M0 vs best hybrid OWLS-M4 vs IR based service I/O matching

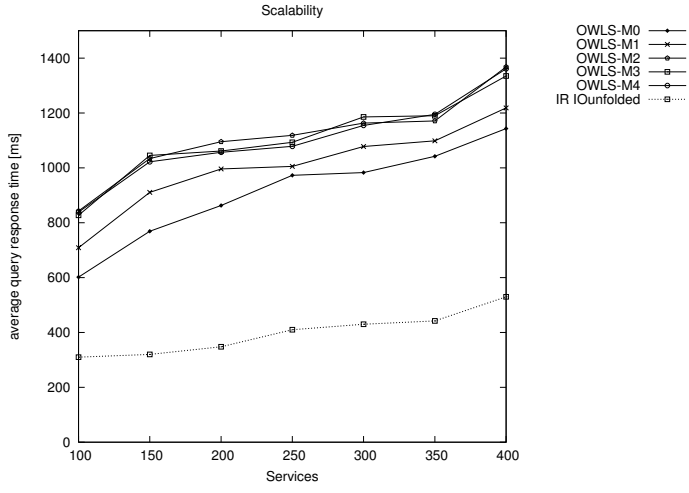

Figure 7: Average query response time of OWLS-MX vs IR based service matching

These experimental results provide, in particular, evidence in favor of following conclusions.

- The best IR similarity metric (Cosine/TFIDF) applied to the concatenated unfolded service profile I/O concept expressions performs close to the pure logic based OWLS-M0 (see figure 6: Best IR SnTdIO (Cos) vs. OWLS-M0). But OWLS-M0 is only superior to IR based matching (cf. figure 6: Worst IR IO (JS) denoting Jensen-Shannon divergence based similarity metric) at the very expense of its recall. However, for discovering semantic web services, precision may be more important to the user than recall, since the set of relevant services is supposed to be subject to continuous change in the semantic Web in practice.

- Pure logic based semantic matching by OWLS-M0 can be outperformed by hybrid semantic matching, in terms of both recall and precision. That is the case, for example, by use of the best performing hybrid matchmaker OWLS-M4 (cf. figure 6). The main reason for this is, that the additional IR based similarity check of the nearest-neighbor filter allows OWLS-M1 to M4 to find relevant services that OWLS-M0 would fail to retrieve.

- Hybrid semantic matching by OWLS-MX can be outperformed by each of the selected syntactic IR similarity metrics to the extent additional parameters with natural language text content are used. That is the case, for example, by applying the cosine similarity metric to the extended set of service profile parameters including not only hasInput and hasOutput but also serviceName and textDescription (cf. figure 6).

- Both pure logic based and all hybrid OWLS-MX matchmakers are significantly outrun by IR based service retrieval in terms of average query response time almost by size of magnitude (cf. figure 7). This is due to the additional computational efforts required by OWLS-MX to determine concept subsumption relationships in NEXPTIME description logic OWL-DL based on the imported large ontologies the OWL-S services refer to.

6. RELATED WORK

Quite a few semantic Web service matchmakers have been developed in the past couple of years such as the OWLS-UDDI matchmaker [16], RACER [11], SDS [12], MAMA [5], HotBlu [6], and [10]. Like OWLS-MX, the majority of them does perform profile based service signature (I/O) matching. Alternate approaches propose service process-model matching [3], recursive tree matching [2], P2P discovery [1], automated selection of WSMO services [20] and METEOR-S for WSDL-S services [19]. Except LARKS [15], none of them is hybrid, in the sense that it exploits both explicit and implicit semantics by complementary means of logic based and approximate matching. To the best of our knowledge, OWLS-MX is the only hybrid matchmaker for OWL-S services yet.

The OWLS-MX matchmaker bases on LARKS [15]. However, LARKS differs from OWLS-MX in that it uses a proprietary capability description language and description logic different from OWL-S and OWL-DL, respectively. Furthermore, LARKS does not perform any subsumes and subsumed-

by nor nearest-neighbour matching, and has not been experimentally evaluated yet.

The purely logic based variant OWLS-M0 of OWLS-MX is quite similar to the OWLS-UDDI matchmaker [16] but differs from it in several aspects. Firstly, the latter makes use of a different notion of plug-in matching, and does not perform additional subsumed-by matching. Secondly, OWLS-M0 classifies arbitrary query concepts into its dynamically evolving ontology with commonly shared minimal basic vocabulary of primitive components instead of limiting query I/O concepts to terminologically equivalent service I/O concepts in a shared static ontology as the OWLS-UDDI matchmaker does.

7. CONCLUSIONS

Our approach to hybrid semantic Web service matching, called OWLS-MX, utilizes both logic based reasoning and IR techniques for semantic Web services in OWL-S. Experimental evaluation results provide evidence in favor of the proposition that building semantic Web service matchmakers *purely* on description logic reasoners may be insufficient, hence should give a clear impetus for further studies, research and development of more powerful approaches to service matching in the semantic Web across disciplines.

ABSTRACT

We present a general method for agents using ontologies as part of their knowledge representation to teach each other concepts to improve their communication and thus cooperation abilities. Our method aims at getting positive and negative examples for a concept only very vaguely understood by a particular agent from the other agents. This agent then uses one of the known concept learning methods to learn the concept in question, involving the other agents again by taking votes in case of conflicts in the received knowledge. This method allows agents that are not sharing common ontologies to establish common grounds on concepts known only to some of them, if these common grounds are needed during cooperation. While the concepts learned by an agent are only compromises between the views of the other agents, the method nevertheless enhances the autonomy of agents using it substantially.

Keywords

ontology, concept learning, multi-agent communication

1. INTRODUCTION

The ability to communicate efficiently is one of the cornerstones of cooperation between human beings. In order to communicate efficiently, not only a common language is needed, people communicating also need to have some basic understanding of world concepts and they can use this basic understanding to teach each other additional concepts, at least up to the point where the understanding of the new concepts by the different people overlaps largely.

If we look at research in multi-agent systems concerning communication between agents, then many researchers have assumed that it is possible to not only establish a common language among agents, but also a complete common understanding of all the concepts the agents communicate about. In cooperative multi-agent systems which aim at solving a particular problem, usually all of the agents are designed by one group of developers and the problem already provides all of the concepts and the needed understanding (i.e. semantics) of them, so that the above assumption is valid. If we look at systems that have agents designed by different developers, many researchers assume that it is possible to have a common ontology for these agents and that the agent developers naturally will integrate this common ontology into their agents, thus allowing for easy communication (and understanding) among agents. But the assumption of a common ontology is often too strong or unrealistic. For many application areas, there is no agreement among developers on one ontology for the area, for many areas the potential ontologies are large, unwieldy and encompass more than a particular agent most probably will ever need and implementing complex ontologies can also easily lead to discrepancies between implementations.

Recently, the idea of having agents *learn* concepts (or languages) from other agents has been suggested as a solution to the problems above (see [3] for learning, resp. making up, a language and [11] for learning a concept). The work in [11] has focused on interactions between two agents only and single concepts, while [3] was not concerned with concepts. In this paper, we present a general method for having agents learn concepts from several other agents and our method also makes use of information from the ontologies in which the concepts to learn are integrated.

The basic ideas behind our method are to have an agent, that realizes that there seems to be a concept it does not currently know of but expects to need to know, query the other agents about this concept by providing features (and their values) or examples the agent thinks are associated with the concept. The queried agents provide the agent with positive and negative examples from their understanding of which of their concepts (i.e. concepts known by them) seem to fit the query which allows the learning agent to use one of the known concept learning techniques from machine learning. To help focus the negative examples, the teaching agents make use of selected relations between concepts from their

ontologies. The agent that wants to learn the concept deals with the fact that the other agents in this group might not totally agree on which examples fit the concept and which not, by letting the teaching agents vote on the examples for which it got contradictory information in the first place. Our learning agent also uses information from the teacher agents about the paths to the concept of interest in their ontologies to prepare its own ontology for potential future concepts it might have to learn.

Our experiments with agents with ontologies representing courses and the organizational unit structure of universities show that our approach allows an agent to learn needed concepts and that what it learns is a compromise of what the other agents think about the concept in question (essentially the common ground of the agents regarding the concept). This is possible, even if the agents do not use the same features. The experiments also show that the use of ontology information allows for more accuracy in the learned concept if the number of exchanged examples is low, thus improving on the amount of information exchanged between agents.

2. BASIC DEFINITIONS

In this section, we will provide some basic definitions about ontologies and agents and we will also provide the instantiations of these concepts that we require for our methods.

2.1 Ontologies and Concepts

The usage of the term "ontology" in (computer science) literature faces problems very similar to the usage of the term "agent": there is no agreed-upon formal definition for the term, but nevertheless it is used very intensively and there are many systems out there that come with a (somehow) build-in definition of the term. Common to most usages of ontology is that it is considered a way for representing objects or concepts in a hierarchy with additional ways to define relationships between these objects/concepts.

This is very nicely reflected by Stume's formal definition (see [9]) who defines a *core ontology* as a structure $\mathcal{O} := (C, \leq_C, R, \sigma, \leq_R)$. C and R are two disjoint sets and the elements of C are called *concept identifiers* and the elements of R are so-called *relation identifiers*. $\leq_C$ and $\leq_R$ are partial orders on C, respectively R, called *concept hierarchy* or *taxonomy* ($\leq_C$), respectively *relation hierarchy* ($\leq_R$). $\sigma : R \rightarrow C^+$ is a function providing a signature for a relation such that $|\sigma(r_1)| = |\sigma(r_2)|$ for every $r_1, r_2 \in R$ with $r_1 \leq_R r_2$ and for every projection π_i $(1 \leq i \leq |\sigma(r_1)|)$ of the vectors $\sigma(r_1)$ and $\sigma(r_2)$ we have $\pi_i(\sigma(r_1)) \leq_C \pi_i(\sigma(r_2))$. If $c_1 \leq_C c_2$ for $c_1, c_2 \in C$, then c_1 is called a *subconcept* of c_2 and c_2 is a *superconcept* of c_1.

By viewing an ontology $\mathcal{O}$ as a structure on top of a set of concepts and a set of relations, this definition is able to cover a lot of the definitions of ontologies in the literature, but without providing a more precise definition of what concepts are, we are far from anything that can be used by agents to provide a basis for communication. Many works in databases and machine learning define concepts as collections of objects that share certain feature instantiations and for this work we will follow this guidance.

So, in the following we assume that we have a set $\mathcal{F} = \{f_1, ..., f_n\}$ of features and for each feature f_i we have its domain $D_i = \{v_{i1}, ..., v_{im_i}\}$ that defines the possible values the feature can have. Then an object $o = ([f_1 = v_1], ..., [f_n = v_n])$ is characterized by its values for each of the features (often one feature is the identifying name of an object and then each object has a unique feature combination). By $\mathcal{U}$ we denote the set of all (possible) objects. In machine learning, often every subset of $\mathcal{U}$ is considered as a concept. In databases and in this work we want to be able to characterize a concept by using feature values. Therefore, a *symbolic concept* C_k is denoted by $C_k = ([f_1 = V_1], ..., [f_n = V_n])$ where $V_i = \{v'_{i1}, ..., v'_{ij_i}\} \subseteq D_i$ (if $V_i = D_i$ then we often omit the entry for f_i). An object $o = ([f_1 = v_1], ..., [f_n = v_n])$ is *covered* by a concept C_k, if for all i we have $v_i \in V_i$. In an ontology according to the definition above, we assign a concept identifier to each symbolic concept that we want to represent in our ontology.

Obviously, the relation $\leq_C$ is supposed to be connected with how concepts are defined. In the literature, taxonomies are often build using the subset relation, i.e. we have

$C_i \leq_C C_j$ iff for all $o \in C_i$ we have $o \in C_j$.

This definition of $\leq_C$ produces a partial order on C as defined above and we will use this definition in the following for the ontologies that our agents use.

From the point of view of knowledge representation the really interesting part of ontologies are the relations in R that a particular ontology allows. This is also the part where we see a lot of differences between different authors. In general, all possible relations between tuples of concepts can be used in ontologies, but usually researchers assume a small set of build-in relations and tool developers sometimes throw in the possibility to have (limited) user-defined relations. But unfortunately, different ontologies can use the same relation identifiers for different build-in relations, so that there is quite some confusion in this area. So, if we have two systems build by different people using ontologies over the same set $\mathcal{U}$ then it is very important to either identify those relations that occur in both ontologies or to find ways how the knowledge contained in the (usage of) relations in one ontology can be used in communications between the systems. In this work, we will show such a usage for one relation that we have called `is-similar-to` with $\sigma(\texttt{is-similar-to}) \in C^2$.

2.2 Agents

A general definition that can be instantiated to most of the views of agents in literature sees an agent $\mathcal{A}g$ as a quadruple $\mathcal{A}g = (Sit, Act, Dat, f_{Ag})$. Sit is a set of situations the agent can be in, the representation of a situation naturally depending on the agent's sensory capabilities, Act is the set of actions that $\mathcal{A}g$ can perform and Dat is the set of possible values that $\mathcal{A}g$'s internal data areas can have. In order to determine its next action, $\mathcal{A}g$ uses $f_{Ag} : Sit \times Dat \rightarrow Act$ applied to the current situation and the current values of its internal data areas.

For the agents that we are interested in, we can instantiate this definition a little bit more. We want to focus on the knowledge representation used by agents, so we start by looking more closely at Dat. We assume that every element of Dat of an agent $\mathcal{A}g$ contains an ontology area $\mathcal{O}_{Ag}$ as defined in the previous subsection that represents the agent's view and knowledge of concepts. For the concepts in the taxonomy of $\mathcal{O}_{Ag}$ there might be additional data, beyond features, that the agent requires from time to time (see Section 3). Naturally, there will be additional data areas representing information about the agent itself, knowledge about other agents and the world that the designer of the agent

may want to be represented differently than in $\mathcal{O}_{Ag}$. But in the rest of this paper, we will concentrate on how the agent uses and manipulates its ontology.

The actions of an agent obviously depend a lot on the application area the agent is designed for. We require our agents to be able to communicate with other agents using information from the agent's ontology and to manipulate this ontology based on information received from other agents and the agent's own deduction actions that include actions performing learning. Again, we will provide more information in the next section.

An element of Sit usually contains parts representing observations of other agents and of the environment the agent is in. In this paper, we assume that among the observations of an agent are all messages send by other agents since the last situation an agent was in. And we will specify the parts of f_{Ag} that deal with the relevant messages and the relevant knowledge in and around the ontology of an agent in the next section.

3. LEARNING OF NEW CONCEPTS

The goal of this research is to develop a method how an agent can learn new concepts for its ontology with the help of other agents. This naturally assumes that not all agents have the same ontology (otherwise learning would not be necessary). In fact, we additionally assume that there are only some base features $\mathcal{F}_{base} \subseteq \mathcal{F}$ that are known, respectively can be recognized, by all agents and that there are only some base symbolic concepts C_{base} that are known to all agents by name, their feature values for the base features and the objects that are covered by them. Outside of this base common knowledge, individual agents may come with additional features they can recognize and additional concepts they know. Agents might refer to the same such features and concepts by different names and they may have features and concepts that have the same name but are not the same. While all the ontologies used by the agents will use as taxonomy the subset-relation, agents may use different other relations in their ontologies and two agents cannot rely on same relation identifiers referring to the same relation and vice versa, again.

Given this setting, agents will develop problems in working together, since the common grounds for communication are not there or too small. To solve this problem, agents need to acquire the concepts outside of C_{base} that other agents have, at least those concepts that are needed to establish the necessary communication to work together on a given task. Our basic idea is to have an agent *learn* required concepts (or at least a good approximation) with the *help* of the other agents. Due to the potential differences in the ontologies of agents, objects that are positive and negative examples for a concept will play the major role in teaching an agent a new concept. We will assume in the following that the identifying name of an object is a feature in $\mathcal{F}_{base}$. We do not see this as a big limitation, since it is usually not too difficult to establish a clear identification of objects. For example, if the objects are part of the environment, pointing to a particular object is sufficient to identify it.

In the following, we will first present the general interaction scheme between agents that is our method to have an agent learn a particular concept. Then we will focus in more detail on the important steps in this interaction scheme.

3.1 Our general interaction scheme

Although we want all agents to be able to learn new concepts, for explaining our interaction scheme we designate one agent, $\mathcal{A}g_L$, as the one that wants to learn a new concept and the other agents, $\mathcal{A}g_1$,...,$\mathcal{A}g_m$, will be its teachers. $\mathcal{A}g_L$ has an ontology $\mathcal{O}_L = (C_L, \leq_C, R_L, \sigma_L, \leq_{R_L})$ and knows a set of features $\mathcal{F}_L$. Analogously, $\mathcal{A}g_i$ has as ontology $\mathcal{O}_i = (C_i, \leq_C, R_i, \sigma_i, \leq_{R_i})$ and knows a set of features $\mathcal{F}_i$. For a concept c known to the agent $\mathcal{A}g_i$, this agent has in its data areas a set $pex_i^c \subseteq \mathcal{U}$ of positive examples for c that it can use to teach c to $\mathcal{A}g_L$. Part of Act_L are actions `QueryConcept`, `AskClassify`, `Learn`, and `Integrate`, while part of the Act_is are the actions `FindConcept`, `CreateNegEx`, `ReplyQuery`, `ClassifyEx` and `ReplyClass`; all with appropriate arguments. These actions form our interaction scheme in the following manner:

1. $\mathcal{A}g_L$ determines it needs to know about a particular concept c_{goal} and performs `QueryConcept`("c_{goal}") to inform the other agents about this need.
2. Each agent $\mathcal{A}g_i$ reacts to $\mathcal{A}g_L$'s query by (see 3.3):
   (a) performing `FindConcept`("c_{goal}"), which leads to a set of candidate concepts C_i^{cand},
   (b) selecting the "best" candidate c_i out of C_i^{cand},
   (c) selecting a given number of elements out of $pex_i^{c_i}$, thus creating p_i,
   (d) performing `CreateNegEx`(c_i) to produce a given number of (good) negative examples for c_i, which we call the set n_i,
   (e) performing `ReplyQuery`($path(c_i)$,p_i,n_i).
3. $\mathcal{A}g_L$ collects the answers ($path(c_i)$,p_i,n_i) from all agents and uses a learner to learn c_{goal} from these combined examples (action `Learn`((p_1,n_1),...,(p_m,n_m))). If there are conflicts, then it resolves them with the help of the other agents using `AskClassify` (resp. `ClassifyEx` and `ReplyClass` by the other agents, see 3.4).
4. $\mathcal{A}g_L$ uses the learned c_{goal} and the collected $path(c_i)$s from the other agents to construct an ontology path C_{path} leading to c_{goal} (see 3.4) within its ontology $\mathcal{O}_L$ (action `Integrate`($path(c_1)$,...,$path(c_m)$)).

The result of this learning/teaching scheme is the description of c_{goal} in terms of $\mathcal{A}g_L$'s feature set $\mathcal{F}_L$ and an updated ontology $\mathcal{O}_L^{new} = (C_L^{new}, \leq_C, R_L, \sigma_L, \leq_{R_L})$. $\mathcal{A}g_L$ will also create a set $pex_L^{c_{goal}}$ in case another agent wants $\mathcal{A}g_L$ to teach it c_{goal}.

3.2 The initial query

In order to initiate the initial query, $\mathcal{A}g_L$ first needs to become aware that there is a concept that it needs to learn. There are a couple of scenarios that can lead to this realization. $\mathcal{A}g_L$ might observe a conversation between other agents in which an unknown concept identifier is used (or an identifier known by $\mathcal{A}g_L$, but in a way that does not make sense). Or $\mathcal{A}g_L$ might be dealing with a set of objects that share certain feature values from $\mathcal{F}_L$ and it wants to know if other agents know more about the similarities of these objects.

Based on these scenarios, we require action `QueryConcept` to have 3 parameters to be used to define c_{goal} to the other

agents:

`QueryConcept`(identifier,{$[f'_1 = V'_1]$,...,$[f'_l = V'_l]$},O_{goal}).
Here identifier is an element of C_i for some agent(s) $\mathcal{A}g_i$, $\{[f'_1 = V'_1],...,[f'_l = V'_l]\}$ is a selection of features $f'_j \in \mathcal{F}_{base}$ and the values $V'_j \subseteq D_{f'_i}$ that $\mathcal{A}g_L$ thinks are related to the concept c_{goal} and $O_{goal} \subseteq \mathcal{U}$ is a set of objects that $\mathcal{A}g_L$ thinks are covered by c_{goal}. Due to the different scenarios from above, each of the three parameters can be empty, if $\mathcal{A}g_L$ does not have any information on the parameter. Also, $\mathcal{A}g_L$ can decide to address only a subset of $\{\mathcal{A}g_1,...,\mathcal{A}g_m\}$ and then it can use as f'_is also features that are known to this subset and itself. If $\mathcal{A}g_L$ uses the identifier parameter, then there is naturally a chance that different agents use this identifier for different concepts. Again, $\mathcal{A}g_L$ might therefore address only some of the agents. Note that if the addressed agents associate different concepts with the identifier, then $\mathcal{A}g_L$ will end up with learning a subconcept of these concepts.

3.3 Answering the query

Due to our basic assumptions about what our agents are not having in common, a teacher agent $\mathcal{A}g_i$ without any additional knowledge about the ontology $\mathcal{O}_L$ of $\mathcal{A}g_L$ is rather limited in what it can put into an answer to the query by $\mathcal{A}g_L$. In fact, we are not even guaranteed that $\mathcal{A}g_i$ can really grasp what $\mathcal{A}g_L$ wants to know, since $\mathcal{A}g_L$ was already limited in its ways to express what concept c_{goal} it wants to know about. But sets of objects are something that all of our agents can communicate to each other, even if they might perceive these objects differently, and therefore we use mostly sets of objects in the answers that our teachers are creating. The answer of $\mathcal{A}g_i$ will also include information about the concept c_i it thinks $\mathcal{A}g_L$ wants to know about and how this concept is placed in $\mathcal{O}_i$, so that $\mathcal{A}g_L$ can use whatever information pieces it can understand (see Section 3.4).

After receiving the query from $\mathcal{A}g_L$, an $\mathcal{A}g_i$ first has to determine which of the concepts in C_i fits the query the best (i.e. what is c_i). Then it has to select positive and negative examples for this concept and finally it sends this information to $\mathcal{A}g_L$.

3.3.1 Finding the best known concept

The query from $\mathcal{A}g_L$ consists of three parts that it uses to describe what concept it wants to learn more about. Due to the differences between agents, each of these parts can point to different concepts that an agent $\mathcal{A}g_i$ knows of. In fact, if $\mathcal{A}g_L$ provides several objects in O_{goal}, they might be classified by $\mathcal{A}g_i$ into several of its concepts. As a consequence, $\mathcal{A}g_i$ has first to collect all the concepts that fulfill the query into a candidate set C_i^{cand} and then it has to evaluate all these concepts to determine the concept that is, in its opinion, the best fit.

A concept is a candidate with respect to identifier, if its identifier is identical to the identifier in the query. A concept $c = \{[f"_1 = V"_1], ..., [f"_p = V"_p]\}$ is among the candidates due to the feature part of the query, if for all $f"_j$ with $f"_j \in \{f'_1, ..., f'_l\}$ –let us assume that $f"_j = f'_a$– we have that $V"_j \subseteq V'_a$. Finally, a concept is also a candidate, if it covers one of the objects in O_{goal}. Note that the last two conditions put all superconcepts of a concept from the candidate set also in C_i^{cand}.

There are many different ways how an evaluation of the candidates can be performed, especially if we allow for criteria coming from the application area the agents are working in. Each of the 3 query parts can contribute to a measure that defines what is "best", but how these contributions are combined can be realized differently. The identifier part does either produce a contribution or not. Every object in O_{goal} also is binary in its contribution. But this favors the more general concepts, so that some additional criterion is needed that makes the count of covered objects relative to the depth of the concept in the taxonomy tree. Finally, the feature part of the query suggests a good fit of a concept if it agrees with the feature values of many of the features used in the query. But this can also be strengthened by looking at how good the fit for a particular feature is.

We will present an example measure for how a concept fits a query in Section 4. Note that in theory different teacher agents could use different such measures. After the best concept c_i for the query is determined, an agent $\mathcal{A}g_i$ includes into its answer information on the path that leads in its taxonomy to c_i and the subtree below c_i's node (we refer to this information by $path(c_i)$).

3.3.2 Selecting positive and negative examples

Since each agent $\mathcal{A}g_i$ stores for each concept c_j in C_i a set $pex_i^{c_j}$ of positive examples for c_j, i.e. a set of objects covered by c_j, coming up with positive example objects for a concept known to $\mathcal{A}g_i$ is not a big problem. While the more examples normally are the better, in our case we have to take into account that the more objects from $pex_i^{c_i}$ are selected, the more expensive the communication becomes and the more effort $\mathcal{A}g_L$ will have to spent on learning. On the other side, less positive examples usually means a less precise result of the learning. Therefore we suggest to have the number of examples communicated to $\mathcal{A}g_L$ by each agent as a parameter of the whole system. Then selecting the appropriate number of elements for p_i is easily realized by randomly sampling $pex_i^{c_i}$.

Selecting negative examples for a concept is not as easy. Obviously, the set of negative examples nex^c for a concept c is defined as

$nex^c = \mathcal{U} - \{o | o \text{ covered by } c\}$.

This can be a very large set and usually different elements of this set provide learners with a different quality of advice. Good negative examples are examples that "nearly" are in the set covered by the concept, a kind of "near-misses" that allow to highlight the borders of a concept. The fact that our agents have ontologies allows us to do a better job in selecting negative examples than randomly selecting out of nex^{c_i} (by $\mathcal{A}g_i$). The key for this better selection is to make use of the taxonomy information $\mathcal{A}g_i$ has and the relations in R_i. The later naturally depends on what relations are available.

Let us first look at the possibilities that the *taxonomy* offers. Each superconcept of the concept c_i –that $\mathcal{A}g_i$ sees as the best concept to answer $\mathcal{A}g_L$'s query– can be used to limit the set of negative examples $nex_i^{c_i}$ that $\mathcal{A}g_i$ should consider for its answer. As a superconcept of c_i, these concepts share a lot of feature values with c_i, so that the elements in their set of positive examples that are not covered by c_i are good candidates for "near-misses". In fact, sibling concepts of c_i or its superconcepts are an even better source for negative examples since all their positive examples are not covered by c_i. Figure 1 indicates these candidates for the selection of negative examples with the help of taxonomy information

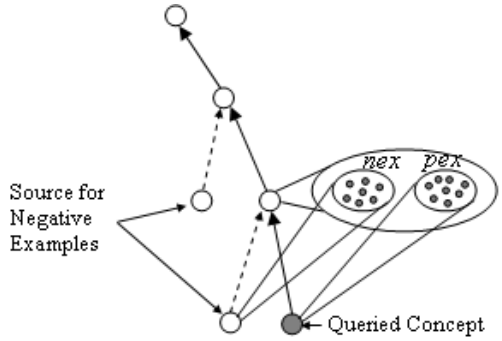

Figure 1: Negative examples using the taxonomy

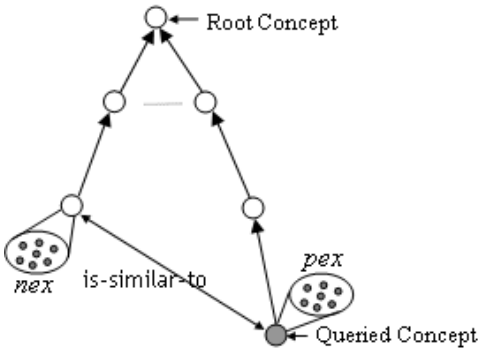

Figure 2: Negative examples using `is-similar-to`

(we use here and in the following the common graphical representation of taxonomies by trees).

Since all agents use the same relation $\leq_C$, all agents can use the taxonomy information to limit the pool of negative examples to choose from. But also information provided by some other relations can be used. As an example, let us look at the usage of the relation `is-similar-to` that we mentioned earlier. The motivation for `is-similar-to` is to allow to express the similarity between two concepts that are far away from each other in the taxonomy tree, but that share a lot of feature values. This makes `is-similar-to` a perfect candidate for helping with the selection of negative examples. Figure 2 shows how we can use concepts that c_i is similar to by using their positive examples as candidates for $nex_i^{c_i}$. After collecting all candidates in $nex_i^{c_i}$, we again select the given number of examples for n_i as a random sample.

Note that an `is-similar-to`-relation can be automatically computed for a given C_i and $\mathcal{F}_i$ by introducing a similarity measure sim_i^f on feature values for each feature $f \in \mathcal{F}_i$ with domain D: $sim_i^f : D \times D \rightarrow [0..1]$. We can create out of this a similarity measure $sim_i^{\mathcal{U}}$ for objects by, for example, summing up the similarities for each feature. More formally, let $o = ([f_1 = v_1], ..., [f_n = v_n])$ and $o' = ([f_1 = v_1'], ..., [f_n = v_n'])$, then

$sim_i^{\mathcal{U}} = \sum_{j=1}^{n} sim_i^{f_j}(v_j, v_j')$

where $sim_i^{f_j}(x, y) = 0$, if $f_j \neq \mathcal{F}_i$.

Out of this, we can create `is-similar-to`$_i$ between two concepts c and c', if $sim_i^{\mathcal{U}}(o, o') \geq simthreshold$ for all $o \in pex_i^c$ and $o' \in pex_i^{o'}$, with $simthreshold$ as a given parameter. While it would be better to use all objects covered by c and c', this can be impossible or at least very expensive, so that we suggest to use the examples that are already there.

3.4 Learning a new concept and path for $\mathcal{O}_L$

Learning a concept, in form of feature values, from a set of positive and negative examples is a problem that is very well researched in literature and there are many algorithms and systems available for this task. Examples are Rocchio (see [6]), k-Nearest-Neighbor (see [5]), and Naive Bayes (see [5]) in our experimental context.

With $pex^{c_{goal}} = \cup_{i=1}^{m} p_i$ and $nex^{c_{goal}} = \cup_{i=1}^{m} n_i$, we have the necessary input for such a learning system, with one potential problem: conflicts between the teacher agents. Due to the differences between agents it can easily happen that the best concepts c_i and c_j that $\mathcal{A}g_i$ and $\mathcal{A}g_j$ identified do not have much in common. The worst case can be that an example that $\mathcal{A}g_i$ sent as being positive for c_{goal} $\mathcal{A}g_j$ sent as a negative one. Obviously, such a contradiction will stop every learner. But we can also have more indirect conflicts where a learning algorithm simply cannot come up with a concept description that covers all objects in $pex^{c_{goal}}$ while not including any objects in $nex^{c_{goal}}$. There are several ways how we can solve this problem and these ways allow us to produce different degrees of willingness to satisfy the teacher agents (by $\mathcal{A}g_L$).

For our system, we have chosen the following conflict resolution. After the learning component of $\mathcal{A}g_L$ has performed `Learn` and produced a more precise c_{goal}, $\mathcal{A}g_L$ will test all elements of $pex^{c_{goal}}$ and $nex^{c_{goal}}$ for correct classification by this new c_{goal}. For all the example objects that are not correctly classified, we get back to the teacher agents and ask them to classify these examples according to the c_i they used to produce their examples. We then treat the answers as votes and have the majority decide how the conflict cases should be classified. Those examples that, according to the vote, are wrongly classified are fed back to the learner with priority. This is repeated until all examples are classified according to the votes. In order to avoid running in cycles we delete examples that keep coming up as misqualified from both example sets (which can be seen as imposing a partial blindness on $\mathcal{A}g_L$ to avoid the problem, but this is definitely something that we can observe in human beings also).

After having created the final description of c_{goal} in terms of $\mathcal{F}_L$, we could use the standard techniques for ontologies to integrate a single new concept into the taxonomy (see [12]). But since the goal of our whole method is to improve the communication between agents, we can use some more of the information provided by the teacher agents to *pre-structure* $\mathcal{A}g_L$'s ontology with concepts that $\mathcal{A}g_L$ will most probably have to learn if it communicates more intensely on the subject of c_{goal}.

The key information used in pre-structuring is the path information send by the teacher agents in their answers to the query. Our pre-structuring uses these paths to create *shells* for concepts that might be useful for future communications. These shells can also be used to indicate to an agent concepts it might want to learn in the future and potential queries for them. For the normal usage of the ontology, we treat shells as non-existent.

Each $path(c_i)$ from an agent $\mathcal{A}g_i$ contains the path in $\mathcal{O}_i$ leading to c_i and the taxonomy tree below c_i in $\mathcal{O}_i$ using the features from $\mathcal{F}_i$ for characterization. We first strip all concepts in $path(c_i)$ that are not in C_{base} of all features

that are not in $\mathcal{F}_{base}$. This creates what we call a concept shell. We then merge shells that are identical in their feature descriptions, both within one $path(c_i)$ and between paths from different agents. Then we combine the shells from all the teachers into one path for $\mathcal{O}_L$ (if there are concept shells that are not comparable with respect to $\leq_C$, then we select the longest path from a concept in C_{base} to c_{goal} that can be formed using the concept shells available; for concept shells smaller than c_{goal} with respect to $\leq_C$ we just create the subtree) and integrate this path into $\mathcal{O}_L$.

4. AN EXAMPLE APPLICATION

Before we present an example for a, in our opinion, very successful application of our ideas from the last section, let us point out that it is relatively easy to construct scenarios in which these ideas may not be very useful. These scenarios have in common that the teacher agents do not only disagree on what concepts fulfill a particular query, their ontologies and their perception of the world, i.e. their $\mathcal{F}_i$'s, are totally different. As a result, their attempts to teach an agent result in total confusion.

If, for example, all teacher agents associate with a particular concept identifier totally different real concepts, then the learning agent will not be able to get useful concepts out of their information. If $\mathcal{F}_{base}$ and C_{base} are empty or nearly empty and $\mathcal{F}_i \cap \mathcal{F}_j = \emptyset$ (or near empty) for all pairs of agents ($\mathcal{A}g_i$,$\mathcal{A}g_j$) (including $\mathcal{A}g_L$), then there is simply no common ground for a successful learning experience. Obviously also a human agent would find it impossible to learn useful information from the teachers in this situation.

With the following application we have chosen an area where the teacher agents have some differences in their "world view", simply because there are different ways how to organize the objects in the world, but where there is nevertheless a large agreement on many things.

4.1 The University Units and Courses Domain

For evaluating our method, we have chosen the course catalog ontology domain (see [2]). The set of objects $\mathcal{U}$ consists of files describing the courses offered by Cornell University, the University of Washington and the University of Michigan. The domain is additionally structured according to the university units of these universities, which creates different ontologies for each of them. In fact, our teacher agents will be agents that each represents one of these 3 universities ($\mathcal{A}g_C$, $\mathcal{A}g_W$, $\mathcal{A}g_M$). The course files (and unit structure) for Cornell and Washington were taken from [2], the ones for Michigan from their web site at [10]. A course file contains course identifier, course description and the prerequisites of a course. Note that this is not a small domain. The three universities together offer 19061 courses and each university's ontology has at least 166 concepts on top of their courses. For each of the following examples, our agents used their full ontologies even if we report only on parts of them.

To represent the courses in terms of features, we had a little bit of preparation to do, borrowing ideas from the field of information retrieval. Obvious features describing a course are its identifier f_{idnt}, a string, and its prerequisites f_{prereq}, a set of course identifiers. Different universities use different systems to create identifiers, so that these features are not really of any help for our purpose. The course description usually determines by which organizational units a course should be taught and the descriptions are text-based.

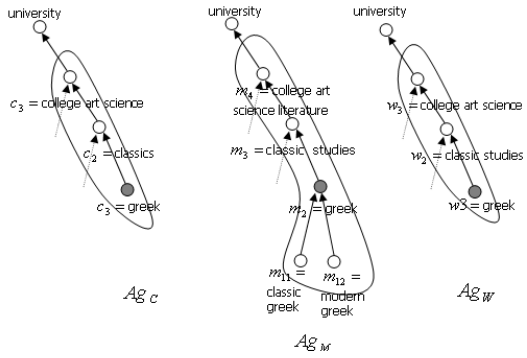

Figure 3: Relevant taxonomy paths of teachers

Defining concepts based on objects that consist of natural language texts is not easy, but an area of quite a lot of interest and practical applications. One way of defining features for such texts to group them is to look for particular words in the texts or word combinations (see [4]). Unfortunately, there is a lot of substitutivity in these word combinations, so that we need features that allow us to express this substitutivity. For example, feature $f_{\texttt{picture,photo,figure}}$: text $\rightarrow$ Boolean is true for a text t, if either `picture` or `photo` or `figure` occurs in t. For our application domain, it is not clear what substitutivities should be considered (just synonyms are not what we are looking for here), so that we base our features for the course descriptions on what we call a set $\mathcal{K}$ of key words. Then we have a feature for each possible subset of $\mathcal{K}$ (excluding the empty set) as described above. Different key sets create different feature sets.

4.2 An example query

To provide a better picture of how our method works, we take a look at a particular query, the relevant parts of the ontologies of the three teacher agents and what an agent can learn from these teachers with regard to this query. Let us assume that the learning agent is supposed to provide someone at a university with suggestions for how a unit concerned with `Greek` should be characterized. This learning agent would pose a query based on providing a key set out of its own key set of words, in our example this query key set would be {`greek, program, attic, literature`} (as stated above, using an identifier does not make much sense here and we are not using example objects for this example due to lack of space). Let us further assume that the relevant concepts in C_{base} are C_{base} = {university} and the relevant concepts in $\mathcal{F}_{base}$ are created using the key set $\mathcal{K}_{base}$ = {`class, course, program, literature, modern, attic, classic, culture, prose, graduate, seminar, grammar, drama, greek`}.

Obviously, different universities can use different key sets of words to express the area a course belongs to, so that this creates additional features for the different agents. In our example, the relevant key sets for the features used in the agents' ontologies are $\mathcal{K}_C$ = {`democritus`}, $\mathcal{K}_W$ = {`tragedy, orator, antique`} and $\mathcal{K}_M$ = {`modern, epic, classic, odyssey, ancient, aristotelian`}. By relevant we mean those key words that really occur in the features that these agents use to characterize the concepts that are related to the query. To make things interesting, we give $\mathcal{A}g_L$ as key set $\mathcal{K}_L$ = {`epic, antique, ancient, tragedy,`

Table 1: Usage of key words in features

key word	$\mathcal{A}g_C$	$\mathcal{A}g_M$	$\mathcal{A}g_W$	a)	b)	c)
`literature`	6	19	6	6	12	15
`greek`	8	55	9	7	26	33
`attic`	3	8	12	3	11	22
`epic`	0	3	0	0	3	3
`antique`	0	0	1	0	0	1
`ancient`	0	6	0	0	4	4
`tragedy`	0	0	3	0	0	3
`orator`	0	0	1	0	0	1

`orator`}.

Figure 3 presents the paths in the taxonomies of the teachers that our system selected as the best concepts for the query. The measure used by the system was calculated as $w_{ident} \times P_{ident}(c) + w_{feat} \times M_{feat}(c) + w_{obj} \times M_{obj}(c)$. w_{ident}, w_{feat} and w_{obj} are weight parameters. In our experiments we used $w_{ident} = w_{feat} = w_{obj} = 1$. $P_{ident}(c)$ is 1, if the concept c's identifier is equal to the identifier in the query and 0 else. The submeasure $M_{obj}(c)$ counts the number of objects from the query covered by c and multiplies it with the length of the path to the concept in the taxonomy. This is then divided by the product of the number of objects in the query and the maximal length of a path in the taxonomy. The submeasure $M_{feat}(c)$ makes use of the key set in the query. For every feature that is true for c, we check if it is formed solely by words from the key set. $M_{feat}(c)$ is the number of these features divided by the number of all features that are true for c.

The set of relevant features for this example is still too big to be easily presented. We used a learner based on Naive Bayes (as described in [4]). This learner can, in fact, use the key sets directly and creates the features implicitely. To provide an idea on how the teachers influence what $\mathcal{A}g_L$ learns, let us look at how many features include some of the key words. As Table 1 shows (a) to c) refer to the concepts learned according to Figure 4, where a) is learned from $\mathcal{A}g_C$, b) from $\mathcal{A}g_C$ and $\mathcal{A}g_M$ and c) from all agents), the difference between the features the different agents know results in rather different numbers for the usage of some key words to make up for words that an agent cannot use in its features. This is especially obvious in the base key set, as the first three examples show.

As the above already suggests, the learned concept c_{goal} is different for different agents used as teachers. For example, with just $\mathcal{A}g_C$ as teacher, among the features enabled in c_{goal} we have $f_{\texttt{attic,prose,greek}}$, which is not enabled by any other agent and also not enabled in the learned concept for the other two scenarios. In the concept learned from $\mathcal{A}g_C$ and $\mathcal{A}g_M$ together, we have the feature using the words `classic, greek, epic, modern, ancient` and `literature` enabled, which is not enabled in the other two scenarios. Finally, learning from all three teachers results in a feature using `greek, tragedy, antique, orator` and `attic` enabled, which is, again, not used in cases a) and b). Remember that an enabled feature means that each course covered by the concept that uses the feature contains at least one word from the set of words associated with the feature!

Figure 4 shows the new taxonomy paths created by prestructuring. The teachers agree on the need for two superconcepts for c_{goal} and $\mathcal{A}g_M$ introduced two subconcepts that are added if $\mathcal{A}g_M$ is one of the teachers. Naturally, we can not associate meaningful names with these concepts

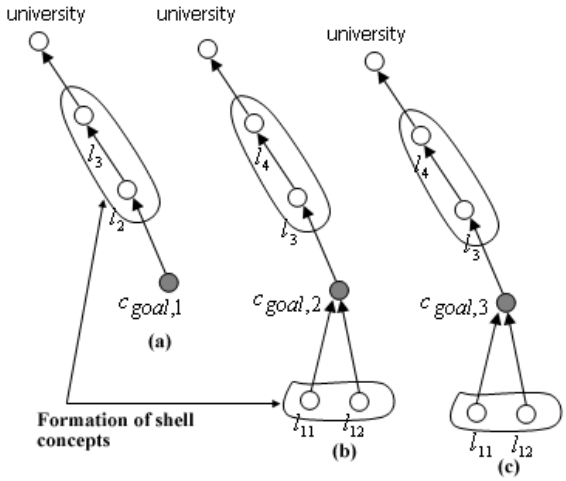

Figure 4: Query results

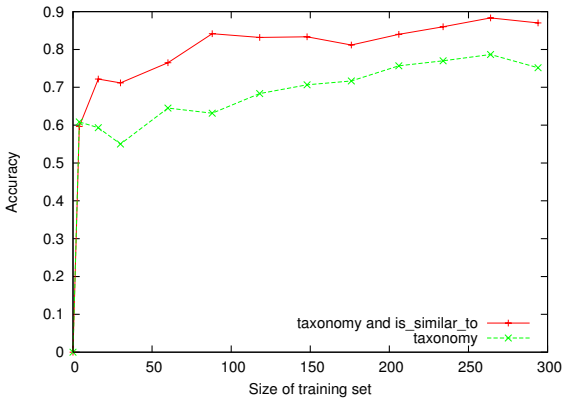

Figure 5: Accuracy results for Mathematics

and, again, there are too many features identifying them to represent them here.

4.3 Using more than the taxonomy

An important question to evaluate our concept is how efficient it is to have an agent learn a new concept. Clearly, the more examples are provided to this agent the better it can learn. But more examples mean more communication overhead, more learning effort and more chances for confusion between the different teachers. We tested several queries in our example domain and present here a typical example. The query is consisting of the key word set {`mathematics, program, arithmetic`} as the feature part and one Mathematics course from each of the three teachers in the example part of the query. Obviously, this query should result in learning the concept "Mathematics Department". Each data point in Figure 5 represents the average value of 5 runs, since the selection of positive and negative examples is performed randomly by the teachers out of the sets they consider (see Section 3.3.2).

Since there is not really a total agreement on what courses constitute Mathematics (beyond a certain strong core, naturally) there is no possibility to achieve 100 percent accuracy. In fact, it can be already debated what accuracy

means in our context, since there is no clearly defined concept $\mathcal{A}g_L$ is supposed to learn. For our experiments, every course classified under Mathematics by one of the 3 teachers was expected to be a positive example, all others a negative one. Naturally, this is not how our approach classifies, but, as Figure 5 shows, we come rather near to that. Figure 5 also shows that using the `is-similar-to`-relation greatly enhances accuracy (especially for small numbers of exchanged examples), due to providing well focused negative examples. $\mathcal{A}g_C$ has in its ontology that Mathematics is similar to theoretical-and-applied-mechanics, computer-science, operations-research-and-industrial-engineering, while $\mathcal{A}g_M$ has it similar to statistics, geological-sciences and astronomy, and $\mathcal{A}g_W$ to statistics, aeronautics-and-astronautics and earth-and-space-sciences. Especially for the range between 50 and 100 training examples, which means 17 to 34 examples per teacher agent, the usage of `is-similar-to` clearly pays off. Note that the "dips" in accuracy are not only due to presenting an average here, more examples also means that more conflicts between teachers occur (remember that using the test set as we do means that a conflict always results in a potential misclassification).

5. RELATED WORK

As already mentioned, most works in literature assume that agents use a common ontology (see, for example, [1]). The works by Williams (see [11]) introduced the idea of using learning to improve the mutual understanding about a concept between two agents. In contrast to our method, Williams uses only a flat repository of concepts, not a real ontology. The learning is used to have only two agents develop a common feature description about a particular concept assuming that the agents share the same perception of objects. No negative examples are used and there is naturally no pre-structuring and no need to deal with conflicts between teachers. [7] presents a method how one agent can train another agent to recognize a concept by providing selected positive training examples. The multi-agent dimension is not addressed and no usage of ontologies is made.

Steels (see [8]), like us, allows for differences in ontologies of agents and wants to minimize these differences for concepts that are of interest to some of his agents. In contrast to us, his agents do not use learning to allow for teaching a concept to an agent, his approach suggests to have the agents cooperatively learn (evolve) a common set of features (using what he calls naming games) and then use a common method for individual agents to create their ontologies by experiencing their environment. For agents with different perceptions, this must pose problems which our approach does not have. But we do not allow for agents to change their feature sets. Also, the emphasis of Steels' work is more on language than concepts.

6. CONCLUSION AND FUTURE WORK

We presented a general concept for improving communication between agents that use ontologies as part of their knowledge representation and that not only have different ontologies but even different features sets that they can recognize. Similar to the behavior of humans, the key idea is to have agents that know a needed concept (but that might not agree totally on all details) teach an interested agent the concept by providing positive and negative examples for the concept that the learning agent feeds into a concept learner. Conflicts are resolved by voting/elimination of examples. We provided an example that illustrates how our method comes up with a concept (and its integration into the agent's ontology) that represents the common ground between the teachers. We also showed in experiments that the use of ontologies allows for a more targeted selection of negative examples resulting in a good understanding of a concept after relatively few exchanged examples.

This work represents a proof-of-concept, not more. We have indicated various parts of our method where alternative realizations of these parts are possible and future work should explore these possibilities. Especially the conflict handling allows for many different ways that could create alternative levels of inclusion of examples. For example, we could have agents vote on every communicated example, not only the clearly problematic ones. Also, selection, resp. filtering, of the available teachers is an interesting future topic. There is also the need for more explorations with the current application, for example by allowing for learning of new features as in [8], and for instantiating our method for other applications.

ABSTRACT

Selecting the right parties to interact with is a fundamental problem in open and dynamic environments. The problem is exemplified when the number of interacting parties is high and the parties' reasons for selecting others vary. We examine the problem of service selection in an e-commerce setting where consumer agents cooperate to identify service providers that would satisfy their service needs the most. Previous approaches to service selection are based on capturing and exchanging the ratings of consumers to providers. Contrary to previous, rating-based service selection, this paper advocates an objective experience-based approach for service provider selection, in which consumers record their *experiences* with service providers rather than the overall, subjective ratings for a provider. A consumer's experience with a service provider is represented using an ontology that can capture subtle details including the context in which the service was requested. When a service consumer decides to share her experiences with a second service consumer, the receiving consumer evaluates the experience using its own context and evaluation criteria. By sharing experiences rather than ratings, the service consumers can model service providers more accurately and thus can select the service providers for their needs more correctly.

1. INTRODUCTION

Selecting partners to cooperate with is a challenging task in open environments, where the participants are autonomous. Open systems are not operated by a central authority that can monitor all agents' activities and ensure that everyone acts in the best interest of others. This implies that for a given service description, a plethora of service providers with substantially different service offerings will exist. A service consumer that is interested in receiving a particular service should then need to select a subset of the service providers that will satisfy her service needs in the best way.

Previous approaches have studied service selection by considering reputation and trust in agent societies. *Reputation systems* enable consumers to rate the service providers in a centralized location. The ratings of the consumers are then aggregated to decide whether a service provider will act as expected [12]. E-bay [1] uses such a reputation system. Whereas in closed settings a central authority (such as the company itself) exists to collect and aggregate ratings, there is no such authority for open systems. Hence the reputation systems are not directly applicable in open systems [16].

Distributed approaches to service selection consider *trust* among entities [17, 16, 9]. Trust captures a truster's expectation from a trustee for a particular service. Most formalizations of trust lack expressiveness and denote trust merely as a rating. However, the episode that leads to the rating is important for understanding the rationale for the rating [5]. For example, a service consumer may give a low rating to a service provider who delivers a book two days late. If the delivery date is not significant for a second service consumer, the first service consumer's low rating will not be significant, either. Hence, consumers should not record and exchange subjective ratings that depend on context, but objective information on actual experiences that can be reevaluated by the recipient based on context.

Accordingly, this paper develops an approach for distributed service selection that allows consumers to capture their experiences with the service providers using ontologies. The ontology used captures the requested service description and the received service in detail. The consumers can then exchange their detailed experiences of service providers rather than plain ratings. A consumer that receives another agent's particular experience evaluates the received experiences individually, considering her own context to decide on which service provider to select. Whereas rating-based approaches reflect the subjective opinion of the raters, the experience-based approach allows the objective facts of the experience to be communicated to the other party.

The rest of this paper is organized as follows. Section 2 explains representation of experiences using an ontology. Section 3 briefly describes our protocol for capturing and exchanging expe-

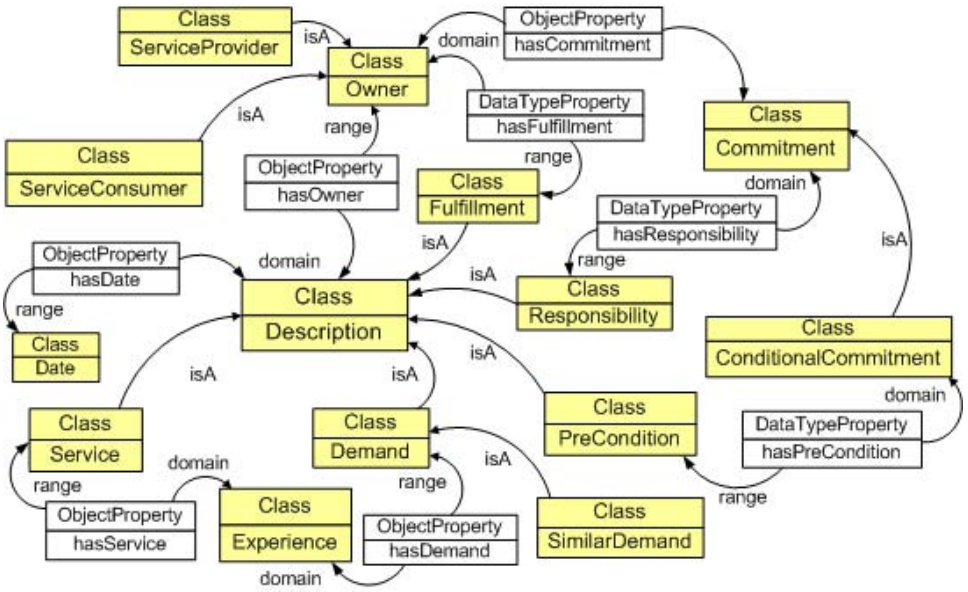

Figure 1: Base level ontology.

riences. Section 4 discusses how service consumers can reason about the experiences of others. Section 5 experimentally evaluates our experience-based service selection with comparisons to rating-based approaches. Section 6 discusses our work with references to the literature.

2. SHARING EXPERIENCES

We consider an architecture where service consumers are looking for service providers to handle their service demands. A *service demand* is expressed in terms of well-defined constraints on attributes of a service such as service completion time, service price, and so on. If a given service does not meet those constraints, then we assume that the owner of the demand be *unsatisfied*. However, another service consumer having weaker demand constraints could potentially be *satisfied*. If consumers only expose their levels of satisfaction (e.g., with a rating), the former service consumer will reveal a low level of satisfaction to the latter consumer. Even though the latter service consumer might have been satisfied with the service provider, she will not choose to interact with the service provider. Instead, if the latter consumer can use the *objective experience* data of the former by knowing the requested and supplied service characteristics, then she can make an informed choice. Consequently, a service consumer can model the service provider using the objective experience data of herself and other service consumers. Example 1 demonstrates how modelling of service providers using actual experiences plays an important role in making right decisions. Model of a service provider may be almost the same for different service consumers but interpretation of the model depends on the specific service consumer, her demand characteristics, and her satisfaction criteria.

EXAMPLE 1. *Consider a book seller who is competent in urgent deliveries to many places except Iowa City. If a service consumer wants an urgent delivery to Iowa City, she can use actual experiences of other consumers to model the service providers and recognize that the service provider could not make timely deliveries to Iowa City and choose another seller instead. Experience ontology should then capture the delivery location to express such nuances in experiences.*

Using objective experience data is promising for the selection of service providers. However, the following challenges need to be addressed:

- How will service consumers express their service demands and experiences?
- How will the experiences of interest be collected by a service consumer?
- How will service consumers use experiences to model service providers and to make decisions?

Service consumers use a common experience ontology for the specified service domain. This ontology covers the fundamental concepts (such as demand, service, and experience), which exist in the base level ontology and domain specific concepts and properties, which exist in the domain level ontology. Using those concepts and properties, a service consumer can express her service demands and experiences.

2.1 Base Level Ontology

The base level ontology (Figure 1) covers domain independent concepts of the experience ontology. Base level ontology is centered around the *Experience* class, whose instances represent experiences of service consumers. This is motivated by the concept of experiences in real life. An experience is a combination of what a consumer request from a service provider and what the consumer receives at the end. Accordingly, in the ontology, an experience consists of a service demand and supplied service for the demand. For this purpose, *Demand* and *Service* classes are included in the base ontology. Both demand and supplied service concepts are descriptions of a service for a specific domain and hence share a number of properties. In order to represent domain specific descriptions, *Description* class is introduced in base level ontology and it is extended in domain level ontology. This class includes generic information to describe basic concepts in the ontology. For example, descriptive classes such as *Demand* and *Service* are sub-classes

of *Description*. Domain-dependent properties of *Description* class can be used to describe service demands, supplied services, responsibilities and fulfillments of sides during transactions. These properties are shown in domain level ontology.

Each *Description* has an owner and a date. *Owner* class is used to represent owners of descriptions. For a demand, owner is a service consumer and for a service, owner is a service provider. *ServiceConsumer* and *ServiceProvider* classes are subclasses of *Owner* class and represent service consumers and service providers, respectively. *Date* class represents the date of description. For an instance of *Service*, *Date* refers to the date of supplied service, whereas, for an instance of *Demand*, it refers to the date on which the demand is created.

An owner may have commitments [15]. Commitments are used to capture the responsibilities of a debtor to a creditor. A commitment always has an instance of responsibility. This means that the owner of the commitment is responsible for the realization of conditions described in the responsibility instance. Example 2 demonstrates a simple responsibility instance. *Commitment* and *Responsibility* classes are used to express commitments and responsibilities respectively in the experience ontology. As a result of transactions, parties have fulfillments. Fulfillments are accomplishments of responsibilities and are denoted with the *Fulfillment* class. *Fulfillment* and *Responsibility* classes are subclasses of *Description*. Owners of responsibilities or fulfillments can be service consumers or providers depending on the context.

EXAMPLE 2. *If a service provider has a commitment and responsibility of the commitment has toLocation property referring to New York City and has hasShipmentCost property referring to 5$, this means that the service provider is responsible for the delivery of the goods to New York City with a shipment cost of 5$.*

Unlike commitments, conditional commitments have preconditions [15]. A conditional commitment $CC(X, Y, P, Q)$ denotes that if the precondition P is carried out by Y, X will be committed to carry out responsibility Q. In this definition, Y is the owner of the precondition and X is the owner of responsibility. *ConditionalCommitment* and *Precondition* classes are used in the ontology to specify conditional commitments and preconditions. *ConditionalCommitment* class is a subclass of *Commitment* and *Precondition* class is subclass of *Description*. Conditional commitments can be used to represent contracts and offers made by service consumers and providers. An example case is demonstrated in Example 3.

EXAMPLE 3. *If the provider makes the shipment one week early, the consumer is committed to pay 1100$ for a product whose actual value is only 1000$. Service providers can also make offers using conditional commitments. The ontology can represent such contracts in demands as well as in offers.*

A service consumer may want to communicate with other service consumers with similar demands. But similarity is a subjective concept and may change for each consumer. To allow a consumer to express her description of a similar demand, *SimilarDemand* class is included in the experience ontology. *SimilarDemand* class is a subclass of *Demand*. A service consumer can express what a similar demand is with respect to her similarity criteria using Semantic Web Rule Language (SWRL) [2]. That is, if a consumer has a particular service demand and a list of others' experiences, then she can apply the SWRL rule to select those experiences in which the service demands were similar to that of her own. If the consumer makes her SWRL rule for similar demands public, other consumers can also use this expression of similarity to reason about whether their past service demands were similar to the demand of the consumer or not.

```

    </swrlx:predicateAtom>
  </ruleml:_body>
</ruleml:imp>
```

Figure 2: Example KAON2 rule for similar demands

We use KAON2 [3] to perform the mentioned reasoning on experiences. In addition to OWL predicates, KAON2 supports some useful non-OWL predicates such as *ifTrue* and *evaluate* to test and evaluate logical and mathematical expressions. A simple rule for similarity is shown in Figure 2. In this rule, the consumer states that a demand for a service is similar demand only if the demand requires a refundable service in addition to a delivery duration less than or equal to 14 days. Unlike this example, rules for similarity can contain complicated logical statements about demand properties and conditional commitments.

2.2 Domain Level Ontology

Domain level ontology captures domain specific properties and concepts. Core class of domain level ontology is *Description* class. Domain specific properties of *Description* class is used to describe service demands, supplied services, responsibilities and fulfillments of parties during transactions. A domain level ontology for online shopping is shown in Figure 3. Properties of Description class in this ontology are *hasShoppingItem*, *toLocation*, *hasDeliveryType*, *hasDeliveryDuration*, *hasShipmentCost*, and *hasPrice*. These properties refer to shopping items, delivery location, delivery type, delivery duration, shipment cost and price respectively. Some boolean properties are also included in this set of properties: *isRefundable* and *hasConsumerSupport*. These properties indicate whether the transaction is refundable or not and whether the service provider supplies consumer support or not. The range of *hasShoppingItem* property is *ShoppingItem* class. This class has properties, *hasQuantity*, *hasUnitPrice* and *hasQuality*. The range of *hasQuality* property is *Quality* class. This class describes quality properties of shopping items. The properties of *Quality* class are not depicted because of space restrictions.

The properties of *Description* class also have slightly different meanings for different concepts. For example, *hasPrice* property refers to the money a consumer is willing to pay for a service if it is used to describe a service demand. This property refers to the money the consumer is requested to pay for the supplied service if it is used to describe provided service. If *hasPrice* is used to describe a responsibility, *hasPrice* refers to the money a service consumer promises to pay for a service or it refers to the money a service provider will accept for a service, depending on the owner of the responsibility. For the first case, service consumer is the owner of responsibility and for the second case owner is service provider. If

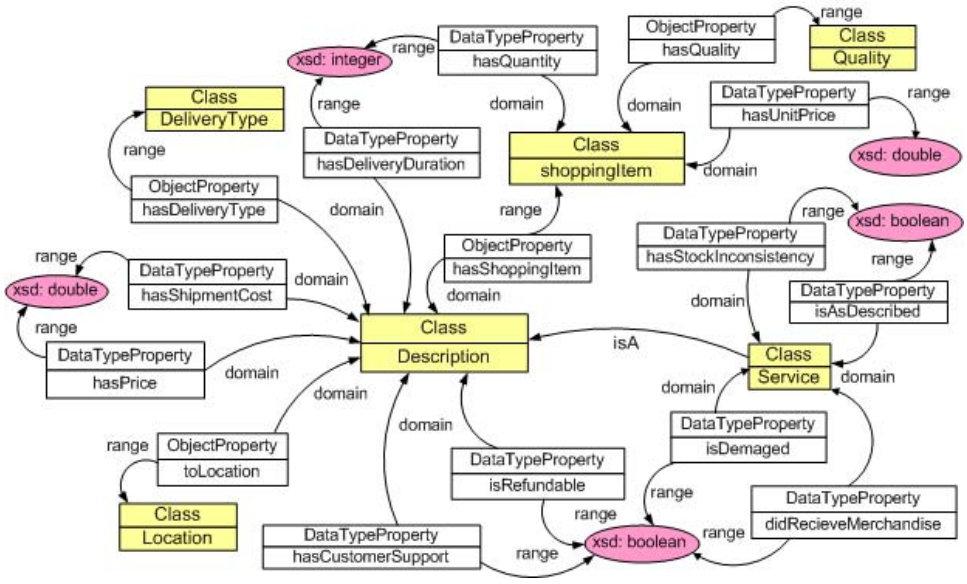

Figure 3: Domain level ontology for online shopping.

hasPrice is used to describe a fulfillment of a service consumer, *hasPrice* refers to the money paid by the service consumer for the specified service.

In addition to the properties of *Description* class, concepts in the ontology may also have domain-specific properties that other concepts do not have. For example, for consumer goods domain, properties such as *didRecieveMerchandise*, *hasStockInconsistency*, *isAsDescribed* and *isDemaged* are included as properties of *Service* class in domain level ontology. The property *didRecieveMerchandise* denotes whether the merchandise is received by the consumer or not. The *hasStockInconsistency* property denotes if the provider claimed to have the product in stock even though it was not. Other properties can be added to this ontology.

3. BUILDING A CONSUMER SOCIETY

A consumer society emerges as a result of consumers' need to retrieve experiences of other consumers. Each service consumer in the society is represented with an agent that is uniquely identified (possibly by an IPv6 address). Each service consumer knows only a subset of all consumers in the society and lists these consumers in an *acquaintance list*. An acquaintance list is a dynamic list of service consumers having service demands classified as similar demand by the owner of the list. When a new service consumer joins the society, its acquaintance list is populated with a small number of randomly chosen service consumers. Acquaintance lists are not symmetric: X may be on Y's list but that does not mean that Y will be on X's list. Each consumer collects others' experiences in an *experience repository*. Each time a service consumer makes a decision, it uses the experiences in this repository. The service consumer refreshes and updates its experience repository periodically by removing old experiences and adding new experiences.

Initially, service consumers do not have any experiences. When a service consumer X needs experiences for reasoning on which service provider to choose, it should discover other service consumers having similar demands and should populate its acquaintance list with those service consumers and their service demands. In real situations, consumers usually change their demand characteristics for the same service domain. Example 4 illustrates such a case. Hence, it may be necessary to collect relevant experiences periodically. In order to accomplish this, a consumer follows the procedure summarized in Algorithm 1 [6].

EXAMPLE 4. *A consumer living in Istanbul orders a best seller for himself and a second copy for his brother living in Iowa City. For the first book, the price is more important than delivery duration. However, the second book is a birthday present and must be delivered on time. For this order, delivery duration is more important than price for the consumer.*

Algorithm 1

```
1:  Decide Shopping
2:  if (Shopping) then
3:     Check Experience Repository
4:     while (Not Have Enough Experience) do
5:        Check Acquaintance List
6:        if (Not Have Enough Acquaintance) then
7:           Get New Acquaintances: Using PDM or RAM
8:        end if
9:        Get Experiences: Using REM
10:    end while
11:    Select Provider
12: end if
```

When a service consumer decides to receive a service (Line 1), it checks its experience repository. In order to make reliable decisions, the service consumer should compute the minimum number of experiences for decision making within a 99% confidence interval [11]. If the number of experiences in the repository is not enough, the service consumer collects new experiences. However, in order to collect new experiences, the consumer should have sufficient number of acquaintances. If it does not have, it should increase the number of its acquaintances (Lines 5, 6).

To increase its acquaintances, a consumer can use two messages: *Peer Discovery Message (PDM)* and *Request for Acquaintances Message (RAM)*. Both PDM and RAM messages contain an SWRL rule that expresses the similar demand criteria of the originator of

the message. When a consumer Y receives a PDM message, it checks if its service demands are similar to that of the originator X. If so, it notifies X and X adds Y as a new acquaintance entry in its acquaintance list. This entry contains identity of Y and its demands classified as similar demand by similarity criteria of X. The consumer Y also forwards the request to a set of service consumers in its acquaintance list. Y selects consumers having demands similar to demand of the originator to forward the request. If there is no such consumer, Y randomly selects consumers from its acquaintance list. How long the request is going to be forwarded is controlled using a time-to-live field. All other agents that receive the request act the same way Y does. When Y receives a RAM message from the originator X, it checks its acquaintance list for entries containing consumers having demands similar to the demand of X. Then Y sends these entries to X and X can add these entries to its acquaintance list.

The service consumer populates it acquaintance list through PDM and RAM messages. After having sufficient number of acquaintances, the consumer uses *Request for Experience Message (REM)* to collect new experiences (Line 9). Interestingly, an REM message also contains a rule for expressing similar demand criteria of the sender. When service consumer Y gets an REM message from service consumer X, it evaluates its demands in its experiences using the similarity criteria in the REM. Later, it can send its experiences to X if the experiences have similar demands with respect to similarity criteria encapsulated in the REM, so that X can populate its experience repository with these experiences. After collecting sufficient number of experiences, X uses experiences in its repository for decision making.

4. MODELLING SERVICE PROVIDERS

When a service consumer decides to receive a service, it models each service provider using the experience data available in its repository and selects a provider with the highest probability to satisfy its needs. In determining a suitable provider, the consumer uses information contained in actual experience data. The consumer can make use of experiences by giving them different weights: for example, it can give more weights to its own experiences than the experiences of others. Demand and service specifications within experiences are received in the form of ontologies, but then they can be converted into internal representation of the service consumer in order to speed up decision making.

For modelling service providers, aggregation of their past service offerings is used. To aggregate the experience instances, agents can use various methods. The method used in the simulations is parametric classification. In this method, the service consumer models each service provider and builds a multidimensional Gaussian model for each service provider using the collected experience data related to that provider. There are two classes for each model: satisfied and dissatisfied.

Demand and commitment information in each experience is represented as a vector. Each field in this vector is extracted from the experience ontology. These fields may correspond to property values in experience ontology such as service price. Then, supplied service for this demand is classified as satisfied or dissatisfied with respect to satisfaction criteria of the consumer. The (vector, class) pairs are used as training set.

For each class, the variance and the mean are extracted from the training set. Those parameters are used for modelling of the class. Then, for each of the classes, a discriminant function is defined to compute the probability of satisfaction [8]. The service consumer performs this computation for every service provider and chooses the provider with the highest satisfaction probability.

5. SIMULATIONS

In order to demonstrate the performance of the proposed methods, we implemented a simulator and conducted simulations on it. The main purpose of these simulations is to see the effect of our model on the selection of an appropriate service provider for a service consumer. In the simulator, two types of service provider selection strategies are implemented and compared with each other in terms of achieved satisfaction. Those strategies are explained below.

- **Service Provider Selection Using Experiences (SPS_{EXP}):** This strategy uses the proposed method for service provider selection. Experiences related to service demand of an agent are collected by the agent and decisions are made using those experiences.

- **Service Provider Selection Using Ratings ($SPS_{ratings}$):** For a new service demand, a service consumer agent can select a service provider using ratings from other consumer agents. In this strategy, in order to make better satisfaction-targeted selections, ratings are taken from those agents who have similar demands with respect to similarity criteria of the agent. So, both SPS_{EXP} and $SPS_{ratings}$ actually use the information from the same service consumers for a given decision process. $SPS_{ratings}$ uses ratings while SPS_{EXP} uses experiences.

To be more focused, the simulations enforce agents to make decisions based on others' experiences rather than their previous experiences. As is the case with real world, service consumers periodically change their service demands. This is done to allow variations on context such as the case shown in Example 1.

5.1 Simulation Environment and Settings

The mentioned simulator is implemented in Java and KAON2 is used as OWL-DL reasoner [3]. Simulations are run on an IBM server with 2.8 GHz CPU and 4.0 GB RAM under Windows 2003 server OS. Simulations are repeated 10 times in order to increase the reliability.

In the simulations, initially there are no experiences accumulated in the agent society yet. As time goes by, the number of experiences increases. During decisions, each agent uses only the experiences of others. Each service consumer changes its demand characteristics after receiving a service with a predefined probability denoted as P_{CD} and collects experiences for its new demand. Each service consumer has a probability of requesting a service for any epoch. This probability is uniformly chosen between 0 and 1. In other words, only around 50% of consumers consume service at a given epoch. An online shopping market with 20 service providers and 400 service consumers are simulated in the simulations. Simulations are run for 100 epochs. Experiences expire after 20 epochs to keep experience repositories fresh and small. Simulations are also conducted for other settings, because of space limitations they are not shown here. Simulation results for other settings are comparable to results shown in Section 5.2.

Note that service consumer X may find the demand of service consumer Y similar to its own, but the service provider that satisfies the demand of Y may not satisfy the demand of X. This could be the case because the satisfaction criteria of Y may be highly different or conflicting with the satisfaction criteria of X. This fact is also imitated in the simulations. That is, a fraction of the service consumers who have the similar service demand to X have a satisfaction criteria that is different from the satisfaction criteria of

X. This fraction is denoted with β. The remaining consumers have satisfaction criteria identical to that of X.

In the simulations, service characteristics of a service provider are generated as follows. Each property of *Service* class represents a dimension in a multidimensional service space. Dimensions of service space used in the simulations are tabulated in Table 1. Each service provider has a multi-dimensional region called service region in this service space. This region is randomly generated. Service space and service regions have 15 dimensions. Service region covers all of the services produced by the service provider.

EXAMPLE 5. *If a consumer located in Istanbul orders two books titled Anagrams from a service provider, then the service that the provider delivers will be constructed as follows: The properties that are specified (shopping item, quantity and location) will be fixed. For the remaining attributes, the service provider will choose random values making sure that the values stay in the range of its service region. So, for this example, the degree of freedom for generating services will be reduced to* 12.

Service description of service providers is enhanced by adding conditional commitments to service regions. Conditional commitments are produced using functions of service space dimensions. Example 6 depicts a production of conditional commitment. Similar conditional commitment functions are generated between other service attributes.

EXAMPLE 6. *If one book is bought, unit price will be 12$ and if four books are bought, unit price will be reduced to 6$. Such conditional commitments are represented using multi-dimensional functions. For the previous example, a non-linear function of quantity and unit price is used, (*$UnitPrice = 8/Quantity + 4$*).*

Demand of a service consumer is generated as the following. Demand space is constructed by removing dimensions of service space, which do not belong to *Demand* class. Then, a region named demand region is chosen randomly. Center of this region represents the demanded service. If provided service for this demand stays within the margins of demand region, the service consumer having this demand gets satisfied, otherwise she gets dissatisfied. If the shipped products are damaged or merchandise is not received, the consumer also gets dissatisfied. Demands are generated so that each demand will be satisfied by at least one service provider.

Similar demand criteria for the service consumer is created as the following. A new region named *similar demand region* is constructed by removing some dimensions of the demand region. Number of dimension to be removed and these dimensions are chosen randomly. Service demands staying within the margins of the *similar demand region* is classified as similar demand by the consumer. In simulations, experience ontology is used to describe experiences and similar demand specifications as explained in Section 2.

Table 1: Dimensions of service space and their ranges

Dimension Name	Type	Range
hasShoppingItem	Integer	1 - 1000
toLocation	Integer	1 - 100
hasDeliveryType	Integer	1 - 6
hasDeliveryDuration	Integer	1 - 60
hasShipmentCost	Double	0 - 250
hasPrice	Double	10 - 11000
hasUnitPrice	Double	1 - 100
hasQuantity	Integer	1 - 100
hasQuality	Integer	1 - 10
isRefundable	Boolean	0 - 1
hasConsumerSupport	Boolean	0 - 1
didRecieveMerchandise	Boolean	0 - 1
hasStockInconsistency	Boolean	0 - 1
isAsDescribed	Boolean	0 - 1
isDemaged	Boolean	0 - 1

5.2 Simulation Results

This section summarizes the results of the simulations. There are two primary parameters in the simulations: P_{CD} and β. Let X be a service consumer making service provider selection, and S be the set of service consumers having demands similar to the demand of X with respect to similarity criteria of X at the time X makes a decision. When X is using $SPS_{ratings}$ for decision making, it takes ratings only from consumers in the set S and X takes experiences from these service consumers while it is using SPS_{EXP} for decision making.

Figure 4 shows the simulation results for P_{CD}=0, β=0.5. This is the case when the consumers do not change their service demands and half of the consumers in set S will have satisfaction criteria conflicting with the satisfaction criteria of X.

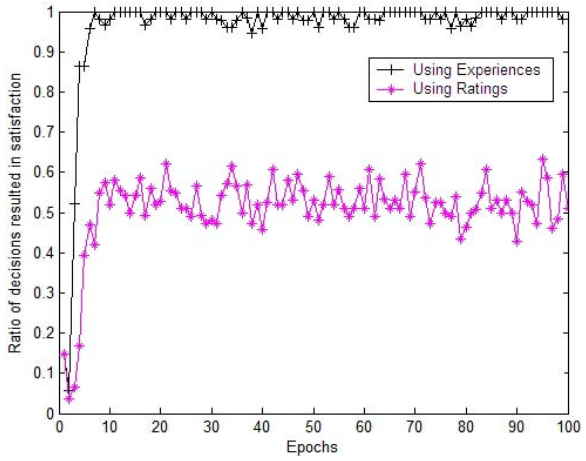

Figure 4: Simulation results for the settings: 20 service providers, 400 service consumers, P_{CD}=0, β=0.5.

When this is the case, only 50% of the services lead to satisfaction of service consumers if these service consumers use $SPS_{ratings}$. On the other hand, service consumers using SPS_{EXP} are almost always satisfied with the supplied service. This is because only half of the ratings taken from the consumers in S lead to decisions that result in satisfaction on the average. However, the other half of the ratings lead to dissatisfaction.

However, as was illustrated in Example 4, consumers change their demand based on circumstances. Figure 5 shows simulation results for parameters P_{CD}=0.2 and β=0. This means that a consumer will change its current service demand with a probability of 0.2 after receiving a service. Figure 5 indicates that the performance of $SPS_{ratings}$ decreases seriously with time, where as the performance of SPS_{EXP} is constant around 100% satisfaction. Since the ratings of a consumer will be aggregation of its past transactions for all of its previous demands, as the consumers change their demands, their ratings will be more misleading than before. However, SPS_{EXP} uses actual experience data, which is free of any evaluation and uses this information for building models of service providers. Hence, as seen in the Figure 5, SPS_{EXP} leads to decisions with 100% satisfaction but satisfaction ratio of

$SPS_{ratings}$ decreases as consumers change their demands.

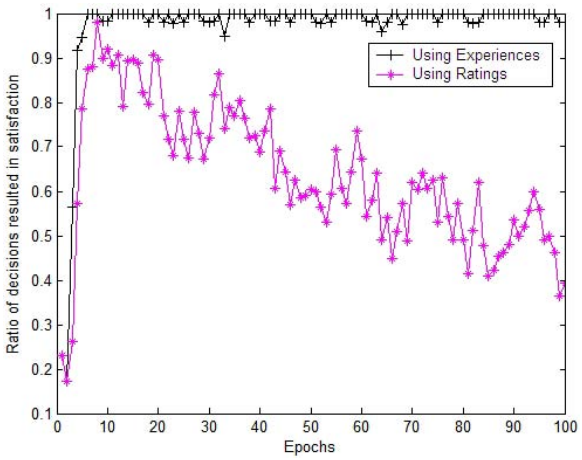

Figure 5: Simulation results for the settings: 20 service providers, 400 service consumers, P_{CD}=0.2, β=0.

Figure 6 shows simulation results for parameters P_{CD}=0.2 and β=0.5. This shows that the consumers will change their service demand with a probability of 0.2 and half of the consumers with the same demand will have conflicting satisfaction criteria. Performance of $SPS_{ratings}$ decreases further for these settings. However, for SPS_{EXP}, satisfaction ratio is around 1 after 5th epoch (before 5th epoch, there are not enough experiences accumulated in the environment for the modelling of service providers). This means that proposed method almost always leads to satisfaction of consumers. In order to see influences of β and P_{CD} on the satisfaction ratios achieved by SPS_{EXP} and $SPS_{ratings}$ strategies, simulations are repeated for different β and P_{CD} values.

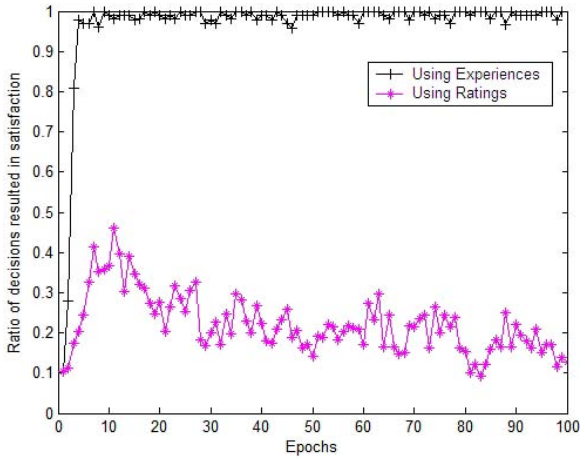

Figure 6: Simulation results for the settings: 20 service providers, 400 service consumers, P_{CD}=0.2, β=0.5.

Average ratio of satisfactions for these simulations are shown in Table 2 and Table 3. Performance of $SPS_{ratings}$ decreases considerably with an increase in the value of β or P_{CD}. These parameters are independent of each other. So, combinatorial effect of these parameters on the performance of $SPS_{ratings}$ is the multiplication of influences of each parameter. Simulations show that proposed method, SPS_{EXP} is robust to changes in β and P_{CD} parameters.

Unlike $SPS_{ratings}$, performance of SPS_{EXP} does not change with changing β and P_{CD} values as well as the achieved satisfaction is 100% if service consumers use SPS_{EXP} for decision making.

Table 2: Average ratio of satisfaction with respect to different β values (P_{CD} is set to 0).

β	0	0.1	0.2	0.3	0.4	0.5
SPS_{EXP}	0.97	0.97	0.975	0.98	0.98	0.98
$SPS_{ratings}$	0.95	0.85	0.76	0.68	0.61	0.53

Table 3: Average ratio of satisfaction with respect to different β and P_{CD} values.

P_{CD}	SPS_{EXP}		$SPS_{ratings}$	
	$\beta = 0$	$\beta = 0.5$	$\beta = 0$	$\beta = 0.5$
0.0	0.97	0.97	0.95	0.53
0.1	0.97	0.96	0.72	0.35
0.2	0.97	0.97	0.56	0.28
0.4	0.98	0.98	0.42	0.18
0.6	0.98	0.97	0.37	0.15
0.8	0.97	0.98	0.32	0.13
1.0	0.98	0.98	0.28	0.12

For the setting β=0 and P_{CD}=0, satisfaction ratio of the strategy $SPS_{ratings}$ approaches 1. However, this setting is far from reflecting the real world. If a consumer classifies the demand of another consumer as similar demand, any provider satisfying the latter will also satisfy the former in case of β=0. This means that satisfaction criteria of the latter is identical to satisfaction criteria of the former. Therefore, ratings will be adequate for the right selection.

6. DISCUSSION

Previous approaches for service provider selection are mostly based on ratings that are inherently subjective. Instead, we are proposing to represent the steps that result in the rating, such as the requested service, the received service, and so on explicitly. This enables the collected information to be reinterpreted based on context. The performed simulations show that the use of experiences improves the decisions of the service consumers and increase the overall satisfaction significantly compared with the rating-based service selection strategy.

Current service provider selection strategies accept ratings as first-class citizens, but do not allow more expressive representations like we have here. Whereas rating-based approaches assume that the ratings are given and taken in similar contexts (e.g., in response to similar service demand), we can make the context explicit. This allows agents to evaluate others' experiences based on their needs. Thus, the use of experiences improves the satisfaction ratio of the consumers.

Different AI techniques, such as case-based reasoning (CBR) can also be applied on objective experience data to select service providers. In [7], we propose a CBR approach for service selection and compare it with the parametric classification. In the CBR approach, a service consumer collects the most similar experiences from other service consumers. Then, the consumer evaluates the supplied services within these experiences using its satisfaction criteria and selects the service provider which provides the most satisfactory service. When service providers do not change the quality of their services, both reasoning techniques perform equally well

in finding service providers. However, CBR approach finds the service providers in a shorter time than the parametric classification. On the other hand, if the service providers vary their service offerings even a small percentage, then the CBR approach performs much worse than the parametric classification.

FIRE [9] is a trust and reputation model consisting of four components: interaction trust, role-based trust, witness reputation and certified reputation. Witness reputation component is directly related to our approach since it allows agents to locate others by making use of other agents' past experiences. However, in FIRE the past experiences are captured only as ratings. However, in our approach, agents exchange their experiences in the form of ontologies so that they can represent their demands, received services, and so on in more depth.

Sen and Sajja [13] develop a reputation-based trust model that is used for selecting processor agents for processor tasks. Each processor agent can vary its performance over time. Agents are looking for processor agents to send their tasks to using only evidence from others. Sen and Sajja propose a probabilistic algorithm to guarantee finding a trustworthy processor. In our framework, service demands among agents are not equivalent; hence a provider that is trustworthy for a consumer need not be so for a different consumer.

Yolum and Singh study properties of referral networks for service selection, where referrals are used among the service consumers to locate the service providers [16]. Current applications of referral networks also rely on exchanging ratings. Hence, suffer from circulation of subjective information. It would be interesting to combine referral networks with the ontology representation here so that agents can exploit the power of ontologies for knowledge representation as well as referrals for accurate routing.

Zhang *et. al.* propose a multiagent approach for distributed information retrieval task [18]. In their work, each agent has a view of its environment called agent-view. The agent-view structure of an agent contains information about the language models of documents owned by each agent. An agent-view reorganization algorithm is run to dynamically reorganize the underlying agent-view topology. An agent-view is analogous to acquaintance list structure in our work. Zhang *et al.*'s protocol does not use ontologies or description logic reasoners during information retrieval. However, if their protocol is modified to accommodate the experience ontology and DL reasoners, their protocol can be used for retrieving experiences instead of the protocol that we have proposed in Section 3.

Soh and Chen propose a multiagent approach to improve distributed information retrieval performance by balancing ontological and operational factors [14]. In this work, collaborating agents enhance their performance by learning ontologically and operationally. Soh and Chen show that their proposed approach is able to improve the quality of the collaborations in terms of the response time, quality of the retrieved results, the number of neighbors contacted and message complexity. A similar approach can also be applied to our work in order to improve quality of collaboration.

Maximilien and Singh develop a QoS ontology to represent the quality levels of service agents and the preferences of the consumers [10]. Their representation of QoS attributes is richer (such as availability, capacity, and so on), however, their ontology does not represent commitments and thus business contract as part of the ontology. Further, their system does not allow reasoning by agents individually as we have developed here.

As future work, we plan to study the role of contracts in service selection. Further, we plan to extend our ontology using OWL-S [4] to make our approach applicable for Web services.

ABSTRACT
This paper introduces a new design method for multi-agent systems (MAS) that incorporate logic programming. The DigitalFriend is an example of a MAS with a built-in logic language interpreter, which is aimed at having the end-user as developer. It uses small fragments of logic as dynamic *glue*, bringing together numerous sub-agents that may exist as Web services. However, application developers need to devise well-formed predicates and logic rules - and there lies the need for a specific *design method*. The well-established techniques of Task Analysis and entity relation Normalization are drawn together into our new design method (TANDEM), introduced here with an example application - the *movie-cinema problem*.

Multi-Agent System, Web Services Orchestration, End-user Systems, Logic Programming Methodology.

1. INTRODUCTION
This paper introduces a new *design method* suitable for developers of multi-agent systems that incorporate a *logic language,* such as the DigitalFriend [3], that wrap web services and other agents. The method draws upon *T*ask *A*nalysis [1] and data *N*ormalization from entity relation (ER) modeling [2], together into a new *DE*sign *M*ethod named *TANDEM*. - for devising the logic predicates and rules, which are distributed amongst the sub-agents. The method is demonstrated in the design of a *movie-cinema* locating application, typical of a modern application scenario that gathers constituent components from distributed web services. The method has broader applicability for logic programming in general.

2. THE *TANDEM* DESIGN METHOD
The analysis begins with a collection of possible *entities* uncovered by a requirements gathering exercise. In the working system, information representing these entities are often dynamically sourced from a number of unrelated distributed Web services. Nonetheless, ER modeling proceeds as if it were going to be implemented as a singular system.

2.1 The Movie-Cinema Problem
We present the methodology via an example application, one typical of projects developed by software engineering students at the University of Melbourne, centered on industry needs. Such projects often involve Internet resources and complex problems, which can benefit from recent research and development advances in software agents and MAS.

The problem: The client, a movie cinema operator, wants a system accessible by movie-going customers via the Internet, one which will allow users of smart hand-held devices, to search for specific movie details, ultimately leading to the booking of cinema tickets. Space prevents a full problem specification here of the *movie-cinema problem.*

2.2 Phase 1 - Applying Task Analysis
Task Analysis identifies a user's goals and the procedure or steps needed to achieve them. It includes the process of analyzing the structure of a task and decomposed the task into related sub-tasks. Some of the tasks identified for the *movie-cinema problem* were extracted using a task analysis and are listed below as *verb-first* directives:

Task 1 - *Movie-oriented search*:

- *Find* all recently released movies.
- *Find* all movies within a particular genre.
- *Find* which movies feature a specific actor.
- *Find* all movies by a specific director.

Task 2 - *Cinema-oriented search* (has a similarly sized list)

Task 3 - *Location-oriented search* (ditto)

Task 4 - *Seat-oriented search and ticket allocation* (ditto)

These four groups of tasks and sub-tasks - represent the first step in a *hierarchical task modeling* exercise [1], which is all we take from task analysis.

2.3 Phase 2 - Applying ER Normalization

In database applications a technique for designing new systems that is widely used and easy to teach, and is taught in both Information Systems and Computer Science, is entity relation (ER) modeling [2].

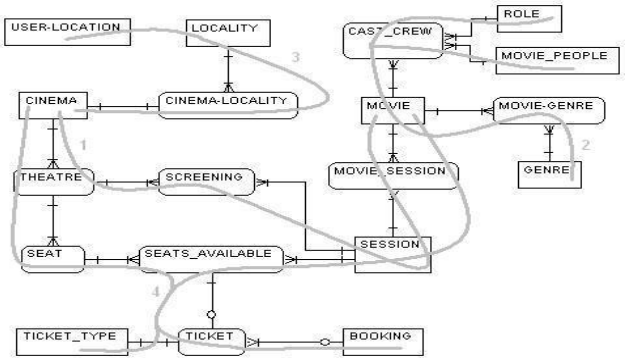

Fig.1 **– Normalized Entity Relation Diagram Modeling the Cinema Problem, with four *Logic Flow Lines***

And a technique that is applied to an ER model to get it into an *ideal form* - one that is most flexible with regard to queries put to it and to future change requirements - is called *Normalization*.

We adopt this well-known technique as a step within the TANDEM methodology - and since it is well-known, the process of normalization is not outlined here. We applied it to the movie-cinema problem above, and arrived at the normalized entity relation (ER) model in Figure 1 above.

Then, in order to divide the ER diagram into appropriate sub-areas, to be implemented as sub-agents (often powered by external web services), we identify *logic flow lines*, also depicted in Figure 1. These lines are mapped by taking the four high level tasks identified in the Task Analysis, and identifying which of the entities in the ER diagram are involved in each task - *without breaking the line*. – a condition that facilitates the process of *unification* [6] during the execution of the logic language.

2.4 Phase 3 - Create well-formed Logic Rules

In a logic program the predicate at the *head-of-the-rule* is a template for many of the queries that can be answered by the whole program. In the MAS application these rules and the associated logic is distributed between the various agents.

In our example solution five rules were derived, with the following five *head-of-the-rule* predicates, the first of which is explained in the next sub-section:

cinemaAssistant(CinemaName, Location, TheatreType, MovieTitle, GenreName, Rating, Date, StartTime)

movieAssistant(MovieTitle, Rating, GenreName, RunningTime, DvdRelease, RoleName, FirstName, Surname)

localityAssistant(Distance, Radius, Location, TownSuburb, Postcode, CinemaName)

seatSelection(CinemaName, Location, TheatreID, ImageMap, MovieTitle, Date, StartTime, RowNumber, SeatNumber, CoordX, CoordY, allocated)

ticketAssistant(CinemaID, TheatreID, Date, StartTime, RowNumber, SeatNumber, TicketNumber, TicketType, Cost, BookingID, FirstName, LastName, PaymentMethod, Paid)

A *query* is constructed by replacing one or more of the variables (i.e. those *terms* starting with a capital) with a specific literal instance, for example, the query in English:

What movies feature Sharon Stone as a star?

would be specified in a logic language (such as CoLoG within the DigitalFriend) as follows:

movieAssistant(***MovieTitle, Rating, GenreName, RunningTime, DvdRelease,*** *star, sharon, stone*)**?**

It can also be specified with under-scores in place of the variable names, leaving only the need to supply the literals:

movieAssistant(_ , _ , _ , _ , _ , *star, sharon, stone*)**?**

In the TANDEM methodology, we first decide on all the head-of-rule predicates that will be necessary to answer all of the tasks extracted via the Task Analysis. The four groupings of *primary tasks*, told us that we needed four predicates as outlined above (the fifth is via a branch in a logic flow line).

2.4.1 Deriving the Cinema Assistant Rule

To identify the actual *terms* needed by each predicate, we use a more detailed diagram than the ER diagram depicted in Figure 1. We could have chosen to depict all sub-area entity *attributes* in a more detailed style of ER diagram, however, in this paper, we have chosen to depict attributes for each of the sub-areas identified by a *logic flow line* in Figure 1, as UML Class diagrams – as we assumed that more agent application developers are likely to be familiar with the UML notation.

The constituent *terms* within each predicate are then determined by the atomic tasks that made up the high level task for which the predicate was instigated.

The next stage of this phase is to identify the best set of predicates on the *right-hand side* of each rule:

Head of the **Rule 1**:

cinemaAssistant(*CinemaName, Location, TheatreType, MovieTitle, GenreName, Rating, Date, StartTime*) ←

requires the following Predicates (from the normalized ER diagram) on the right hand side of the *implies* operator (←):

cinema(*CinemaID,* ***CinemaName***, ***Location***, *CinemaLatitude, CinemaLongitude*),

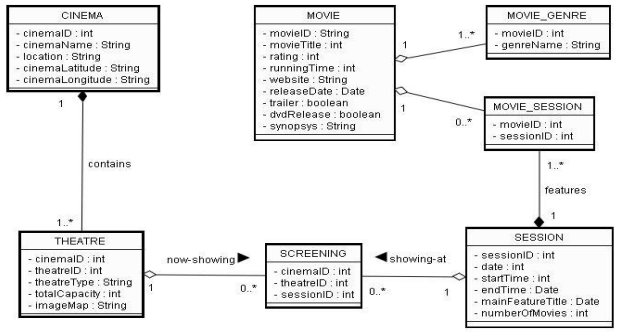

Fig.2 **– A UML Class diagram detailing attributes for entities associated with the *cinemaAssistant* rule.**

theatre(*CinemaID, TheatreID,* ***TheatreType****, TotalCapacity*),

session(*SessionID,* ***Date****,* ***StartTime****, EndTime, MainFeatureTitle, NumberOfMovies*),

movie(*MovieID,* ***MovieTitle****,* ***Rating****, RunningTime, Website, ReleaseDate, Trailer, DvdRelease, Synopsys*),

movieGenre(*MovieID,* ***GenreName***),

screening(*CinemaID, TheatreID, sessionID*),

movieSession(*MovieID, SessionID*);

Note: Commas between predicates are logical ANDs.

These *required* predicates making up the *body* of the rule, are identified via their member terms within the entity/class. i.e. Entities in Fig.2 with an *attribute* corresponding with a *term* in the head *predicate,* is included as a *rule body* predicate. Such attributes are highlighted in ***bold-italic*** font above.

3. IMPLEMENTING THE DESIGN

The DigitalFriend [3] - a user-friendly MAS - is the tool we used to *implement* the design. It is especially good at incorporating sub-agents that *wrap a web service* [4].

A tree view of the various agents is displayed via an octagonal-tile interface, recursively deep, but which displays three levels at a time. An insert in Figure 3 shows where *MovieAssistant*, *CinemaAssistant* and *LocalityAssistant* are grouped together under the EOC (envelope-of-capability) agent *MoviesCinemas.*

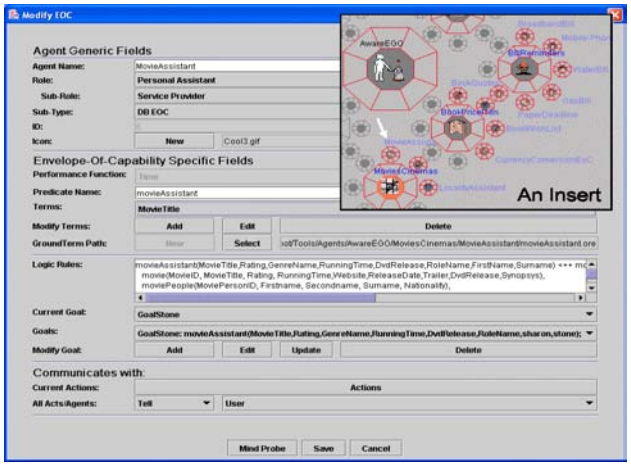

Fig.3 **– Modification of EoC Agent properties**

Both EOC agents and non-EOC sub-agents encompass predicates, which are created within the DigitalFriend interface via GUI dialog boxes. E.g. Figure 3 represents the property dialog box for an EOC agent – specifically for MovieAssistant.

There are four main sub-areas of input/edit fields in the dialog: *role and identity* fields; *predicate* and *term* related fields and buttons for interaction; logic *rules* and a series of predefined *goals/queries* for the agent; and an *inter-agent communication language* section (beyond the scope of this paper). The rule for *movieAssistant* – the second rule, as designed according to Phase 3 outlined in Section 2.4 – has been entered into the field *Logic Rules*. The goal/query that will return any movies involving the actress *Sharon Stone* as *star*, is the agent's *current goal*.

Sub-agents that retrieve records/ground-terms from web-services are similarly represented by a predicate with a list of terms – however, rather than rules, they also have *timers* set to retrieve new information at regular intervals set by the user, and they update stores of *ground-terms* that they maintain as agent *state*.

The DigitalFriend dynamically collects all rules, predicates and ground terms for an EOC agent and its sub-agents, and effectively combines them into a temporary logic program in the internal CoLoG language – built and executed when triggered [3]. Many of the resultant terms are passed to other agents – as specified via the inter-agent communication language in CoLoG – and many are passed as *messages* for the user's attention.

The CoLoG program which is dynamically constructed for a given EOC agent, can be inspected and executed (and tested and debugged) by the user from within the GUI, via the '*Mind Probe*' button at the bottom of the property dialog seen in Figure 3.

The only CoLoG code that the end-user had to devise is the *Rule*, entered via the 'Logic Rule' field in the property dialog in Figure 3. All other details have been entered via less textual GUI interaction, involving only buttons and single name terms.

4. DISCUSSION

Several current MAS development environments use internal logic languages, which then obligates the application developer to write well-formed logic predicates and rules. There is currently *a gap* in available methods for writing such predicates and rules [5].

ER modeling is more widely known than logic programming, and more teachable. Basic Task Analysis is straight forward. TANDEM combines these well-known techniques to find appropriate predicates, their constituent terms and the rules that bind them. It fills a gap in the methods for logic programming.

As seen via the *Movie-Cinema problem*, there is a need for such design methods in developing solutions that use such MAS. Compounding this need, the DigitalFriend is aimed at the *end-user*/developer market, where technical skills are at the spreadsheet-developer or the desktop-database-designer level. Our TANDEM design method provides *strong guidance* in finding appropriate predicates as early as possible, using well-tested techniques that can be learned in a short timeframe.

ABSTRACT
In this paper, we propose an alternative solution for approaching the problem of semantic interoperability, based on recent projects to develop software agents and systems that attempt to reconcile ontological differences without explicit formal ontologies. An application capable of reconciling ontologies based on example data is first described. The results from one of the case studies where the proposed solution has been applied are reported. Finally, the design of an agent embedding the solution is sketched. The solution is aimed at the creation of assistant agents helping the users to cope with heterogeneity in both information sources and contexts of their usage.

1. INTRODUCTION
It can be envisioned that in the near future the users of the Internet will make more use of different services, which are commonly termed as Web services [1], instead of just passive browsing. Increasingly important is the delivery of customised Web services which return information based on the profile and context information, for example the location and connection mode, of the user. With the growing diversity of access terminals other than computers, such as mobile phones and portable digital assistants (PDAs), mobile information access and remote transactions are becoming commonplace. Already today, wireless carriers offer services that allow information such as weather, stock quotes, news, traffic situation and sports updates to be accessed by a mobile phone. Mobile phones are also capable of proactive invocation of useful Web services depending on the user's context. For example, business or leisure travellers by car or train may interact with different systems in order to find and utilize context-based information or services offered by various content and service providers.

The data returned by a Web service is structured by using tags (labels) of the Extensible Markup Language (XML) [2]. An information source represented by a Web service can been seen as having an implicit view of the world – *ontology*[1] – that is defined by the tags it uses to present its data and the structure and representation it gives to that data. In a similar manner, the user can be seen as having his/her own ontology which is the user's view of the world. However, the ontologies of information sources are usually different from each other and from users' ontologies. Further, tags used for data structuring may be cryptic or represented in a language that the user doesn't master. Therefore we propose to interpret the data returned by a Web service by mapping the data elements of an unfamiliar information source to the data elements of another information source the tags of which the user understands. This can be done by means of a software agent, commonly understood as an *active* entity, possessing the features of *autonomy*, *proactiveness*, *responsiveness*, and *social behaviour* [4]. A user's access terminal would then be equipped with such an agent, termed an *assistant agent*, which helps the user to make sense of the information gathered from the Internet.

2. AReXS
AReXS (Automatic Reconciliation of XML Structures) is an application built at the Intelligent Agent Lab of the University of Melbourne that reconciles heterogenous information sources by aligning them according to their implicit ontological structure. It is able to reconcile differences of expression and representation across data streams structured by means of XML tags from heterogeneous sources without any predefined knowledge or human intervention [5, 6]. It achieves this by identifying XML elements whose meanings are similar enough to be considered equivalent. AReXS requires no knowledge or experience of the domain in which it works, and indeed is completely domain independent. It uses Example-Based Frame Matching (EBFM) [7] and is able to achieve very high recall with modest precision on real world data collected from commercial Web services and

[1] A *problem-oriented ontology* is a description by truth values of the concepts and relationships of the problem domain [3].

sites. By requiring no domain knowledge, AReXS is suitable for application to any field; its success relies on its ability to identify and resolve the differences in representation that result from sourcing data from a multi-cultural environment.

AReXS does not fit into the traditional mould of an ontology management tool, as it does not use any type of formal ontology representation. Instead, it works in much the same way that two people who do not share a common language might teach each other by pointing at objects and saying the names that each person's language gives to that object. In formal terms, AReXS attempts to automatically resolve the problems of synonymy and polysemy that are significant hurdles to semantic interoperability [6, 8].

As a result of experiments conducted at the Intelligent Agent Lab, we modified the original EBFM algorithm described in [7] in two important ways. Whereas, in its original form, the algorithm would discard hypotheses that are based on a single element pair, we deliberately retain these hypotheses. Further, we made the reward for matching contents of data elements independent of the uniqueness of the match. The original EBFM algorithm devalues matches if they are common, whereas we found that this reduced the effectiveness of the reconciliation process.

3. PRACTICAL RECONCILIATION

Suppose that a user with a mobile access terminal requests a weather forecast for a particular geographical location. A currently available real Web service returned the following data:

```
<AYPY>
 <1>Moresby</1>
 <2>Papua New Guinea</2>
 <3>-09.26</3>
 <4>147.13</4>
 <5>Moresby, Papua New Guinea</5>
 <6>Sep 08, 2005 - 07:00 PM EDT</6>
 <7>from the SE (140 degrees) at 15 MPH (13 KT)</7>
 <8>greater than 7 mile(s)</8>
 <9>mostly cloudy</9>
 <10>78 F (26 C)</10>
 <11>68 F (20 C)</11>
 <12>69%</12>
 <13>29.85 in. Hg (1011 hPa)</13>
 <14>AYPY 082300Z 14013KT 9999 FEW018 BKN040 BKN140
26/20 Q1011</14>
</AYPY>
```

As one can see, the data returned makes use of cryptic tags and is therefore hard to comprehend at a glance, nor should the user have to consult the documentation page of the service. Here a personal software agent can come to the user's help. We propose that an agent faced with a situation described would retrieve data or use cached data from other information source(s) of the same purpose that the user is familiar with in order to interpret the data such as presented in the example above. For instance, another similar Web service returns the following record reporting the weather conditions of the same geographical location:

```
<AYPY>
 <1 Location>Moresby, Papua New Guinea</1 Location>
 <2 Humidity>69%</2 Humidity>
 <3 Pressure>29.85 in. Hg (1011 hPa)</3 Pressure>
 <4 Sky>mostly cloudy</4 Sky>
 <5 Temperature>78 F (26 C)</5 Temperature>
 <6 Visibility>greater than 7 mile(s)</6 Visibility>
 <7 Wind>from the SE (140 degrees) at 15 MPH (13 KT)
</7 Wind>
</AYPY>
```

In order to demonstrate how "understanding by reconciliation" could be achieved, we tested our proposed approach to ontology reconciliation on two sets of Web services. One of the sets consisted of two public Web services returning weather forecasts. The first of these services was the "World Weather" by InnerGears [9]. It retrieves the weather report for all airports in the world registered by the International Civil Aviation Organization (ICAO) based on a specified ICAO identifier. The second service "Airport Weather" by CapeScience [10] is similar to the first one but returns elements with different tag names. We devised a series of experiments where both services were invoked with the same ICAO identifiers which had been selected so that the weather forecasts returned were on the airports from all over the world. After applying AReXS to the data streams returned by the Web services, the application reported the candidate element pairs and its confidence in each match:

```
Slot 0 [1] <-> Slot 0 [1 Location]: 0.95012
Slot 1 [2] <-> Slot 0 [1 Location]: 0.95575
Slot 4 [5] <-> Slot 0 [1 Location]: 0.97643
Slot 6 [7] <-> Slot 6 [7 Wind]: 0.99999
Slot 9 [10] <-> Slot 4 [5 Temperature]: 0.97845
Slot 10 [11] <-> Slot 4 [5 Temperature]: 0.95376
Slot 11 [12] <-> Slot 1 [2 Humidity]: 0.99923
Slot 12 [13] <-> Slot 2 [3 Pressure]: 0.99968
```

The results of automatically reconciling the data streams returned by two Web services are that the elements labelled <1>, <2> and <5> of the first stream have unsurprisingly been matched with the element <1 Location> of the second stream. Analogously, the elements of the first data stream labelled <7>, <12> and <13> have been matched with the elements <7 Wind>, <2 Humidity> and <3 Pressure> of the second stream, respectively, with the highest possible degree of confidence. The degree of matching confidence between the elements <10> and <11> of the first data stream with the respective element <5 Temperature> of the second stream is somewhat lower because the first service returns both minimum and maximum temperatures, while the second service returns only the latter. Note that the elements of the two data streams could not have been matched by only considering the element names, as would generally occur in an explicit ontology alignment algorithm, such as, for example, Chimaera [11]. Also, it is worth noting that AReXS is able to cope with blank data tags.

One could argue that the matching reported between the elements of the two data streams is self-evident. It is really not impossible for the user to achieve with some effort the same results, but the user with a mobile access terminal usually lacks the time and an appropriate interface required for it.

4. DESIGNING AN ASSISTANT AGENT

In the Internet, it is inherently difficult to predict the information needs of individual agents, let alone which particular data representations they require. Although many proposed multi-agent systems enforce system-wide global ontologies, this is not always desirable or feasible, especially when the agents are embedded in mobile access terminals.

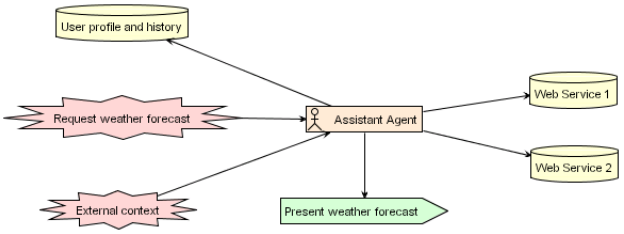

Figure 1. A system overview diagram.

We will now provide a sketch of the design of a system that has in its centre an assistant agent embedded in a mobile phone or PDA. For this purpose, we make use of the ROADMAP/Prometheus methodology [12, 13] of agent-based software engineering which is especially suitable for developing open multi-agent systems. Figure 1 represents an overview diagram of the system to be formed around the Assistant Agent. As Figure 1 reflects, the Assistant Agent perceives a request for a weather forecast by its user. In addition to that, the external context of the request, containing, for example, the current location of the user, serves as another input *percept* for the Assistant Agent. The agent also utilizes some previously collected data consisting of the user profile and the history of the previous actions by the user. Based on this information, the Assistant Agent determines a Web service that it queries for a weather forecast. However, the information returned by the Web service that the user is most familiar with may be incomplete or this Web service may not respond. In such a case, some or all parts of the weather forecast are retrieved from a different Web service. In order to decide in which form the information retrieved should be presented to the user, the Assistant Agent utilizes the data about the user profile and history. For example, provided that the Assistant Agent has cached some data from previous invocations of the user's favourite weather forecast Web service, it is able to "translate" the names of data elements used in the information retrieved from "alien" information sources to the data element names known by the user. As a result, the weather forecast is finally presented to the user in the form which is as close as possible to the one preferred by her/him. In Figure 1 this is reflected by the agent's *action* "Present weather forecast". Please note that the whole process described occurs in a dynamic manner without the use of *any* pre-specified domain ontology.

5. CONCLUSIONS

Even though the Internet is in principle global, a lot of information available in it is of only local significance. Context-dependent invocation of Web services and context-dependent retrieval of Web pages are therefore of an increasing importance. This implies that a growing number of different views of the world will be present in the Internet. However, it seems unlikely that any single proposed solution for adding semantics to the Internet, such as Ontology Web Language (OWL) [14], will be widely accepted in the near future. Even if such an event occurred, it is doubtful that many smaller commercial and individual publishers of information would be willing to devote the time and effort required to comply with a standard that requires ontology development. For this reason, we are proposing and developing technologies and methodologies that cope with heterogeneity and change in information sources and in contexts of their usage by performing implicit ontological reconciliation.

ABSTRACT

In multiagent systems ontologies are essential because they facilitate tasks like communications and reasoning. In this paper, inspired by studies in cognitive psychology, we present a theoretical framework of ontologies that model concepts and properties in a way that typicality of objects can be reflected, and in which context plays a major role in determining the interpretation of the concepts. Typicality is a very common phenomenon observed in different cognitive tasks, while context has been proved to have significant influences on reasoning and categorization. This framework brings together these issues and gives a formal representation of context-sensitive ontologies.

1. INTRODUCTION

With the development of the Semantic Web [3], multiagent systems are expected to play a more essential role in information processing. Ontology [7] also becomes more important because it specifies the definitions of and relations between different concepts. In this paper, we focus on two problems of the Semantic Web. The first problem is the representation of fuzzy concepts and graded membership of instances in ontologies, while the second problem is categorization and forming of taxonomies of concepts in different contexts. We try to solve the problems by proposing a framework for context-sensitive ontologies.

2. TYPICALITY AND CONTEXT

2.1 Prototype View and Typicality

Concepts are usually defined as crisp sets of objects in ontologies [11]. However, graded membership in concepts is found to be very common [8]. The *prototype view of concepts* [9] suggests that a concept is represented by a prototype which has all the salient properties of the objects that are classified to this concept. The term *typicality* refers to the degree that an object is considered as a member of a concept, and is determined by the number of matching properties of the object and the concept prototype [8, 9]. Moreover properties that are not necessarily in the definition of a concept (*non-necessary properties*) may also affect typicality of an object.

2.2 Context and Context Effect

In general *context* refers to the situation in which an event happens or an action is taken, or the surroundings that help to understand a particular concept. In this paper, we focus on its role in categorization, since this is a major task in the Semantic Web. According to [1], categorizations depends on the circumstance and perspective. In cognitive psychology, the term "context effect" [5] is used to refer to the influence of context in cognitive tasks. Barsalou [2] suggested that properties of a concept can be classified as context-independent or context-dependent. Roth and Shoben [10] also investigated the effect of context in categorization, and suggested context causes a re-weighing of the importance of the properties in a concept and resulting in a different categorization.

3. A COGNITIVE MODEL FOR CONTEXT-SENSITIVE ONTOLOGIES

Inspired by research on the prototype view and context effect, we propose a cognitive model of concepts which takes into account the calculation of typicality of instances, and propose a framework in which categorization of instances are dependent on the context.

3.1 Definition of an Ontology

Ontology is defined as an explicit specification of conceptualization [6]. Here we define an ontology O as a four-tuple

$O = (C, P, I, R)$, where C is a set of concepts, P is a set of properties of the concepts, I is a set of data instances, and lastly R is a set of rules, propositions or axioms.

3.2 Concepts and Properties

In this model, each concept is basically characterized by a set of properties which are singly necessary and jointly sufficient. In addition, a weight is associated with each property in a concept to reflect its importance. Each instance possesses a set of properties and a value is used to indicate the degree to which it possesses each property.

Definition 1. A **concept** $c \in C$ is a fuzzy subset of I, with a membership function μ_c assigning each instance $a \in I$ a membership grade in this concept.

3.3 Characteristic Vector, Property Vector and Subsumption of Concepts

We propose two data structures to represent how properties characterize concepts, and how individuals possess different properties. A *characteristic vector* of a concept is defined as a vector of real numbers in the range of 0 to 1, in which each element corresponds to the weight of a property.

Definition 2. A **characteristic vector** $\vec{c}_c$ of a concept c is a vector of real numbers, $\vec{c}_c = (c_{c,1}, c_{c,2}, ..., c_{c,n}), 0 \leq c_{c,i} \leq 1$.

A *property vector* of an individual is a vector of real numbers, in which each element corresponds to the degree to which the individual possesses a property.

Definition 3. The **property vector** $\vec{p}_a$ of an individual a is a vector of real numbers, $\vec{p}_a = (p_{a,1}, p_{a,2}, ..., p_{a,n}), 0 \leq p_{a,i} \leq 1$.

In addition, we have the following definitions concerning the concept subsumption relations.

Definition 4. For two concepts c and d, c is said to be **subsumed by** d, denoted by $c \sqsubseteq d$, if and only if $c_{c,i} \geq c_{d,i}$ for all $i = 1, 2, ..., n$.

Definition 5. If $c \sqsubseteq d$, then c is said to be a **sub-concept** of d, and d is said to be a **super-concept** of c.

Definition 6. The set of **defining properties** of c is the set which consists of properties having weights greater than zero in the characteristic vector of a concept c.

Definition 7. The set of **properties possessed by** a is the set which consists of properties having a degree greater than zero in the property vector of an individual a.

3.4 Likeliness of an Individual in a Concept

Likeliness of an individual refers to the degree that an individual is an instance of a concept according to the *defining properties* of a concept. This can be considered as the generalization of the crisp membership in existing ontological frameworks, and is similar to the fuzzy membership grade in fuzzy ontologies like [13]. A suitable formula for calculating likeliness should satisfy the following axioms.

AXIOM 1. *An individual a has a degree of likeliness of* 1 *in a concept c if and only if $c_{a,i} > 0 \rightarrow p_{a,i} = 1$ for all $i = 1, 2, ..., n$.*

AXIOM 2. *An individual a has a degree of likeliness of* 0 *in a concept c if and only if $c_{a,i} > 0$ and $p_{a,i} = 0$ for some $i \in [1, n]$.*

AXIOM 3. *For a concept c, and two individuals a and b, if for some j such that $c_{c,j} > 0$, $p_{a,j} > p_{b,j}$ and $p_{a,i} = p_{b,i}$ for all $i \neq j$, then $\mu_c(a) > \mu_c(b)$.*

AXIOM 4. *For two concepts c and d, and an individuals a, if for some j such that $c_{c,j} > c_{d,j} > 0$, $p_{a,j} > 0$ and $c_{c,i} = c_{d,i}$ for all $i \neq j$, then $\mu_d(a) > \mu_c(a)$.*

AXIOM 5. *For two concepts c and d such that c is a sub-concept of d, the degree of likeliness of an individual a must satisfy $\mu_c(a) \leq \mu_d(a)$.*

A possible function for calculating likeliness is

$$\mu_c(a) = \min_i \{l_i\} \tag{1}$$

where

$$l_i = \begin{cases} p_{a,i} + (1 - c_{c,i}) \times (1 - p_{a,i}) & \text{if } c_{c,i} > 0, p_{a,i} > 0 \\ 0 & \text{if } c_{c,i} > 0, p_{a,i} = 0 \\ 1 & \text{if } c_{c,i} = 0 \end{cases}$$

3.5 Prototype Vector and Typicality

Typicality is a measure of an individual's degree of membership in a concept depending on properties (both necessary and non-necessary) that are shared by most of the instances of the concept. The characteristic vector cannot handle typicality because it only contains information of necessary properties. Thus we introduce here the *prototype vector*. To calculate typicality of an instance, we construct a prototype for the concept, in the form of a *prototype vector*.

Definition 8. The **prototype vector** $\vec{t}_c$ of a concept c is a vector of real numbers, $\vec{t}_c = (t_{c,1}, t_{c,2}, ..., t_{c,n}), 0 \leq t_{c,i} \leq 1$, and is determined by the following equation:

$$\vec{t}_c = \frac{1}{|S|} \sum_{s \in S} \vec{c}_s$$

where S is the set of sub-concepts of c.

Typicality of an instance is determined by a "*weighted feature (property) sum*" [12]. This involves matching the properties in the prototype vector of a concept and the property vector of an individual. The typicality function of a concept, τ_c, should satisfy the following axioms.

AXIOM 6. *An individual a has a degree of typicality of* 1 *in a concept c if and only if $t_{c,i} > 0 \rightarrow p_{a,i} = 1$ for $i = 1, 2, ..., n$.*

AXIOM 7. *An individual a has a degree of typicality of* 0 *in a concept c if and only if $t_{c,i} > 0 \rightarrow p_{a,i} = 0$ for $i = 1, 2, ..., n$.*

AXIOM 8. *For a concept c, and two individuals a and b, if for some j such that $t_{c,j} > 0$, $p_{a,j} > p_{b,j} > 0$ and $p_{a,i} = p_{b,i}$ for all $i \neq j$, then $\tau_c(a) > \tau_c(b)$.*

AXIOM 9. *For a concept c, and two individuals a and b, if for some j such that $t_{c,j} > 0$, $p_{a,j} > p_{b,j} = 0$ and $p_{a,i} = p_{b,i}$ for all $i \neq j$, then $\tau_c(a) > \tau_c(b)$.*

AXIOM 10. *For two concepts c and d, and an individuals a, if for some j such that $t_{c,j} > t_{d,j} > 0$, $p_{a,j} > 0$ and $t_{c,i} = t_{d,i}$ for all $i \neq j$, then $\tau_d(a) > \tau_c(a)$.*

Here, we present a possible function for calculating an individual's typicality in a concept. The typicality of an individual a of a concept c, denoted by $\tau_c(a)$ is given by:

$$\tau_c(a) = \frac{\vec{p}_a \cdot \vec{t}_c}{\sum_{i=1}^{n} t_{c,i}} \quad (2)$$

4. CONTEXT IN CATEGORIZATION

The model described above serves as a basis for formalizing context in ontology. We consider contexts as different conditions which cause an agent to process information thereafter with different perspectives, and focuses on different properties of a concept.

4.1 Formal Definitions

We define a context x as a collection of propositions, objects and concepts perceived by an agent in the Semantic Web environment.

Definition 9. A **context** x is a three-tuple $\langle N_r, N_c, N_i \rangle$, where $N_r \subseteq R$, $N_c \subseteq C$ and $N_i \subseteq I$.

When an agent perceives a particular context, the agent forms a certain perspective, which is a certain view point on the concepts and individuals. We define perspective as a view point from which an agent assigns different weights to properties in concepts to reflect its foci on certain properties.

Definition 10. A **perspective** v is a mapping from the set $C \times P$ into the set of real numbers in the range 0 to 1, which represents the weights of the properties in the concepts: $v : C \times P \longrightarrow [0, 1]$.

Furthermore, we define the function *View* that maps a context to a perspective formed in an agent.

Definition 11. Let X be the set of contexts and V be the set of perspectives, the function ***View*** is a mapping from X to V: $View : X \longrightarrow V$.

4.2 Contextualized Ontology

After an agent has chosen a perspective according to the context, the agent forms a context-sensitive ontology by applying the weights to the properties in concepts. This can be formalized by a set of interpretations similar to those in description logics [4]. An interpretation assigns to each concept a characteristic vector which contains the corresponding weights of the properties according to the perspective.

Definition 12. An **interpretation** for context i, m_i, consists of a domain Δ_i and an interpretation function $\mathcal{I}_i$: $m_i = \langle \Delta_i, \mathcal{I}_i \rangle$, where Δ_i refers to the domain and $\mathcal{I}_i$ is an interpretation function.

The interpretation function $\mathcal{I}_i$ is a function that maps each concept $c \in C$ to a fuzzy subset of I, and assign a characteristic vector to the concept c. $\mu_{c,i}$ is the membership function of c in the context represented by interpretation m_i. On the other hand, the typicality of an individual can be different due to the different weights of the properties. We use $\tau_{c,i}(a)$ to denote the typicality of individual a in concept c under the interpretation m_i.

4.3 Contextual Subsumption Relations

A hierarchy of concept can be constructed by determining concept subsumption relations. Once contexts are modeled, a subsumption relation between concept c and d, say $c \sqsubseteq d$, may only hold within a certain context.

Definition 13. For two concepts c and d, c is said to be **subsumed by** d under the interpretation m_x, denoted by $c \sqsubseteq_{m_x} d$, if and only if $c_{c,j} \geq c_{d,j}$ for all $j = 1, 2, ..., n$.

5. CONCLUSION AND FUTURE WORKS

This paper attempts to provide a theoretical framework of context-sensitive ontology, which handles both fuzzy membership grades, typicality of objects, and models context so that agents are able to interpret concepts according to the current situations. Future works on this framework include investigation of how the function *View* can be implemented such as by using some learning algorithms, and extension of the framework to handle other aspects of context such as disambiguating terms with multiple meanings.

ABSTRACT

This work considers encapsulation of multimedia contents as services, and their autonomous provision and distribution by agents. This approach enables content providers to have their contents provided and distributed together with their own business logics regarding interaction with other services and contents, control logic for various options upon provision, and value-added services. This paper proposes a framework for development of agents that provide and distribute such content services. In the framework, the interaction logic of agents is first developed in the same way as in development of ordinary Web services. Control descriptions are then given for each aspect, such as selection of partner agents, negotiation on service options, and migration. The separated descriptions for each aspect facilitate incremental development and test, as well as later modification, of agents with complex behaviors.

Agent Framework, Service-Oriented Computing, Multimedia, Mobile Agents, Agreement

1. INTRODUCTION

Rapid progress in computing and network technologies has enabled people to use various kinds of multimedia contents, e.g., movies, business documents, and electronic medical charts, with their computers or mobile devices. Operations on multimedia contents include not only to play and edit but also to translate between different formats, extract properties to annotate the contents, and generate customized view. Currently, multimedia contents are often treated as data and operated using applications, e.g.,players, installed on users' computers, and content providers can only set control parameters for them in advance. Consequently, flexible policies regarding how their contents are manipulated after delivered cannot be incorporated, for example, flexible license control such as license division for multiple contents or multiple devices, design and license restriction upon content composition, and content-specific value-added functions such as generation of customized view.

In response to this problem, this work considers encapsulation of multimedia contents by autonomous agents. Multimedia contents are encapsulated together with business logic or control policies given by content providers, provided and distributed autonomously by agents in complying with the policies. This model enables for content providers to keep control on how their contents are handled and to provide value-added services such as integration of related contents or content-specific customization.

Agents encapsulating multimedia contents need to discover and cooperate with other agents providing other contents or functions to form composite services or contents. Issues in implementation of such behavior are not specific to this domain and have been investigated especially in the Service-Oriented Computing (SOC) activity. In SOC, software systems provide services to other applications through published and discoverable interfaces, and the services can be invoked over a network [2]. It thus leads to autonomous composition of a new service by integrating existing ones at runtime. In addition to the above general issues, agent mobility is necessary to implement (possibly autonomous) contents distribution as well as to allow for function migration. In addition, agents should be able to be part of another agent, to represent atomic contents embedded in composite contents or functions embedded in contents. They especially should work cooperatively, for example, migrate between hosts together as a unit and adjust their interfaces and behaviors so that they are seen as one consistent composite agent [4]. Besides, services that provide multimedia contents have various kinds of application-specific service options as mentioned above. It is thus necessary to introduce a mechanism to handle agreements on application-specific service options [3], though the effort on SLAs (Service Level Agreements) for SOC has considered only application-independent service options, especially QoS parameters.

The control flow of agents including these features can be very complex. For example, when an agent wants to initiate interaction with another agent providing required services or contents, it first needs to discover and select an agent playing the required role. It may then migrate and/or ne-

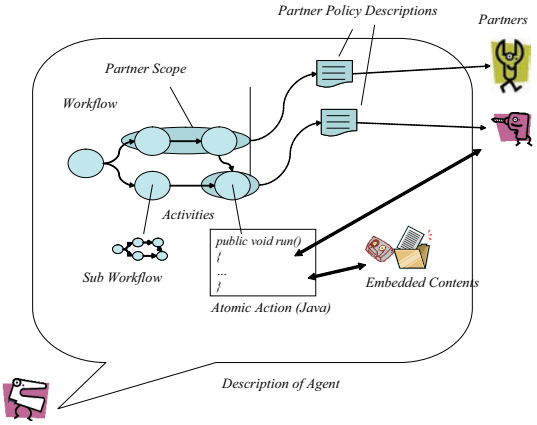

Figure 1: description Model for Active Contents

gotiate about service options such as licenses. The whole control flow woven with such behaviors for each partner agent is very complex and unmanageable. In response to the problem, this study proposes a framework named Freedia for development of agents encapsulating multimedia contents. It aims to enable developers to handle the complexity in development of agents including various aspects such as partner discovery, migration, and agreements on service options. The proposed Freedia framework allows developers to first specify the main interaction logic of an agent, that is, control and data flow between atomic actions including messaging actions. It is thus possible to start with development of agents that simply interact with their partners through remote messaging and without migration nor agreements. Developers can then incorporate policy descriptions that specify requirements and related behaviors for each interaction partner. The separated descriptions for each aspect facilitate incremental development and test, as well as later modification, of agents with complex behaviors.

2. FREEDIA FRAMEWORK

2.1 Workflow and Partner Scopes

This section describes the proposed framework, Freedia, for development of agents that autonomously distributes and provides multimedia contents. The model for agent description in Freedia is shown in Figure 1. The main logic, including interaction with partner agents as well as internal behavior, is described as a workflow description. The workflow description is based on a common approach in process languages for Service-Oriented Computing [5, 6], that is, interaction with partner agents of required types is specified without concrete description for binding partners. Information used for discovery and selection of partners is given separately. The workflow description specifies control and data flow between actions in a graph-oriented way. The activities are implemented in Java and include messaging actions (sending or receiving messages in FIPA ACL), internal computation, and/or operation on contents the agent contains. The notation and operational semantics of workflow are based on Web Services Flow Language [5]. For each partner declared in the workflow description, policy descriptions are given to control behaviors related to the partner, including discovery, negotiation and selection for service agreements, and migration/synthesis (*Partner Policy* descriptions described in Session 2.2).

In definition of activities in a workflow, types of the partner agents the agent interacts with during execution of the activity are declared. Types of partner agents are called *roles* and denote interface of agents in terms of observable messaging actions. If an agent has a certain role, it means the agent can send or receive messages in a certain sequence specified in a certain interaction protocol. In definition of an activity in a workflow, a partner is declared by specifying a set of roles required for the partner.

As partners that the agent can interact with are declared in each activity, a set of activities where interaction with a partner occurs can be extracted. This set of activities is called a *partner scope*, and used by Freedia to determine when to activate initialization of a partnership, e.g., discovery and negotiation, or termination, e.g., disposal of service agreements. For each partner, initialization is activated when execution enters the scope for the partner, that is, when execution reaches an activity where interaction with the partner occurs. Termination is activated when execution exits of the scope for the partner, that is, by default when execution gets out of the outermost loop enclosing the partner scope (intuitively, when interaction with the partner turns out not to occur anymore). It is also possible to specify whether interaction is iterated in a loop with the same partner or switching the partner. Details of initialization and termination are described in the following.

2.2 Partner Policy Descriptions

2.2.1 Overview

For each partner declared in the workflow description, Partner Policy descriptions are given to specify requirements for and behaviors related to the partner. Currently, a partnership is built between two agents, and connection of partnerships between agent pairs leads to a collaborative group of agents. Preliminary interaction is held to build a partnership according to Partner Policy descriptions. In each agent pair for any protocol, one agent is classified as a *requester* and initially sends a request in preliminary interaction to build a partnership. The other is a *responder* and waits for a request for interaction. Below each item in Partner Policy descriptions is first described separately, and how to integrate them is then described.

2.2.2 Items in Partner Policy Descriptions

2.2.2.1 Agent Properties.

Requirements for properties of partner agents, such as organizations providing them and service quality, are given in Partner Policy descriptions. In the case of a requester, these requirements descriptions are used for discovery of agents, together with required roles declared in the workflow description. In the case of a responder, they are used to determine whether to accept a request for interaction or not.

2.2.2.2 Interaction Style.

Requirements for interaction styles with partners are specified in Partner Policy descriptions (based on the authors' previous study [4]). Here interaction styles include whether migration is conducted to be on the same host or not, and where the agent pair gathers if conducted. They also include whether an agent compound is established or not, where multiple agents work cooperatively and migrate as a unit (called agent synthesis), and what kinds of control are enforced in the agent compound (if established). For example, monitoring and operating on messages allows for encapsu-

lation of the contained agent, e.g., inhibiting the containing agent from providing services directly. It also allows for override of services by the contained agent, e.g., adding additional access control check or filtering. Each agent has requirements on these aspects in Partner Policy descriptions, and Freedia framework matches them and builds agreements on interaction styles if matched. The Freedia framework is also responsible to enforce the agreements, i.e., to activate migration of an agent, to monitor and pass messages to given handlers of containing agents, and so on.

2.2.2.3 Service Agreements.

Behaviors regarding agreements on service options, both interaction to build agreements and change to comply with the agreements, are specified in Partner Policy descriptions (based on the authors' previous study [3]).

For behaviors to build agreements, templates to implement Iterated Contract Net Protocol (CNP) [1] to build agreements are provided. Various existing or emerging techniques are thus incorporated such as iterated negotiation. The Iterated CNP protocol considers the most complex situation, iterated negotiation and selection between a consumer and multiple candidates for service providers. Each internal behavior in this process is implemented by using Java abstract classes provided by the Freedia framework. In Partner Policy descriptions, such components are specified and the framework conducts the negotiation and selection process by invoking the given components and messaging actions including time-out check according to the protocol.

For change in behaviors to comply with established agreements, Aspect-Oriented rule descriptions are provided. Some service options are strongly related to the workflow and originally expected to be customizable, e.g., bandwidth and size of movies. In the case such options are determined not in each request but in long-term service agreements, rule descriptions for setting parameters in the workflow can be adopted. Other service options are independent of the workflow and require additional actions, e.g., access control check and merger of value-added contents. In this case, rule descriptions that insert additional actions before/after activities or upon receiving/sending messages.

2.2.3 Putting Together

At runtime, initialization and termination are conducted for each partner at execution points determined according to partner scopes. Each item described above includes preliminary interaction for initialization, i.e., requirements matching and negotiation. At runtime, requirements matching for service properties and migration/synthesis is integrated into the given interaction for service agreements by Freedia. Partnerships are established only if matching for both aspects is succeeded and service agreements are successfully built. After agreements for interaction styles and for service options are established, migration/synthesis is conducted and rules for enforcing service agreements are activated (if necessary). When execution of workflow descriptions exits out of the partner scope, dissolve of synthesis and deactivation of rules for enforcing service agreements are conducted as finalization (if necessary).

Every item in Partner Policy descriptions does not always need to be given. For example, if requirements for service properties are not given, candidates for a partner are obtained by querying directory services only with roles. This default behavior, together with separation of concerns in the description model, facilitates incremental development, that is, first develop and test the interaction logic, and then give control descriptions for each aspect and test one by one.

2.3 Experiences

The proposed Freedia framework is currently implemented in Java. The framework includes a visual editor and debugger for workflow descriptions, as well as the infrastructure for interpretation of the workflow and Partner Policy descriptions and agent management.

Three applications developed using the proposed Freedia are described briefly. In the first one, agents encapsulating electronic medical charts are delivered to different organizations while obeying policies given by the original distributor. Second, agents encapsulating instruction manual of health supplements follow movement of human users, proactively showing instruction of the supplements timely and offer value-added services such as setting parameters of electronic exercise equipments. Last, agents encapsulating e-learning contents interact with each other to support experiences of English conversation between students while cooperating with agents given teachers' management policies. All the scenarios include aspects of partner discovery, migration/synthesis (e.g., following mobile users or override of services using the mechanisms for agent synthesis), and service agreements (authentication and authorization or learning level). These applications were developed incrementally. First only the interaction logic of agents was implemented, without any policies on coupling, negotiation, or synthesis, i.e., only workflow descriptions are given. Policies about discovery, cooperative migration, and service agreements were introduced and tested gradually.

3. SUMMARY

This study has considered encapsulation of multimedia contents as agents. This approach enables content providers to have their contents provided and distributed together with their own business logics regarding interaction with other agents that provide required services or contents, control logic for various options upon provision, and value-added services. For implementation of such agents, this study has proposed a framework that facilitates incremental development of agents with complex behavior including various aspects.

ABSTRACT

Ontologies play a key role in agent communication and the emerging Semantic Web. Axioms are an important component of ontologies to describe the relationships among the concepts. The current research on ontology mapping and ontology translation mainly focuses on how to map and translate the vocabularies and associated data instances from one ontology to another. However, when extending one ontology using axioms from another, we must confront the problem of translating axioms. In this paper, we show that simple symbol replacement will not solve the problem of axiom translation because of *asymmetry of translation*. Instead we extend our inferential ontology translation for facts (ground atomic formulas) and queries to cover axioms using a method we call *axiom derivation*.

Keywords

Ontologies, the Semantic Web, Agent Communication, Ontology Translation

1. INTRODUCTION

Ontologies, which can be defined as the formal specification of a vocabulary of concepts and the relationships among them, play a key role in both agent communication and the emerging Semantic Web. We can distinguish several different *semantic heterogeneity* problems among multiple agents and web services, which may use different ontologies.

1. *Ontology mapping:* Finding correspondences between the symbols of two ontologies; the correspondences are often equivalences and subset-superset (or subproperty-superproperty) relationships.
2. *Ontology translation:* Translating a dataset (assertions) or a query expressed using one ontology into a form that uses a different ontology.
3. *Theory translation:* Translating the axioms of one ontology into the vocabulary of another, preserving their validity.

Much previous work (see a survey in [4]) has been in the first category; ours [2] has been mainly in the second. In this paper we focus on the third, in which the translation approach for simple assertions by replacing the symbols of one vocabulary with the corresponding symbols from another will not work for axioms in general. For example, in one genealogy ontology G_1, husband and married are two concepts (properties) and there may be a first-order logic (FOL) axiom to describe their relationship:

$$(\forall x, y)\mathsf{husband}(x, y) \rightarrow \mathsf{married}(x, y) \qquad (1)$$

where x and y are universal variables to represent man and woman respectively. Suppose another genealogy ontology G_2 has male_partner and in_marriage as corresponding (mapping) properties. Some facts (assertions) expressed in the language of G_1, can simply be translated into the language of G_2 by replacing corresponding properties:

$$\mathsf{husband}(\mathsf{John}, \mathsf{Mary}) \rightsquigarrow \mathsf{male\_partner}(\mathsf{John}, \mathsf{Mary})$$

$$\mathsf{married}(\mathsf{John}, \mathsf{Mary}) \rightsquigarrow \mathsf{in\_marriage}(\mathsf{John}, \mathsf{Mary})$$

We use a symbol $\rightsquigarrow$ to represent the process of translation. The translations are correct in terms of the semantics of G_1 and G_2, where husband can be thought of as a special kind of male_partner. However, if we use the same technique to translate the axiom (1) of G_1 to G_2, we will get:

$$(\forall x, y)\mathsf{male\_partner}(x, y) \rightarrow \mathsf{in\_marriage}(x, y) \qquad (2)$$

It is obvious that (2) is not always true since a man is a partner of a woman doesn't mean that he must be in a marriage with her; (2) is not a valid axiom in G_2.

What is the reason that the above translation for facts is correct, and the translation from (1) to (2) is not correct? Can we find a formal method for translating axioms from a source ontology to a target ontology that guarantees that the translations are also true in the target ontology?

In this paper, we will give a formal characterization of ontology translation that unifies the translation of facts, queries and axioms in one inferential framework (section 2). We call the translation of axioms from one ontology to another ontology *axiom derivation*. We point out that it is the *asymmetry of translation* that makes axiom derivation difficult. In section 3, we will elaborate how to derive axioms across different ontologies as the extension of our previous work for translating datasets and queries.

2. FRAMEWORK

2.1 Merged Ontologies & Bridging Axioms

In this section we first briefly review our previous work [2] on ontology translation. We assume that in order to translate facts from one ontology to another there must be a *merged ontology* in which all the relevant symbols are allowed to interact. For example, consider the pair of genealogy ontologies G_1 and G_2. The mappings between them can be represented as first order axioms:

$$(\forall x, y)\mathsf{husband}(x, y) \rightarrow \mathsf{male\_partner}(x, y) \quad (3)$$

$$(\forall x, y)\mathsf{married}(x, y) \leftrightarrow \mathsf{in\_marriage}(x, y) \quad (4)$$

We call these axiomatic mapping rules *bridging axioms*. We have developed a strongly typed first-order logic language, *Web-PDDL*, to express bridging axioms. These axioms are embedded in a *merged ontology* complete with namespace declarations and type-equivalence rules.

2.2 Inferential Ontology Translation

We will use the symbol $\rightsquigarrow$ to indicate translation: $\alpha \rightsquigarrow \beta$ means that β is the translation of α. We call the ontology O_s that α uses the *source* ontology and O_t, the one β uses, the *target*. In the case of sets of assertions ("datasets"), we stipulate that the translation of α_d is simply the strongest set of assertions, β_d, in O_t entailed by α_d. A consequence of this stipulation is that

$$(KB; \alpha_d) \rightsquigarrow \beta_d \textit{ only if } (KB; \alpha_d) \models \beta_d$$

where we have added to the left-hand sides the symbol KB to refer to the merged ontology with bridging axioms.

If α_q is a query in O_s, its translation is a query β_q in O_t such that any answer (set of bindings) to β_q is also an answer to α_q. In other words:

$$(KB + DB_\beta; \alpha_q) \rightsquigarrow \beta_q \textit{ only if } (KB + DB_\beta; \theta(\beta_q)) \models \theta(\alpha_q)$$

for any substitution θ, where $KB + DB_\beta$ now includes both the merged ontology and the facts from the target data instances. The point is that β_q need not be (and seldom is) *equivalent* to α_q, in the sense that any answer to one is an answer to the other. All we need is that any answer to β_q be an answer to α_q. If we take O_s to be G_2 and O_t to be G_1 (section 2.1), the query $\mathsf{male\_partner}(?x, ?y)$ in G_2 will be translated into the query $\mathsf{husband}(?x, ?y)$ in G_1. But the set of all husbands is not equivalent to the set of all male_partners.

2.3 Asymmetry of Translation

Given our approach, translation exhibits certain asymmetries that one must be wary of. We will subscript the symbol $\rightsquigarrow$ with a "Q" to indicate the query translation ($\rightsquigarrow_Q$), and with a "D" (for "data") to indicate the assertion or dataset translation($\rightsquigarrow_D$). (We leave the subscript off in those cases where the context allows either reading.) The asymmetry is: if β_t is the translation of α_s: $(KB; \alpha_s) \rightsquigarrow \beta_t$ that doesn't mean α_s is the translation of β_t: $(KB; \beta_t) \rightsquigarrow \alpha_s$. Slightly less obviously, if $(KB; P) \rightsquigarrow Q$ we can't conclude $(KB; \neg P) \rightsquigarrow \neg Q$.

Instead (not surprisingly), negation ends up involving the same duality as query translation. Assume that R is an expression which can be derived from KB and $\neg P_s$ by inference. Using the deduction theorem in FOL and considering that $\neg P_s \rightarrow R$ is an equivalent to $\neg R \rightarrow P_s$, we know that

$$\begin{aligned}(KB; \neg P_s) \vdash R \quad &\Leftrightarrow \quad KB \vdash (\neg P_s \rightarrow R) \\ &\Leftrightarrow \quad KB \vdash (\neg R \rightarrow P_s) \\ &\Leftrightarrow \quad (KB; \neg R) \vdash P_s\end{aligned}$$

This gives us a way to translate negations. We can think of P_s as a "ground query" ($\theta(P_s) = P_s$): Given P_s, try to find a $Q_t^{'}$, which satisfies $(KB; Q_t^{'}) \vdash P_s$. But this is just the problem of translating the query P_s: $(KB; P_s) \rightsquigarrow_Q ?$.

Therefore, if the query translation of P_s is $Q_t^{'}$, $\neg Q_t^{'}$ can be derived from KB and $\neg P_s$ by the data translation and vice versa:

$$\begin{aligned}(KB; P_s) \rightsquigarrow_Q Q_t^{'} \quad &\Rightarrow \quad (KB; \neg P_s) \rightsquigarrow_D \neg Q_t^{'} \\ (KB; P_s) \rightsquigarrow_D Q_t^{'} \quad &\Rightarrow \quad (KB; \neg P_s) \rightsquigarrow_Q \neg Q_t^{'}\end{aligned}$$

Axioms are usually more complex than a typical dataset element, and it would be useful if we could attack this complexity by translating the pieces of a complex formula and composing the results. For conjunctions and disjunctions, composition of translation is straightforward. Translating implications includes an algorithm for translating negations.

3. OUR APPROACH

3.1 Conditional Facts and ICF Axioms

To explain our approach to theory (axiom) translation, we first show how to translate *conditional facts* using our inference engine, OntoEngine [2]. A conditional fact is a formula of the form:

$$P_1 \wedge \cdots \wedge P_i \cdots \wedge P_n \rightarrow Q_1 \wedge \cdots \wedge Q_j \wedge \cdots \wedge Q_m$$

where all $P_i (1 \leq i \leq n)$ and $Q_j (1 \leq j \leq m)$ are ground atomic formulas (facts). All axioms, such as axioms 1, can be put in this form which we called *ICF (Implicative Conjunction Form)*, but of course axioms have quantified variables. It is unusual, but not unheard of, for people to need to express that some facts are true only if some other facts are also true:

$$\begin{aligned}&\mathit{precedes}(\mathit{deathof}(\mathit{Roosevelt}),\ \mathit{endof}(\mathit{WW2})) \rightarrow \\ &\qquad \mathit{president}(\mathit{Truman},\ \mathit{endof}(\mathit{WW2}))\end{aligned}$$

"If Roosevelt died before the end of World War 2, then Truman was president at the end of World War 2."

3.2 Conditional Fact Translation

Conditional fact translation is the translation of a conditional fact from the source ontology to the target ontology. It is not as simple as translating both the antecedent and conclusion in the source ontology to the antecedent and conclusion in the target ontology by the data translation with forward chaining. This is a typical example which we need to consider asymmetry of translation since the translation of implications actually includes the translation of negations and disjunctions, which has been discussed in section 2. For example, suppose we have a simple conditional fact:

$$@\mathsf{Onto1} : \mathsf{P}(A, B) \rightarrow @\mathsf{Onto1} : \mathsf{Q}(A, B)$$

where @Onto1:P means predicate P from Onto1. We want to translate this conditional fact to Onto2. Suppose @Onto1:P(A,B) can be translated to @Onto2:R(A,B) and @Onto1:Q(A,B) can

be translated to @Onto2:S(A,B), both by forward chaining. It doesn't mean that

$$@\mathsf{Onto2} : \mathsf{R}(\mathsf{A},\mathsf{B}) \rightarrow @\mathsf{Onto2} : \mathsf{S}(\mathsf{A},\mathsf{B})$$

is true. However, if there exists @Onto2:R'(A,B) satisfies:

$$@\mathsf{Onto2} : \mathsf{R}'(\mathsf{A},\mathsf{B}) \rightarrow @\mathsf{Onto1} : \mathsf{P}(\mathsf{A},\mathsf{B})$$

we know that

$$@\mathsf{Onto2} : \mathsf{R}'(\mathsf{A},\mathsf{B}) \rightarrow @\mathsf{Onto2} : \mathsf{S}(\mathsf{A},\mathsf{B})$$

is a true statement in Onto2. To get this, we need to do query translation with backward chaining from @Onto1:P(A,B) to a corresponding expression in the target ontology, such as @Onto2:R'(A,B).

It should be obvious that this process yields a valid result, in the sense that the translated fact follows from the original fact and the axioms. If backward chaining from the antecedent fails to find any goals in the target ontology, then the antecedent of the translated conditional fact will be the empty, or false, making the translation itself equivalent to true — and hence useless.

3.3 Axiom Derivation

Axiom derivation for ICF axioms still can be thought of as an inference process, if we can transform the axioms to conditional facts and transform the conditional facts back to axioms. The idea is to substitute Skolem constants for the variables temporarily. (A similar technique was used in [3].) In general, axiom derivation can be broken into three steps:

From ICF axioms to conditional facts: we can use Universal Elimination and Existential Elimination to transform ICF axioms to conditional facts. For instance, suppose that we have an axiom in the source ontology O_s:

$$(\forall x, y)@\mathsf{O\_s} : \mathsf{P}(x, y) \rightarrow (\exists z)@\mathsf{O\_s} : \mathsf{Q}(x, z) \wedge @\mathsf{O\_s} : \mathsf{R}(z, y)$$

We can substitute the universal quantified variables with constants (e.g., Atx and Bty) and substitute the existential quantified variables with uniquified Skolem terms (e.g., Skz01):

$$@\mathsf{O\_s} : \mathsf{P}(\mathsf{Atx}, \mathsf{Bty}) \rightarrow$$
$$@\mathsf{O\_s} : \mathsf{Q}(\mathsf{Atx}, \mathsf{Skz01}) \wedge @\mathsf{O\_s} : \mathsf{R}(\mathsf{Skz01}, \mathsf{Bty})$$

Conditional facts translation: suppose that the target ontology is O_t and we already have the merged ontology of O_s and O_t. The conditional fact in O_s can be translated to O_t. By backward chaining from @O_s:P(Atx,Bty) and forward chaining from @O_s:Q(Atx,Skz01) and @O_s:R(Skz01,Bty), we may finally get a conditional fact in O_t:

$$@\mathsf{O\_t} : \mathsf{S}'(\mathsf{Atx}, \mathsf{Ctc}) \wedge @\mathsf{O\_t} : \mathsf{T}'(\mathsf{Ctc}, \mathsf{Bty}) \rightarrow$$
$$@\mathsf{O\_t} : \mathsf{U}(\mathsf{Atx}, \mathsf{Skz01}) \wedge @\mathsf{O\_t} : \mathsf{V}(\mathsf{Skz01}, \mathsf{Skd02})$$
$$\wedge @\mathsf{O\_t} : \mathsf{W}(\mathsf{Bty}, \mathsf{Skz01})$$

where Ctc is a constant and Skd02 is a new generated Skolem term by forward chaining.

From conditional facts to ICF axioms: we can use Universal Generalization [3] and Existential Introduction to transform conditional facts back to ICF axioms.

For example, considering the above translated conditional fact in O_t, we can use Universal Generalization to replace all constants which have substituted universal variables with universal variables. Atx, Bty and Ctc can be replaced by x, y and c. We also can use Existential Introduction to replace all Skolem terms with existential variables. Skz01 and Skd02 can be replaced by z and d. Therefore, the generated ICF axiom looks thus:

$$(\forall x, y, c)@\mathsf{O\_t} : \mathsf{S}'(x, c) \wedge @\mathsf{O\_t} : \mathsf{T}'(c, y) \rightarrow$$
$$(\exists z, d)@\mathsf{O\_t} : \mathsf{U}(x, z) \wedge @\mathsf{O\_t} : \mathsf{V}(z, d) \wedge @\mathsf{O\_t} : \mathsf{W}(y, z)$$

It's not so obvious that this procedure works, but we have proved that it does. The detail proof can be found in a long version[1] of our paper.

3.4 Axiom Derivation for Time Ontologies

We have evaluated our axiom derivation algorithm in some real application scenarios, in which complex ontologies always have large sets of axioms. There are several time ontologies in current popular knowledge bases and (semantic) web resources, such as Cyc time [2], SUMO time and OWL-Time (formerly DAML-Time) [3]. They describe the temporal concepts, such as Instant, Interval and durationOf, and their relationships, which are represented as sets of logic axioms (e.g. OWL-Time has around 180 first order axioms.)

Researchers have manually built some mappings among the concepts of some time ontologies, but have not talked about how to represent the axioms in different ontologies. The axioms in the Cyc time ontology can be automatically translated to the OWL-Time ontology with our algorithm.

4. RELATED WORK AND CONCLUSION

To the best of our knowledge, the only other work on axiom (theory) translation is [1]. This work presents a formalism for knowledge translation based on the theory of contexts [3]. The authors define knowledge translation in terms of truth, and propose, as we do, using a theorem prover to perform the translations. However, the paper does not say exactly *how* the theorem-proving process would work.

Based on the inferential ontology translation framework, our paper has pointed out the asymmetry of translation and described an algorithm for theory translation from one ontology to another, which we call axiom derivation. Although our algorithm is provably correct, practical application requires further work on problems of incompleteness and redundancy, because our algorithm does not by itself guarantee that the axioms we produce are sufficient, nor does it avoid producing axioms that are already present in the target ontology.

ABSTRACT
Constructing presentations as stories is about presenting events that receive their relevance and meaning within the context of the presentation, and about means to define a well-structured relationship between events and the whole presentation scheme. Information in the form of annotated web content has become the most preferred source to create functional and interesting presentations because of its flexibility and availability. Nevertheless, due to the large and diverse amount of information contained in the web, the automatic construction of presentations becomes increasingly difficult in terms of the content annotation and selection in order to define events and the arrangement of such events in a coherent and story-like manner.

In this paper, we present a novel method for the construction of web presentations by implementing a simple event annotation scheme based on Rhetorical Structure Theory and an ontology-based reasoning engine that handles event sequencing to produce presentations in the form of dialogs between character agents.

Storytelling, Narrative Construction, Story Ontology, Rhetorical Structure Theory

1. INTRODUCTION
Throughout the course of our lives, we are constantly incorporating experiences to enrich our personality. These experiences, perceived in the form of world events, are organized by our minds, so we can better grasp their significance. Narrative construction through stories helps us not only to organize these experiences, but also to communicate them to others. In this context, stories are unique sequences of events, mental states, or happenings involving human beings as characters or actors [1].

The notion of "story event" is defined in several ways, each one to suit a particular way to deliver the intended message to the audience. Events can be represented as plain text, speech with intonation features, video fragments, or multimedia content based on web technology (web events). Of all these types of events, web events are the most easily accessible and flexible in terms of construction and content delivery. However, given the large and diverse body of information, the creation of a coherent sequence of events that conforms to the principle of narrative construction can become a difficult task, not only in terms of event selection, but also in terms of event sequencing.

In this paper, we will propose a new method for story construction for presentations using web events with a simple annotation scheme based on Rhetorical Structure Theory (RST Events) [5], and an ontology-based story event arrangement engine.

The rest of the paper is organized as follows. The next section will present related work in the field of story construction applications. Section 3 discusses our approach to story construction using RST. Finally, our plans for future research topics and a summary will conclude the paper.

2. RELATED WORK
Several researchers assume a concept of "event" in order to organize the content of their storytelling applications. In the work of Silva et. al [9], the story construction process is implemented through the creation of events called StoryBits. Here, each event corresponds to a piece of text that will be read out by an agent. The author defines the links between StoryBits prior to the execution of the storytelling, which makes story updating cumbersome when the number of events increases.

Similarly, Wolff et. al [11] used the concept of domino tiles to let children construct their own story, based on beginning and ending conditions of each event, which in this case are video clips from a TV show. Other works dealt with different kinds of output like text [3,10] and 3D characters [2,6]. In most of these cases, events were generated for the particular purpose of the application,

which renders them unfit for reusability in other scenarios or even in other kind of stories. Other research like that of Geurts et. al [4] used ontology driven mechanisms to select and present events (in this case multimedia content) with very interesting results, but the dependence on highly customized annotated information may complicate their deployment in a more heterogeneous medium like the Web.

3. STORY CONSTRUCTION USING RST EVENTS

3.1 Basic Definitions

An RST Event is defined as a single utterance in the context of dialog acts, performed by an Agent. As implied by its name, this utterance corresponds to the minimal unit within a rhetorical relation as established in RST. In most cases, this unit is a sentence, although it could also represent a phrasal clause. Linking RST Events through rhetorical relations forms a Dialog structure. In terms of RST, Dialogs represent the tree formed by the rhetorical analysis on a set of RST Events, and help us establish the conditions under which Events will be presented.

On the other hand, Concept Ontology refers to a hierarchical organization of concepts relevant to a unique main topic, also defined as Taxonomy of Concepts. In our model, a Concept is the description of a topic that will constrain the scope of a Dialog, that is, to define what a particular Dialog is about. Thus, a Scene is defined as a set of Dialogs that have a Concept as their common topic. In practical terms, Scenes are organized around the Concept Ontology, with one Scene object per Concept.

3.2 RST Event Organization

As stated before, RST Events are linked through rhetorical relations to create Dialogs. In order to allow easy content creation and dialog flexibility, rhetorical relations in our model are classified as either Inferable, which are relations that can be automatically generated during the presentation, or Non-Inferable, which are relations that cannot be generated and must be included as content to guarantee dialog coherence. The *Non-Inferable relations* that have to be determined for RST Events in the present version of our model are: Background, Enablement, Evidence, Circumstance, Elaboration, Solutionhood, Cause, Result, Purpose, Evaluation, and Restatement. By using these relations, the application combines the events located in Dialogs to create an inferable relation, through the use of discourse markers. For example, to create a Justify relation, the application can use Events related by an Evidence relation and emphasize through verbal cues such as "I am sure because …", or "I believe so because …" When this construction is uttered by an Agent, it will produce the sense of justification of one Event for another. *Inferable relations* defined in the present version of the model are: Motivation, Concession, Contrast, Sequence, and Joint. For a detailed explanation of the meaning of each relation, please refer to the work of Mann and Thompson on Rhetorical Structure Theory [5].

3.3 RST Event Presentation

The concepts outlined in the previous sections define how information is stored. In order to use that information to create presentations, our model defines the concepts of Talk and Conversation.

A Talk is a unique path in the set of Dialogs defined for a Scene that determines the precise, sequential way in which Agents present RST Events. In order to comply with narrative principles, Talks are centered in the notion of Intra-Talk Conflict, which is primarily defined as a question in an Elaboration or Solutionhood relation when events are taken from only one Dialog. This type of conflict is solved in the model when a solution of detailed information is given to the initial question. Additionally, an Intra-Talk Conflict can include Contrast or Sequence relations. In this case, taking events from more than one Dialog creates Talks. Therefore, a Talk can be represented by the following pattern of relations (in Extended Backus-Naur Form-like notation; ">>" denotes the "next state" relation):

```
Background >>
((Elaboration | Solutionhood) >>
(Circumstance | Purpose | (Result >> Cause) | Interpretation)+ >>
(Motivation | Enablement | Evidence | Justify | Concession)* >>
(Restatement)* >>
(Evaluation)*) >>
(Sequence | Contrast)*
```

A Conversation is defined as a set of different Talks. An appropriate selection of Concepts (as determined by the designer) characterizes a Conversation. Like in the case of Talks, narrative principles are ensured through the use of a particular type of conflict called Inter-Talk Conflict. Inter-Talk Conflicts are mostly attained by the use of a Contrast relation between two Talks, and its resolution is mainly based on a direct comparison on the number of non-inferable relations in both Talks. Nevertheless, the use of conflicts between Talks is not restricted to Contrast relations, since Talks can be performed one after the other without any conflict at all, as in the case of Talks that constitute a list of events (defined by a Sequence or Joint relation). Thus, a Conversation can be represented by the following sequence of processes:

```
Opening >> Talk1
        >> (Sequence | Joint | Contrast)
        >> Talk2 >> … >> TalkN >>
Closing
```

The Opening and Closing processes refer to discourse markers that the system uses in order to introduce the Agents to the Conversation, and their utterances are defined depending on the role of each Agent in it. The present version of our model supports two main roles: Knowledgeable (the Agent that gives the explanation) and Not-Knowledgeable (the Agent that receives the explanation as a listener). Therefore, in this paradigm, the conversation is guided into the context of a person who looks for information from another regarding a particular topic, and the use of such utterances as greetings is in accordance to this environment.

Fig. 1 shows a code example in OWL [8] of a Conversation object that has one Scene with one Dialog and a Concept named "Multimedia", which means that each Dialog defined inside that Scene is about the Multimedia topic.

```

3.4 Putting Everything Together: RST Event-based Story Ontology

Using the above-mentioned concepts as guidelines to implement our application, we have developed an OWL-based [8] story ontology to guide the decision process of constructing the story. The ontology diagram is shown in the Figure 2.

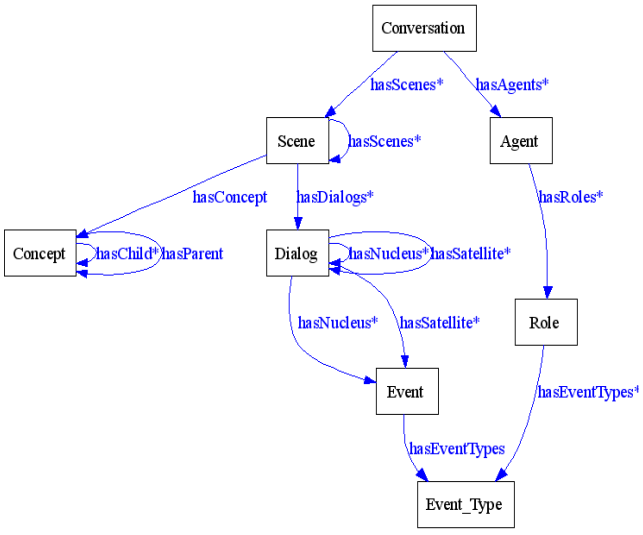

Figure 2. RST Event-based story ontology diagram

4. CONCLUSION AND FUTURE WORK

In this paper we briefly outlined a new method that may flexibly construct coherent stories using existing web content in the form of annotated events using RST.

Our most immediate consideration to improve this model is the addition of user interaction in the form of personalized, emotion-based stories. To this effect, we plan to use our emotion recognition module that detects the user's affective state and may thus support a user-dependent event selection process [7]. In this way, the application will be able to create presentations considering the user's sensitivity to the content being presented. For instance, if the user perceives certain events as boring or frustrating, the application may decide to skip that part of the story or introduce new events based on rhetorical relations that increase user's motivation.

Since there is still a fairly good amount of information that has to be manually annotated, another model improvement is to transform non-inferable relations into inferable ones. In this way, we can make the content creation task easier.

ABSTRACT
Affective reasoning plays an increasingly important role in cognitive accounts of social interaction. Humans continuously assess one another's situational context, modify their own affective state accordingly, and then respond to these outcomes by expressing empathetic behaviors. Synthetic agents serving as companions should respond similarly. However, empathetic reasoning is riddled with the complexities stemming from the myriad factors bearing upon situational assessment. A key challenge posed by affective reasoning in synthetic agents is devising empirically informed models of empathy that accurately respond in social situations. This paper presents CARE, a data-driven affective architecture and methodology for learning models of empathy by observing human-human social interactions. First, in CARE training sessions, one trainer directs synthetic agents to perform a sequence of tasks while another trainer manipulates companion agents' affective states to produce empathetic behaviors (spoken language, gesture, posture). CARE tracks situational data including locational, intentional, and temporal information to induce a model of empathy. At runtime, CARE uses the model of empathy to drive situation-appropriate empathetic behaviors. CARE has been used in a virtual environment testbed, and an evaluation suggests that the CARE paradigm can provide the basis for effective empathetic behavior control for companion agents.

1. INTRODUCTION
Recent years have witnessed significant progress on synthetic agents. With a broad range of applications in entertainment, education, and training, foundational work on synthetic agents has yielded expressive models of embodied cognition and behavior that support rich interactions in virtual environments [1, 2, 6, 16, 20, 27]. Complementing advances in cognition and behavior, affective reasoning [10, 12, 22, 25] has begun to play a central role in synthetic agents [4, 5, 20, 21], and the community is now well positioned to investigate affective reasoning in the context of social interaction [17, 23, 26]. Transitioning affective synthetic agents into the social arena could yield companion agents that provide motivating support and comfort. *Companion agents* can facilitate social interaction, a critical capability in virtual environments for education [5, 7, 20] and training [26]. Companion agents help users cope with frustration [5], deal with stress [26], and counsel children on social behaviors [23].

Empathy is a key component of social interaction [14]. Because empathetic companion agents hold much promise for socially engaging virtual environments, empathy modeling is a logical next step in the evolution of synthetic agents. One can distinguish two fundamental approaches to modeling empathy: analytical and empirical. In the *analytical* approach, models of empathy can be constructed by analyzing the findings of the empathy literature. However, empathy is not well understood. It is only in the past two decades—this is very recent in the history of psychology—that empathy has become a focus of study for social psychologists [9]. Perhaps as a result of its limited study, while we have expressive computational models of affect, e.g., the OCC model [22], we do not have similarly rich models of empathy. Moreover, because empathetic reasoning requires drawing inferences about another's intentions, her affective state, and her situational context, devising a universal model of empathy seems to be well beyond our grasp at the current juncture.

An alternative to analytically devising models of empathy for synthetic agents is the *empirical* approach. If somehow we could create models of empathy that were derived directly from observations of "empathy in action," we could create empirically grounded models based on human-human empathetic behaviors exhibited during the performance of a specific task within a given domain. While it is not apparent that this approach could produce a universal model of empathy—a universal model may not even be achievable, at least in the near term—the empirical approach could nonetheless generate models of empathy that significantly

Figure 1: Treasure Hunt virtual world with companion agent (left) and the target's agent (right).

extend the communicative capabilities of socially intelligent companion agents.

The empirical approach calls for a data-driven framework for modeling empathy. This paper presents CARE,[1] a data-driven affective architecture and methodology for learning empirically informed models of empathy from observations of human-human social interactions. During training sessions, CARE monitors situational data including locational, intentional, and temporal information while one trainer (the *target*) directs her synthetic agent to perform a sequence of tasks in a virtual environment as another trainer (the *empathizer*) reactively manipulates her synthetic agent's affective state to produce empathetic behaviors (spoken language, gesture, and posture). Inducing a model of empathy, CARE uses situational data as predictive features for empathy assessment (when to exhibit an empathetic behavior) and for empathy interpretation (which levels of valence and arousal should be chosen, i.e., the affective state). At runtime, CARE uses the resulting model to drive situation-appropriate empathetic behaviors in the companion agent as it interacts with actual users.

The paper is organized as follows: Section 2 provides background on empathy and affective reasoning in synthetic agents. Section 3 presents the CARE architecture and methodology. CARE has been used to create a model of empathy for a companion agent inhabiting Treasure Hunt (Figure 1), a virtual environment in which a user and a companion agent search for treasures. Section 4 describes the CARE implementation and its generation of the empathy models for the Treasure Hunt companion agent. Section 5 presents an evaluation of CARE based on a 31-subject experiment. The study suggests that CARE models can provide the basis for effective empathetic behavior control for companion agents.

2. Empathetic Synthetic Agents

Devising computational models of empathy contributes to the broader enterprise of modeling affective reasoning [24]. Beginning with Elliott's implementation [10] of the OCC model [22], advances in affective reasoning have accelerated in the past few years, including the appearance of a sophisticated theory of appraisal [12] based on the Smith and Lazarus Appraisal Theory [19]. We have also begun to see probabilistic approaches to assessing users' affective state in educational games [7] and investigations of the role of affect and social factors in pedagogical agents [3, 5, 11, 17, 20, 26]. Recent work on empathy in synthetic agents has explored their affective responsiveness to biofeedback information and the communicative context [26]. It has also yielded agents that interact with one another and with the user in a virtual learning environment to elicit empathetic behaviors from its users [23].

Empathy is a complex socio-psychological construct. Defined as "the cognitive awareness of another person's internal states, that is, his thoughts, feelings, perceptions, and intentions" [15], empathy enables us to vicariously respond to another via "psychological processes that make a person have feelings that are more congruent with another's situation than with his own situation" [14].

Social psychologists describe three constituents of empathy. First, the *antecedent* consists of the empathizer's consideration of herself, the target's intent and affective state, and the situation at hand. Second, a*ssessment* consists of evaluating the antecedent. Third, *empathetic outcomes*, e.g., behaviors expressing concern, are the products of assessment [9] including both affective and non-affective outcomes (e.g., judgment, cognitive awareness). Two types of affective outcomes are possible. In *parallel outcomes*, the empathizer mimics the affective state of the target. For example, the empathizer may become fearful when assessing a target's situation in which the target is afraid. In *reactive outcomes*, empathizers exhibit a higher cognitive awareness of the situation to react with empathetic behaviors that do not necessarily match those of the target's affective state. For example, empathizers may become frustrated when the target does not meet with success in her task, even if the target herself may not be frustrated. Accurately modeling parallel and reactive empathetic reasoning presents significant challenges.

3. DATA-DRIVEN EMPATHY MODELING

The prospect of creating an "empathy learner" that can induce empirically grounded models of empathy from observations of human-human social interactions holds much appeal. To this end, this paper proposes CARE, an affective data-driven paradigm that learns empathetic assessment (when to be empathetic) and empathetic interpretation (how to be empathetic). CARE consists of a trainable agent architecture and a two-phase methodology of training and learning.

3.1 Architecture

The CARE architecture operates in two modes: empathetic model induction in which the architecture interacts with two trainers (depicted in the diagram with dotted arcs), and runtime operation, in which it manages empathetic behaviors for a companion agent interacting with a user (depicted in the diagram with solid arcs) (Figure 2):

- **Empathetic Model Induction:** Trainers interact with CARE via interfaces through which they direct synthetic agents in the virtual environment. The virtual environment tracks all

[1] CARE: Companion-Assisted Reactive Empathizer.

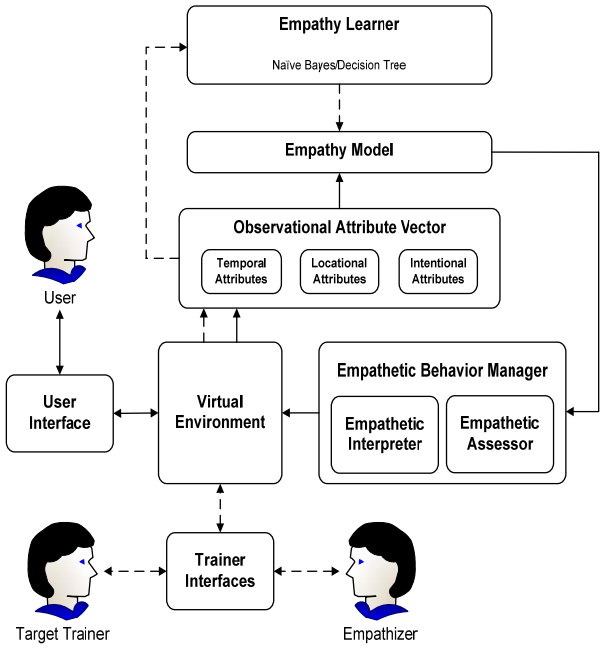

Figure 2: General Architecture

activities in the world and reports observable attributes pertaining to temporal, locational, and intentional information. These are passed to the empathy learner during the training phase. During the subsequent learning phase, the learner induces a model of empathy that is operational, i.e., it can be used at runtime.

- **Runtime Operation:** Users interact with CARE via an interface through which they direct a synthetic agent in the virtual environment. Throughout their experience, they interact with a companion agent controlled by CARE. The virtual environment again tracks all activities in the world and monitors the same observable attributes reported to the empathy learner during empathetic model induction. The induced model is used by the empathetic behavior manager to (1) assess the situation to determine *when* to be empathetic, and (2) interpret situations deemed "empathy-worthy" to decide *how* to be empathetic. When a situation calls for empathy, a suitable empathetic behavior (including speech, gesture, and posture) is selected for execution by the companion agent to react empathetically to the user's situation. Spoken components of companion agent empathetic behaviors explicitly state the affective state being conveyed with commonly associated gestures and posture, i.e., *dropped shoulders*, *arms crossed*, *looking down*, and *head shaking* gestures and postures accompany the companion agent's verbal communication, "This has become quite frustrating."

3.2 Training and Learning

In the training phase, CARE's trainable agent must be exposed to social situations similar to the ones it will encounter at runtime. Because empathy by its very nature involves multiple actors (here we focus on two), the training experience should revolve around

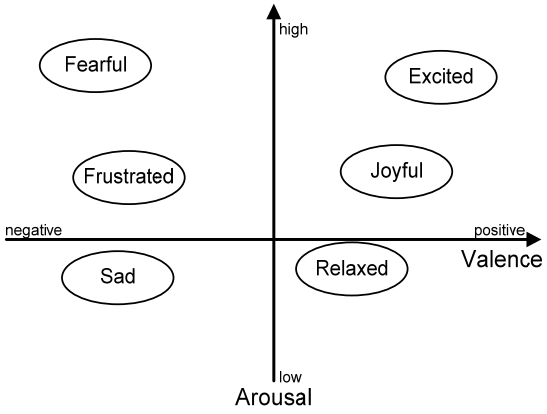

Figure 3: Two-dimensional Affective Space

the interaction of multiple subjects in situations that elicit empathetic behaviors.

CARE training sessions are therefore situated in task-oriented scenarios involving two trainers, a *target* and an *empathizer*, each of whom is represented by a synthetic agent in the 3D virtual environment where training takes place. The target, whom is given a multi-objective mission to complete, controls her agent to navigate and perform tasks in the virtual environment from a first person point-of-view (POV). It is the task of the empathizer, who looks on from a third-person POV, to monitor the target's activities and select suitable empathetic affective states based on the target's observed behaviors. Selecting an affective state causes her agent to perform an empathetic behavior.

To collect empathy data that is as representative as possible of that which will be encountered by the companion agent at runtime, training sessions must satisfy the following requirements:

- ***Affective space coverage***: At each stage of the mission, to promote the target's experiencing a range of emotions spanning the classic two-dimensional affective space defined by *valence* (degree of attraction, ranging from negative to positive) and *arousal* (level of stimulation, ranging from low to high) [18] (Figure 3), the target should be faced with goals of varying degrees of difficulty: some should be very easy to achieve, while others should be very challenging. For example, in Treasure Hunt, the virtual environment that serves as a testbed for CARE, some treasures are in plain view of the target while others are partially occluded and some are hidden altogether. Some targets should be exposed to virtual environments in which goals are easy to achieve, and some should be introduced into worlds in which goals are difficult to achieve. Thus, in some Treasure Hunt worlds, targets can score a specified number of points by collecting treasures very easily, while other worlds pose significant challenges stemming from the accessibility and varying point values. These unique situations offer opportunities for users to experience a variety of reactive emotions.

- ***Double-blind training***: Training sessions should be conducted such that the target is unaware that an empathizer is at the controls of the empathetic behaviors of the companion agent in the virtual world. Likewise, restricting the empathizer's

environment to the virtual world (i.e., without access to the target's facial or vocal expressions) enables empathetic decisions to be based solely on inferences from the observed virtual world (thus, similar inferences are likely to be made by the empathy models at runtime).

- ***Empathy-centered control***: The empathizer should be able to focus exclusively on empathy decision making. Thus, navigation control for the companion agent is provided by an autonomous path planning mechanism that ensures that the companion agent is always within a specified proximity to the target's agent in the virtual environment and that the empathizer has an adequate view of the target agent's experiences.

- ***Training session length***: Each training session must strike a careful balance between being long enough to yield a large body of data and short enough so that the trainers do not become overly fatigued. In the Treasure Hunt environment, experimentation indicated that 7-minute sessions satisfied this requirement and provided sufficient data for empathy modeling.

- ***Controlled affective expression***: Minimizing the complexity of the empathizer's task can be achieved by limiting the set of emotions at her disposal. For example, empathizers in Treasure Hunt have access to six affective states: excited, joyful, relaxed, fearful, frustrated and sad. This particular set of emotions was chosen because it covers the four quadrants of the two-dimensional affective space [18] and considers three levels arousal (high, medium and low) for each level of valence (positive or negative).

- ***Uniform agent personae***: While investigating different personae is a promising direction for future work, e.g., pedagogical agent personae experiments [3], baseline training should control for personae by holding both the target's agent and the empathizer's agent constant throughout training sessions.

- ***Situation data collection intervals***: Situation data should be collected at least as often as significant events occur, where an event is deemed significant if it can plausibly affect the empathizer's decisions. In Treasure Hunt, locational data were collected when events in the world indicated notable state changes, e.g., an agent's entering of a room, while some temporal data were monitored continuously, e.g., the amount of time between goal achievement. A typical training session in Treasure Hunt yields approximately 6,000-9,000 data points.

Accurately modeling empathy requires a representation of the situational context that satisfies two requirements. First, it must be sufficiently rich to support empathetic assessment and empathetic interpretation. Second, it must be encoded with features that are readily observable at runtime so that they may drive companion agents' empathetic decision making. CARE therefore employs an expressive representation of all activities in the virtual environment by encoding them in an observational attribute vector that is used in both modes of operation: during empathetic model induction, the *observational attribute vector* is passed to the empathy learner for model generation; during runtime operation, the attribute vector is monitored by the empathetic behavior manager for determining empathetic

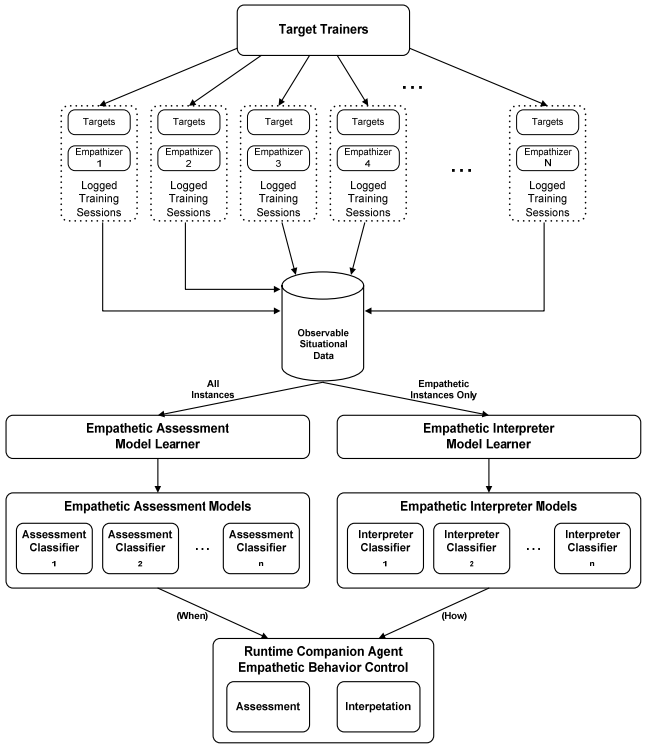

Figure 4: CARE Framework Data Flow.

behavior. CARE's observable attribute vector represents three interrelated categories of features for making empathetic decisions:

- **Temporal features**: CARE tracks the amount of time that has elapsed since the target/user arrived at the current location, since the target/user achieved a goal, since the empathizer/companion agent last behaved empathetically, and since the target/user was last presented with an opportunity to achieve a goal.

- **Locational features**: CARE continuously tracks the location of all agents in the environment. It monitors locations visited in the past, locations recently visited, locations not visited, and locations being approached. Locations are associated with specific areas in the virtual environment or areas containing significant objects or obstacles, e.g., goals or locked doors.

- **Intentional features**. CARE tracks goals being attempted (as inferred from locational and temporal features, e.g., approaching a location where a goal can be achieved), quantity and quality of goals achieved, the rate of goal achievement, and the effort expended to achieve a goal (as inferred from recent exploratory activities and locational features).

In the CARE implementation for Treasure Hunt, the observational attribute vector encodes 192 features. During empathetic model induction, an instance of the vector is logged every time a significant event occurs. On average, vectors are updated several hundred times each minute. At runtime, the same features are updated continuously by the virtual environment and are used by the empathetic behavior manager to select situation-appropriate empathetic behaviors. Figure 4 shows how information from

Figure 5: A relaxed companion agent and target agent.

Figure 6: A frustrated companion agent and target agent.

observations in CARE training sessions flows from the training phase to the learning phase for empathetic model induction.

Finally, in the learning phase, CARE induces a dual model of empathy. One component will be used at runtime to support empathetic assessment, and the other will be used to support empathetic interpretation. CARE's empathy learner first uses all of the data collected in the training session to induce the empathetic assessment model. Induction may be based on any standard classifier learning technique.

Two versions of CARE have been implemented in Treasure Hunt, one with a naïve Bayes classifier and one with a decision tree classifier. The evaluation reported in Section 5 discusses the performance of both approaches. CARE's empathy learner next uses a subset of the data collected in the training sessions to induce the empathetic interpretation model. Here, it only considers data instances in which empathy was in fact exhibited. The second induction produces a model of empathy interpretation that at runtime is used to guide agent's empathetic behaviors. The products of the learning phase are two classifiers used to determine when and how the companion agent should be empathetic as dictated by a generalized model induced from all of the empathizing trainers' empathetic behavior decisions. Because the classifiers employ features directly observable in the environment, they can be easily integrated into the runtime behavior control systems of companion agents in the form of rules or probabilistic statements.

4. EXAMPLE APPLICATION

The CARE paradigm has been used to train models of empathy and to control the behavior of a companion agent at runtime in Treasure Hunt, a virtual environment testbed in which targets/users are instructed to collect treasures in the allotted time. After introducing the Treasure Hunt virtual environment, we describe the implementation and present an illustrative example of CARE'S generating an empathetic behavior.

4.1 Treasure Hunt Virtual Environment

Treasure Hunt is a prototype virtual environment featuring a synthetic agent controlled by the user and a companion agent whose empathetic behaviors are controlled by CARE. The user navigates the 3D virtual world in search of hidden (and some not-so-hidden) treasures. Each treasure box is labeled with the value of its contents, representing points the user obtains when collecting the associated treasure. Throughout the users' quest for treasure, the companion agent follows along and expresses empathetic behaviors as appropriate situations arise in the users' experiences (Figure 5).

4.2 Implementation

CARE's empathetic assessment model and interpretation model have been implemented using naïve Bayes and decision tree approaches. A discussion of their relative performance follows in Section 5. The empathetic models were induced from a dataset consisting of a 192-dimensional observational attribute vector. The observational attribute vector consists of temporal, locational, and intentional features. For example, a sliding ten-second window was used as a temporal feature for tracking user goal attainment, while a binary locational feature monitored whether the user had yet visited the docks or rocky beach area, and an intentional feature was used to detect when the user was moving in the direction of a high-valued goal in the her view.

Treasure Hunt was implemented using a high-performance 3D game platform from Valve Software. The virtual environment, observational attribute monitoring, and empathetic models were implemented with Valve's Source™ engine (the game engine for Half-Life[2]) and the accompanying 3D game platform for Half-Life[2].

4.3 Example Scenario

To illustrate the empathetic behavior control posed by CARE, consider the following scenario, which repeatedly played out in CARE training sessions. As we catch up with the user, she has navigated her synthetic agent throughout the virtual environment struggling to find significant, high-valued treasure. The user and empathizer are aware that the user has not yet met her expected treasure collection quota (as depicted in the graphical HUD representation in the bottom corner of the display) and is quickly running out of time. Only 30 seconds remain.

Now, the user has found her agent's way into a location on the beach of the Treasure Hunt virtual environment, a location

visited by the user's agent in the early moments when the session began. The empathizer realizes that this particular location has been previously visited and was already determined to be an area without any treasure boxes. It has now been over one minute since the user last discovered any treasure at all. Assessing the situation, the empathizer selects the frustrated affective state, thereby initiating a behavioral sequence in which the companion agent announces her frustration by directly stating, "This is becoming quite frustrating," and using gestures and posture similar to the companion agent depicted in Figure 6. (The agent's speech segments are stored in pre-rendered audio clips.)

CARE's empathy learner monitored a variety of environmental characteristics, including those described above, during its training sessions. These recorded instances aid the empathy models in reproducing similar appropriate inferences in analogous situations where time is running out, the user's agent is in a previously visited location known to be without treasure, and the user's intended treasure collection goal is likely to fail. Thus, given the same situation with CARE driving the empathetic behaviors of the companion agent at runtime, empathetic assessment and interpreter models are likely to make similar appropriate empathetic decisions. The following section discusses how accurately the models learned by the agent are able to predict empathizer actions.

5. EVALUATION AND DISCUSSION

This section discusses the user study and CARE training sessions, assesses the naïve Bayes and decision tree classification approaches used for modeling empathetic assessment (when) and empathetic interpretation (how), and suggests several design implications.

5.1 User Study

In a formal evaluation, more than two hours of data were gathered from thirty-one subjects in an Institutional Review Board (IRB) of North Carolina State University approved user study. Participation included 25 targets and 6 empathizers. There were 20 male subjects and 5 female subjects varying in race, ethnicity, age and martial status who participated as training targets. There were 3 male and 3 female subjects participating as training empathizers. On average, empathizers completed 4 training sessions (SD = 1.94), each with its own unique target trainer.

Before empathizers began training, they completed Davis's Interpersonal Reactivity Index (IRI) [8], which provides a measure of an individual's empathetic nature. The index consists of 28 statements in which respondents are instructed to rate the degree to which each item describes them on a Likert scale of 0 to 4. The result is a set of 4 subscale values quantifying the following qualities of empathy: fantasy, perspective taking, empathic concern and personal distress [10]. Female empathizers scored higher than male empathizers in each quality except for perspective taking, in which the males scored one-half point higher than the female empathizers. Subjects were found to be representative of the general population in empathetic qualities, as reported in [8].

Next, empathizers were provided standard definitions of emotion and empathy, similar to those discussed in Section 2, and they were instructed to rely on these definitions for their empathetic decision making. In the meantime, training targets were prepared for the session and completed a pre-session demographic survey. Training targets were unaware of the empathizer's role until the training session was complete. In fact, the empathizer and target were housed in separate rooms for the entire session and were never exposed to the other's presence.

Once sessions began, empathizers observed training target interactions and made empathetic behavioral decisions based on the situation with which they were presented. Sessions lasted for 7 minutes. Both training targets and empathizers received post-session surveys and were interviewed to gain insight into the overall experience. In these interviews it was often mentioned by training targets that they felt the role of the companion agent was solely to provide "emotional commentary." In post-interviews with empathizers it was discovered that up to an additional set of 4 emotions, for a set of set of 10 emotions, would have been preferred.

5.2 Experiment

Both naïve Bayes and decision tree models were induced from data collected in the training sessions described above. As noted earlier, 192 observational attributes were used to define the feature vectors. Naïve Bayes and decision tree classifiers are effective machine learning techniques for generating preliminary predictive models. Naïve Bayes classification approaches produce probability tables that can be incorporated into runtime systems and used to continually update probabilities for monitoring when and how to be empathetic. Decision trees provide interpretable rules that support runtime decision making. Both the naïve Bayes and decision tree machine learning classification techniques are useful for preliminary predictive model induction for large multidimensional data. Because it is unclear precisely which runtime variables are likely to be the most predictive, naïve Bayes and decision tree modeling provide useful analyses that can inform more expressive machine learning techniques (e.g., Bayesian networks) that also leverage domain experts' knowledge.

All models were evaluated using a tenfold cross-validation scheme for producing training and testing datasets. In this scheme, data is decomposed into ten equal partitions, nine of which are used for training and one used for testing. The equal parts are swapped between training and testing sets until each partition has been used for both training and testing. Tenfold cross-validation is widely used for obtaining a sufficient estimate of error [28].

5.3 Results

Cross-validated ROC curves are useful for presenting the performance of classification algorithms for two reasons. First, they represent the positive classifications (true positives), included in a sample, as a percentage of the total number of positive classifications along the vertical axis, against the negative classifications (false positives) as a percentage of the total number of negative classifications [28]. Second, the area under ROC curves is widely accepted as a generalization of the measure of the probability of correctly classifying an instance [13]. Figure 7 shows the ROC curves for CARE's naïve Bayes and decision tree classification approaches for modeling empathetic assessment. Figure 8 shows ROC curves for CARE's naïve Bayes and decision tree classification approaches for empathetic interpreter modeling. Associated areas under each of the curves can be found in the figures' captions.

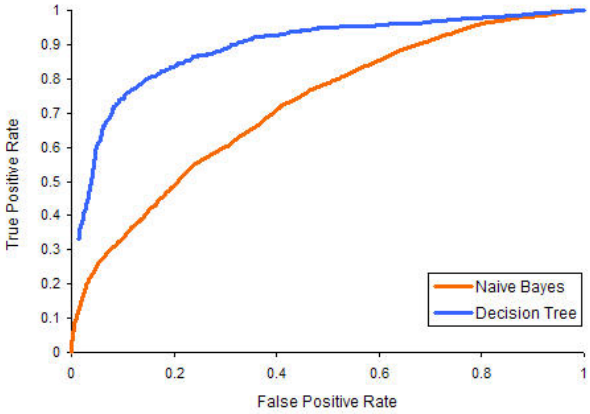

Figure 7: Empathetic Assessment (When) ROC Curves. The ROC curves for each model predicting empathetic behavior triggers in a ten second interval. The area under the naïve Bayes curve is 0.72 and the area under the Decision Tree curve is 0.89.

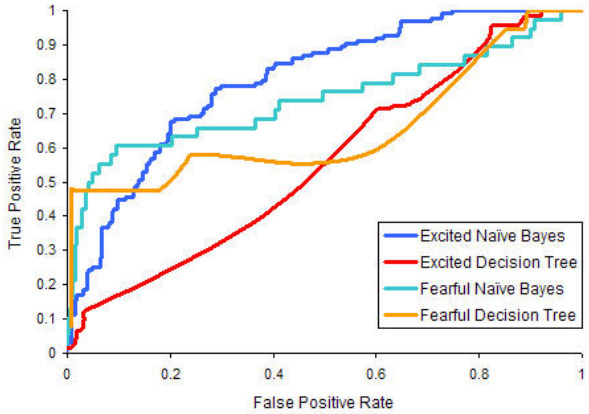

Figure 8: Empathetic Interpretation (How) ROC Curves. The ROC curves represent naïve Bayes and decision tree models for empathetic interpretation for the affective states *excited* and *fearful*. Areas under each curve are as follows: 0.80 (Excited Naïve Bayes), 0.56 (Excited Decision Tree), 0.74 (Fearful Naïve Bayes), and 0.66 (Fearful Decision Tree).

Two categories of functionality can be distinguished. First, the decision tree classifier was best suited for modeling empathy assessment, i.e., it was better able to determine *when* to be empathetic (Figure 7). Second, the naïve Bayes classifier was best suited to modeling empathy interpretation, i.e., it was better able to determine *how* to be empathetic (Figure 8). Although the figure shows only the excited and fearful emotions, all six emotions were evaluated and the naïve Bayes classifier bested the decision tree classifier in every case.

The smoothness of the curve in Figure 7 indicates that sufficient data seems to have been used for training empathy assessment, while the jaggedness of the curve in Figure 8 indicates that more data covering a large space of situations is called for in training empathy interpretation. For example, many empathizers only rarely used particular emotions, e.g., sad, and some trainers suggested that having more affective states available would have been helpful. In general, however, it appears that effective classifiers can indeed be learned for both empathy assessment and empathy interpretation.

6. CONCLUSIONS AND FUTURE WORK

Recent advances in affective reasoning have demonstrated that emotion plays a central role in human cognition and should therefore play an equally important role in synthetic agents. A key affective capability of human social intelligence is empathy. Because empathy is paramount in successful human-human interactions, it would therefore be useful to endow companion agents who are to accompany users in interactive virtual environments with the ability to empathize. Empathy modeling requires accurately assessing a social situation context in order to determine (1) if an empathetic reaction is warranted, and (2) if so, what sort of empathetic behavior should be performed.

This paper has presented a data-driven approach to learning empirically grounded models of empathy from observations of human-human social interactions. In this approach, training data is first generated as a by-product of trainers' interactions with a virtual environment, and models of empathy are induced from the resulting data sets. Critically, the training data employs only observable features, i.e., features that can be directly observed in the environment, so that at runtime, the same features can be used by the empathy models to drive the behavior of companion agents interacting with users. An evaluation of an implemented data-driven empathy modeler suggests that this empirical paradigm offers a promising technique for extending the affective capabilities of synthetic agents. Coupling models of social constructs with expressive controls of agent behavior could perhaps contribute to a new generation of socially and emotionally intelligent synthetic agents in the coming years.

In the future, it will be important to investigate mechanisms for varying empathetic responses in a manner that is most appropriate for individual users, perhaps integrating them with tools such as socio-psychologically validated empathy response instruments. It will also be important to devise integrated methods for employing user physiological response monitored via biofeedback apparati with empirically grounded models of empathy to further extend their range and increase their accuracy. Agent personae offer another direction for future research. For example, females tend to be more empathetic, supported by the fact that a disproportionately large percentage of all empathetic instances in CARE training sessions were performed by female trainers (one-half of all training empathizers were female). Furthermore, exploring models of empathy induced from attributes monitored at varying levels of abstraction may yield models that are transferable between different environments.

7. ACKNOWLEDGMENTS

The authors would like to thank members of the IntelliMedia Center for Intelligent Systems at North Carolina State University for their contributions to the implementation of CARE. Special thanks to Seung Lee for assisting with data analysis. The authors

also wish to thank Valve Software for authorizing the use of their Source™ engine and SDK.

ABSTRACT
The move in many societies toward individuals having multiple networked computational devices – workstations, notebooks computers, mobile phones, PDAs – radically changes the ways in which people engage those devices. However, we lack interaction paradigms that enable a coherent experience across these technologies. One possible approach to this problem involves the use of embodied mobile agents (EMAs), that is, graphically animated, autonomous or semi-autonomous software systems that can migrate seamlessly from one computational device to another. This paper describes an interactive museum exhibit that was implemented with EMAs, discusses the opportunities and challenges presented by this new form of agent, and consider other potential applications for EMAs. While not a universal solution to challenges of interacting with heterogeneous networks of devices, embodied mobile agents can help to provide a coherent user experience across multiple computational devices.

Categories and Subject Descriptors
H.5.1 [**Information Interfaces and Presentation**]: Multimedia information systems – *animation; artificial, augmented, and virtual realities.* I.3.6 [**Computer Graphics**]: Methodology and Techniques – *interaction techniques.*

General Terms
Design, Human Factors.

Keywords
Animated agents, virtual embodiment, mobile agents.

1. INTRODUCTION
Over the past several decades, computational devices have spread rapidly among many human societies. These devices are now sufficiently common that some people have more than one of them, for example owning a workstation, a notebook computer, a PDA, and a mobile phone. These devices are often networked to each other and to the Internet, together providing the platform for an individual's personal information space. However, the varied interaction paradigms that we use when engaging these devices do not always facilitate a coherent experience across multiple devices. In order for these devices to integrate smoothly together and for people to understand their cooperation, new interaction paradigms are needed.

This paper proposes the use of embodied mobile agents[1] (EMAs) – that is, graphically animated, autonomous or semi-autonomous software systems that can migrate seamlessly from one computational device to another – to help enable the development of more intuitive multi-device interaction paradigms. These EMAs may either be animated characters (personified agents designed to elicit social responses from people), animated creatures (biomorphic agents designed to offer some of the capabilities of animals), or animated objects (virtual agents designed to mimic real-world mobile physical objects). EMAs can help to streamline the process of working with several devices simultaneously, to increase the understanding that people have for how information is flowing among their devices, and to help different people collaborate using the capabilities of their multiple computational devices.

Applications of EMAs could reach across a wide variety of domains. In education, EMAs could be used to build multi-device, agent-based participatory simulations that enable people to interact with and learn about a variety of content domains from ecology to economics to the spread of disease. In an industrial setting, EMAs could be used to visualize the flows of information among human collaborators and their computational devices. In entertainment, EMAs could make possible entire new genres of games, with agents jumping quickly between devices carried by players in real space. Other application domains could include social computing systems, healthcare systems, and simulation & training.

To create these kinds of applications, there are a number of problems that need to be solved. How does an agent's embodied form adapt to the capabilities of each device? How can an agent be perceived by people as the same entity as it moves from device to device? How can an animated agent be socially and emotionally engaging across devices? Is it possible for the affordances of the heterogeneous networked devices to facilitate the presence of agents? By addressing these and other related problems, this research project has demonstrated that EMAs can be a robust and deployable technology.

[1] The term "embodied mobile agents" was chosen over "mobile embodied agents" because of research on the latter term deals primarily with the navigation sense of the word "mobile". Here, the focus is on creating embodied forms of mobile agents in the sense of [12].

Embodied Mobile Agents have the potential to change the way in which people interact with our growing networks of stationary and mobile computational devices. From interactive educational systems to new forms of entertainment to multi-device industrial applications, EMAs could have a significant positive impact on society.

2. RELATED WORK

The EMAs in the two projects discussed in this paper have three main characteristics: they are animated (featuring expressive device-specific graphics), they are interactive (by means of engaging interfaces and autonomous behavior), and they are able to operate seamlessly across multiple devices (such as desktop computers, tablet PCs, PDAs and cell phones).

This work is most similar to two previous projects. The project relates closely to the work of Rekimoto [23], whose Pick-and-Drop system allowed people to drag digital objects from one computer's screen to another. The proposed research builds on this idea, but places the autonomy in the software itself, rather than having the transfer happen only when specifically controlled by a user. The work also draws inspiration from McIntyre *et al.* [18], who developed a system in which an embodied mobile agent could transfer among different workstations, interacting with people via webcams at each workstation. The proposed research is different from this work in two ways: first, the proposed work deals with heterogeneous networks – engaging the challenges that come from operating on different computational platforms – and second, it focuses on the moment of transfer as an important part of the process – the animation, sound, etc. that enables people to see where the agent has come from and where it is going.

Several other research projects have also combined physical elements and virtual agents. Sumi and Mase's AgentSalon [27] is an interactive installation that uses animated agents on large displays and handheld computers to facilitate face-to-face communication. PEACH [26] features agents on handheld computers that provide information to museum visitors. Agent Chameleons [20] described agents that can migrate between robotic and virtual platforms. The project described here is different from AgentSalon, PEACH, and Agent Chameleons as this project places greater emphasis on the animated transfer between devices and on seamless cross-device 3D character animation. Agent Chameleons also does not have a tangible interface.

The development of EMAs is based on a wide range of previous work in autonomous agents and multi-agent systems. Embodied agents (those with a virtual or physical body through which they sense and act on their environment) have also been a topic of much recent research, having been studied in fields including robotics [3] and human-computer interaction [7].

Mobile agents have also been an active area of research and development in recent years, e.g., [22]. Gray *et al*. [12] defined mobile agents as "programs that can move through a network under their own control, migrating from host to host and interacting with other agents and resources on each." (p. 8) Note that the term "mobile agent" is sometimes used to refer to an agent that is able to navigate around its world. While the mobile agents described in this paper are also able to navigate around their worlds, the term "mobile" is used here to denote the interdevice capabilities of the agents, rather than their world navigation capabilities.

Many researchers have explored different aspects of mobile agent technologies, including mobile agents for networked virtual environments [9], mobile agents for network management [28] and a virtual machine for mobile agents [19]. However, non-animated mobile agents are not designed to be engaging for the users in an interactive setting, as the users will only see the result, not the process in between. This engagement is especially important for applications in the domains of entertainment and education. To enhance this engagement, the mobile agents described in this document are embodied as graphically animated entities.

To enable EMAs to animate expressively, this research builds on previous work from both academic and industrial contexts. Academic researchers have looked closely at the topics of expressiveness and believability in autonomous agents, focusing most frequently on interactive virtual humans (e.g., [11]). The computer/video game industry has also expended great effort to make engaging embodied agents. Many character-based games have been exceedingly successful financially, selling millions of copies and generating billions of dollars in sales. Some commercial products have explored the use of virtual characters in handheld devices. Tamagotchi is a handheld device inhabited by a virtual character that owners can play with and feed. Animal Crossing is a computer game that allows the transfer of virtual characters from one virtual environment to another using a memory stick.

Special effects technicians have experimented with breaking the plane of the screen as a way of increasing the believability and impact of the characters and events portrayed. For example, a show at Walt Disney World features several Muppets walking back and forth between different monitors. This project also builds on work in distributed display environments, which investigates the ways that multiple monitors may enhance the user experience, e.g. [13]. Other researchers have explored ways to use distributed display environments to represent virtual environments, e.g. [10]. The project described here seeks to have the same seamlessness in transfers between computing machines as exists in these transfers between displays.

The animation of the EMAs moves beyond this previous work in several ways. This research focuses on the moment of transfer from one device to another as a critical component in the success of EMAs. No previous project has sought to produce expressive real-time animation across the boundary between devices. The interdevice animation in these projects involves the close coordination of autonomous behavior, interactive animation, real-world sensing, interdevice communication, interface design, physical set construction, and graphical and sound effects. This research has explored the details of each of these aspects as it applies to interdevice animation, and the persistence of an agent's identity across devices. This emphasis helps to connect the real and virtual worlds by enabling the EMAs to appear to move through real space. People are accustomed to seeing animated entities on single screens, but the movement of an EMA from one screen to another helps to reduce the inherent separation that usually occurs between the physical world and a virtual environment. Finally, it engages the physical sensing capabilities of the multiple computational devices on which the EMAs operate. The Virtual Raft Project [30] used accelerometers, webcams and IrDA to enhance the believability of EMA animation. EMAs

sense both their virtual environment and aspects of the real world through a blackboard architecture through which entities in the virtual environment exchange information.

The research described here also builds on previous work in autonomous behavior and interface design. In the area of autonomous behavior, Perlin and his colleagues have done pioneering work in creating synthetic actors, e.g., [21]. Cassell and her colleagues built virtual humanoids with the ability to express themselves like real people, in particular in the area of embodied conversational agents, e.g., [5]. Blumberg and his colleagues have contributed in several areas including agent learning [1].

In order to enable EMAs and people to interact with each other, the EMA system features input and output interfaces that connect the two. These interfaces are informed by previous work in engaging and tangible interface design [15]. In the areas of pervasive computing and mobile entertainment, researchers have explored the use of tangible hardware and social computing to enhance user experience in a reality game space [6]. Borovoy and his colleagues developed Meme Tags that allows the transfer of text fragments among mobile devices [2]. Research has been done to investigate ways to enhance the interaction paradigm between a user and a cellular phone [25]. Hand and head gestures have also been suggested as an interface to a mobile interactive paradigm [17].

3. EMA-BASED EXHIBITIONS

Embodied mobile agents have been implemented in two major projects in the past year – the Virtual Raft Project and the EcoRaft Project.

3.1 Virtual Raft Project

The first, the Virtual Raft Project, is an interactive exhibit involving three standard computer workstations and three tablet PCs. The workstations represent "virtual islands" populated by groups of animated humanoid EMAs and the tablet PCs represent "virtual rafts" that participants can carry between the islands (see Figure 1). When a raft is brought up to one of the islands, an EMA can jump onto it. When the participant then carries that raft to a different island, the EMA can jump off the raft onto this new island. A video demonstrating the Virtual Raft Project can be found at:

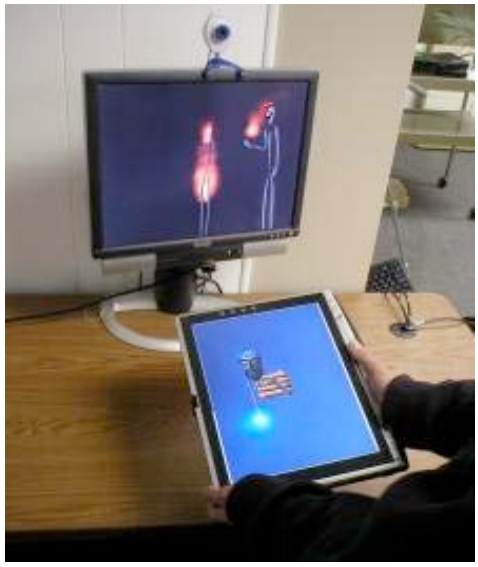

Figure 1: Embodied Mobile Agents may animate seamlessly between a desktop computer and a tablet PC.

http://www.ics.uci.edu/~wmt/movies/VirtualRaftProject.mov

This project enables people to engage physically with EMAs in three main ways. First, the act of moving the tablet PCs between the islands gives people a physical connection to the space and enables them to control the movements of EMAs among the islands. Second, webcams above each of the virtual islands, running a simple background subtraction algorithm, enable the EMAs to react to the presence of people standing in front of that island and respond to their motion. Third, accelerometers in each tablet PC let the EMAs react to the physical motion of the tablets as people carry them, swaying back and forth as the tablets are carried between islands. These three components of the implementation contribute to a sense that the EMAs inhabited the same physical space as people.

The Virtual Raft Project began several key research directions that relate to the proposed work. First, it offered a novel and intuitive interaction paradigm for a person to engage with autonomous animated characters. Second, the project began the exploration of EMAs as viable elements in a multi-user experience. Third, it explored the relevance of EMAs as part of an affective interaction, having a social and emotional impact on people. Fourth, it developed the idea of heterogeneous character animation – that is, animation that enables a real-time animated character to animate seamlessly among two or more heterogeneous devices.

Through four public exhibitions (the ACM CHI 05 conference, the CSCL 05 conference, the Games Learning and Society 05 conference, and the opening of a new building on the campus where it was developed) and numerous smaller scale demonstrations, approximately 800 people have interacted with the Virtual Raft Project to date.

3.2 EcoRaft Project

A second EMA-based project, the EcoRaft Project, was an extension of the Virtual Raft Project developed in collaboration with a team of restoration ecologists and the staff of Discovery Science Center, a science museum in Santa Ana, CA. Instead of featuring humanoid EMAs, this exhibit contained EMAs in the form of animated animal and plant species and was designed to enable 8- to 12-year-old children learn about restoration ecology. The installation consists of three stationary computers that represent virtual islands, and three mobile devices that represent rafts or boxes. Each virtual island represents a different ecosystem. The ecosystems can be populated with hummingbirds, coral trees, and heliconia flowers. Participants can use the mobile devices to transport species from one island to another by bringing a mobile device near one of the stationary computers. One of the virtual islands is the national forest, which has a fully populated ecosystem and can act as the reserve, while the other two virtual islands can be deforested by the press of a button. Participants can repopulate a deforested island by bringing different species in the right order by means of the mobile devices.

In addition to developing further the other themes mentioned above, the EcoRaft Project began to explore the viability of EMAs as tools for education. The Virtual Raft metaphor provides a set of organizing principles for an interactive

Figure 2: A group of children engaged with the Virtual Raft Project.

educational simulation. It distinguishes the operational domain of virtual creatures from that of people, thereby providing a way of explaining how people are meant to interact with the system. It provides inspiration for subject matter that may be effectively conveyed through this kind of simulation. And it provides guidance for the visual, acoustic, tactile, and other elements of the interactive experience. While the platform is not ideal for all topics of education, it does provide a useful framework for exploring topics that deal with groups of people (e.g., social or cultural education), groups of biological organisms (ecology, evolution, etc.), movements between those groups (invasive species, cultural migration, etc.), and potentially other topics (economics, math, languages) as well [29].

The EcoRaft Project was exhibited in the Emerging Technologies program at SIGGRAPH 2005, and was shown to approximately 2000 people over five days in summer 2005. In addition, the project was exhibited publicly at Discovery Science Center on two occasions, and was shown to a group of children in the research lab where it was developed (see Figure 2), with a total of approximately 200 participants.

4. IMPLEMENTATION

The hardware for both the Virtual Raft Project and the EcoRaft Project includes three stationary computers and three tablet PCs. All the computers have 3D graphics cards, infrared (IrDA) sensors, and Ethernet connectivity. Each stationary computer is connected to a webcam and each tablet PC has built-in accelerometers. Both the Virtual Raft Project and EcoRaft Project are written primarily in Java with a module written in C++ to interact with the IrDA sensors. The graphics are displayed using JOGL, the Java version of OpenGL graphics library. A number of factors combined to create an engaging moment of transition for the EMAs – animation, graphical effects, sound, autonomous behavior, networking, interface elements, and interaction context. Following are examples from both of these projects to demonstrate various ways to design engaging EMAs.

Animation is an important element of EMAs, as it represents the embodiment of the agent. It is also one of the distinct features and advantages of EMAs comparing to ordinary mobile agents. One of the challenges is that the animation must look similar on both sides of the transfer, so the users will believe that the character that appears on the source and the destination devices are actually the same character. To contribute to this believability and engagement, the EMAs on different sides of the transfer should also be consistent. The EMA before and after transfer should appear the same and the EMA should appear from the expected direction. In the Virtual Raft Project, the jump animation of a humanoid in the source computer and the landing animation in the destination computer are technically two separate animations and are played in two different machines, but the timing is precise so as to simulate a fluid and seamless transfer between the two devices.

Graphical effects can also augment the animations to make the experience more engaging and life-like. For example, the Virtual Raft includes water ripples near a moving raft, and the hummingbirds in the EcoRaft have iridescent feathers on their breast. However, the level of details of the graphical effects needs to be balanced to maintain the frame rate. For example, since the graphical capabilities of the tablet PCs did not match those of the desktop computers, the iridescence for the hummingbirds was disabled on the tablets to maintain an acceptable frame rate.

In addition, sound plays a significant role in enhancing the believability and engagement of EMAs. Sound serves as a transition indicator to convey a more convincing sense of continuity than animation alone is able to as agents move between platforms. For instance, in the EcoRaft Project when a seed rolls from one device to another, it emits a sound like a slide whistle. This slide whistle sound played an ascending tone from the device of origin followed by a descending tone on the destination device. Similarly, hummingbirds emit a distinctive set of sound effects when flying between devices. Using complementary pairs of sounds emitted from the two devices in sequence supports the illusion that a single agent leaves one platform and then appears on the other. They also provide confirmation for the user that a transfer is occurring. Furthermore, each type of agent has its own signature sound. For example, the each species of hummingbird sings a different tone, with the tones of the four species combining to form a chord. The signature sounds attached to each entity texture the soundscape much as the instrumental signatures of various characters do in Prokofiev's "Peter and the Wolf." Using sound in these various ways strengthens the connection between the embodied agent and its surroundings by giving an agent multiple avenues through which to contribute to its acoustic environment.

People often feel more engaged when they see directly visual feedback [14]. The EMAs in our implementation incorporate certain behaviors in response to human activities. Each stationary computer, which represents a virtual island, has a webcam mounted on top of the display. It allows the EMAs in the virtual world to sense the activities of users in the real world. When the webcam detects human motion, the humanoids in the Virtual Raft get up and approach the virtual camera, and the hummingbirds in the EcoRaft will have a higher probability of flying near the virtual camera. This response from the EMAs gives the impression that they have an awareness of the physical world. Also, the tablet PCs have built-in accelerometers, which can detect the tablet's motion in two axes. Our implementation allows the EMAs to respond to this data, thus reacting to the physical orientation of the tablet. In the Virtual Raft, humanoid EMAs try to balance on the raft; in the EcoRaft, hummingbirds fly to highest point of

the tablet, and seeds will roll inside the box. The added interactivity helps increase the engagement for the users interacting with the exhibit. Furthermore, these examples show ways in which EMAs are able to respond to their physical environment, blurring the line between the physical and virtual worlds.

In the EcoRaft installation, many people felt that they needed guidance to learn the ecological principles in the installation. Since this installation was designed as a science museum exhibit and it is not feasible to have a museum staff member available to demonstrate to the visitors at all times, our research team added a text overlay on the screen showing the status of the ecosystem. An accompanying voiceover also plays when the text overlay changes. This feedback loop allows visitors to try the installation and learn how to interact without needing someone to explain the system to them. It also provides an additional channel for educational content.

The transfer of EMAs from one computer to another computer also involves networking. With other mobile agents, the transfer of an agent involves packaging up the agent's behavior and memory, sending the agent data to the destination computer, and then reassembling the agent on the destination computer when it receives the data. Only one agent exists during the entirety of the transfer. The sequence of transferring an EMA is similar to the transfer of a mobile agent, involving packaging up data, sending to the destination, and reassembling the agent. In the case of an EMA, the transfer must occur during the animation so that the agent appears to transfer seamlessly; otherwise the time that it takes to transfer the agent would interrupt the animation and break the fluidity. The user will see the beginning of a transfer animation on the source device while the agent's data is being sent across. When the destination computer receives the agent data, it starts reassembling the agent and starts playing end of the transfer animation. At this point, two animated agents representing the same character exist in two different computers at the same time, but only one is visible to the user. When the whole animation sequence is complete, the agent in the source computer will be removed from the virtual world and the agent in the destination computer will continue to execute. Timing is very important in this process. If the timing is off, users may see both agents at the same time, or they may need to wait for a long time before the agent appears on the destination computer, thus decreasing the believability.

The tablet PCs have built-in infrared (IrDA) sensors and the stationary computers are connected to external IrDA dongles. The devices use the IrDA sensors to detect proximity and orientation of the other devices and TCP/IP to exchange animated characters. In this implementation, IrDA is used to detect proximity, as it is directional and the range is small. IrDA sensors require line of sight to detect each other and the detection angle is about thirty degrees, which make them good candidates to detect proximity. The sensing range of other technology, such as Bluetooth or GPS, is too broad and not precise enough for this purpose. This ensures that islands will only receive signals from tablet PCs that are in close proximity, in front of the island, and oriented correctly. When the infrared device detects that another device is in range, the two computers establish a network connection (TCP/IP) through Wireless Ethernet (802.11) and use this network connection for data transfer. TCP/IP was chosen for the communication protocol because it is faster than IrDA, especially for transferring all the attributes of the EMAs. If we had used IrDA to transfer the attributes of the EMA, it might have introduced a visible pause during the data transfer and interrupted the flow of the animation. While this method is somewhat more complex, it serves to minimize transfer delays, since wireless Ethernet allows for much faster transfer than IrDA.

5. EVALUATION

In all, approximately 3000 people have interacted with the two EMA implementations. At each exhibition of the projects, the research team observed people interacting with the system in various capacities, ranging from listening to an explanation of the system, to actually using the tablets, to watching people use the tablets, to explaining and demonstrating the system to others. During these exhibitions, groups of participants were successful in achieving basic tasks with EMAs such as distributing them evenly among specified devices with minimal introduction and in short periods of time.

In order to evaluate EMAs' capability to engage participants, the research team analyzed participants' interactions with one of the EMA-based installations described above, the EcoRaft project. A combination of qualitative techniques were employed, including non-interactive observation, participant observation, and semi-structured open-ended interviews [16]. Also, some of Druin's techniques for working with children [8] were employed. Non-interactive observation and participant observation were employed with nearly all of the 3000 participants. Interviews were done with 40 participants – 35 of them interviewed both before and after the interaction, and 5 interviewed only afterward. These interviews were conducted by one interviewer and one notetaker. The exact methodology differed slightly at the three deployment sites for these projects due to the exigencies of the various environments.

The first deployment site was in the Emerging Technologies program at the 2005 ACM SIGGRAPH Conference in Los Angeles, California. The researchers engaged in non-interactive observation; in addition, at SIGGRAPH the researchers conducted semi-structured interviews of one to two participants at a time. During set blocks of time, random participants were approached and asked if they would like to participate in an evaluation of the installation. The process began with a preliminary interview, which was done before participants had a chance to interact with the system. Participants were asked about their initial impressions regarding the EcoRaft exhibit, as well as their demographic information and technological background. A research member then gave a demonstration of the exhibit to the subject while the interviewer and notetaker observed the participants' interaction with the system. After finishing the interaction, the participants returned for a follow-up interview in which they were asked about their general impressions, their understanding of the ecological concept behind the game, the ease or difficulty in comprehending and using the system, their perspective on the realism of the exhibit, and whether or not the interface was natural and intuitive.

The second deployment site was at the Discovery Science Center, a hands-on science museum in Santa Ana, CA. The participants consisted of children, ages 7 to 13, visiting with family members or with day camps and summer schools. In addition to making non-interactive observations, the researchers asked some of the children to describe their experiences in an interview and give their impressions about

the system. Interviews were conducted with children randomly selected from those who interacted with the system for at least three to five minutes. Those children who agreed to participate in the interview were brought, with their parent or guardian accompanying, to a quiet room separate from the exhibit space for the interview. Interview questions were similar to those asked of other participants, as well as questions about whether they worked with other children and what they had learned.

The third setting was in a research lab on the campus of UC Irvine. The subject group consisted of local home-schooled children ages 5 through 9, all of whom were familiar with the Virtual Raft Project. The participants were split into focus groups of 4 to 5 children accompanied by parents or guardians. Before interacting with the system, participants were interviewed to determine their familiarity with rainforest ecology and restoration, as well as general familiarity with technology and what they remembered from the previous interaction. The focus groups were then combined and allowed to interact with the system together as one large group. After the interaction, follow-up interviews were conducted with the same small focus groups. The questions in these interviews were similar to the questions asked of the children at Discovery Science Center.

Researchers' observations and participants' responses indicated that participants of varying ages and levels of technical experience were able to quickly learn how to interact with the system. When asked about the interaction with the EMAs, participants indicated that "it seemed fairly intuitive" and that the interaction "was really easy, it's very accessible, that's definitely a very big plus." One of the most engaging aspects was what happened while the object being transferred was located on the participant's tablet. As described in the implementation section, accelerometers in the tablet PCs allowed virtual objects contained therein to move around as if affected by gravity, transforming these virtual objects into "quasi-physical objects," as one participant put it. According to another, "the ability to actually roll the seed around makes it an actual real object." This "quasi-physicality" made the EMAs seem so much a part of the physical world that many participants, especially the children, tried to interact with them by touching the screens of the tablet or the stationary computers. Also important was the seamless transfer between devices. "I am really impressed with how well images transfer from the tablet right to the screen," said one participant. "Everything seems to jump out." The coordination of animation, sound, networking, and other aspects of the implementation created a physicality that served to increase the engagement level for the large majority of participants.

However, the evaluations demonstrate that not every aspect of the EMAs was as successful at engaging participants. In the EcoRaft, very few participants noticed the effect of the webcams. When asked about them, one participant knew that they had "something to do with the recognition of something [in front of the screen]… it senses that basically there's something trying to interact." However, this individual thought that it was related to sensing the presence of the tablet, not the motion of participants, and had no idea that it affected the behavior of the hummingbirds. With the Virtual Raft, though, far more people noticed the change is the humanoids' behavior when a participant approached; many thought the humanoids were coming over to say hello when participants approached the screen. It could be that people are more willing to attribute that sort of intelligent behavior to humanoids rather than hummingbirds, but it is more likely due to the fact that the change in the humanoids' behavior is very sudden and obvious in comparison with that of the hummingbirds. The important point here is that people's effects on the behavior of EMAs should be obvious, such as that of the accelerometers, and less subtle, such as that of the webcam in EcoRaft.

The evaluations suggest that the EcoRaft is an effective tool in teaching about the process of restoration ecology. One of the core concepts behind the installation is that one cannot simply plant a bunch of seeds and expect them to grow, but rather specific species have to be brought to deforested areas in a specific order [4]. This concept is key to the process of restoration ecology. Many participants, when asked about the concept behind the installation, responded with comments such as "[the process] needs to be [done] in a specific order, that you need to put the tree first before you take the flower over there," or "you can't just put a bird there and expect it to stay without having a plant and the plant needs to be fed by the trees."

These evaluations demonstrate that EMAs are an effective approach to designing engaging autonomous agents. They point to some of the aspects of the design that act to increase that engagement, chiefly animation across heterogeneous devices and ways for the agents to react to the state of the surrounding physical world, as well as some other aspects that do not help as much to increase engagement. Furthermore, these evaluations show that EMAs can be and have been deployed as an effective educational tool, harnessing the increased levels of engagement they provide to teach concepts from restoration ecology.

6. DISCUSSION

This research anticipates the continued expansion of mobile devices into many aspects of life around the world. Many of these devices will have a variety of input and networking technologies such as high-bandwidth connections, global positioning, machine vision, and voice recognition. This is already the case in many places in the world. Software agents will operate on many of these machines, performing complex tasks both autonomously and at the explicit request of users. These agents will operate readily across devices, taking action fluidly on heterogeneous computational systems. The research described in this document examines the process by which these agents may be embodied on heterogeneous networks of devices. As the various aspects of embodied mobile agents begin to be addressed, this area may begin to develop as a platform for educational technology, new forms of computer gaming, and other work-related and social multi-device interactions.

EMAs could have applications in a number of different areas. As has been described above, EMAs could be applied to the area of ecology education by creating a participatory simulation in which several computers serve as virtual habitat niches populated by several EMA species, and mobile devices let children move EMAs from niche to niche. The EcoRaft Project seeks to serve this purpose. In addition, EMAs could be useful in teaching a wide range of complex topics, from economics (the flow of trade) to physiology (the transport of nutrients in the body) to chemistry (the reactions of chemicals as they mix) to global health issues (the transmission of disease). The project seeks to design EMA technologies that

are sufficiently general to be applicable in these and other domains, as well as to provide a specific example of the application of EMAs to education through the EcoRaft Project.

An industrial application could involve a system to support a group of people collaborating on a project, where the flows of information are embodied as animated information objects moving from device to device. For a person on the East Coast, EMA-based information objects coming in from the West Coast could appear on the west side of his or her PDA's screen; similarly EMAs coming from upstairs could drop from the top of a desktop monitor. Size, speed, appearance and behavioral characteristics could provide immediate feedback about the content of the information object, and interactions among EMAs could convey the relationships among them. This kind of contextual information could help each person to understand both the geographical and the conceptual dynamics of the project.

An entertainment application could involve a game in which several humanoid EMAs are jumping rapidly from device to device, and the goal is to catch certain EMAs, while passing off others to one's competitors. This game would be a kind of mixed reality "hot potato" game, incorporating aspects of both virtual world and real world engagement.

These potential applications point to the relevance of EMAs to several domains that currently exist or are not far into the future. In the longer term, EMA research could also help to create entirely new forms of human-machine interactions, where autonomous systems play a more significant role in computation. Currently, many people are skeptical of computational systems with too much autonomy, and there is a focus on interacting "through" computers rather than interacting "with" computers [24]. As computational systems grow more powerful, it may be relevant for paradigms to develop through which people can utilize this potential. EMAs may be of some use in designing systems where people interact effectively with multiple computing devices and autonomous computational entities.

7. FUTURE WORK

With regard to the EcoRaft Project, the research team is working on a number of topics that will enable the permanent installation of the exhibit at Discovery Science Center. Specifically, the tablet PCs need to be mounted on rolling platforms that will prevent them from being dropped by participants and will also store longer-lasting batteries. As an alternative, the research is also being done on implementing a version for smaller, more durable mobile devices such as PDA's, as discussed below. Also, the flat panel displays need to be covered with Plexiglas to protect them from interactions where participants assume that they must be touch screens, and poke them with their fingers or bump them with the tablet PCs. There are numerous robustness challenges beyond the software itself in an installation designed for 250,000 annual visitors.

In addition to designing the first museum exhibit, the team is beginning the development of a network of regionally specific ecological exhibits for science centers and museums around the world. Each exhibit will feature a collection of animal and plant species that are tailored to a specific regional ecosystem, to help visitors learn about the ecological issues of their region. For example, a Minnesota exhibit might focus on the reintroduction of wolves, while other exhibits might address the spread of invasive species such as snakehead fish or American bamboo. These exhibits will be built on the same basic Virtual Raft platform.

The authors are also currently working on the integration of Palm devices into the system, and anticipate a number of opportunities and challenges in this regard. The differences in input, output and networking capabilities will require additional effort to incorporate these devices. For example, the smaller size of the device will entail a variety of modifications to the graphical representations of the EMAs. In addition, the limited memory and processing capacity will also entail the implementation of new subsystems to enable EMAs to scale effectively in both memory footprint and processing needs.

With regard to developing EMAs for broader application, security becomes a significant concern. An autonomous agent capable of moving between devices could easily be seen as a kind of computer virus. There are at least two main potential security problems. First, an agent from one's own device could migrate to someone else's device, carrying with it potentially sensitive information. Second, an agent from an unknown or undesirable source could migrate to one's own device, carrying with it a harmful payload or at least being a new kind of spam. Therefore, having a substantial mechanism for preventing unwanted mobility of agents will be an important part of this project.

In addition to these topics, there are significant areas of future work in the integration of EMAs with existing software systems. For example, how can existing mobile agents be given an animated embodiment so that people can perceive their actions more clearly, and how could existing embodied agents be enhanced by allowing them to cross smoothly between devices? These areas of future work could be relevant to a great number of current agent-based systems.

8. CONCLUSION

This paper has proposed that embodied mobile agents (EMAs) can help to provide a coherent user experience across networks of multiple computational devices. Two interactive projects implemented with EMAs have been demonstrated at several major conferences (ACM CHI, ACM SIGGRAPH, CSCL), a public science center, and a number of other venues, to a total audience of approximately 3000 participants. Evaluations of the EMA system based on these participants' experiences were presented, demonstrating some of the advantages and challenges of EMA-based systems. While EMAs are not a solution to all multi-device interactions that people might wish to have, they could be an effective tool in the effort to create seamless interactions across the heterogeneous networks of devices that people increasingly use for learning, work, and play.

ABSTRACT
Recent years have seen significant growth in work on interactive storytelling environments. A key challenge posed by these environments is narrative planning, in which a *director agent* orchestrates all of the events in a storyworld to create an optimal experience for a user, who is herself an active participant in the unfolding story. To create effective stories, the director agent must cope with the task's inherent uncertainty, including uncertainty about the user's intentions and the absence of a complete theory of narrative. Director agents must be efficient so they can operate in real time. In this paper, we present U-DIRECTOR, a decision-theoretic narrative planning architecture that dynamically models narrative objectives (e.g., plot progress, narrative flow), storyworld state (e.g., plot focus), and user state (e.g., goals, beliefs) with a dynamic decision network that continually selects storyworld actions to maximize *narrative utility* on an ongoing basis. The U-DIRECTOR architecture has been implemented in a narrative planner for Crystal Island, an interactive storyworld in which users play the role of a medical detective solving a science mystery. Preliminary evaluations suggest that the U-DIRECTOR architecture satisfies the real-time constraints of interactive environments and creates engaging narrative experiences.

Categories and Subject Descriptors
H.5.1 [**Multimedia Information Systems**]: Artificial, augmented, and virtual realities.

General Terms
Algorithms, Design.

Keywords
Interactive Narrative, Synthetic Agents.

1. INTRODUCTION
Narrative plays a central role in communication and cognition. With the demand for increasingly sophisticated entertainment and education applications, recent years have witnessed significant growth in research on interactive storytelling environments that create engaging narrative experiences [21, 22, 28, 33]. A critical component of this enterprise is devising effective computational models of narrative [1, 9, 20, 26, 30, 35]. These models support *director agents* that dynamically direct a cast of believable virtual characters in rich 3D storyworlds with coherent narrative structures that play out interactively in real time.

Director agents for interactive storytelling environments operate on at least two distinct but interacting levels: They craft the global story arc, typically by traversing a *plot graph* [2] that encodes a partial order of significant events in a story, and they plan the behaviors of the virtual characters and physical events in the world [3, 19]. To create an engaging experience for the user, director agents must carefully balance character believability and plot coherence [30], cope with deviations from a previously devised narrative structure caused by user actions [20, 29], provide fine-grained character control (both dialogue and actions) [22], all the while creating stories that obey the author's aesthetic, perhaps represented as an evaluation function that guides a search through a plot graph [2, 26, 35]. Director agents must also interface with believable agent functionalities supporting the story's virtual characters [14, 19, 32].

A key challenge posed by narrative planning is coping with the multiple sources of uncertainty inherent in the task. First, it is difficult to precisely infer users' goals, beliefs, and experiential attributes. It is difficult to accurately predict what effects changes in the storyworld may have on the user. Because it is important that users believe that their actions affect the ongoing story [24], predicting the effects of narrative planning actions is further complicated by the fact that users are active participants in the narrative. Second, we do not have—perhaps we *cannot* have—a complete theory of interactive narrative. We do not even have well defined theories of narrative for specific genres or particular storyworlds. Third, despite the episodic nature of narrative, however inaccurate our predictions might be over very short periods, they become even less accurate as we attempt to predict effects farther into the future.

The high degree of uncertainty, together with the multiple factors affecting narrative planning, call for a principled decision-making framework that enables director agents to rationally choose among candidate storyworld actions. The framework

must not only be able to effectively cope with uncertainty, it must be able to exploit the evidence available about the user and storyworld state to achieve the (possibly competing) narrative objectives, and it must be able to meet the real-time performance requirements of interactive environments.

In this paper we present U-DIRECTOR,[1] a decision-theoretic narrative planning architecture that uses a dynamic decision network [11] to model the narrative objectives, storyworld state, and user state. Rather than adopting an *ad hoc* approach to reasoning about the multiple sources of evidence, at each tick of the clock, U-DIRECTOR systematically evaluates the available evidence, updates its beliefs, and selects the storyworld action that maximizes expected narrative utility. The U-DIRECTOR architecture has been implemented in a narrative planner for Crystal Island, an interactive storyworld in which users play the role of a medical detective solving a science mystery. Preliminary evaluations suggest that the U-DIRECTOR architecture satisfies the real-time constraints of interactive environments and creates engaging narrative experiences.

2. NARRATIVE PLANNING

Narrative experiences are powerful, and there is growing awareness of narrative's foundational role in psychology [7], cognitive models of reading comprehension [13], and film theory [5]. In Gerrig's seminal work on comprehension [13], he identifies two properties that readers experience. First, they are *transported*, i.e., they are somehow taken to another place and time in a manner that is so compelling it seems real. Second, they *perform* the narrative. Like actors in a play, they actively draw inferences and experience emotions as if the experiences were somehow real. Because narrative is compelling on many levels, interactive applications in entertainment, education, and training increasingly leverage narrative to create engaging experiences through rich virtual storyworld environments.

Early interactive narrative-based media were either partially or entirely scripted. All events were either completely linear or were ordered in a pre-determined branching structure [6]. However, the simplicity of the tree-like representations severely limited the level of interactivity that users could experience, and the combinatorics of highly interactive storyworlds could not be accommodated. Interestingly, the pre-scripted tradition lives on and thrives today; it is the approach used by most educational software and video games.

Dynamic narrative generation, in which stories are created on the fly (perhaps in response to users' actions), offers a promising alternative to pre-defined branching structures. Work on text-based dynamic narrative generation has yielded computational models of narrative that manipulate characters' goals and actions [23], reason about the "virtual author's" goals [18, 34], and generate extended natural language prose for narratives [8]. Dynamic narrative generation is particularly well suited to interactive storytelling environments. If narratives can be created incrementally in response to users' actions, then users can (legitimately) be made to believe that they are empowered as active participants in the story, thereby increasing their sense of agency and immersion [24].

Narrative planning for interactive storytelling environments has been the subject of increasing interest [21, 22, 28, 33]. Recent work on narrative planning has investigated a broad range of issues for interactive story environments. The narrative community has devised techniques for tightly-coupled plot creation and character behavior in dialogue-oriented interactive stories [22], search paradigms for encoding author aesthetics with an evaluation function [26, 35], and monitoring users' actions to determine if they are threatening the plot and, if so, either accommodating the new development or intervening [20, 29]. Work on emergent narratives, in which highly believable synthetic agents are given initial goals in a simulated world, has been particularly active [1, 9]. For example, a promising technique for creating emergent narratives is providing virtual characters with hierarchical task networks to drive their interactions with one another and the user [9]. Recognizing the "authoring bottleneck," some have explored efficient techniques for designing virtual characters [19, 32].

3. DECISION-THEORETIC NARRATIVE PLANNING

A key challenge posed by narrative planning is coping with the significant uncertainty associated with the task. First, narrative planning must deal with unobservable aspects of the user. These include her beliefs about the storyworld, her goals, and her experiential state, such as her level of engagement. Being able to effectively reason about these user characteristics is essential for proper user-story mediation. For example, it is important to have an accurate picture of the user's state to determine when and how to intervene or to accommodate the user's actions [15, 20, 29]. Second, we do not have available to us a formally represented theory of interactive narrative that supports sound and complete inference about story construction and its impact on the user. Further complicating the problems posed by uncertainty is the multitude of factors that bear on narrative decision-making activities. For example, narrative objectives such as ensuring plot progress and maintaining narrative coherence are affected by factors associated with the user's state as well as activities in the storyworld, e.g., character behaviors. Finally, narrative planning must weight all of these factors as it drives towards the goal of creating the best possible narrative experience at each juncture of the unfolding story. In short, it should satisfy the following requirement:

> ***Narrative Rationality****:* Reasoning in a principled manner about narrative objectives, storyworld state, and user state, each with its own associated uncertainty, in the absence of a complete theory of interactive narrative, to rationally select actions that maximize expected narrative utility.

It is important to note that narrative rationality must be realized in real time to accommodate the demands of interactivity.

To address these requirements, we introduce U-DIRECTOR, a decision-theoretic *director agent* architecture that uses a dynamic decision network to achieve narrative rationality. Inspired by innovative decision-theoretic approaches to inference in intelligent tutoring systems [10, 25], U-DIRECTOR explicitly models the uncertainty in narrative objectives, storyworld state, and user state. In each decision-making cycle, it systematically evaluates the available evidence, updates its beliefs, and selects the storyworld action that maximizes expected narrative utility.

[1] U-DIRECTOR: Utility-based Director Agent

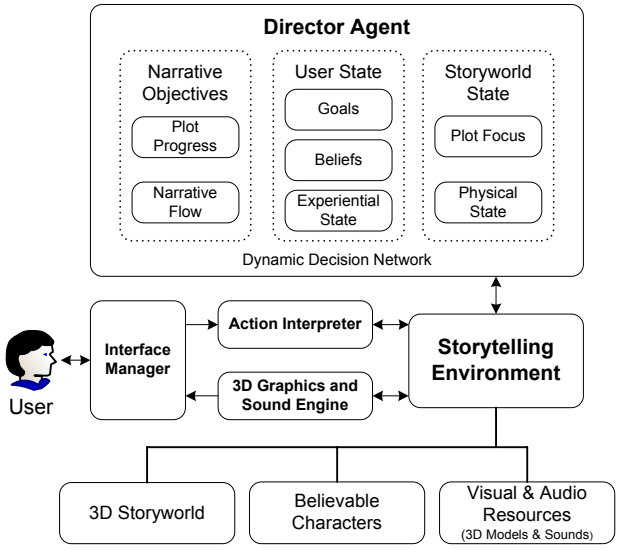

Figure 1. General Architecture.

3.1 Architecture

The U-DIRECTOR architecture is shown in Figure 1. All user activities in a U-DIRECTOR storytelling environment are mediated by the interface manager, which provides interaction and rendering functionalities. The storytelling environment, which drives the rendering and sound engines, employs three sets of resources: a representation of the 3D storyworld, a cast of semi-autonomous characters, and media libraries housing 3D models and sound effects. So that the director agent may carry out its primary tasks of plot creation and character behavior control, it monitors the user's activities and the actions of the semi-autonomous characters in the storytelling environment to craft the narrative.

The director agent has access to three principle knowledge sources: narrative objectives, storyworld state, and user state. The director agent continuously monitors and seeks to achieve the *narrative objectives* to ensure that steady progress is made through the plot (plot progress) and that global coherence is maintained (narrative flow) so that the story does not seem disjoint as a result of non-motivated actions occurring. Its *storyworld state* knowledge includes information about which plot points are currently active (plot focus), as well as basic knowledge of the storyworld and characters (physical state), e.g., the characters' goals, behaviors, and current locations. Its *user state* represents knowledge about the user's current goals, her beliefs about the storyworld, and experiential attributes, such as engagement, which are inferred from her actions in the storytelling environment. Details of knowledge source representation are discussed in Section 3.3. To cope with the uncertainty in narrative planning, the three sets of knowledge sources are integrated into a dynamic decision network (DDN) maintained by the director agent. The director agent evaluates the DDN to solve the decision problem in each cycle to select the next narrative action.

3.2 Dynamic Decision Networks

Dynamic decision networks (DDNs) extend decision networks, which in turn extend Bayesian networks. *Bayesian networks* [27] are composed of chance nodes with their associated conditional probabilities and influence arcs that collectively form a directed acyclic graph. Bayesian networks provide a compact representation of the full joint probability distribution and allow inferences to be made about any attribute within the network once priors, conditional probabilities, and available evidence have been specified.

Decision networks [16], also known as *influence diagrams*, extend Bayesian networks to provide a mechanism for making rational decisions by combining probability and utility theory. In decision networks, in addition to chance nodes, the network contains utility and decision nodes. The decision nodes represent the choices of the decision-maker while utility nodes model the decision-maker's preferences. In a decision cycle, a decision theoretic agent chooses the action with the maximum expected utility.

Dynamic decision networks [11] provide a principled approach for agents to make rational decisions in the face of uncertainty within changing environments. To cope with time varying attributes, DDNs maintain a series of time slices to represent attributes at successive moments in time. An arc connecting an attribute in a previous time slice to an attribute in a later time slice encodes an influence on the attribute's value from the previous attribute value. Dynamic decision networks provide a useful framework for modeling beliefs about the world, associating preferences with states of the world, and making decisions.

3.3 Director Agent DDNs

Narrative is fundamentally a time-based phenomenon. Director agents must therefore take into account the narrative history and be able to as accurately as possible predict (1) the effects of candidate actions on the user and (2) the effects of user's actions on possible future courses of the narrative. Therefore, in each decision cycle, U-DIRECTOR considers candidate narrative actions to project forward in time the effects of the actions being taken and their consequent effects on the user. To do so, it evaluates its narrative objectives in light of the current storyworld state and user state. Each decision cycle considers three distinct time slices (*narrative state*$_t$, *narrative state*$_{t+1}$, and *narrative state*$_{t+2}$), each of which consists of interconnected sub-networks containing chance nodes in the DDN (Figure 2). The three slices represent (1) the current narrative state, (2) the narrative state after the director agent's decision, and (3) the narrative state after the user's next action. The DDN's *director action* is a decision node, the DDN's *user action* is a chance node, and *utility*$_{t+2}$ is a utility node in the DDN. Each time slice encodes a probabilistic representation of the director's beliefs about the overall state of the narrative, represented with the following knowledge sources:

- *Plot Progress*: Models the storyworld's plot graph, a representation of temporal relations that hold between storyworld events; identifies which elements in the plot graph are waiting, ready, or completed.
- *Narrative Flow*: Models thought flow (coherence of actions to support a particular goal, e.g., searching a room after being asked to do so) and location flow (coherence of actions within spatial constraints of the storyworld, e.g., discovering multiple physical clues within the same room, one after another) associated with plot point completion; thought flow and location flow are both represented by annotations on

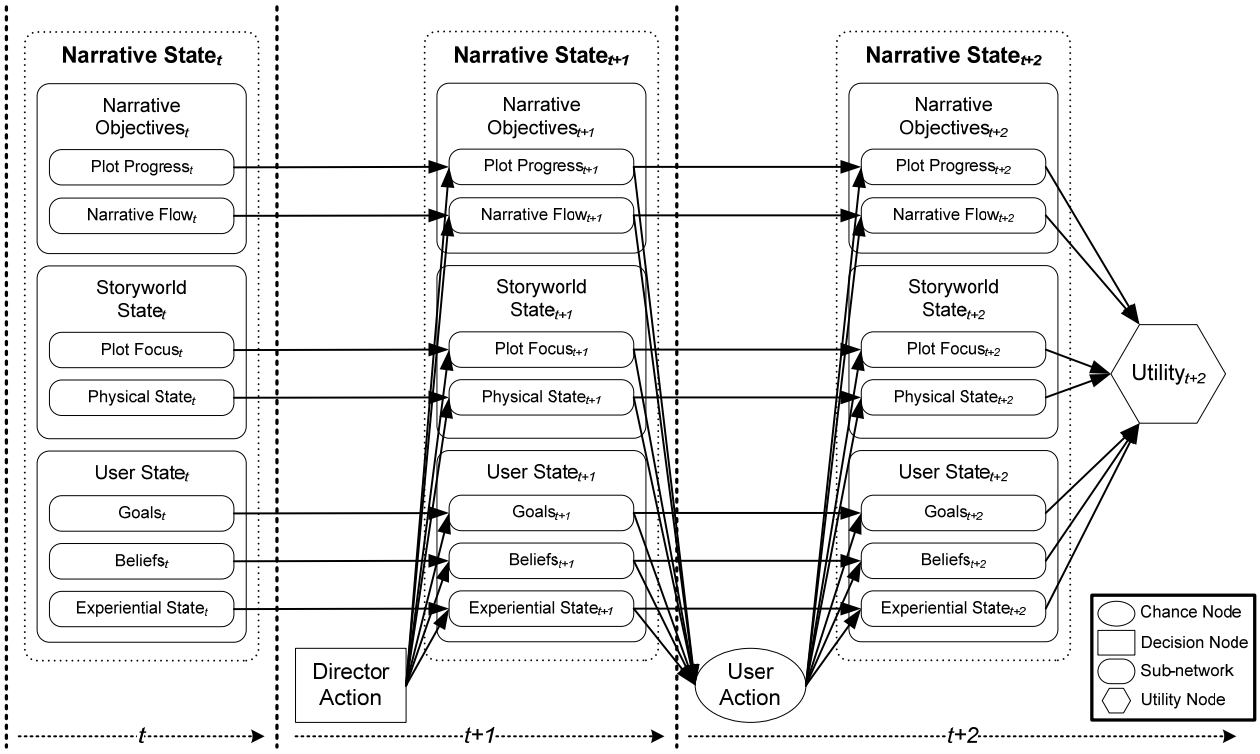

Figure 2. Director Agent Dynamic Decision Network.

user actions, indicating the relative importance for particular plot points.

- *Plot Focus*: Models the plot points that are currently active to which (it appears to the director agent) the user is currently attending.
- *Physical State*: Models the current location of the user and characters in the storyworld, and models the user's activity level as indicated by her character's interactions with objects and characters in the storyworld.
- *User Goals and Beliefs*: Models the user's knowledge about the salient facts of the story that she has learned through interactions with the environment and other characters, as well as her plot progress and focus (see above).
- *User Experiential State*: Models the user's independence (as indicated by how much manipulation the director agent has performed), her engagement (as indicated by how active she is in the environment – see physical state above), and her excitement (as indicated by changes in her knowledge about the facts of the world and pacing information).

Representations of each of these knowledge sources are integrated directly into U-DIRECTOR's DDN. It is important to note that each knowledge source is itself in fact a sub-network encoding many beliefs about particular components of the narrative state. For example, Figure 3 depicts a portion of a plot focus network and its influences by a plot progress network. Nodes in the plot progress network are used to predict likely user actions as they make their way through the narrative. The director agent takes them into account during each decision-making cycle as described below.

Computation begins by considering the current beliefs about the narrative objectives, storyworld state, and user state, represented in *narrative state*$_t$. U-DIRECTOR models candidate director actions and how they influence the story using links from the director action to *narrative state*$_{t+1}$. Example director actions include providing various levels of hints to the user to guide them through the plot and instructing characters to perform actions that the user is either neglecting or does not seem to be capable of performing. To constrain the number of candidate actions to evaluate, U-DIRECTOR models abstract director actions [26, 35] so that it does not in this step have to attend to the plethora of concrete storyworld actions. Next, it models how the user's actions depend on the possible worlds encoded in *narrative state*$_{t+1}$. In turn, it models how possible user actions influence the story in *narrative state*$_{t+2}$.

Finally, the director's preferences over potential narrative states are modeled with links from *narrative state*$_{t+2}$ to the utility node *utility*$_{t+2}$. Preferences provide a representation in which authors specify the relative importance of salient features of the narrative state. Narrative utility serves a similar function in the director agent's DDN as evaluation function serve in search-based narrative planning [35]. For example, the importance of "location flow" [26] can be appropriately weighted to suit an author's aesthetic when the DDN is constructed.

Once the director agent has fully updated the network, it selects the director action that maximizes the expected narrative utility, waits to see what action the user takes (if any) and updates its beliefs as necessary. It then begins the cycle over again, performing a "rollup" operation (also known as "filtering"), which usually involves the use of approximation techniques [4], to reduce the number of slices needed in memory at a given moment in time.

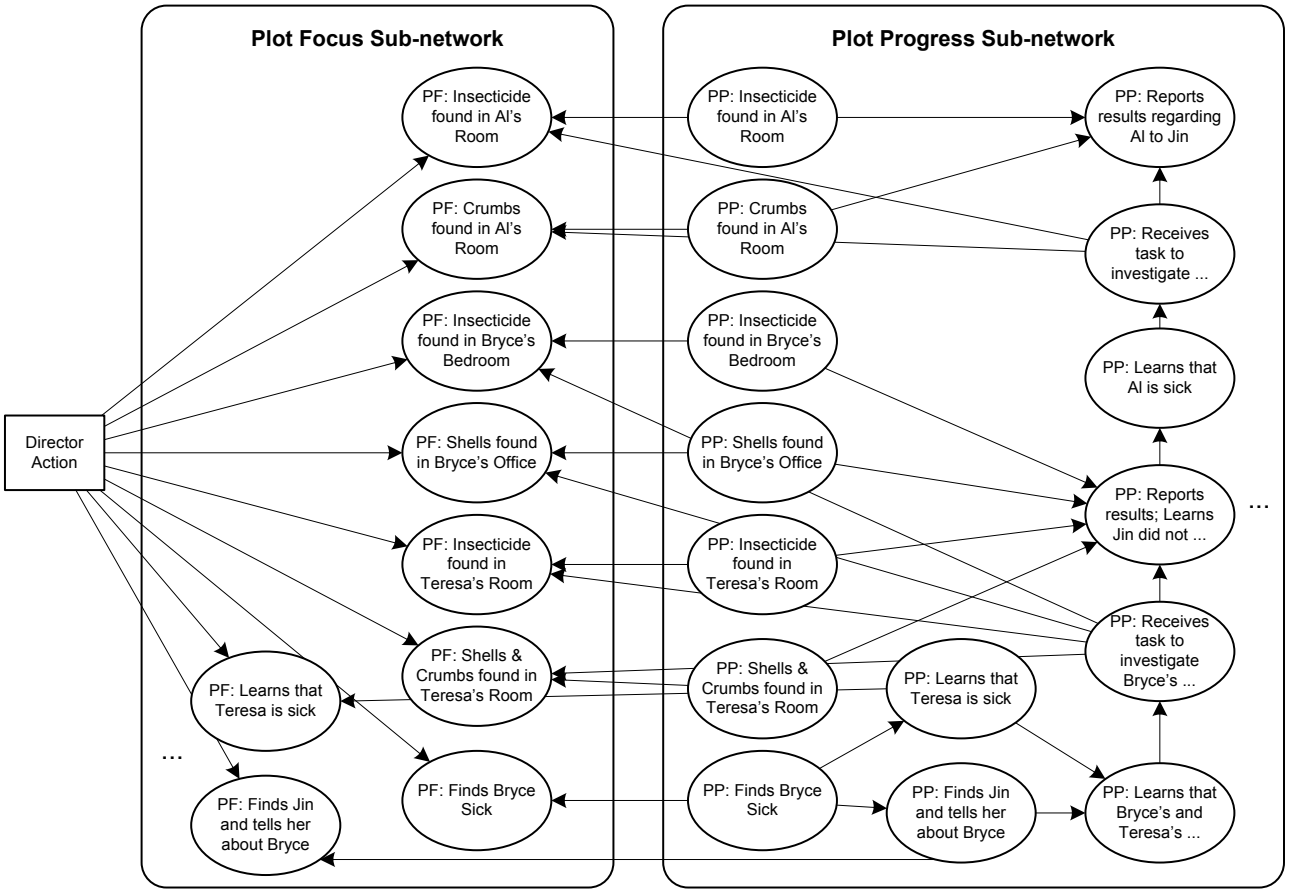

Figure 3. Selected Elements of the Plot Focus and Plot Progress Sub-networks.

4. EXAMPLE DOMAIN

The U-DIRECTOR architecture has been implemented and evaluated in a narrative planner for Crystal Island, an interactive storyworld in which users play the role of a medical detective solving a science mystery. After introducing the Crystal Island storyworld, we describe the implementation and present a sample interaction illustrating U-DIRECTOR's behavior.

4.1 Crystal Island Storyworld

Crystal Island is a prototype interactive storytelling environment featuring a science mystery set on a recently discovered volcanic island where a research station has been established to study the unique flora and fauna. The user plays the protagonist attempting to discover the origins of an unidentified outbreak at the research station. The story opens by introducing her to the island and the members of the research team for which her father serves as the lead scientist. She is immediately confronted with her father's sudden paralysis (Figure 4(a)). As other members of the team fall ill, it is her task to discover the cause of the outbreak as quickly as possible. She is free to explore the world to collect physical evidence and interact with other characters (Figure 4(b)). She must quickly gather enough evidence to correctly choose among candidate diagnoses including botulism, Guillain-Barré syndrome (a disorder caused by nerve inflammation), paralytic shellfish poisoning, stroke, and tick paralysis to solve the mystery and save the research group.

4.2 Implementation

U-DIRECTOR and the Crystal Island storytelling environment are implemented with a dynamic decision network modeled with an efficient Bayesian inference engine—a discussion of runtime performance follows in Section 5—and a high-performance 3D game platform. The director agent consists of a dynamic decision network containing approximately 200 chance nodes connected by over 400 links representing the narrative objectives, storyworld state, and user state. Collectively, the sub-networks explicitly encode over 7,000 conditional probabilities.

The director agent's narrative utility preferences are represented in a separate structured utility network with over 50 utility nodes. The dynamic decision network for Crystal Island is modeled and implemented with the SMILE Bayesian inference engine [12], while the storytelling environment, semi-autonomous characters, and presentation layer are implemented with Valve Software's Source™ engine, the 3D game platform for Half-Life 2.

4.3 Example Scenario

To illustrate U-DIRECTOR's behavior, consider the following situation as a story unfolds on Crystal Island. The user's character awakens from a good night's sleep and the adventure begins. At this juncture, several elements in the plot graph are available for her to address. For example, she could find her father paralyzed in his bedroom, she might notice that a plate with

leftover food is in his office, or she might discover other facts such as that her good friend, Teresa, has also been stricken with the mysterious illness.

Although many possible actions may be taken by the user, it is the task of the director agent to determine if there is any action it might select to ensure that she is making steady progress through the plot. As the director agent assesses the situation, it notices that (1) the user is currently exhibiting high independence (since the director agent has not yet had to intervene in the story), (2) the user has not discovered any facts about the case, (3) the user is currently located in her father's house, and (4) her father is in his room. These observations, combined with a number of other factors (e.g., the fact that the user is somewhat active in the world), lead the director to make the decision to provide a hint that might lead her to find her father sick in his room since this action yields good location flow.

Once this decision is made, the system can realize the hint in many ways. For example, if the user were nearby, her father might make a moaning noise; however, if she were farther away, he might blink the lights in his room or have another character contact his daughter. The director agent then awaits the user's reaction to see how the events play out. In this case, the user hears her father's call for help, walks to his room, learns of his illness, and quickly departs to find the camp nurse. Observing that the user has found her father sick, the director agent updates its plot graph by marking the corresponding node complete and marking subsequent nodes ready for execution.

At this point the director agent must once again decide if there is anything it should do. As it notices that there are a number of plot graph elements (such as finding the partially eaten plate of food) which could be executed at the user's current location (i.e., to maintain location flow), it also takes into account the fact that these plot elements do not coincide with the user's current train of thought, as evidenced by the fact that she should be attempting to locate the camp nurse. It combines this evidence with the fact that it recently presented a hint and decides to take no action at this juncture and await the user's next action.

After some time has passed and the user has made limited progress toward completing the available plot graph elements, the director agent decides to provide a hint to the user to get her back on track. After reviewing all of the available evidence, the director agent decides that the user should be attempting to find the camp nurse and therefore directs the camp nurse to come to the user. The mystery continues with the director agent continuously monitoring the unfolding situation as the user rules out all but one of the possible diagnoses. The user solves the mystery by determining that the source of all the illnesses was botulism from last night's dinner and the research team is saved.

While the artifacts and character behaviors in the 3D world of Crystal Island and their connections to the director agent's network are the subject of continued work, the narrative reasoning described in this scenario is fully implemented. Each of the knowledge sources in the architecture (plot progress, narrative flow, plot focus, physical state, user goals, user beliefs, and user experiential state) are fully functioning and currently support this and many other scenarios.

5. EVALUATION

Two key aspects of narrative planning that must be addressed in a viable solution are tractability and effectiveness. Section 5.1 discusses a performance analysis of the U-DIRECTOR implementation for Crystal Island, and Section 5.2 examines U-DIRECTOR's decision-making.

(a)

(b)

Figure 4. The Crystal Island Storyworld.

5.1 Performance Analysis

Real-time performance of narrative planning is critical for interactive storytelling environments. While probabilistic reasoning has much to offer, tractability in probabilistic reasoning is always a challenge. Because exact inference in Bayesian networks is known to be extraordinarily inefficient (in the worst case *NP*-hard), U-DIRECTOR exploits recent advances in approximate Bayesian inference via stochastic sampling. The accuracy of these methods depends on the number of samples used. Moreover, stochastic sampling methods typically have an "anytime" property which is particularly attractive for real-time applications.

Considering the activity level in Crystal Island and the level of abstraction at which directions are modeled, it was determined that the director agent should be able to perform a complete network update at least five times per minute. To ensure that the response time of the director agent was adequate, a performance analysis was conducted to measure the network update time using an exact Bayesian inference algorithm (*Clustering* [17]) and two

approximate Bayesian inference algorithms (*EPIS-BN* [36] and *Likelihood weighting* [31]).

Results of updating the director agent's network using the clustering, EPIS-BN, and likelihood weighting algorithms implemented in SMILE are presented in Table 1. These results were obtained on a 2.4 GHz AMD Mobile Athlon 64 PC with 1 GB of RAM running Windows XP.

Table 1. Response times for Bayesian inference algorithms

	Samples	Mean (seconds)	Standard Deviation
Clustering	N/A	18.41	8.48
EPIS-BN	1,000	2.32	0.18
	5,000	6.02	0.12
	10,000	10.70	0.16
Likelihood	1,000	1.59	0.19
	5,000	7.31	0.06
	10,000	14.65	0.03

Results of the study indicate that the clustering algorithm's running time has the greatest variability and may not satisfy the performance requirements of interactive narrative. EPIS-BN appears to provide acceptable response times while utilizing larger sample sizes than likelihood weighting and therefore yielding better approximations; however, the errors introduced by these approximation techniques can be problematic. Future work involves exploring alternative approximation techniques (e.g., [4]).

5.2 Simulated User Experiments

While the quality of narrative is inherently subjective, it is nonetheless important to attempt to gauge the overall effectiveness of a director agent's decision-making activities. To systematically investigate U-DIRECTOR's narrative planning, two families of simulated users were created. Simulated c*ooperative* users followed the director agent's guidance 60% of the time for hints and 80% of the time for strong suggestions. In contrast, simulated *uncooperative* users followed the director agent's guidance 10% of the time for hints and 25% of the time for strong suggestions. Six simulated users (3 cooperative and 3 uncooperative) interacted with Crystal Island director agent to create six different narrative experiences.

Analyses of the traces indicate that the director agent took appropriate action to guide the user through the narrative. As was desired, the director agent tended to adopt a hint-centered approach for more cooperative users and was more heavy-handed with users who were less cooperative. The simulated user approach appears to offer a promising means for establishing baseline performance prior to conducting extensive focus group studies with human users.

6. CONCLUSION AND FUTURE WORK

Decision-theoretic narrative planning offers a unified approach to dynamically guiding narratives in a storytelling environment. This paper describes a decision-theoretic director agent that has been implemented in a narrative planner for an interactive storytelling environment in which the user plays the role of a medical detective. By providing a principled approach to coping with the intrinsic uncertainty of interactive narrative, decision-theoretic director agents can systematically draw inferences about the broad range of factors affecting an unfolding story. It can thereby reason about narrative objectives, the state of the storyworld, and the state of the user to direct the course of the plot and the behaviors of the semi-autonomous characters, all with the result of creating engaging interactive narrative experiences.

Three areas of future work are particularly intriguing. First, in the current approach to constructing DDNs, devising networks by hand is very labor intensive. For example, the DDNs for the prototype interactive storytelling environment described in this paper required several person-weeks of effort. The prospect of learning the conditional probabilities in the DDNs holds much appeal.

Second, developing pedagogically oriented narrative environments that support education via narrative-based learning experiences is a promising direction for future work. However, integrating pedagogical goals into the narrative planner undoubtedly poses significant challenges because the resulting system would need to reason about (possibly competing) pedagogical and narrative goals. Nonetheless, utility-based computing could contribute to balancing these goals.

Finally, affect plays an important role in narrative. However, the current director agent includes only an impoverished representation of the user's affective state. Introducing more sophisticated techniques for affective reasoning could significantly extend the director agent's ability to accurately assess the user's engagement and motivation, which could directly contribute to its ability to create more engaging experiences.

7. ACKNOWLEDGMENTS

The authors wish to thank the members of the IntelliMedia Center for Intelligent Systems at NC State University for their assistance in implementing U-DIRECTOR, the Decision Systems Laboratory of the University of Pittsburgh for access to the SMILE Bayesian inference engine, Omer Sturlovich and Pavel Turzo for use of their 3D model libraries, and Valve Software for access to the Source™ engine and SDK. Thanks also to Michael Young and the members of the Liquid Narrative Group at NC State University for insightful discussions on narrative.

ABSTRACT
Intelligent agents are typically situated in a social environment and must reason about social cause and effect. Such reasoning is qualitatively different from physical causal reasoning that underlies most intelligent systems. Modeling social causal reasoning can enrich the capabilities of multi-agent systems and intelligent user interfaces. In this paper, we empirically evaluate a computational model of social causality and responsibility against human social judgments. Results from our experimental studies show that in general, the model's predictions of internal variables and inference process are consistent with human responses, though they also suggest some possible refinement to the computational model.

1. INTRODUCTION
A growing number of applications seek to incorporate automatic reasoning techniques into intelligent agents. Many intelligent systems incorporate planning and reasoning techniques designed to reason about *physical* causality. Since intelligent agents are typically situated in a multiagent environment and multiagent interactions are inherently *social*, physical causes and effects are simply inadequate for explaining social phenomena. In contrast, social causality, both in theory and as practiced in everyday folk judgments, emphasizes multiple causal dimensions, involves epistemic variables, and distinguishes between physical cause, responsibility and blame.

The multiagent research community has considered many aspects of social reasoning (e.g., [1, 20]), but has largely ignored this crucial distinction between physical and social causal reasoning. A model of the process and inferences underlying social causality can enrich the cognitive and social functionality of intelligent agents. Such a model can help an agent to interpret the observed social behavior of others and impact the way an agent acts on the world, which is crucial for successful interactions among intelligent entities. With the advance of multi-agent systems and systems that socially interact with people, it is increasingly important to model this central form of human social inference. Social causal reasoning can inform the design of human-like agents, guide conversation strategies and help modeling and understanding social emotions [6].

We have developed a general computational model of social causality and responsibility [10, 11] that formalizes the factors people use in reasoning about social events. Psychological and philosophical theories identify intermediate constructs that determine social causality. In these theories, social causality involves not only physical causality, but also epistemic variables such as freedom of choice, intention and foreknowledge [19, 22, 24]. As a result, an actor may physically cause an event, but be absolved of responsibility and blame. Conversely, a person may be held responsible and blameworthy for what she did not physically cause. Our model serves as a bridge between such theoretical distinctions and their computational realization, by inferring these additional factors from a representation of the physical and social context.

To evaluate this computational model, we need to assess the model's consistency with human judgments of social cause and responsibility. This is challenging given that people's judgment results often vary, and sometimes, there might be even no consensus among people. But further, we are interested in the more challenging task of testing whether the inferential mechanism of the model is consistent with the intuition of human inference, that is, does our model infer judgment results *in the way* people actually do?

In the rest of the paper, we first review the psychological theory for social causality and responsibility, and the computational model we develop. We then discuss the details of the experimental evaluation of the model, including the methodology, results and some empirical findings.

2. ATTRIBUTION THEORY

Our work is based on the influential attribution theories of Shaver [19] and Weiner [22] of social causality and responsibility (we adopt the terminology of Shaver in this paper). Their theories argue that physical causality and coercion identify *who* is responsible for some outcome under judgment, whereas epistemic factors, intention and foreseeability, determine *how much* responsibility and blame/credit are assigned. Below we summarize their theories.

The assessments of physical causality and coercion identify the responsible party. *Physical causality* (including personal causality and environmental causality) refers to the connection between events and the outcomes they produce. Only when human agency is involved, does an event become relevant to the investigation of responsibility and blame/credit. In the *absence of coercion*, the actor whose action directly produces the outcome is regarded as responsible. However, in the *presence of coercion* (as when some external force, such as a more powerful individual or a socially sanctioned authority, limits an agent's freedom of choice) some or all of the responsibility may be deflected to the coercive force.

Intention and forseeability determine the degree of responsibility. *Intention* is generally conceived as the commitment to work towards a certain act or outcome. Most theories view intention as the major determinant of the degree of responsibility. If an agent intends an action to achieve an outcome, then the agent must have the foreknowledge that the action brings about the outcome. The higher the degree of intention, the greater the responsibility assigned. *Foreseeability* refers to an agent's foreknowledge about actions and their consequences. The lower the degree of foreseeability, the less the responsibility assigned.

An agent may intentionally perform an action, but may not intend all the action effects. It is *outcome intention* (i.e., intended action effect), rather than *act intention* (i.e., intended action) that are key in responsibility judgment [23]. Similar difference exists in *outcome coercion* (i.e., coerced action effect) and *act coercion* (i.e., coerced action). The result of the judgment process is the assignment of certain blame or credit to the responsible agent(s). The intensity of blame or credit is determined by the severity or positivity of the outcome as well as the degree of responsibility. The latter is based on the assessed values of attribution variables.

3. THE COMPUTATIONAL MODEL (A REVIEW)

To model the process of social causality and responsibility attribution, we have constructed a computational model that can automatically derive the judgments that underlying attributions of responsibility and blame from observations and knowledge about social acts. Two important sources of information facilitate this inference process. One source is the actions performed by the observed agents (including physical acts and speech acts). The other is the causal knowledge about actions and their effects. To represent causal knowledge, we have adopted a hierarchical plan representation used by many intelligent systems. This representation provides a concise description of the causal relationship between events and states. It also provides a clear structure for exploring alternative courses of actions, and plan interactions. The computational model is described in detail elsewhere [10, 11, 6]. Here we briefly review the inference techniques.

Figure 1 illustrates an overview of the computational model. The inference process infers beliefs from dialogue evidence and causal evidence. Both dialogue inference and causal inference make use of commonsense heuristics, and derive beliefs about the attribution values.

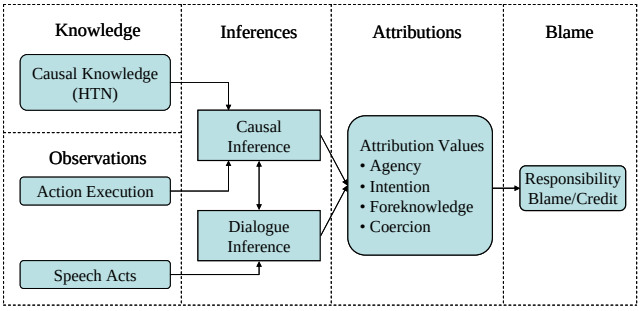

Figure 1. Computational model of responsibility attribution.

Dialogue inference reasons about beliefs of participating agents' desires, intentions, foreknowledge and choices from dialogue communication, represented as a sequence of speech acts. For example, *inform* gives evidence that both the speaker and the hearer know the content of the act, given the conversation between agents is *grounded* [21]. A *request* shows the speaker's desire (or want). An *order* shows the speaker's intent, and if it is successfully issued, it creates an obligation for the hearer to perform the content of the act. The hearer may *accept*, *reject* or *counter-propose* the request or order. Various inferences can be made depending on current beliefs and the response of the hearer [10].

Causal inference adopts a plan-based approach to reason about agency, coercion and intentions. To infer *agency*, the approach first identifies the performing agent whose action directly causes the outcome. Other agents who assist the performer by enabling action preconditions are viewed as indirect agency.

Determinations of *coercion* are informed by dialogue and causal inference. Two concepts are important in assessing coercion. One is social *obligation*, created by utterance, role assignment, etc. The other is *unwillingness*. For example, if an authorizing agent commands another agent to perform a certain action, then the latter agent has an obligation to do so. If there is no clear evidence that an agent intends beforehand, and the agent accepts the obligation, there is evidence of *weak* coercion. Note, intend(x, p, $t1$) denotes that agent x intends that proposition p at time $t1$, obligation(x, p, y, $t2$) represents that x has an obligation p by agent y at time $t2$, accept(x, p, $t3$) represents that x accepts that p at time $t3$, and coerce(y, x, p, $t4$) represents that y coerces x that p at time $t4$.

$$\neg(\exists t1)(t1<t3 \wedge \text{intend}(x, p, t1)) \wedge \text{obligation}(x, p, y, t2) \wedge \text{accept}(x, p, t3) \wedge t2<t3<t4 \Rightarrow \text{coerce}(y, x, p, t4)$$

If there is clear evidence of the unwillingness (i.e., intend(x, p, $t1$) is false), there is evidence of *strong* coercion.

$$\neg\text{intend}(x, p, t1) \wedge \text{obligation}(x, p, y, t2) \wedge \text{accept}(x, p, t3) \wedge t1<t3 \wedge t2<t3<t4 \Rightarrow \text{coerce}(y, x, p, t4)$$

Causal inference helps infer outcome coercion from evidence of act coercion, by examining the plan structure and action alternatives. For example, assume an agent is coerced to perform an ab-

stract action. If there is only one way to realize (i.e., decompose) this act, the model concludes that the agent must perform all the subsequent actions within this realization and the occurrences of all the action effects are unaviodable. If, instead, the coerced action has multiple realizations (i.e., decompositions), only the effects shared across all of these alternatives are necessarily coerced. Non-shared effects only occur if the coerced agent chooses that particular realization of the coerced act. Outcomes can also be coerced indirectly, for example, some agents can block other alternatives by disabling action preconditions; or they can enable a conditional effect. Similarly, indirect coercion can be inferred from plan knowledge and action alternatives [13].

Intentions (i.e., act intention and outcome intention) can be inferred from dialogue evidence. For example, rejecting what the speaker wants or intends shows no intention. Besides, causal inference helps partially infer outcome intention from act intention. For example, if an agent intends an action voluntarily, the agent must intend at least one action effect. If there is only one action effect (significant to the agent), we can exactly infer which effect the agent intends. As plans provide context in evaluating intention, with association to the goals and reasons of an agent's behavior, in the absence of clear evidence from dialogue inference, we employ a general plan-based algorithm to recognize intentions [12]. If a plan is intended by agents, then the actions and effects that are *relevant* to goal achievement (i.e., in the path from initial states to goal states of the plan) are intended. Other action effects are viewed as *side effects* in goal attainment and thus are not intended by the agents.

Foreknowledge refers to an agent's epistemic state before action execution. It is inferred from dialogue evidence (e.g., speech act inform, tell or assert). Intention recognition also helps infer an agent's foreknowledge, as intentions entail foreknowledge (*Axiom 4* in [11]).

The attribution values derived from causal inference and dialogue inference serve as inputs of the attribution process. The algorithm is detailed in [11]. As the last step, this algorithm determines responsibility and assigns proper blame or credit to the responsible agent(s) based on the implications of attribution theory.

4. RELATED WORK

Recent computational approaches have addressed social causality and responsibility judgment by extending causal models [7, 3]. Halpern and Pearl [7] proposed a definition of *actual cause* within the framework of structural causal models. As their approach can extract more complex causal relationships from simple ones, their model is capable of inferring indirect causal factors including social causes. Take the "firing squad" example [17]: there is a two-man firing squad; on their captain's order, both riflemen shoot simultaneously and accurately, and the prisoner dies. Besides the two riflemen who physically cause the death, Halpern & Pearl's model can find the captain as one actual cause for the death. Chockler and Halpern [3] extended this notion of causality, to account for degree of *responsibility*. They gave a definition of responsibility. For example, if a person wins an election 11-0, then each voter who votes for her is a cause for the victory, but each voter is less responsible for the victory than each of the voters in a 6-5 victory. Based on this definition of responsibility, they then defined the *degree of blame*, using the expected degree of responsibility weighed by the epistemic state of an agent.

Chockler & Halpern's extended definition of responsibility accounts better for multiple causes and the extent to which each cause contributes to the occurrence of a specific outcome. Another advantage of their model is that their definition of degree of blame takes an agent's epistemic state into consideration. However, they only consider one epistemic variable, that is, an agent's knowledge prior to action performance (corresponding to foreseeability in Shaver's term). Important concepts in moral responsibility, such as intention and freedom of choice are excluded in their definition. As a result, their model uses foreknowledge as the only determinant for blame assignment, which is inconsistent with psychological theories. As their model is the extension of counterfactual reasoning within the structural-model framework, and structural-model approach represents all the events as random variables and causal information as equations over the random variables, this brings about other limitations in their model. For instance, causal equations do not have direct correspondence in computational systems, so it is hard to obtain them for practical applications. As communicative events are also represented as random variables in their model (which is propositional), it is difficult to construct equations for communicative acts and infer intermediate beliefs (e.g., beliefs about desires, intentions, etc) that are important for social causal reasoning.

In contrast, our approach is built on general plan representation commonly used in many intelligent systems. Causal inference is a plan-based evaluation over this representation. Our model takes different forms of interactions into account, and makes use of commonsense reasoning to infer beliefs from dialogue communication. In Mao & Gratch [13], we use four variants of the original firing squad scenario in the related work [3], to empirically compare our model with Chockler & Halpern's model and two other models (i.e., simple cause model and simple authority model). The results show that for responsibility and blame assignments, our model better approximates human judgments than these alternative models [13].

Social psychological studies show that people consider intentions, coercion and foreknowledge in their judgments. In our work, we have come up with computational account of all these variables. We would like to directly assess our model's ability in predicting the internal variables with respect to human results, and the veracity of the inference process that leads to the corresponding results.

5. EXPERIMENTAL EVALUATION

To evaluate the model, first we need to assess its consistency with human responses (i.e., given the same inputs, do people and the model produce the same outputs). Rather than simply viewing the model as a black box, however, we are also interested in assessing the consistency of the model's internal structure and processes underlying human attributions of responsibility and blame (i.e., do people use the same sources of evidence and generate the same intermediate conclusions). The results for the first task were already demonstrated in [13], though here we seek to extend these finding to additional scenarios. The second task is the focus of this paper.

5.1 Method

Our model embodies the theoretical view that people will judge social cause and responsibility differently based on their perception of the key variables such as intentions and coercion. Thus, a good test is to see how the model performs when the evidence for

such judgments is systematically varied. In this study, we take a description of a single social situation and systematically generate several variants, using the inference rules of our model as a guide. For example, if our model suggests that a particular line of evidence is necessary to infer coercion, than an obvious variation would be to eliminate that line.

As a starting point, we adopt the well-known "company program scenario" (*Figure 3*: *Scenario 2*) in experimental philosophy research [5, 8]. In our study, descriptions of each scenario are organized into separate labeled statements of evidence (e.g., *E1-E6*). In *Scenario 1* (*Figure 2*), we manipulate evidence related to foreknowledge of the outcome:

Scenario 1:

E1 The vice president of Beta Corporation goes to the chairman of the board and requests, "Can we start a new program?"

E2 The vice president continues, "The new program will help us increase profits,

E3 and according to our investigation report, it has no harm to the environment."

E4 The chairman answers, "Very well."

E5 The vice president executes the new program.

E6 However, the environment is harmed by the new program.

Questions:

1. Does the vice president want to start the new program?
   Your answer: Yes No
   Based on which information (circle all that apply)?
   E1 E2 E3 E4 E5 E6
2. Does the chairman intend to start the new program?
   Your answer: Yes No
   Based on which information (circle all that apply)?
   E1 E2 E3 E4 E5 E6
3. Is it the chairman's intention to increase profits?
   Your answer: Yes No
   Based on which information (circle all that apply)?
   E1 E2 E3 E4 E5 E6
4. Does the vice president know that the new program will harm the environment?
   Your answer: Yes No
   Based on which information (circle all that apply)?
   E1 E2 E3 E4 E5 E6
5. Is it the vice president's intention to harm the environment by starting the new program?
   Your answer: Yes No
   Based on which information (circle all that apply)?
   E1 E2 E3 E4 E5 E6
6. How much would you blame the individuals for harming the environment?
   Blame the chairman: 1 2 3 4 5 6
   Blame the vice president: 1 2 3 4 5 6
   Little Lots

Figure 2. Scenario 1 and the questionnaire

Each scenario is followed by a questionnaire. The questions in the questionnaires are designed to test the beliefs about different variables. *Figure 2* shows the wording of the questions after *Scenario 1*.

Scenario 2:

E1 The chairman of Beta Corporation is discussing a new program with the vice president of the corporation.

E2 The vice president says, "The new program will help us increase profits,

E3 but according to our investigation report, it will also harm the environment."

E4 The chairman answers, "I only want to make as much profit as I can. Start the new program!"

E5 The vice president says, "Ok," and executes the new program.

E6 The environment is harmed by the new program.

Figure 3. Scenario 2

In *Scenario 3*, we manipulate the degree of perceived coercion and willingness of the coerced agent by introducing an alternative course of action that will not harm the environment and which the vice president prefers. Specifically, we add one line to Scenario 2 between *E3* and *E4*:

Scenario 3:

E1 The chairman of Beta Corporation is discussing a new program with the vice president of the corporation.

E2 The vice president says, "The new program will help us increase profits,

E3 but according to our investigation report, it will also harm the environment.

E4 Instead, we should run an alternative program, that will gain us fewer profits than this new program, but it has no harm to the environment."

E5 The chairman answers, "I only want to make as much profit as I can. Start the new program!"

E6 The vice president says, "Ok," and executes the new program.

E7 The environment is harmed by the new program.

Figure 4. Scenario 3

In *Scenario 4*, we manipulate freedom of choice. We introduce an alternative, but the preference of the vice president is based on a feature unrelated to the environment and the vice president is allowed to choose the option:

Scenario 4:

E1 The chairman of Beta Corporation is discussing a new program with the vice president of the corporation.

E2 The vice president says, "There are two ways to run this new program, a simple way and a complex way.

E3 Both will equally help us increase profits, but according to our investigation report, the simple way will also harm the environment."

E4 The chairman answers, "I only want to make as much profit as I can. Start the new program either way!"

E5 The vice president says, "Ok," and chooses the simple way to execute the new program.

E6 The environment is harmed.

Figure 5. Scenario 4

Table 1. Model predictions and people responses for sample scenarios

		Question 1		Question 2		Question 3		Question 4		Question 5		Question 6	
		Yes	No	Yes	No	Yes	No	Yes	No	Yes	No	Chair	VP
S1	Model	√		√		√			√		√		√
	People	30	0	27	3	29	1	2	28	0	30	3.00	3.73
S2	Model	√		√		√			√	√		√	
	People	30	0	30	0	30	0	10	20	22	8	5.63	3.77
S3	Model	√			√	√		√		N/A		√	
	People	21	9	2	28	29	1	21	9			5.63	3.23
S4	Model	√			√		√	N/A		N/A			√
	People	21	9	5	25	5	25					4.13	5.20

5.2 Results

At the level of assessing internal variables, we have no computational alternative to compare with (as the related work only infers part of the variables). In our experiment, we directly compare the predictions of the model with human data.

5.2.1 Assessing Inferred Beliefs

Table 1 shows the number of responses to each question in the sample scenarios. The values for the last questions are the averages of people's answers (on a 6-point scale). The model's predictions are checked with '√'. The data show that for most questions, people agree with each other quite well. But certain disagreement exists on some of the questions.

Though people sometimes may disagree with each other on specific questions, our purpose is to assess the model's general agreement with people. We measure the agreement of the model and each subject using *Kappa statistic*. *Kappa* coefficient is the de facto standard to evaluate inter-rater agreement for classification tasks [1]. It corrects the raters' proportional agreement $P(A)$ due to chance agreement $P(E)$:

$$K = \frac{P(A) - P(E)}{1 - P(E)}$$

Di Eugenio & Glass [4] argue that the computation of K coefficient is sensitive to the skewed distribution of categories (i.e., prevalence). In our treatment, we account for prevalence and construct contingency tables for the calculation. We average the results of *Kappa* agreement of the model's predictions with each subject's answers. *Table 2* gives the results of *Kappa* agreement of the model's predictions with each subject's answers.

Table 2. The *Kappa* agreement of the model and subjects

Subjects	*P*(*A*)	*P*(*E*)	*K*
1	.824	.526	.628
2	.882	.543	.742
3	.706	.491	.422
4	.882	.509	.761
5	.941	.526	.876
6	.882	.543	.742
7	.941	.561	.866
8	.941	.561	.866
9	.882	.543	.742
10	.941	.526	.876
11	1	.543	1
12	.882	.543	.742
13	1	.543	1
14	.941	.526	.876
15	.765	.543	.485
16	.824	.491	.667
17	.824	.561	.598
18	.765	.543	.485
19	.882	.509	.761
20	.941	.526	.876
21	.824	.561	.598
22	.882	.543	.742
23	.765	.543	.485
24	.941	.526	.876
25	.941	.561	.866
26	.882	.509	.761
27	.765	.578	.443
28	.882	.543	.742
29	.824	.491	.667
30	.882	.509	.761
Average			.732

The average *Kappa* agreement between the model and subjects is *0.732*. According to [18], $0.61<K<0.80$ indicates substantial agreement. The empirical results show good consistency between the model's generation of intermediate beliefs and human data.

5.2.2 Assessing Inference Rules

In our model, each belief is derived by a specific inference rule, so each question in the questionnaire corresponds to the firing of one rule (with the exception of three questions in the questionnaire designed to test two rules each). Currently, we have 37 dialogue and causal inference rules in the model. This survey study covers 19 of them. To assess the inference rules, we compare the conditions of each rule with the evidence people use in forming each answer. For every subject and every question, we build a confusion matrix [9] to compute the numbers of true positive *TP* (i.e., evidence both the rule and the subject use), true negative *TN* (i.e., evidence both the rule and the subject ignore), false positive (i.e., evidence the rule incorrectly uses) and false negative (i.e., evidence the rule incorrectly ignores).

For each question Q_i, the correct prediction of the corresponding rule with respect to people's evidence choice is measured by accuracy (*AC*), where N_s is the total number of subjects and N_e is the total number of evidence for Q_i.

$$AC(Q_i) = \frac{\sum_{j \in Subjects} AC(j, Q_i)}{N_S} = \frac{\sum_{j \in Subjects} (TP(j, Q_i) + TN(j, Q_i))}{N_S * N_e}$$

Table 3 gives the accuracy of each tested rules (*R**). Given that each question contains 6 or 7 lines of evidence and people choose multiple lines in most cases, the accuracy results are fairly good (well above those generated by a random model). The empirical results show that the sources of evidence the model uses for inference are consistent with human data.

Table 3. Accuracies of inference rules

	Question/Rule	Average Accuracy
Scenario 1	Q1/R7	0.76
	Q2/R13	0.96
	Q3/R2	0.85
	Q4/R5	0.94
	Q5/R1	0.91
Scenario 2	Q1/R6	0.92
	Q2/R10	0.96
	Q3/R24	0.86
	Q4/R25	0.70
	Q5/R11&R14	0.84
Scenario 3	Q1/R17	0.94
	Q2/R18&R19	0.88
	Q3/R11&R16	0.80
	Q4/R27	0.74
Scenario 4	Q1/R29	0.71
	Q2/R28	0.84
	Q3/R30	0.75

In the next section, we discuss how our model appraises each scenario and some experimental findings.

5.3 Discussions

5.3.1 Scenario 1

In *Scenario 1*, we manipulate the variable foreseeability to be false (from evidence *E3*). Evidence is encoded into the model as follows (*VP* and *CH* refer to the vice president and the chairman, respectively):

(E1) request(*VP*, *CH*, do(*VP*, new-program))
(E2) inform(*VP*, *CH*, profit-increase∈effect(new-program))
(E3) inform(*VP*, *CH*, env-harm∉effect(new-program))
(E4) accept(*CH*, do(*VP*, new-program))
(E5) do(*VP*, new-program)
(E6) occur(environmental-harm)

The evaluation shows that the model and people draw similar intermediate conclusions from this evidence, suggesting both that our representation of the evidence and the underlying inference rules are largely correct. For example, the questionnaire specifically queries the perceived desire, foreknowledge and intentions of the characters (see *Figure 2*). The belief that the vice president desires the new program can be inferred from speech act *request* in *E1*. The chairman's intention to start the new program can be inferred from speech act *accept* in *E4*. As starting *new program* has only one action effect (*E2*), we can infer outcome intention from act intention. The chairman must intend the only effect (i.e., *increase profits*). The vice president has no foreknowledge of the environmental harm can be inferred from the content of *inform* in *E3* (note that our approach assumes Grice's maxims of *Quality* and *Relevance*). According to a causal inference rule, no foreknowledge entails no intention.

As the goal of agent(s) was not explicitly expressed in this scenario, intention recognition method is not involved. However, from dialogue evidence and from causal connection of foreknowledge, act intention and outcome intention, the beliefs about intentions are properly inferred.

Subjects gave quite consistent answers to the questions in *Scenario 1*. Their answers to the last question show that blameworthiness is mitigated by no foreknowledge. This result is consistent with psychological findings. Though people assigned relatively more blame to the vice president, the data also suggest that the chairman should share blame with the vice president.

The accuracies of inference rules are also good in general. The accuracy of the rule tested in *Question 1* is lower than the others because besides evidence *E1*, many people chose *E2* as well. Post-experiment interviews with the subjects uncovered that many subjects had assumed that making profits should be desirable to the vice president (because of his role), and therefore, he should desire to start the new program to increase profits (which is supported by *E2*).

5.3.2 Scenarios 2&3

Scenarios 2 & 3 manipulate the degree of perceived coercion and willingness of the coerced agent. The agents have clear foreknowledge about the harm (*E3*). The chairman's goal of making *more profits* is also clearly informed (*E4* in *Scenario 2*, *E5* in *Scenario 3*).

The following beliefs can be inferred from *Scenario 2*:

(B1) know(*CH*, profit-increase∈effect(new-program))
(derived from *E2*: inform)
(B2) know(*CH*, env-harm∈effect(new-program))
(derived from *E3*: inform)
(B3) intend(*CH*, do(*VP*, new-program))
(derived from *E4*: order)
(B4) obligation(*VP*, do(*VP*, new-program), *CH*)
(derived from *E4*: order)
(B5) coerce(*CH*, *VP*, do(*VP*, new-program))
(derived from *B4* & *E5*: accept)
… …

As there is no evidence of unwillingness, perceived coercion (*B5*) is in a weak sense. The inferred beliefs *B2*, *B3*, *B4* and *B5* give predictions to *Questions 1, 2 & 5* in *Scenario 2*. As there is only one plan in this scenario and the chairman intends the action (i.e., starting *new program*) in the plan (*B3*), intention recognition is trivial[1]. Making *more profits* is the goal of the plan, so it is intended by the

[1] Note that our intention recognition method is generally applied to a plan library with multiple plans and sequences of actions. In this oversimplified example, intention recognition becomes trivial.

chairman (*Question 3*). *Environmental harm* is a side effect of goal attainment, so it is not intended by the chairman (*Question 4*).

In *Scenario 3*, the vice president's counter-proposal provides additional information (*E4*). More beliefs can be derived:

(B3) know(*CH*, alternative(new-program, alternative-program))
(from *E4*: counter-propose)
(B4) want(*VP*, do(*VP*, alternative-program))
(from *E4*: counter-propose)
(B5) ¬intend(*VP*, do(*VP*, new-program))
(from *E4*: counter-propose)
(B6) intend(*CH*, do(*VP*, new-program))
(from *E5*: order)
(B7) obligation(*VP*, do(*VP*, new-program), *CH*)
(from *E5*: order)
(B8) coerce(*CH*, *VP*, do(*VP*, new-program))
(from *B5*, *B7* and *E6*: accept)
(B9) coerce(*CH*, *VP*, achieve(environmental-harm))
(from *B2* and *B8*)
… …

Beliefs *B3*, *B4*, *B8* and *B9* give predictions to *Questions 1, 2, 3 & 4* in *Scenario 3*, respectively. Belief *B5* gives strong evidence of coercion.

There are several disagreements among the subjects in *Scenarios 2 & 3*. In *Question 4* of *Scenario 2*, one-third of the subjects think it the chairman's intention to harm the environment. Whether side-effects are intended is controversial in philosophy, and other empirical studies show similar results [16]. Also in *Question 5* of *Scenario 2*, some subjects think the vice president is not coerced to start the new program by the chairman, as evidence is weaker than in *Scenario 3*. Half of them referred to evidence *E5*, indicating that they expect the vice president to negotiate with the chairman rather than directly accept the order. This suggests a limitation in our current model. In contrast, when asking the same question in *Scenario 3* (*Question 3*), almost all the subjects agreed that the vice president is coerced to start the new program.

In the first question of *Scenario 3*, some subjects think the chairman does not know the alternative program, though the vice president clearly informs this in the scenario. Most of these subjects (80%) referred to evidence *E5*, showing that they looked for grounding information. As our model infers grounded information from conversation, it is our mistake to omit this information in scenario design. Last, in *Question 4* of *Scenario 3*, some subjects seemed reluctant to infer outcome coercion from evidence of act coercion. Nonetheless, they still assigned high degree of blame to the chairman. Comparing the blame assignments in *Scenarios 2 & 3*, it shows that on one hand, the higher the degree of coercion, the less blame is assigned to the actor. This is consistent with psychological findings. On the other hand, even when perceived coercion is not strong, people still assign high degree of blame to the coercer, as in *Scenario 2*.

The accuracies of two tested rules are relatively lower than the others. One is the rule used in *Question 4* of *Scenario 2*. In our model, there are three evidence needed for the inference, *E2*, *E3* and *E4*. Almost all subjects chose evidence *E4*, but most ignored *E2* (except two subjects). One reason is that *E2* as knowledge (i.e., the new program helps increase profits), seems implied in *E4* (otherwise people will have difficulty understanding *E4*). Similarly, for the rule used in *Question 4* of *Scenario 3*, most subjects did not choose knowledge *E3*. However, we think this knowledge is necessary for the inference.

5.3.3 Scenario 4

In *Scenarios 2 & 3*, action and alternative are coerced by authority, whereas in *Scenario 4*, the vice president has some freedom of choice. While the high-level plan (i.e., starting the new program) is still coerced (*E4*), the agent can choose to execute either alternative (simple way or complex way in *E2*). As both ways will increase profits (*E3*), increasing profit is unavoidable in either way: the vice president is coerced to achieve this effect (*Question 1*). However, he is neither coerced to choose the simple way (*Question 2*), nor is he coerced to achieve the specific effect *environmental harm* that only occurs in the simple way (*Question 3*).

In *Question 1*, some subjects think that the vice president is not coerced to increase profits, for the same reason mentioned earlier. They think it the vice president's job to increase profits, so he must be willing to do so. People assigned more blame to the vice president, as he could have done otherwise. This result is consistent with psychological findings. However, people still assigned considerable blame to the chairman, though it was the vice president's choice to harm the environment.

The inference rules in *Question 1* and *Question 3* are based on evidence *E3*, *E4* and *E5*. Many subjects ignore knowledge *E3*. This lowers the accuracies of the two rules.

5.3.4 Discussion on limitations

Although results show general support for the model, they reveal some limitations of the approach. Subjects tended to assign shared blame to the individuals involved. Though our model is able to handle joint activity and multiagent plan, one limitation of the model is that it always blames one most deserving agent (or group of agents).

It is clear that people made assumptions about the scenarios that were not explicitly represented in the model. For example, people assumed the vice president had the goal of increasing profits even though this was not explicitly stated. This relates to the more general issue of ensuring the correspondence between the model's encoding of the scenario and the subjects' interpretation of the scenario. Currently, we construct this mapping by hand. This has the disadvantage that, as designers of the scenarios, we may unintentionally introduce discrepancies. Alternatives would be to explore ways to automatically generate descriptions from their representation in the model, or at least to use an independent set of coders to characterize the textual encoding.

It is well known that responsibility judgment is influenced by the observer's emotional state, interpersonal goals such as impression management [15], and dispositional differences such as personality. Further, our model of dialogue inference assumes that parties faithfully articulate their actions and beliefs, whereas people are notoriously biased when describing their involvement in creditworthy/blameworthy events. Although we have not accounted for these biases, our current model provides a framework for both generating and recognizing such influences [14].

6. CONCLUSION

A growing number of applications seek to incorporate automatic reasoning techniques into intelligent agents. In contrast to physical causal reasoning that underlies most intelligent systems, social causal reasoning emphasizes multiple causal dimensions, involves

epistemic variables, and distinguishes between physical cause, responsibility and blame. In this paper, we empirically evaluate a computational model of social causality and responsibility using human data. Results from our experimental studies are encouraging in general, though they also indicate some limitations and possible refinement to the computational model.

Our future work needs to better model shared responsibility and blame, and consider the influences of individual difference and the perceiver's subjective bias on the judgment process. We also need to improve experimental design, using objective device to minimize the discrepancies of information encoding.

7. ACKNOWLEDGEMENTS

ABSTRACT

In stressful situations such as combat, emotion is at least as important as rational analysis in determining behavior. DETT (Disposition, Emotion, Trigger, Tendency) is a model of emotion for situated agents that captures the essential features of the OCC (Ortony, Clore, Collins) model in a computationally efficient framework. We motivate and describe this architecture, and report preliminary experiments in simulating combat scenarios.

1. INTRODUCTION

Most computational models of emotion [13] require extensive symbolic reasoning, and are not practical in highly populous real-time domains. DETT (Disposition, Emotion, Trigger, Tendency) captures the essential features of the OCC (Ortony, Clore, Collins) emotion model efficiently, using digital pheromones as the agents' main source of perceptions. It extends current emotional models by defining a Disposition parameter that distinguishes agents' differing susceptibility to various emotions. DETT is designed for situated agents. An agent's emotions are triggered by its percepts, not just by internal reasoning.

Section 2 reviews previous work in computational emotions, particularly in the context of combat modeling. Section 3 describes the DETT model. Section 4 concludes.

2. PREVIOUS WORK

Our work rests on previous research in emotional modeling, and two existing agent-based combat models that can be interpreted as supporting elements of our approach.

2.1 Emotional Modeling

Research in agent-based modeling and human interfaces (including gaming) has increased interest in computational models of emotion [13], each drawing on different segments of a long psychological tradition [3]. For our purposes, a cognitive perspective on emotions (rather than an expressive or physiological one) is most appropriate, in particular the OCC model [8], where emotions are "valenced reactions to events, agents or objects." That is, the strength of an emotion depends on stimuli in the agent's environment. Their presence is mapped to a "valence," a positive or negative score, by a process called "appraisal."

Emotion can focus attention, increase the prominence of memories, affect cognitive style and performance, and influence judgments [1]. In OCC, "behavior is a response to an emotional state in conjunction with a particular initiating event." We focus on the impact of emotion on an agent's analysis, the process by which it selects intentions from desires. The left side of Figure 1 summarizes the Belief-Desire-Intention [14] model. Beliefs (derived from the environment by Perception) and Desires (constant over the time horizon of our model) feed Analysis, which produces Intentions, which in turn drive actions that change the environment. The right side enhances this model with OCC emotion. Beliefs feed not only Analysis, but also Appraisal, which generates Emotions. These Emotions in turn influence Analysis and Perception. (We do not implement the latter link in our current system).

Gratch and Marsella [4] offer one of the more mature current computational models of agent emotion. Table 1 summarizes the correspondence between the two models.

2.2 Emotional Combat Models

Explicit emotional modeling is rare in combat models, but elements of two recent models anticipate DETT.

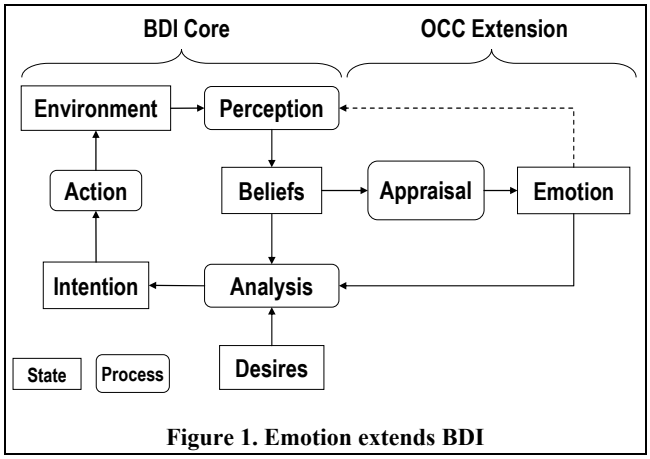

Figure 1. Emotion extends BDI

EINSTein [5] represents an agent's personality as six scalars in [-1, 1], describing the agent's response to six percepts: the number of alive friendly, alive enemy, injured friendly, and injured enemy troops within the agent's sensor rang, and the agent's distance from its own and its adversary's flag. (Each team seeks to capture the adversary's flag while protecting its own.) A positive weight indicates that the agent is attracted to the entity described by the weight, while a negative weight indicates that it is repelled.

Table 1. Comparison of Models

BDI + OCC	Gratch-Marsella
Environment	Environment
Perception	Causal Interpretation
Beliefs	Causal Interpretation
Appraisal	Appraisal
Emotion	Affective State
Analysis	Coping
Desires	???
Intention	Control Signals
Action	Action

MANA [7] extends EINSTein. Friendly and enemy flags are replaced by the waypoints being pursued by each side. MANA includes four additional components: low, medium, and high threat enemies. It also defines triggers (e.g., reaching a waypoint, being shot at, making contact with the enemy, being injured) that shift the agent from one personality vector to another. A default state defines the personality vector when no trigger state is active.

The notion of being attracted or repelled by friendly or adversarial forces in various states of health is an important component of what we informally think of as emotion (e.g., fear, compassion, aggression), and the use of the term "personality" in both EINSTein and MANA suggests that the system designers are thinking anthropomorphically, though they do not use "emotion" to describe the effect they are trying to achieve.

EINSTein and MANA implement subsets of Figure 1. The personality corresponds to the agent's Desires. EINSTein's personality vector guides the agent's decisions, but does not change in response to the agent's beliefs about the events, objects, or agents in its environment. Thus it is not a "valenced reaction." EINSTein does not capture OCC emotion. MANA's personality vectors depend on a trigger state, and implement a valenced reaction.

Both EINSTein and MANA do analysis by multiplying a vector of percepts by the personality, yielding a movement vector. In both models, the agent has perfect knowledge within a vision radius. These processes are much simpler than those in [4]. The differences reflect the systems' objectives. Gratch-Marsella supports a training environment with few agents. Regular human interaction slows the pace, permitting significant computation. EINSTein and MANA manipulate dozens or hundreds of agents in non-interactive simulations, and must minimize execution time.

3. The DETT Model

DETT supports the DARPA RAID program [6], whose objective is to anticipate enemy actions and deceptions to provide real-time support to a tactical commander. Our module [11] evolves agents against observations to learn their characteristics and determine which ones are most likely to reflect future behavior. These agents must execute faster than real time, so they cannot conduct complex symbolic reasoning, but use numerical computation via DETT. We also use the model in another project to automate the reactions of non-combatants with combatants. This capability requires us to recognize that non-combatants will have a range of personality types and to incorporate these differences in their behavior. Details are in the full paper.[1]

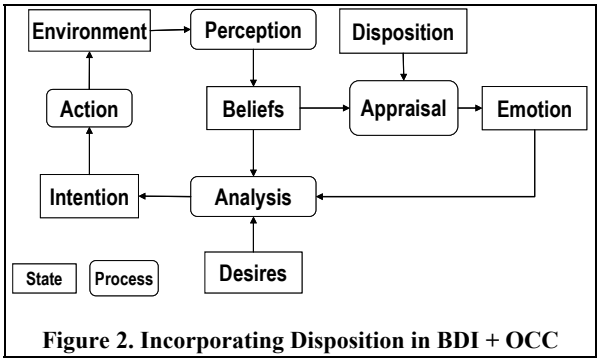

Figure 2. Incorporating Disposition in BDI + OCC

Both applications require an efficient way to include emotions in modeling combat. This reasoning takes place at two locations in Figure 1: Appraisal and Analysis.

3.1 Appraisal

MANA's triggered personality vectors are a useful model for appraisal, but have two limitations. First, MANA defines vectors and triggers for the squad, all of whose members share the same values. Individual combatants (e.g., new recruits vs. seasoned veterans) will differ widely in their susceptibility to different emotions. To use evolution to learn the characteristics of entities, we must parameterize this kind of difference. Second, MANA assumes that emotions arise and disappear immediately with the appropriate trigger. Empirically, emotions rise rapidly but not instantaneously, and persist after the trigger is removed.

To address the first concern we add a new component, Dispositions, to the model (Figure 2). Emotions and Dispositions correspond one to one. Like Desires, Dispositions are constant over each simulation. A Disposition modulates Appraisal to determine how much a Belief triggers the corresponding Emotion. The Emotion then modulates Analysis to impose a Tendency on the resulting Intention. The main elements of this model are thus the Disposition, Emotion, Trigger, and Tendency (the effect on intentions) (DETT). Table 2 gives two examples.

Agents sense one another through digital pheromones [2], labeled scalars that they deposit in the environment and that diffuse and evaporate over time. An agent believes what it senses in the form of pheromones. Our pheromone vocabulary for RAID includes flavors for live and dead friendly, hostile, and neutral individuals, weapons fire, key sites, and topographical features that provide cover from fire or that enhance mobility.

An agent's desires are values in [-1, +1]: ProtectRed (the adversary), ProtectBlue (friendly forces), ProtectGreen (civilians), ProtectKeySites, AvoidCombat, AvoidDetection, and Survive. Negative values reverse the sense: a negative ProtectRed is a desire to harm Red. Table 2 in [9] shows which pheromones attract or repel an agent with a given desire, and how that tendency translates into action. For example, an agent with a high positive ProtectRed will be attracted to RED-ALIVE, RED-CASUALTY, and MOBILITY pheromone, and will move at maximum speed.

Let $\boldsymbol{P}$ be the vector of pheromone strengths at an agent's location. The agent's Disposition is a matrix $\boldsymbol{D}$. $D[i,j] \in [0,1]$ is the relevance of the ith pheromone to the jth emotion. The jth emotion depends (nonlinearly) on the jth element of $\boldsymbol{P}^{\mathrm{T}}\boldsymbol{D}$.

A digital hormone [12], one per

[1] www.altarum.net/~vparunak/AAMAS06EmotionModel.pdf

agent per Emotion, models change in emotion with time. $\boldsymbol{P}^{\mathrm{T}}\boldsymbol{D}$ determines the current deposit to the hormone vector E, so the longer an agent is exposed to a trigger pheromone, the higher the level of the associated emotions. When the trigger is removed, its emotions decay exponentially. The higher the disposition, the more quickly the emotion grows in the presence of a trigger.

Table 2. Sample DETT Semantics

Disposition	Emotion	Trigger	Tendency
Cowardice	Fear	Armed enemy Incoming attack	Less attention to orders Tend to avoid threat
Irritability	Anger	Presence of enemy	More likely to fight Tend to move toward threat

3.2 Analysis

Analysis draws on the same pheromone vector $\boldsymbol{P}$ of beliefs as does Appraisal, and takes as input the current state of the emotion vector $\boldsymbol{E}$. In addition, it considers the values of the agent's vector of Desires or Wants $\boldsymbol{W}$. The desires we are modeling are Protect Red, Protect Blue, Protect Green, Protect Key Sites, Avoid Combat, Avoid Detection, and Survive. Each has a real value in the range [-1,1], where a negative value indicates that the agent wants the opposite state of affairs described by the desire. A movement matrix $\boldsymbol{M}$ indicates whether a given Desire tends to attract or repel the agent toward a given flavor of pheromone: $\boldsymbol{M}$[i,j] is 1 if desire j is attracted to pheromone i, -1 if it is repelled, and 0 if the pheromone is irrelevant to the desire.

In the absence of emotions, the agent's behavior is a nonlinear function of $\boldsymbol{P}^{\mathrm{T}}\boldsymbol{MW}$. Emotions modulate these behaviors. Elevated Anger increases movement likelihood, weapon firing likelihood, and tendency toward an exposed posture, while elevated Fear decreasse these likelihoods. Level of a particular emotion models the extent to which the emotion modulates the agent's behavior. Someone who experiences high fear, but continues to behave as if he were not afraid, would be modeled as having low fear. We are not trying to model emotion as experienced by an agent, only as perceived by its impact on the agent's behavior.

4. CONCLUSION

Emotion is critical in modeling agent behavior in stressful environments such as combat. The Gratch-Marsella model is a sophisticated implementation of current psychological theories of emotion, but is computationally too expensive for large populations of combatant agents. EINSTein and MANA are efficient, but their notion of personality is psychologically naïve. DETT combines the theoretical richness of Gratch-Marsella with the computational efficiency of EINSTein and MANA, and adds dispositions, accounting for differences in the emotional susceptibility of various agents by reasoning about the reaction of an internal agent characteristic to the external environment in which the agent is situated. We have demonstrated the basic computational cycle in implemented software and in actual wargame experiments.

The model is still an approximation. It does not implement the known effect of emotion on perception, and does not consider other possible linkages (e.g., between emotion and desire). Such simplifications are in the nature of simulation, and are justified empirically by the notion of "universality": the dynamics of a multi-agent simulation often depend more on the interactions of the agents than on the details of individual agents' reasoning [10].

ABSTRACT

We describe an agent-based commentary system for computer games which produces real-time and post-game commentary for spectators. Our system adopts an embodied approach in which reporter agents are directly embodied within the game and are subject to the same constraints as players in terms of perception and movement. We analyse the results of an initial evaluation of the system in terms of the conflicting needs of players and spectators, and show that there is an 'optimal' number of reporter agents that is small enough to be tolerated and even welcomed by the players while at the same time producing commentary which is judged to be sufficiently complete, accurate and interesting by the spectators.

1. INTRODUCTION

The increasing availability of broadband Internet connections has led to a rise in popularity of networked games. These range from large, complex, persistent online environments supporting a large number of simultaneous participants, e.g., Massively-Multiplayer Online Games (MMOGs), to more conventional, first person shooter games supporting a relatively small number of players. More recently, games have started to emerge as a spectator sport, with professional players competing for prestige and prizes [2, 5], and semi-professional commentators, players who takes part in a game in order to report on events in the game [1].

Commentating on games and online environments involves balancing two sets of potentially conflicting interests: spectators who want to know what is going on and players (or more generally, participants) who may wish to reveal some events while concealing others—either because an element of surprise is important in the game, or simply because there is a natural expectation of a degree of privacy, even in a shared virtual environment. At the same time, players may benefit from commentary in some situations, e.g., in-game commentary may enhance the enjoyment of the game, and appearing in reports may be a way of building a reputation and progressing in the community of players.

In previous work we have presented a framework for agent-based commentary systems based on embodied reporting agents which can produce real-time and post-game commentary which is individually tailored to the interests of the spectators and provided preliminary results on objective measures of system performance in terms of the number of events reported [3, 4]. In this paper we focus on the players' perspective. We analyse the results of an initial evaluation of our system in terms of the conflicting interests of players and spectators, and show that there is an 'optimal' number of agents which balances the needs of both groups, i.e., that is small enough to be tolerated and even welcomed by the players while at the same time producing commentary which is judged to be complete, accurate and interesting by the spectators.

2. CONTROLLING COMMENTARY

Spectators and players interact with a commentary system in different ways. Spectators want "good" commentary. This could be defined in many ways, e.g., how interesting or engagingly the commentary is, or how well presented. However, at a minimum good commentary requires that certain events be reported. Precisely which events, depends on the type of spectator and their situation. We wish to support different kinds of spectators, from those who don't play but may perhaps become spectators, to those who are actively playing. Some spectators will require real-time commentary covering key events, perhaps delivered via SMS, while others need detailed, post game commentary delivered by an animated presenter, while yet others require commentary in the game itself. A key question is how can spectators control the system to get the commentary they want in the format they want it.

Players on the other hand may wish certain events reported (e.g., when they are playing well) and certain events not reported (e.g., when they are playing badly or when an element of surprise is necessary to the game). What should or shouldn't be reported depends on the nature of the game. For example, in games in which the play-

ers are always on display (e.g., gladiatorial combat) a lower level of privacy may be expected or even desired than in games where the demands of tactical or social play require privacy. In more unstructured virtual environments, such as SecondLife [6] the expectations of privacy may be higher still.

A key question is how can the players control the commentary, or at a minimum, the events which are recorded by the commentary system. The players' main focus is on playing the game; a commentary system which is too intrusive, e.g., one which explicitly requires a player to define before or after an event whether it is to be reported, will interfere with the gameplay. However simply recording every event in the environment is equally undesirable in environments where either a degree of privacy is required or where recording everything introduces scalability issues (e.g., MMOGs). Ideally, a commentary system needs to achieve a balance between providing a useful and engaging commentary, while at the same time minimising the degree of intrusion into the gameplay.

In our approach commentary is generated by agents that are directly embodied within the game. Being embodied means that the agents are subject to the same constraints as human players in terms of what they can sense. It also means that agents are visible to players and can be affected by their actions. Players can therefore choose whether to try to hide from the agents, or conversely approach them, perhaps 'acting up' for the camera (e.g., celebrating a victory). Our hypothesis was that embodiment and the familiar metaphor of reporters in the field would provide players with the affordances they need to control the commentary system.

3. THE STUDIO SYSTEM

Our solution, the *Studio System*, is a MAS framework in which responsibility for generating commentary is distributed between three kinds of agents: reporters, editors and presenters, which cooperate to produce commentary [3, 4].

The role of the reporters is to collect information about "interesting" events in the game world. "Interesting" events are those which are of particular interest to groups of spectators (e.g., which determine the outcome of the game or involve a particular team or player). Reporters are embodied in the virtual environment, but unlike the players cannot influence it directly. They are subject to the same sensory limitations as human players, and to obtain information about events taking place in the game world, the reporter must move to the relevant location within it. Events the reporters judge interesting are forwarded to the editors. Since reporters are not infallible, the editors attempt to verify the data produced by the reporters, e.g., by clarifying conflicting reports or by requiring multiple reporters to detect the same event. In addition, the editors attempt to maximise the collection of relevant and interesting information by assigning reporters in such a way as to provide good coverage of the events in the environment, e.g. by directing idle reporters to under-reported or interesting regions within the environment. Editors pass confirmed reports to the presenter(s). The role of the presenters is to deliver commentary to players and spectators at an appropriate time and in an appropriate format. Different presenters may have differing temporal relationships to reported events, e.g. real-time versus retrospective commentary, or may report differing degrees of detail to different output devices.

By interacting with the presenters, spectators can influence the importance the editors and reporters attach to different events, and so indirectly control what gets presented by the presenters. Editors direct the activities of reporters based on the spectators' expressed preferences and what they know of coverage and the activities of the other reporters. However, reporters are autonomous, and will follow the most interesting event they see (according to spectators' interests and assumptions about which events are interesting), notifying the editor if they abandon their allocated task.

We implemented a prototype *Studio System* based on "Capture the Flag", one of the game types provided by Unreal Tournament (UT). This is a "first person shooter" game, in which two teams of players (Red and Blue), each attempt to collect the flag from the opposing team's flag base and carry it back to their own team's flag base to score a point, while at the same time preventing the opposing team from doing the same to their flag (typically by shooting them). In a first person shooter game like UT it can be difficult for players to avoid the reporters. However the embodiment of the reporters means that they are subject to the same rules as other players; in particular they can be killed. Killing a reporter removes it from the game temporarily, and causes it to forget any information it has not passed to an editor. Killing reporters therefore gives the players a way of preventing the current state of the game being reported. To discourage players from killing reporters indiscriminately, a (small) number of points are deducted from their score for each reporter killed.

A more detailed description of the system can be found in [3, 4].

4. EVALUATION

We ran a series of online trials of our extended CTF game to determine whether the system can generate 'good enough' commentary (especially whether it can provide sufficient coverage of game events), and the impact of the system on playing the game (especially whether reporters interfere with play or otherwise change its feel). The UT server was set to six player slots; connecting players occupied these slots, and any slots unused by such connections were filled by UT's built-in bots. We varied the number of reporters present between 1, 2, 4 and 6, as we expected this to be a major factor affecting both questions. We used the relatively small CTF-Simple game map which we felt should offer the possibility of crowding even with a relatively small number of reporters present.

We invited all players to complete an online questionnaire after playing the game that probed their attitudes to the in-game commentary and the impact of reporters being present. We received 26 completed questionnaires from an estimated 45 players who took part, distributed evenly across the test conditions. We also captured logs from the UT server and from the Studio System.

4.1 Accuracy and Coverage

We assessed coverage by comparing the number of game events (flag captures, pick-ups, takes, drops and returns) that were present in the studio logs compared to the full game logs. For each event, we awarded the Studio one point if its report completely matched the UT server log in all four respects; half a point for a 'partial match' where the player was incorrect or not specified but the report was otherwise correct; and zero points otherwise. Coverage was then computed as the percentage of points awarded out of those that were potentially available. Figure 1 shows the average coverage level for each event type across all games logged on the server.[1]

With the exception of flag captures, coverage for all event types improves as more reporters are introduced into the game environment. However, this improvement becomes smaller as more reporters are added. The greatest increase is seen when going from 1 reporter to 2, with a slightly smaller increase when going from 2 to 4, and the smallest increase when going from 4 to 6. For flag-capture events, even a single reporter yields a high coverage (over 90%) because reporters can reliably deduce that a capture has taken

[1]Note that parts of the system have been reimplemented and the coverage results presented here differ from that in [3].

place (though not which player performed the flag capture) by observing the team scores.

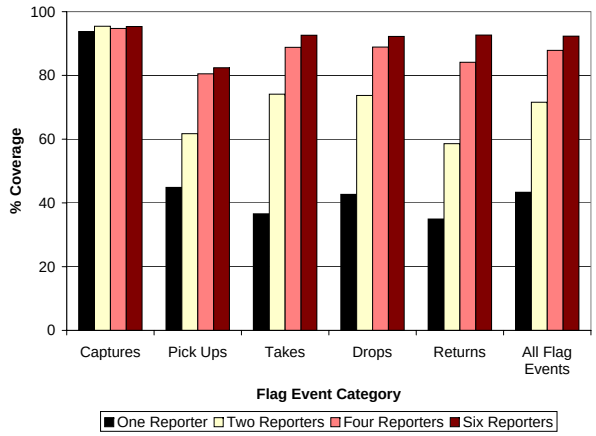

Figure 1: System coverage during live tests.

To supplement the coverage data, our exit questionnaire asked the players to assess the quality of the commentary. Our prototype system supports a number of presenters. To separate the question of coverage and accuracy from the details of presentation as much as possible, we used the "in game" presenter, which produces brief, topical reports of events in the game in the form of regular player chat. We asked players to rate whether reported events were described accurately. Responses indicate that the accuracy of the system improved with more than one reporter. We also asked them to rate whether the commentary missed out important events. Only one player felt that this was the case with only one reporter present and no players felt this was the case with six reporters present.

In summary, player feedback also suggests that the perceived coverage of the system improves as the number of reporters increases, which is in line with our objective measure of coverage. However, even with only two reporters, only one player agreed with the suggestion that the system missed a large number of events. In other words, players may find a relatively low coverage of events acceptable.

4.2 Intrusiveness

Our questionnaire also asked players to rate a number of statements about the impact of reporters on playing the game, along with free-form comments. Here we focus on the statements concerning whether reporters got in the way of movement and combat; and whether they were intrusive or annoying.

Adding more reporters results in them increasingly obstructing combat and, to a lesser extent, movement. With six reporters, four of the seven players who responded indicated strong agreement that they obstructed combat. However, one observed that they could enhance combat: "Oddly enough, they offered good meatshields. When I was carrying the flag, their presence not only took away enemy points, but helped me escape". Players did not appear to find the system particularly intrusive regardless of the number of reporters. However, some commented that the game did feel different, though not necessarily in a negative way: "It was interesting to have actual, physical spectators, much like any other 'extreme' sport much like what UT tires to portray itself as. I liked the idea of a cameraman or spectator following the action or when I grabbed the flag".

On balance, we would argue that our study shows that deploying a framework of reporter, editor and presenter agents is a viable approach to generating commentary from games. Objectively, two or more reporters were able to cover 50% or more of the events in this particular game, and players appear to have found the resulting in-game commentary to be generally appropriate and reasonably accurate. At the same time, the presence of small numbers of reporters does not appear to have had a negative impact on game play, and may even have enhanced the experience for some due to the feeling of being watched and new opportunities for tactical play.

In terms of the numbers of reporters required, there appear to be rapidly diminishing returns from using more than two in for the test map, both in terms of objective coverage and player perception, while there is increasing cost as we move towards four and six reporters in terms of negative impact on gameplay. In this particular case, we would suggest that two reporters is the most appropriate number. Of course, other maps and other games may have their own 'sweet-spots' in terms of an ideal number of reporters, but we anticipate that the general principle of diminishing returns and increasing costs should hold true.

5. CONCLUSIONS AND FUTURE WORK

We have presented a framework for reporting on computer games, the Studio System, which attempts to balance the requirements of spectators and players. The system is novel in its use of embodied reporters, agents which are directly embodied in the game world and subject to the same constraints as human players. We have described the implementation of the system and summarised the results of a preliminary study of how players experienced the system, showing that there is an 'optimal' number of agents which is small enough to be tolerated and even welcomed by the players while at the same time producing commentary which is judged to be complete, accurate and interesting by spectators.

In future we plan to extend our current basic teamwork model to approaches that can scale to larger worlds, building on previous work on teamwork, e.g., [7]. We also plan to develop embodied presenter agents that can provide engaging news feeds within virtual worlds. A final direction is further validating our framework through more in depth studies with more complex games.

ABSTRACT

This paper provides a general mechanism and a solid theoretical basis for performing planning within Belief-Desire-Intention (BDI) agents. BDI agent systems have emerged as one of the most widely used approaches to implementing intelligent behaviour in complex dynamic domains, in addition to which they have a strong theoretical background. However, these systems either do not include any built-in capacity for "lookahead" type of planning or they do it only at the implementation level without any precise defined semantics. In some situations, the ability to plan ahead is clearly desirable or even mandatory for ensuring success. Also, a precise definition of how planning can be integrated into a BDI system is highly desirable. By building on the underlying similarities between BDI systems and Hierarchical Task Network (HTN) planners, we present a formal semantics for a BDI agent programming language which cleanly incorporates HTN-style planning as a built-in feature. We argue that the resulting integrated agent programming language combines the advantages of both BDI agent systems and hierarchical offline planners.

Keywords

BDI agent-oriented programming, HTN planning

1. INTRODUCTION

The BDI (Belief-Desire-Intention) model is a popular and well-studied architecture of agency for intelligent agents situated in complex and dynamic environments. The model has its roots in philosophy with Bratman's [2] theory of practical reasoning and Dennett's theory of intentional systems [9]. There are a number of agent programming languages in the BDI tradition, such as PRS [13], AGENTSPEAK [19], 3APL [12], JACK [3], and CAN [24].

BDI agent-oriented systems are extremely flexible and responsive to the environment, and as a result, well suited for complex applications with real-time reasoning and control requirements. However, a limitation of these systems is that they normally do no *lookahead* or *planning* in the traditional sense; execution is based on a user-provided "plan library" to achieve goals. BDI frameworks rely entirely on context sensitive subgoal expansion, acting as they go. In some circumstances, however, lookahead deliberation (i.e., hypothetical reasoning) about the effects of one choice of expansion over another is clearly desirable, or even mandatory in order to guarantee goal achievability and to avoid undesired situations. In general, this is the case when (a) important resources may be used in taking actions that do not lead to a successful outcome; (b) actions are not always reversible and may lead to states from which there is no successful outcome; (c) execution of actions take substantially longer than "thinking" (or planning); and (d) actions have side effects which are undesirable if they turn out not to be useful.

In this paper, we develop a traditional BDI-style agent programming language that includes an *on-demand planning mechanism* in the style of Hierarchical Task Networks (HTN), whose semantics and implementations are well understood in the planning community [11]. The language we propose, named CANPLAN, provides a flexible approach regarding when to perform full lookahead and is provably more expressive than either BDI or HTN systems alone. CANPLAN is based on CAN [24] and AGENTSPEAK [19]. One could argue, of course, that it is always possible, in critical situations, to explicitly program lookahead within existing BDI systems. However, such code would generally be domain dependent, can be fairly complex, and would lie outside the infrastructure support provided by the BDI agent platform. Alternatively, there are many frameworks that attempt to interleave BDI-type execution with offline planning (e.g., [1, 23, 10, 17, 14]). Still, these are mostly implemented systems with no precise semantics and with little programmer control over when to plan. Our approach, instead, is to provide a formal specification of planning as a *built-in feature* of the BDI infrastructure that the programmer can use as appropriate.

The contributions of this paper are threefold. Firstly, a precise account of planning within a typical BDI agent programming language is provided. Secondly, the intrinsic relationship between lookahead planning in the context of BDI agents and the HTN approach to planning is formally explored. Lastly, the semantics of CAN given in [24] is substantially improved and simplified.

The rest of the paper is organised as follows. In section 2, we provide a brief overview of BDI agent programming languages and HTN planners; we also provide an informal discussion on their similarities. In section 3, we describe the basic BDI agent language we will use, namely the CAN notation described in [24], but with some modifications to include actions with preconditions and ef-

fects, multiple variable bindings, and a simpler, though equivalent, account of declarative goals. We chose CAN from the numerous available options because it has the desirable features of (a) combining a declarative and procedural view of *goals*, and (b) capturing the semantics of BDI failure recovery and goal persistence. In section 4, we develop CANPLAN, our new integrated account of planning and BDI execution. Besides showing some intuitively expected properties for the combined framework, we prove that, under suitable assumptions, CANPLAN's planning module reduces to HTN planning. In section 5, a brief discussion on a prototype implementation is given. Section 6 discusses related work. Finally, in section 7, we draw conclusions and outline future lines of research.

2. BDI AND HTN SYSTEMS

There are a number of BDI agent languages and HTN systems. In this section, we provide a brief abstract overview of these and comment on their similarities.

2.1 BDI Agent Programming Languages

Generally speaking, BDI agent-oriented programming languages are built around an explicit representation of beliefs, desires, and intentions. A BDI architecture addresses how these components are represented, updated, and processed to determine the agent's actions. There are a substantial number of implemented BDI systems, as well as a number of formally specified languages.

An agent consists, basically, of a belief base $\mathcal{B}$, a set of recorded pending events (goals), a plan library Π, and an intention base Γ. The *belief base* encodes the agent's knowledge about the world. The *plan library* contains *plan rules* of the form $e : \psi \leftarrow P$ encoding a *plan-body program* P for handling an event-goal e when *context* condition ψ is believed to hold. The *intention base* contains the current, partially instantiated, plans the agent has already committed to in order to handle or achieve some event-goal.

A BDI system responds to *events*, the inputs to the system, by committing to handle one pending event-goal, selecting a plan rule from the library, and placing its plan-body program into the intention base. The execution of this program may, in turn, post new sub-goal events to be achieved. If at any point a program fails, then an alternative plan rule is found and its plan-body is placed into the intention base for execution. This process repeats until a plan succeeds completely or until there are no more applicable plans, in which case failure is propagated to the event-goal.

In section 3, we shall discuss in detail one formal BDI language of this sort, namely, the CAN language [24].

2.2 HTN Planning

Hierarchical Task Network (HTN) planning is an approach to planning based on the decomposition of (high-level) *tasks* in order to accomplish an (initial) *task network*. Two examples of HTN systems include SHOP [15] and its successor SHOP2 [16]. Below, we mostly follow the definitions of HTN-planning from [11].

Tasks can be of two types. A *primitive task* is an action $act(\vec{x})$ that can be directly executed by the agent (e.g., $drive(x_1, x_2)$). A (high-level) *compound task* $e(\vec{x})$ is one that cannot be executed directly (e.g., $build\_trip(origin, dest)$). A *task network* $d = [T, \phi]$ is a collection of tasks T that need to be accomplished and a boolean formula of constraints ϕ. Constraints impose restrictions on the ordering of the tasks ($e \prec e'$), on the binding of variables ($x = x'$) and ($x = c$) (c is a constant), and on what literals must be true before or after each task (l, e), (e, l), and (e, l, e'). A *method* (e, ψ, d) encodes a way of decomposing a high-level compound task e into lower-level tasks using task network d when ψ holds. Methods provide the procedural knowledge of the domain.

An HTN *planning domain* $\mathcal{D} = (\Pi, \Lambda)$ consists of a library Π of methods and a library Λ of primitive tasks. Each primitive task in Λ is a STRIPS style action with corresponding preconditions and effects in the form of *add* and *delete* lists. An HTN *planning problem* **P** is a triple $\langle d, \mathcal{B}, \mathcal{D}\rangle$ where d is the task network to accomplish, $\mathcal{B}$ is the initial state (i.e., a set of all ground atoms that are true in $\mathcal{B}$), and $\mathcal{D}$ is a planning domain. A *plan* σ is a sequence $act_1 \cdot \ldots \cdot act_n$ of ground actions (that is, ground primitive tasks).

Given a planning problem instance **P**, the planning process involves selecting and applying an applicable reduction method from $\mathcal{D}$ to some compound task in d. This results in a new, and typically more "primitive," task network d'. This reduction process is repeated until only primitive tasks (i.e., actions) remain. If no applicable reduction can be found for a compound task at any stage, the planner "backtracks" and tries an alternative reduction for a compound task previously reduced. If all compound tasks can eventually be reduced, a plan solution σ is obtained

In [11], a clear operational semantics for HTN planning was given. The set of plans $sol(d, \mathcal{B}, \mathcal{D})$ that solves a planning instance $\mathbf{P} = \langle d, \mathcal{B}, \mathcal{D}\rangle$ is defined as $sol(d, \mathcal{B}, \mathcal{D}) = \bigcup_{n<\omega} sol_n(d, \mathcal{B}, \mathcal{D})$, where $sol_n(d, \mathcal{B}, \mathcal{D})$ is, in turn, defined as follows:

$$\begin{aligned} sol_1(d, \mathcal{B}, \mathcal{D}) &= comp(d, \mathcal{B}, \mathcal{D}), \\ sol_{n+1}(d, \mathcal{B}, \mathcal{D}) &= sol_n(d, \mathcal{B}, \mathcal{D}) \cup \bigcup_{d' \in red(d, \mathcal{B}, \mathcal{D})} sol_n(d', \mathcal{B}, \mathcal{D}). \end{aligned}$$

Intuitively, $comp(d, \mathcal{B}, \mathcal{D})$ is the set of all plan *completion* of a network d containing only primitive tasks (i.e., plans for which the constraint formula ϕ in d is satisfied), and $red(d, \mathcal{B}, \mathcal{D})$ is the set of all *reductions* of d in $\mathcal{B}$ by methods in $\mathcal{D}$. We refer to [11] for more details on HTN and its formal semantics.

2.3 Similarities Between HTN and BDI

As stated in [7], BDI agent programming languages and HTN planners share many similarities despite their different purposes. The similarities come from the knowledge used by both systems as well as from how this knowledge is manipulated to create solutions.

First of all, HTN systems and BDI languages assume an explicit representation of the agent's knowledge (i.e., the belief base or state) and a set of primitive tasks or actions that the agent can directly execute in the world. Secondly, procedural knowledge about the domain is available in both HTN and BDI systems in the form of reduction methods and plan rules, respectively. Thirdly, and most importantly, both systems create solutions by reducing higher-level entities into lower-level ones by appealing to a given set of reduction recipes. Whereas a BDI system "reduces" an event into an plan-body program using a plan rule from the plan library, an HTN planner reduces a compound task into a task network using a reduction method from the method library.

The following table gives an indication of the mapping between HTN and BDI entities.

BDI SYSTEMS	HTN SYSTEMS
belief base	state
plan library	method library
event	compound task
action	primitive task
plan-body/program	network task
plan rule	method
plan rule context	method precondition
test $?l$ in plan-body	state constraints
sequence in plan-body	ordering constraint $\prec$
parallelism in plan-body	no ordering constraint

The above table is not complete—whereas some entities have a straightforward mapping some others require a more elaborate translation (we refer to [7, 22] for a more detailed mapping).

BDI agent systems and HTN planners, despite their close relationship, differ fundamentally in their objectives. The former are focused on the *execution* of agent programs where "backtracking" can only happen in the real world. The latter, in contrast, are concerned with *hypothetical reasoning* about actions and their potential interactions within a whole plan for achieving a goal or task.

3. THE BASIC BDI LANGUAGE

The CAN (**C**onceptual **A**gent **N**otation) notation [24] is a high-level plan language in the style of typical agent languages, both in the BDI tradition and elsewhere (e.g., AGENTSPEAK [19], 3APL [12, 21], and even CONGOLOG [5, 6]). Its syntax and semantics attempt to extract the essence of a class of implementable agent platforms and could be considered as a superset of AGENTSPEAK. Unlike AGENTSPEAK, though, the semantics for CAN includes both *failure handling* and *declarative goals*—two appealing features for our planning agents.

An agent is created by the specification of a set of base beliefs $\mathcal{B}$ and a set of plans Π. The *belief base* of an agent is a set of formulas from some (knowledge representation) logical language. The programmer may choose any logical language; all that is required is for operations to exist that check whether a condition ϕ—a logical formula over the agent's beliefs—follows from a belief set (i.e., $\mathcal{B} \models \phi$), and to add and delete a belief b to and from a belief base (i.e., $\mathcal{B} \cup \{b\}$ and $\mathcal{B} \setminus \{b\}$, respectively). In practice, however, the belief base contains ground belief *atoms* in a first-order language.

As explained in section 2, an agent *plan library* Π consists of a collection of plan rules of the form $e : \psi \leftarrow P$, where e is an event and ψ is the context condition which must be true in order for the plan-body P to be applicable.[1] The *plan-body* or *program* P is built from primitive actions act that the agent can execute directly, operations to add $+b$ and delete $-b$ beliefs, tests for conditions $?\phi$, and events or (internal) achievement goals $!e$. Complex plans can be specified using sequencing $P_1; P_2$, parallelism $P_1 \| P_2$, and declarative goals $\mathsf{Goal}(\phi_s, P, \phi_f)$ (explained later). Hence, the *user language* is described by the following grammar:

$$P ::= act \mid +b \mid -b \mid ?\phi \mid !e \mid P_1; P_2 \mid P_1 \| P_2 \mid \mathsf{Goal}(\phi_s, P_1, \phi_f).$$

There are also a number of auxiliary plan forms which are used internally when assigning semantics to constructs: basic (terminating) program *nil*; and compound plans $P_1 \triangleright P_2$, which executes P_1 and then executes P_2 only if P_1 failed; and $(\!|\psi_1 : P_1, \ldots, \psi_n : P_n|\!)$, which is used to encode a set of (relevant) guarded plans. The *full language* is therefore described by the following grammar:

$$P ::= \mathit{nil} \mid act \mid ?\phi \mid +b \mid -b \mid !e \mid P_1; P_2 \mid P_1 \triangleright P_2 \mid P_1 \| P_2 \mid \mathsf{Goal}(\phi_s, P_1, \phi_f) \mid (\!|\psi_1 : P_1, \ldots, \psi_n : P_n|\!).$$

In contrast with [19, 24], we take actions as the usual basic means of the agent to change its environment and, hence, actions may have preconditions and effects. One possibility would be to follow [12] and assume that a *partial* function $\mathcal{T}$ specifying the update semantics of basic actions is given: if $\mathcal{T}(act, \mathcal{B})$ is defined, it yields the new updated belief base $\mathcal{B}'$; otherwise, we say that the action's precondition is not met in $\mathcal{B}$. However, for simplicity, we shall restrict ourselves to agents that are equipped with a (simple) STRIPS-like *action description library* Λ containing rules of the form $act : \psi_{act} \leftarrow \Phi^-_{act}; \Phi^+_{act}$, one for each action type in the domain. Formula ψ_{act} corresponds to the action's precondition, and Φ^+_{act} and Φ^-_{act} stand for the add and delete lists of atoms, respectively.[2] For example, action $move(x, y, z)$, which moves object x from y to z, could be represented in Λ as follows:

$$move(x, y, z) : Free(z) \wedge At(x, y) \longleftarrow \{Free(z), At(x, y)\}; \{Free(y), At(x, z)\}.$$

Next, we show the operational semantics for the above language along the lines of [24]. A *transition relation* $\longrightarrow$ on so-called *configurations* is defined by a set of derivation rules. A transition $C \longrightarrow C'$ specifies that executing configuration C a *single step* yields configuration C'. We write $C \longrightarrow$ to state that there exists C' such that $C \longrightarrow C'$, and $\xrightarrow{*}$ to denote the usual reflexive transitive closure of $\longrightarrow$. A derivation rule consists of a, possibly empty, set of premises, which are transitions together with some auxiliary conditions, and a single transition conclusion derivable from these premises. (see [18] for more on operational semantics).

Two types of transitions will be used to define the semantics of our agents. The first type defines what it means to execute a single intention and is defined in terms of *basic* configurations. The second type of transition is defined in terms of the first type and defines what it means to execute an agent. A *basic configuration* is a tuple $\langle \mathcal{B}, \mathcal{A}, P \rangle$ consisting of the current belief base $\mathcal{B}$ of the agent, the sequence $\mathcal{A}$ of primitive actions executed so far, and the plan-body program P being executed (i.e., the current intention).[3]

Here are some of the core derivation rules for the language:

$$\frac{\Delta = \{\psi_i\theta : P_i\theta \mid e' : \psi_i \leftarrow P_i \in \Pi \wedge \theta = \mathsf{mgu}(e, e')\}}{\langle \mathcal{B}, \mathcal{A}, !e \rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, (\!|\Delta|\!) \rangle} \; Event$$

$$\frac{\psi_i : P_i \in \Delta \quad \mathcal{B} \models \psi_i\theta}{\langle \mathcal{B}, \mathcal{A}, (\!|\Delta|\!) \rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, P_i\theta \triangleright (\!|\Delta \setminus P_i|\!) \rangle} \; Sel$$

$$\frac{\langle \mathcal{B}, \mathcal{A}, P_1 \rangle \overset{\mathsf{bdi}}{\not\longrightarrow}}{\langle \mathcal{B}, \mathcal{A}, (P_1 \triangleright P_2) \rangle \overset{\mathsf{bdi}}{\longrightarrow} \langle \mathcal{B}, \mathcal{A}, P_2 \rangle} \; \triangleright_f \qquad \frac{\mathcal{B} \models \phi\theta}{\langle \mathcal{B}, \mathcal{A}, ?\phi \rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, \mathit{nil} \rangle} \; ?$$

$$\frac{a : \psi \leftarrow \Phi^-; \Phi^+ \in \Lambda \quad a\theta = act \quad \mathcal{B} \models \psi\theta}{\langle \mathcal{B}, \mathcal{A}, act \rangle \longrightarrow \langle (\mathcal{B} \setminus \Phi^-\theta) \cup \Phi^+\theta, \mathcal{A} \cdot act, \mathit{nil} \rangle} \; act$$

$$\frac{\langle \mathcal{B}, \mathcal{A}, P_1 \rangle \longrightarrow \langle \mathcal{B}', \mathcal{A}', P' \rangle}{\langle \mathcal{B}, \mathcal{A}, (P_1; P_2) \rangle \longrightarrow \langle \mathcal{B}', \mathcal{A}', (P'; P_2) \rangle} \; Seq$$

Rule $Event$ handles achievement goal events by collecting all *relevant* plans for the event in question. Rule Sel selects one *applicable* plan from a set of (remaining) relevant plans: program $P \triangleright (\!|\Delta|\!)$ states that program P should be tried first, falling back to the remaining alternatives in Δ if necessary. Notice that plan rules' context conditions are handled in a lazy manner. Rule ? deals with test goals by checking that the condition follows from the current belief base, whereas rule act handles the case of primitive actions by using the domain action description library Λ. Rule Seq handles sequencing of programs in the usual way. Rule $\triangleright_f$ is used along with rule Sel for *failure handling*: if the current plan $P_i\theta$ for a goal fails (e.g., at some point the precondition of an action or a test goal is not met), rule $\triangleright_f$ applies first, and eventually, rule Sel may select another *applicable* alternative for the event-goal, if any.

A central distinguishing feature of CAN is its $\mathsf{Goal}(\phi_s, P, \phi_f)$ goal construct, which provides a mechanism for representing both declarative and procedural aspects of goals. Intuitively, a *goal-program* $\mathsf{Goal}(\phi_s, P, \phi_f)$ states that we should achieve the (declarative) goal ϕ_s by using (procedural) program P; failing if ϕ_f becomes true. The execution of a goal-program is consistent with

[1] An omitted ψ is equivalent to *true*. Notice that e, ψ, and P may contain free variables; a plan rule is of the form $e(\vec{x}) : \psi(\vec{x}, \vec{y}) \leftarrow P(\vec{x}, \vec{y}, \vec{z})$, where $\vec{x}, \vec{y}$ and $\vec{z}$ are vectors of (distinct) variables.

[2] Free variables in ψ_{act}, Φ^-_{act} and Φ^+_{act} are free in act too.

[3] Strictly speaking, the plan and action libraries Π and Λ should also be part of basic configurations. For legibility purposes, we omit them as they are assumed to be static entities. Configurations must also include a variable substitution θ for keeping track of all bindings done so far during the execution of a plan-body. Again, for legibility, we keep substitutions implicit in places where they need to be carried across multiple rules. See [12] on how substitutions are propagated across derivation rules for 3APL.

some desired properties of declarative goals (namely, persistent, possible, and unachieved). For instance, if P is fully executed but ϕ_s is still not true, P will be re-tried; and if ϕ_s becomes true during P's execution, the whole goal will succeed immediately.

In order to capture the desired behaviour of goal-programs, a sophisticated operational semantics was given in [24], based on explicit exceptions, a set of conditions being "watched," and derivation rules with priorities. Here, we provide an alternative much *simpler* semantics that is equivalent to the original one. The following is the new set of rules for goal-programs:

$$\frac{P \neq P_1 \rhd P_2 \quad \mathcal{B} \not\models \phi_s \vee \phi_f}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P, \phi_f)\rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P \rhd P, \phi_f)\rangle}\ \mathsf{G}_I$$

$$\frac{\mathcal{B} \models \phi_s}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P, \phi_f)\rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, \mathit{nil}\rangle}\ \mathsf{G}_s$$

$$\frac{\mathcal{B} \models \phi_f}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P, \phi_f)\rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, ?\mathit{false}\rangle}\ \mathsf{G}_f$$

$$\frac{P = P_1 \rhd P_2 \quad \mathcal{B} \not\models \phi_s \vee \phi_f \quad \langle \mathcal{B}, \mathcal{A}, P_1\rangle \longrightarrow \langle \mathcal{B}', \mathcal{A}', P'\rangle}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P, \phi_f)\rangle \longrightarrow \langle \mathcal{B}', \mathcal{A}', \mathsf{Goal}(\phi_s, P' \rhd P_2, \phi_f)\rangle}\ \mathsf{G}_S$$

$$\frac{P = P_1 \rhd P_2 \quad \mathcal{B} \not\models \phi_s \vee \phi_f \quad \langle \mathcal{B}, \mathcal{A}, P_1\rangle \not\longrightarrow}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P, \phi_f)\rangle \longrightarrow \langle \mathcal{B}, \mathcal{A}, \mathsf{Goal}(\phi_s, P_2 \rhd P_2, \phi_f)\rangle}\ \mathsf{G}_R$$

When a goal-program is first encountered during execution, rule G_I applies: G_I "initialises" the execution of a goal-program by setting the program in the goal to $P \rhd P$, where the first P is to be executed and the second P is just used to store and carry the *original* program P in case rule G_R may eventually apply later on. The second and third rules handle the cases where either the success condition ϕ_s or the failure condition ϕ_f become true. The fourth rule G_S is the one responsible for performing a single step on an already initialised goal-program. Notice that the second part in the pair $P_1 \rhd P_2$ remains constant. Finally, rule G_R restarts the original program (stored as the second program in pair $P_1 \rhd P_2$) whenever the current program has finished or got stuck, but the desired, and still possible, goal has not been achieved yet.

The above semantics for Goal is substantially simpler than the original one in [24] in that we do not appeal to explicit exceptions, "watched" conditions, or special prioritised derivation rules. Although it is not hard to prove that this alternative semantics is equivalent to the original one, due to lack of space, we do not do that here. Finally, we point out that, in the original semantics of CAN, an agent also included a goal base $\mathcal{G}$ to account for the declarative goals the agent has already committed to via goal-programs. Although not done in CAN, the goal base could potentially be used to perform (meta)reasoning about goals at the agent level execution, such as goal conflict detection and resolution ([20]). Since we are also not concerned in this paper with this type of reasoning, we completely omit the goal base from our agents.

Agent Level Execution

On top of the above basic rules, we define the evolution of an agent. An *agent configuration*, or just an agent, is a tuple of the form $\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma\rangle$ where $\mathcal{N}$ is the agent name, Λ is an action description library, Π is a plan library, $\mathcal{B}$ is a belief base, $\mathcal{A}$ is the sequence of actions already performed by the agent, and Γ is the set of current intentions (that is, plan-body programs). Transitions between agent configurations are dictated by the following three rules:

$$\frac{P \in \Gamma \quad \langle \mathcal{B}, \mathcal{A}, P\rangle \longrightarrow \langle \mathcal{B}', \mathcal{A}', P'\rangle}{\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma\rangle \Longrightarrow \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}', \mathcal{A}', (\Gamma \setminus \{P\}) \cup \{P'\}\rangle}\ A_{step}$$

$$\frac{e \text{ is a new external event}}{\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma\rangle \Longrightarrow \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \cup \{!e\}\rangle}\ A_{event}$$

$$\frac{P \in \Gamma \quad \langle \mathcal{B}, \mathcal{A}, P\rangle \not\longrightarrow}{\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma\rangle \Longrightarrow \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \setminus \{P\}\rangle}\ A_{clean}$$

The first rule performs a single step in one intention; the second rule creates a new intention from an external event; and the last rule removes a completed intention from the intention base, that is, an intention *nil* or one that is blocked and cannot make a transition.

Next, we define the meaning of an agent execution and two related notions that will be used later in the paper.

DEFINITION 1 (BDI EXECUTION). *A BDI execution E of an agent $C_0 = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}_0, \mathcal{A}_0, \Gamma_0\rangle$ is a, possibly infinite, sequence of agent configurations $C_0 \cdot C_1 \cdot \ldots \cdot C_n \cdot \ldots$ such that $C_i \Longrightarrow C_{i+1}$, for every $i \geq 0$. A terminating execution is a finite execution $C_0 \cdot \ldots \cdot C_n$ where $C_n = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}_n, \mathcal{A}_n, \{\}\rangle$. An environment-free execution is one in which rule $\mathcal{A}_{event}$ has not been used.*

Sometimes we will be only interested in those steps of an execution where changes occur in either the executed actions or the belief of the agent—agent steps where the belief base and the executed actions remain unchanged can be disregarded. So, if $E = C_0 \cdot \ldots \cdot C_n$ is a (finite) execution, then the *derived execution* $\overline{E}$ is the sequence of configurations obtained from E by deleting all configurations C_j in the sequence such that $\mathcal{B}_j = \mathcal{B}_{j+1}$ and $\mathcal{A}_j = \mathcal{A}_{j+1}$.

In addition, we give the following notation to track an intention during an execution. If $C_0 \cdot \ldots \cdot C_n$ is a normal or derived execution and P is an intention in C_0 (i.e., $P \in \Gamma_0$), then the sequence $P_0 = P, P_1, \ldots, P_n$ denotes P's evolution within the execution and either (i) $P_i \in \Gamma_i$; or (ii) $P_i = \epsilon$, if the intention has already been removed from the intention base at some C_j, where $j \leq i$.

DEFINITION 2. *Two, possibly derived, agent executions $C_0 \cdot \ldots \cdot C_n$ and $C'_0 \cdot \ldots \cdot C'_n$ are equivalent modulo intentions iff $C'_i = \langle \mathcal{N}_i, \Lambda_i, \Pi_i, \mathcal{B}_i, \mathcal{A}_i, \Gamma'_i\rangle$, for every $0 \leq i \leq n$. Also, the two executions are equivalent modulo intentions $P_0 \in \Gamma_0$ and $P'_0 \in \Gamma'_0$ if they are equivalent modulo intentions and for every $0 \leq i \leq n$, $(\Gamma'_i \setminus \{P'_i\}) = (\Gamma_i \setminus \{P_i\})$ (where P_i (P'_i) is P_0's (P'_0's) evolution in configuration C_i (C'_i)).*

Lastly, we define what we mean by the execution of an intention and by a program (weakly) simulating another program.

DEFINITION 3 (INTENTION EXECUTION). *Let E be a BDI execution $C_0 \cdot C_1 \cdot \ldots \cdot C_n$ for an agent $C_0 = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}_0, \mathcal{A}_0, \Gamma_0\rangle$, where $\Gamma_0 = \Gamma'_0 \cup \{P_0\}$. Intention P_0 in C_0 has been fully executed in E if $P_n = \epsilon$; otherwise P_0 is currently executing in E. In addition, intention P_0 in C_0 has been successfully executed in E if $P_i = nil$, for some $i \leq n$; intention P_0 has failed in E if it has been fully but not successfully executed in E.*

DEFINITION 4 (PROGRAM SIMULATION). *Let E be an execution of $C = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \cup \{P\}\rangle$. Program P' simulates program P in execution E iff there is an execution E' of configuration $C' = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \cup \{P'\}\rangle$ such that (a) $\overline{E}$ and $\overline{E'}$ are equivalent modulo P and P'; and (b) if P has been successfully executed in E, so has P' in E'. We say that P' simulates P iff P' simulates P in every execution of any configuration.*

We have, so far, defined the necessary technical foundations for adding HTN-style planning into the CAN BDI agent language, including substantially polishing and simplifying the original CAN's semantics from [24], incorporating extra representation for actions, and providing the necessary definitions of agent execution that were not addressed in [24]. Let us now move on to the core of the paper.

4. PLANNING IN BDI SYSTEMS

In this section, we shall integrate hierarchical planning into the BDI architecture of section 3. To do so, several issues need to

be addressed. Firstly, we want to keep the language as *uniform* as possible. Secondly, we allow control over when and on what planning is to be performed within the BDI architecture. Thirdly, we need to decide what domain information the planner will use—we want the planner to re-use as much information as possible from an existing BDI specification. Lastly, the result of the planning process ought to be carried on, and possibly monitored, within the BDI execution cycle in a uniform manner.

To address the above issues, we extend the CAN language by introducing a new language construct Plan for offline lookahead planning, so that $\mathsf{Plan}(P)$, where P is a plan-body program, is intended to mean "*plan for P offline, searching for a complete hierarchical decomposition.*" In this way, the BDI agent on Plan does a full lookahead search before committing to even the first step.

As with other constructs in the language, we need to provide the operational rules for the Plan construct. To do this, we shall distinguish, from now on, between two types of transitions on basic configurations, namely, bdi and plan (labelled) transitions. We write $C \xrightarrow{\mathsf{t}} C'$ to specify a single step transition of type t (when no label is stated, both types apply). Intuitively, bdi-type steps will be used to model the normal BDI execution cycle, whereas plan-type transitions will be used to model (internal) deliberation steps within a *planning* context.

Following [6], the main operational rule states that configuration $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle$ can evolve to $\langle \mathcal{B}', \mathcal{A}', \mathsf{Plan}(P')\rangle$ provided that $\langle \mathcal{B}, \mathcal{A}, P\rangle$ can evolve to $\langle \mathcal{B}', \mathcal{A}', P'\rangle$ from where it is possible to reach a *final* configuration in a finite number of *planning* steps:

$$\frac{\langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{plan}} \langle \mathcal{B}', \mathcal{A}', P'\rangle \quad \langle \mathcal{B}', \mathcal{A}', P'\rangle \xrightarrow{\mathsf{plan}_*} \langle \mathcal{B}'', \mathcal{A}'', nil\rangle}{\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}} \langle \mathcal{B}', \mathcal{A}', \mathsf{Plan}(P')\rangle}\ \mathsf{Plan}$$

There are also two more simple rules associated with construct Plan that are shown in Figure 1. Rule Plan_t deals with the trivial case of planning on program *nil*; and, lastly, Plan_P handles the Plan construct within a planning context.

In addition to these three derivation rules for Plan, we need to restrict the two derivation rules $\rhd_f$ and G_R from section 3 to the bdi context only. This is because failure handling and goal restarting should not be made available during planning—they are features of the BDI execution cycle only. Hence, planning is *not* merely doing lookahead on the BDI execution cycle. We refer to the new versions of the rules as $\rhd_f^{bdi}$ and G_R^{bdi}, respectively. Also, since we now have two types of transition for basic configurations, we need to slightly modify the top-level agent rules A_{step} and A_{clean} to be defined in terms of bdi-type transitions. We only show here rules $\rhd_f^{bdi}$ and A_{step} (rules G_R^{bdi} and A_{clean} should be obvious):

$$\frac{\langle \mathcal{B}, \mathcal{A}, P_1\rangle \xrightarrow{\mathsf{bdi}}\!\!\!\!\!\!/\ \ }{\langle \mathcal{B}, \mathcal{A}, (P_1 \rhd P_2)\rangle \xrightarrow{\mathsf{bdi}} \langle \mathcal{B}, \mathcal{A}, P_2\rangle}\ \rhd_f^{bdi}$$

$$\frac{P \in \Gamma \quad \langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{bdi}} \langle \mathcal{B}', \mathcal{A}', P'\rangle}{\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma\rangle \Longrightarrow \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}', \mathcal{A}', (\Gamma \setminus \{P\}) \cup \{P'\}\rangle}\ A_{step}$$

Observe that, with the alternative rule $\rhd_f^{bdi}$, only the BDI execution cycle would be allowed to re-try alternative plans for an event upon the failure of some failed alternative. Indeed, a program of the form $(?\mathit{false} \rhd (\!|\Delta|\!))$ has no transition within a plan context, whereas program $(\!|\Delta|\!)$ would be tried within a bdi context.

In [24], it was required that the success and failure conditions in a goal-program be mutually exclusive. There is also another sensible restriction on goal-programs, namely, that the program P provided as a method for achieving a (declarative) goal ϕ_s does not make the failure condition ϕ_f true by itself.

DEFINITION 5. *A goal-program $\mathsf{Goal}(\phi_s, P, \phi_f)$ is coherent (relative to a plan library and an action library) if for every belief bases $\mathcal{B}, \mathcal{B}', \mathcal{B}''$ and sequences of actions $\mathcal{A}, \mathcal{A}', \mathcal{A}''$ such that $\langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}', \mathcal{A}', P'\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}'', \mathcal{A}'', nil\rangle$, it is the case that $\mathcal{B}' \not\models \phi_f$. An agent is coherent if every goal-program mentioned in its plan library is coherent.*

From now on, we assume that agents are *coherent*—only the environment or other concurrent intentions may make the failure condition of a goal-program true.[4] As expected, if the agent's only intention $\mathsf{Plan}(P)$ is able to start executing, then there is at least one full successful BDI execution for such intention, provided there is no intervention from the outside environment. Equally important, under the same provisions, no execution of the agent will end up failing the intention.

THEOREM 1. *Let $C = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \{\mathsf{Plan}(P)\}\rangle$ such that $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}}$. If E is an environment-free agent execution of C, then intention $\mathsf{Plan}(P)$ is either executing or has been successfully executed in E. Moreover, there is an execution E^s of C in which intention $\mathsf{Plan}(P)$ has been successfully executed in E^s.*

PROOF. *This relies on the following lemma: if $\langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{plan}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$, then $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$.*

On the contrary, suppose there is an environment-free execution E of the form $C_0 = C \cdot \ldots \cdot C_k$ such that $\langle \mathcal{B}_k, \mathcal{A}_k, \mathsf{Plan}(P_k)\rangle \xrightarrow{\mathsf{bdi}}\!\!\!\!\!\!/\ \ $. Observe, though, that $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}_k} \langle \mathcal{B}_k, \mathcal{A}_k, \mathsf{Plan}(P_k)\rangle$. By the rule Plan, $\langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{plan}_k} \langle \mathcal{B}_k, \mathcal{A}_k, P_k\rangle \xrightarrow{\mathsf{plan}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$ and $\langle \mathcal{B}, \mathcal{A}, P\rangle \xrightarrow{\mathsf{plan}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$ applies. By using the above lemma, we get that $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$. Next, since $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}}\!\!\!\!\!\!/\ \ \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$, there exist $\mathcal{B}'', \mathcal{A}'', P''$ such that $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}} \langle \mathcal{B}'', \mathcal{A}'', P''\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}_f, \mathcal{A}_f, nil\rangle$. Thus, $\langle \mathcal{B}, \mathcal{A}, \mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}}$ and the execution E cannot exist.

The second part follows easily from the fact that $\xrightarrow{\mathsf{plan}_*}$ stands for a finite chain of transitions: if the agent follows those exact transitions, P will eventually terminate successfully. □

Thus, by using the new lookahead construct $\mathsf{Plan}(P)$, the programmer can make sure—to some extent—that *failing* executions of program P will be avoided. This contrasts with the usual (default) BDI execution of P which may potentially *fail* program P due to wrong decisions at choice points. Nonetheless, it should be clear that the proposed deliberation module is *local* in the sense that it does not take into account the potential interactions with the external environment and other concurrent intentions.

Let us now focus on the relationship between our planning construct Plan and existing HTN planners. To that end, we say that a CANPLAN agent is a *bounded agent* if its belief base and all belief conditions are defined in a language which follows the same constraints as those imposed by HTN planners [11] (e.g., first-order atoms, finite domains, close world assumption). It is worth pointing out that, in practice, most existing BDI programming language implementations do actualise such constraints and deal only with bounded agents. We also assume, without loss of generality, that bounded agents do not make use of $+b$ and $-b$ statements in their plans—only primitive actions can change the belief base. ($+b$ and $-b$ statements can always be represented using special actions.)

[4] This definition is a bit too strong in that it requires a goal-program to be "sound" w.r.t. the failure condition for *every* possible belief base and *every* chain of bdi-transitions, including failed recovered executions. Even though a weaker version could be obtained with a more involved definition, we stick, for simplicity, to the above one.

$$\frac{}{\langle \mathcal{B},\mathcal{A},(nil \rhd P')\rangle \longrightarrow \langle \mathcal{B},\mathcal{A},nil\rangle}\ \rhd_t \qquad \frac{}{\langle \mathcal{B},\mathcal{A},+b\rangle \longrightarrow \langle \mathcal{B}\cup\{b\},\mathcal{A},nil\rangle}\ +b \qquad \frac{}{\langle \mathcal{B},\mathcal{A},-b\rangle \longrightarrow \langle \mathcal{B}\setminus\{b\},\mathcal{A},nil\rangle}\ -b$$

$$\frac{\langle \mathcal{B},\mathcal{A},P_1\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',P'\rangle}{\langle \mathcal{B},\mathcal{A},(P_1 \rhd P_2)\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',(P' \rhd P_2)\rangle}\ \rhd \qquad \frac{}{\langle \mathcal{B},\mathcal{A},(nil\,;P)\rangle \longrightarrow \langle \mathcal{B},\mathcal{A},P\rangle}\ Seq_t \qquad \frac{}{\langle \mathcal{B},\mathcal{A},(P \parallel nil)\rangle \longrightarrow \langle \mathcal{B},\mathcal{A},P\rangle}\ \|_{t_2}$$

$$\frac{\langle \mathcal{B},\mathcal{A},P_1\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',P'\rangle}{\langle \mathcal{B},\mathcal{A},(P_1 \parallel P_2)\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',(P' \parallel P_2)\rangle}\ \|_1 \qquad \frac{\langle \mathcal{B},\mathcal{A},P_2\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',P'\rangle}{\langle \mathcal{B},\mathcal{A},(P_1 \parallel P_2)\rangle \longrightarrow \langle \mathcal{B}',\mathcal{A}',(P_1 \parallel P')\rangle}\ \|_2 \qquad \frac{}{\langle \mathcal{B},\mathcal{A},(nil \parallel P)\rangle \longrightarrow \langle \mathcal{B},\mathcal{A},P\rangle}\ \|_{t_1}$$

$$\frac{}{\langle \mathcal{B},\mathcal{A},\mathsf{Plan}(nil)\rangle \longrightarrow \langle \mathcal{B},\mathcal{A},nil\rangle}\ \mathsf{Plan}_t \qquad \frac{\langle \mathcal{B},\mathcal{A},P\rangle \xrightarrow{\mathsf{plan}} \langle \mathcal{B}',\mathcal{A}',P'\rangle}{\langle \mathcal{B},\mathcal{A},\mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{plan}} \langle \mathcal{B}',\mathcal{A}',\mathsf{Plan}(P')\rangle}\ \mathsf{Plan}_\mathsf{P}$$

$$\Delta = \{A_{step}, A_{clean}, A_{event}\} \cup \{Event, Sel, +b, -b, act, ?, Seq, Seq_t, \rhd, \rhd_t, \rhd_f^{bdi}, \|_1, \|_2, \|_{t_1}, \|_{t_2}, \mathsf{G}_I, \mathsf{G}_s, \mathsf{G}_S, \mathsf{G}_R^{bdi}, \mathsf{Plan}, \mathsf{Plan}_t, \mathsf{Plan}_\mathsf{P}\}.$$

Figure 1: CANPLAN's complete set of rules Δ is built from the rules described in the text plus the ones shown here.

The next theorem establishes, formally, the link between the Plan construct and HTN planning. First, we prove that the new construct Plan could indeed be seen as an HTN planner. Second, we show that executions of program $\mathsf{Plan}(P)$ encode HTN plan solutions. Lastly, and not so surprisingly, we demonstrate that a straight-line HTN plan solution could be successfully executed by the BDI execution cycle. For clarity, we keep the translation between the BDI domain knowledge (i.e., libraries Π and Λ, and programs) and the HTN procedural knowledge (i.e., planning domain and task networks) implicit. (the theorem's proof is based on the relationship between the BDI's and HTN's entities as discussed in section 2.3.)

THEOREM 2. *For any bounded agent,*

1. $\langle \mathcal{B},\mathcal{A},\mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}}$ *iff* $sol(P,\mathcal{B},\Pi\cup\Lambda)\neq\emptyset$.
2. $\langle \mathcal{B},\mathcal{A},\mathsf{Plan}(P)\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}',\mathcal{A}\cdot act_1\cdot\ldots\cdot act_k,\mathsf{Plan}(P')\rangle$ *with* $k\geq 1$ *iff there exists a plan* $\sigma\in sol(P,\mathcal{B},\Pi\cup\Lambda)$*, such that* $\sigma = act_1\cdot\ldots\cdot act_k\cdot\ldots\cdot act_n$*, for some* $n\geq k$.
3. *If there exists a plan* $\sigma = act_1\cdot\ldots\cdot act_n\in sol(P,\mathcal{B},\Pi\cup\Lambda)$*, then* $\langle \mathcal{B},\mathcal{A},(act_1;\ldots;act_n)\rangle \xrightarrow{\mathsf{bdi}_*} \langle \mathcal{B}',\mathcal{A}\cdot\sigma,nil\rangle$.

Therefore, provided we restrict to the language of HTN [11], our deliberator construct Plan provides a built-in HTN planner within the whole BDI framework. The above theorem is an important practical result as it gives us the rationale for using existing HTN planner systems, such as SHOP and SHOP2 within current BDI implementations, such as AGENTSPEAK and JACK.

4.1 Planning for Declarative Goals

So far we have seen how lookahead planning can be performed on (procedural) programs. Let us now discuss how (classical) planning for a *declarative* goal ϕ_s using a procedural program P can be done. There are a few choices for this and the following five properties that we may be interested in satisfying:

(A) P is used towards the eventual satisfaction of goal ϕ_s.
(B) P may execute partially if goal ϕ_s is achieved before P completion. That is, P need not be executed completely.
(C) There is a commitment to the goal ϕ_s so that P is reinstantiated and retried until the goal in question is established.
(D) There exists a mechanism for dropping the goal when a failure condition ϕ_f becomes true.
(E) At planning time, P is solved up to the point where the goal is met. That is, it may not be required to solve P completely.

The different alternatives that we shall consider, together with the properties satisfied by each one, are depicted in the following table:

ALTERNATIVES	A	B	C	D	E
$\mathsf{Plan}(P;?\phi_s)$	$\surd$				
$\mathsf{Plan}(\mathsf{Goal}(\phi_s,P,\phi_f))$	$\surd$	$\surd$		$\surd$	
$\mathsf{Goal}(\phi_s,\mathsf{Plan}(P),\phi_f)$		$\surd$	$\surd$	$\surd$	
$\mathsf{Goal}(\phi_s,\mathsf{Plan}(P;?\phi_s),\phi_f)$	$\surd$	$\surd$	$\surd$	$\surd$	
$\mathsf{Goal}(\phi_s,\mathsf{Plan}(\mathsf{Goal}(\phi_s,P,\phi_f)),\phi_f)$	$\surd$	$\surd$	$\surd$	$\surd$	$\surd$

Interestingly, a *first-principles* account of planning can easily be obtained by using the first alternative $\mathsf{Plan}(P;?\phi)$ and taking $P = !seqActions$, where the distinguished event $seqActions$ can be solved with any sequence of primitive actions.

Notice that the last four alternatives make use of the special Goal construct available in CANPLAN to handle declarative goals within the BDI execution cycle. Observe also that the last option is the only one satisfying all five properties, combining then the advantages from the BDI execution cycle and the planning module. Consequently, it is sensible to define a new language construct $\mathsf{Plan}(\phi_s,P,\phi_f)$ that the user may use, as follows:

$$\mathsf{Plan}(\phi_s,P,\phi_f) \stackrel{\text{def}}{=} \mathsf{Goal}(\phi_s,\mathsf{Plan}(\mathsf{Goal}(\phi_s,P,\phi_f)),\phi_f).$$

Among other results, it can be shown that $\mathsf{Plan}(\phi_s,P,\phi_f)$ subsumes all the executions of $\mathsf{Plan}(\mathsf{Goal}(\phi_s,P,\phi_f))$.

THEOREM 3. *For every* ϕ_s,ϕ_f *and* P*, program* $\mathsf{Plan}(\phi_s,P,\phi_f)$ *simulates program* $\mathsf{Plan}(\mathsf{Goal}(\phi_s,P,\phi_f))$.

To recap: combinations of the Plan and Goal constructs suggest an interesting range of programs for declarative goals. We believe that $\mathsf{Plan}(\phi_s,P,\phi_f)$ provides a convenient mechanism for dealing with declarative goals at both planning and execution time.

4.2 Planning vs BDI Execution

We conclude this section by exploring the differences between the execution of a planning program and the normal BDI execution. A CANPLAN$^-$ agent is a CANPLAN agent whose plan language does not include the $\|$ and Goal constructs. This restriction corresponds to classical BDI agent programming languages like AGENTSPEAK and to *total-order* HTN planners like SHOP; neither system include concurrency and goals natively. Under such restricted CANPLAN agents, the planning module is no more than a lookahead mechanism on top of the BDI execution cycle.

THEOREM 4. *Program* P *simulates program* $\mathsf{Plan}(P)$ *in every* CANPLAN$^-$ *agent.*

On the other hand, when concurrency or goal-programs are considered, performing planning may result in extra executions. In fact, it can be shown that executing $\mathsf{Plan}(\mathsf{Plan}(P_1)\|P_2)$ is equivalent to executing $\mathsf{Plan}(P_1\|P_2)$, which in turn, is very different

from executing $(\mathsf{Plan}(P_1)\|P_2)$.[5] A similar situation arises with program $\mathsf{Plan}(\mathsf{Goal}(\phi_s, \mathsf{Plan}(P), \phi_f))$. The reason, informally, is that a Plan construct is ignored within the context of another Plan construct—there is no notion of planning within planning.

Surprisingly, also, the BDI execution engine may obtain successful executions that the planner cannot produce.

THEOREM 5. *There exists an agent configuration C of the form $\langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \cup \{P\}\rangle$ for which there is an execution where P is successfully executed, but such that no execution of $C' = \langle \mathcal{N}, \Lambda, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \cup \{\mathsf{Plan}(P)\}\rangle$ can successfully execute* $\mathsf{Plan}(P)$.

PROOF. *Let us build a counter-example. Suppose that all actions are possible and that action act_1 just makes p true, that p and q are both false initially, and that there are only two plan rules in the plan library Π for handling event e: (i) $e : true \leftarrow act_1; ?q; act_2$; and (ii) $e : p \leftarrow act_3; act_2$. There is no solution for* $\mathsf{Plan}(!e)$*, but a BDI execution that would successfully execute $!e$ can be obtained by partially executing plan rule (i) (action act_1) and then, upon failure, fully executing plan rule (ii).* □

As one can observe, the proof's counter-example relies on both the plan failure handling mechanism built into the BDI execution cycle and the programmer not having provided a full set of plans. In fact, if the plan library in the above proof's counter-example had included a third rule of the form $e : true \leftarrow act_1; ?p; act_3; act_2$, then the planner would have found a full execution. Still, as agent programs—that is, plan libraries—are often developed incrementally and in modules, the above situation could well arise.

It follows then that the combined framework of (default) BDI execution plus local hierarchical planning is strictly more general than hierarchical planning alone. Furthermore, as discussed after Theorem 1, by using the new local planning mechanism the programmer can rule out BDI executions that are bound to fail.

5. IMPLEMENTATION ISSUES

In earlier work [8], we presented an implementation that combined BDI reasoning with HTN planning. We used JACK[6] BDI system [3] and JSHOP[7] HTN planner, a Java version of SHOP [15]. Although the integrated framework does not fully realise the operational semantics presented here, it does incorporate some important concepts from it. In particular, it allows the programmer to specify from within a JACK program the points at which JSHOP should be called, in a manner similar to the Plan construct. Consistent with the semantics of Plan, JSHOP uses the same domain representation as JACK does (i.e., the plan library Π and belief base $\mathcal{B}$). In fact, the framework builds at runtime a JSHOP planning problem representation automatically from the JACK domain knowledge.

Some differences in the implementation arise from the nature of the systems chosen for the implementation. Since JSHOP is a total-order HTN planner, it cannot accommodate the concurrent construct $\|$. However, since parallelism has benefits, the integrated framework converts JSHOP's total-order solutions into partial-order solutions so that JACK can exploit possible parallelism at execution time. Some other differences exist between the implementation and the semantics for the sake of simplicity. For example, we excluded the $\mathsf{Goal}(\phi_s, P, \phi_f)$ construct in our system, as this construct does not have a direct matching concept in JACK or JSHOP. Including this goal construct and using SHOP2 [16] to accommodate parallel execution of sub-goals natively are left for future work.

The main difference, however, is that the implementation *does not* re-plan at every step, as indicated by the Plan derivation rule defined in the semantics. This would clearly be unnecessarily inefficient. Instead, JSHOP was modified to return the relevant methods and bindings (rather than simply the actions); the BDI execution engine then follows step-by-step the decomposition suggested by the planner. Relevant environmental changes are detected by virtue of a step in the returned plan no longer being applicable within the BDI cycle. At that point, the planner is then called once again to provide an updated plan, and if none is available failure will occur in the BDI system. A disadvantage of this is that environmental changes leading to failure may be detected later in the implemented version than in the semantic rules. However, this drawback is offset by the much greater efficiency in what can be expected to be the majority of cases. This approach also has the benefit that an intention produced by a call to Plan will, in fact, *terminate*—successfully if there is no environmental interference. This is stronger than what Theorem 1 states, in which we needed to account for the strange, but potentially possible, situation where the Plan module continually returns a new and different plan prior to termination.

6. RELATED WORK

Except for INDIGOLOG [6], which is not *per se* a typical BDI agent programming language (see below), we are not aware of any other *formal* BDI-style agent programming language (e.g., 3APL [12], AGENTSPEAK [19], PRS [13]) providing a clean account of planning as we do here with CANPLAN. There are however a number of (implemented) *systems* or *frameworks* which do, in some way or another, mix planning and BDI-style execution. Some of these are *planners*, such as IPEM [1] and SAGE [14], that allow for the interleaving of action execution during the planning process. Others are *agent architectures*, such as RETSINA [17], CYPRESS and CPEF [23], and PROPICE-PLAN [10]; they are able to do lookahead planning. CYPRESS is based on the ACT [22] formalism that provides a uniform representation framework for BDI execution systems and hierarchical planners, hence supporting the type of mapping we have proposed in section 2.2. PROPICE-PLAN is perhaps the most similar system to ours, in that it is a typical BDI agent system that is able to call a planning module to find a solution for a particular problem. Like CANPLAN, a unified representation is used by both the planner and the BDI system. The work done in this paper differs, at least, in two ways form the above systems. First of all, we are particularly concerned with the *formal specification* of a BDI agent with built-in planning capabilities as well as with the *formal relation* between BDI systems and HTN planners. To our knowledge, none of the above systems come with a precise formal semantics. In some sense, however, our work was much motivated by the existence of these systems in an analogous way to how AGENTSPEAK [19] was motivated by systems like PRS [13]. Secondly, CANPLAN provides a mechanism for local deliberation *on-demand* that the programmer can use, as opposed to a fixed integration of planning within the execution engine (e.g., planning always [17] or just on (goal) failure [10, 23]).

Our work is possibly most related to that of De Giacomo and Levesque [6] in which INDIGOLOG, an incremental version of CONGOLOG [5] with a local deliberation module Σ, is proposed in the context of the situation calculus. Several ideas are taken from that work and applied to the BDI context. Our work is however different in that (i) INDIGOLOG is a cognitive agent language, with no explicit notions of events, plan library, plan selection, failure handling, intention base, etc., whereas our approach is linked to a

[5] A framework where $\mathsf{Plan}(\mathsf{Plan}(P_1)\|P_2)$ is not equivalent to $\mathsf{Plan}(P_1\|P_2)$ would require an account of HTN planning within an HTN planner. This framework can be obtained by dropping rule Plan_P and making rule Plan also available within the plan context.

[6] www.agent-software.com.au

[7] www.cs.umd.edu/projects/shop/description.html

whole family of typical BDI languages and systems; (ii) our planning mechanism is provably linked to a well understood approach in the planning community, namely HTN planning, whereas, as far as we know, the INDIGOLOG deliberator module is very general and is not directly related to any planning system; and (iii) the integration of the planning module with the notion of declarative goals in CANPLAN has no counterpart in INDIGOLOG. In some ways, our approach has a more practical orientation than that of INDIGOLOG. It would be interesting to investigate the relations between INDIGOLOG and CANPLAN (e.g., identify the BDI subclass of agents that could be written and executed in INDIGOLOG).

7. CONCLUSION AND FUTURE WORK

We have proposed a mechanism for planning within BDI systems based on the intrinsic requirements of the BDI architecture. To do so, we provided an operational semantics that substantially simplifies and extends that presented in [24] to incorporate a new *planning* construct Plan. The new construct offers power and flexibility to the BDI programmer for specifying lookahead planning points in programs. We described results showing that the integration between the planning module and the whole BDI execution is the one intuitively expected, and proved that, under suitable assumptions, the planning task reduces to HTN planning. Lastly, we showed that the combined system allows a larger set of "good" executions than the planning module alone and discussed an implementation that incorporates many of the concepts from the semantics. We believe the work presented here is a significant step towards incorporating lookahead deliberation into BDI-type agent systems in a principled manner. More importantly, it provides a firm foundation for a range of interesting further work.

The fact that we have chosen to provide planning via a new construct is very much in the spirit of BDI systems, namely, allowing for direct encoding of programmer or domain expertise. In this case, the knowledge about when planning would be beneficial. It may be argued, though, that an intelligent agent should (also) make its own decisions as to when to plan. It is therefore worth investigating a more general account in which the agent could itself take the initiative to plan; for example, when all plans for a goal fail or when there is substantial spare time. *Re-planning* following failure of a plan produced by the planner module is also a topic we have not explored here and which deserves further work (see [23]).

We have already started exploring how to accommodate extensions to classical HTN planning within our formal framework. For instance, decoupling the hierarchical structure of BDI plans and using a planning account more akin to first principles would allow for potential discovery of new plan structures. This, in turn, could provide the basis for the agent to "learn" new plans that could be added to the plan library. Also, it can be useful to plan only to a certain level of abstraction or detail, leaving further remaining decompositions to execution time or until absolutely necessary as done in [4]. Both above generalisations are likely to require (or benefit from) extra representation of effects for high-level plans. Such extra representation would also provide support for reasoning about interactions of the plan being explored with other goals and intentions of the agent [4, 20]. In particular, we would like to extend our current *local* lookahead mechanism so that the agent considers, at least, all of its own active intentions when engaging in planning.

The framework presented here provides a basis for exploring the role of declarative goals [24, 21] in planning—preliminary results were given in section 4.1 but further investigation is needed.

Lastly, it would be interesting to develop *resource-bounded* version of our planning module. To that end, we are considering developing an *anytime* or *incremental* version of the Plan construct.

ABSTRACT

One of the main challenges in agent-oriented programming is the design of *specialized programming languages* for single agent development. They should provide transparent interfaces to existing mainstream programming languages for easy integration with external code and legacy software. The underlying architecture of such programming languages has to be robust enough to support various approaches to knowledge representation and agent reasoning models.

In this paper we propose a modular BDI agent programming architecture, which is independent of the internal structure of its components and agent reasoning model. The connections between the components of such a BDI system are provided by interaction rules. Using this separation, we are able to draw a clear distinction between knowledge representation issues of a BDI agent system components and its dynamics.

1. INTRODUCTION

In [15] Rao and Georgeff introduced an abstract architecture for rational agents based on BDI logic together with a proposal for a practical implementation of this architecture in a software system. Their proposal introduced three data structures for *beliefs*, *goals* and *intentions*, relations and interactions of which are governed by a set of basic axioms of rationality [14].

Apart from a mass of theoretical work inspired by this abstract architecture a number of programming languages for development of rational agents have been implemented as well. State-of-the-art BDI agent programming frameworks implementing this abstract schema fall into two main groups. On the one hand, there are agent programming platforms like Jadex [12] and JACK [9, 17], in which agent programming support is integrated into an existing programming language by addition of a layer of specialized agent oriented programming constructs. The main advantage of this approach is to enable clear and transparent integration of agent system with external and legacy software systems. Additionally, these platforms provide access to a wide range of supporting programming libraries of the underlying programming language. As the main motivation for these systems is to exploit the strengths of mainstream programming frameworks, these approaches lack a strong formal semantics defined in terms of BDI logic. Therefore a formal investigation of agent system properties relies more or less only on the semantics of the underlying programming language.

On the other hand, standalone agent programming languages like AgentSpeak(L) [3, 13] and 3APL [5, 8] provide a clear semantics of the agent system. Most of these programming languages build on the use of logic based knowledge representation and support a declarative way of encoding the dynamics of the agent system. This allows deeper theoretical insights into the behaviour and the properties of systems built with these programming languages and allows the use of formal methods like verification, or model checking. Unfortunately, they usually provide only a basic interface to external software systems. Because of this lack of integration with mainstream programming languages and various knowledge representation techniques, they still remain more theoretical tools than widely applied software development environments.

Clearly, if agent oriented programming languages are going to gain ground in software engineering in general, besides providing a solid theoretical basis for studying properties of applications built with them, they also have to support traditional software development techniques to the largest

possible extent. Therefore programming languages providing transparent integration with legacy systems and robust interfaces to external software systems are of high interest for agent oriented programming community [11].

In this paper, we address this issue and propose a modular BDI programming architecture to bridge this gap (Section 2). We describe syntax and semantics of an abstract programming language, together with an interpreter providing the dynamics of the system. The architecture consists of independent components for beliefs, desires, intentions and agent's capabilities, which are glued together by rules governing their interactions in terms of component queries and updates. This distinction provides a *separation of concerns* of knowledge representation issues for individual BDI components and the agent system dynamics encoding. It also allows the exploitation of a wide range of knowledge representation techniques, programming languages and libraries.

We do not focus specifically on development of rational agents in the traditional BDI sense. Rather we consider more general schemes, in which the rational agent reasoning model is only one of their possible specializations. We also show how various agent models can be implemented in it (Section 3) and discuss its relation to existing agent programming systems (Section 4). We conclude by pointing out directions for future work (Section 5).

2. MODULAR BDI ARCHITECTURE

The inspiration for our work was a particular aspect of the agent programming language 3APL [8], in which the interactions between BDI components are independent of the internal structure of agent's belief base. Essentially, only a query and update interfaces are important for interactions of a belief base with other components of a 3APL agent system.

Our main idea is to *generalize this independence of components* also for goals and intentions of BDI agent schema, thus allowing replacement of individual modules of an agent system as far as they provide a proper interface which integrates with the rest of the BDI system.

Our BDI agent consists of four basic components for *beliefs*, *desires*, *intentions* and *capabilities*, where the last one serves as a technical shortcut for encapsulating implementation of agent's capabilities w.r.t. its environment (i.e. agent's *sensors* and *effectors* influencing the environment). Each of these components provides an interface for *query* and *update*. Interactions between components of an agent are defined by *interaction rules* similar to usual production rules of the form: *"if query Q holds, then update U is performed"*. The dynamics of the whole system is provided by *selection* and *execution* of interaction rules by an interpreter. This is provided by an interpreter. By specialising the rule selection and imposing constraints on rule types allowed, we can implement various agent reasoning models (see Section 3).

Figure 1 depicts a schema of the proposed BDI agent system architecture. Replaceable modules of a BDI system (depicted as rectangles with round corners) provide query and update interfaces. Apart from using these basic operations, no other means of interaction between components of a BDI system is considered. When an interpreter executes an interaction rule, the query part of it (left side of a rule) is consulted, and when evaluated to true, the update part (right side) is executed. The result of such an execution is an update of a certain BDI component. In the subscript of

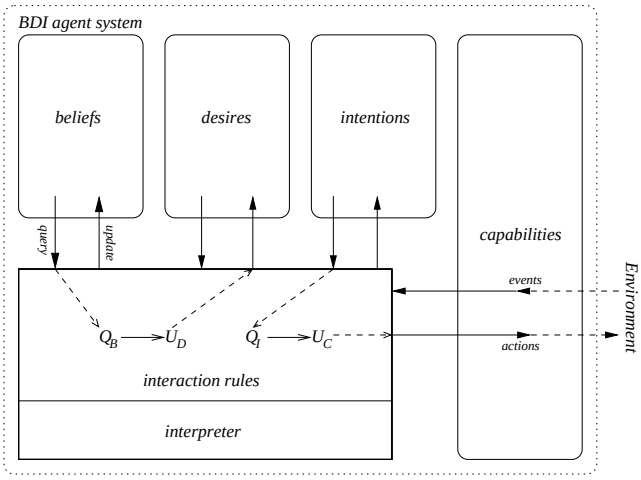

Figure 1: BDI Agent System

query and update expressions, the consulted component is indicated (depicted by dashed arrows). Agent's interaction with the outer environment is facilitated by its capabilities. Events are perceived by sensory capabilities, so that when the base of capabilities is queried, it provides information about state of the outer environment and events occurred in it. Based upon its mental state, an agent can act in its environment by updating its base of capabilities, what in turn results in performing an action by agent's effectors.

Note that we consider only the run-time representation of an agent. Design-time form, or syntax of an agent programming language associated with our framework, is not in the scope of this paper.

2.1 Syntax

In order to investigate the strengths of various approaches to knowledge representation (for implementation of a component of BDI system), we need an abstract programming language general enough to accommodate interfaces of wide range of programming languages from Prolog to C++, or LISP. Therefore we reduce the requirements on this language as much as possible and assume only the existence of generic domains and variables over them.

DEFINITION 1. ***(BDI component languages)*** *Let $D_1, \ldots, D_n$ be a set of domains and $Var_{D_1}, \ldots, Var_{D_n}$ be mutually disjoint sets of corresponding domain variables. Let $\mathcal{L}_B$, $\mathcal{L}_D$, $\mathcal{L}_I$, $\mathcal{L}_C$ be languages possibly involving elements of $D_1, \ldots, D_n$ and $Var_{D_1}, \ldots, Var_{D_n}$.*

We call $\mathcal{L}_B$, $\mathcal{L}_D$, $\mathcal{L}_I$, $\mathcal{L}_C$ BDI component languages of beliefs, desires, intentions and capabilities with typical element belief, desire, intention and capability respectively. We also assume w.l.o.g., that BDI component languages are mutually disjoint.

Domains and domain variables over them are elements of BDI component languages which can be shared between theories in these languages. Typical example would be domain of natural numbers and set of variables standing for them. From this point on, we will denote formulas of BDI component languages by φ. Formulas which do not include variables are called *ground* and those which do are *non-ground*.

From formulas of BDI component languages, query and update expressions can be constructed.

DEFINITION 2. ***(query and update)*** *Let $\mathcal{L}$ be a BDI component language. Then query and update languages $\mathcal{L}_Q$ and $\mathcal{L}_U$ are defined as follows:*

- *if $\varphi \in \mathcal{L}$, then $Q(\varphi) \in \mathcal{L}_Q$ and $U(\varphi) \in \mathcal{L}_U$,*
- *if $\phi_1, \phi_2 \in \mathcal{L}_Q$ then $\phi_1 \wedge \phi_2 \in \mathcal{L}_Q$,*
- *if $\psi_1, \psi_2 \in \mathcal{L}_U$ then $\psi_1 \circ \psi_2 \in \mathcal{L}_U$.*

EXAMPLE 1. ***(running example)*** *Consider a simple crane agent which is able to take/put a container from/to a cart. The belief base of the agent is implemented using C++ and contains the following code chunk:*

```
class CCraneBelief {
public:
  bool isHolding(int & nContID) const;
  void tookCont(int nContID);
  bool isCartPrepared() const;
  void cartArrived(bool bValue);

  int m_nContId;
  bool m_bCartOK;
  ...
};
static CCraneBelief crane;
```

Querying and updating the belief base corresponds to execution of valid C++ expression invoking the interface of object crane*. Sample query and update formulas look as follows:*

$$Q(\text{crane.isHolding}(2)) \wedge Q(\text{crane.isCartPrepared}()) \quad (1)$$

$$U(\text{crane.tookCont}(3)) \quad (2)$$

As BDI component languages can be arbitrarily expressive, we consider only conjunctions of query formulas and sequences of updates. More complex binary connectives of queries and updates are left to abilities of particular BDI component language.

Intersection of any two BDI component languages is empty, therefore each query and update formula is uniquely associated with only one BDI component language. However, for clarity, we will indicate the corresponding BDI component language in the subscript of Q and U whenever necessary. From this point on, we will usually denote query formulas by ϕ and update formulas by ψ.

Interactions between components of a BDI agent system are defined by interaction rules as follows.

DEFINITION 3. ***(interaction rules)*** *Let $\mathcal{L}_Q$ and $\mathcal{L}_U$ be query and update languages, $\phi \in \mathcal{L}_Q$ and $\psi \in \mathcal{L}_U$. We say that a rule of the form*

$$\phi \longrightarrow \psi$$

is an interaction rule.

The informal semantics of interaction rules is that of production rules. If the query ϕ is true w.r.t. given theory from a BDI component language, then the update operation defined by update formula ψ can be performed on another theory.

2.2 Semantics

The formal semantics of our BDI system is, in tradition with other BDI agent programming languages such as AgentSpeak(L) and 3APL, provided in terms of a transition system. A transition system is a set of derivation rules for deriving transitions. A transition is a transformation of one system configuration into another and it corresponds to a single computation step. The configuration of a BDI agent is a record of its current mental state at a certain point of time. Components of a BDI agent are defined as theories in given BDI component languages. Transitions between them are performed via execution of interaction rules.

DEFINITION 4. ***(BDI agent configuration)*** *A BDI agent configuration is $(\beta, \delta, \iota, \kappa)$, a tuple of theories, where theory $\beta \subseteq \mathcal{L}_B$ is a belief base of an agent, $\delta \subseteq \mathcal{L}_D$ is the base of desires, $\iota \subseteq \mathcal{L}_I$ stands for the base of intentions of it and finally $\kappa \subseteq \mathcal{L}_C$ represents the base of capabilities.*

A BDI agent configuration is a run-time representation of an agent.

Bases of beliefs, desires, intentions and capabilities are structures storing information about corresponding aspect of agent's mental state: they provide interfaces for its manipulation. Formally, they are represented as theories in corresponding BDI component languages. From now on, we will formally speak about theories in languages of individual BDI components β, δ, ι and κ and on the technical level we will use term *base* for them.

EXAMPLE 2. ***(running example cont.)*** *A belief base of the crane agent from Example 1 at a certain point in time is a state of member variables of the* crane *object. If, let's say,* m_nContId=2 *and* m_bCartOK= true*, the agent believes that it is holding a container No.* 2 *and the cart is prepared to be loaded.*

In order to evaluate queries and perform updates on BDI components we define semantical operators *Query* and *Update*.

DEFINITION 5. ***(query and update operators)*** *Let $\mathcal{L}$ be a BDI component language and $\tau \subseteq \mathcal{L}$ be a theory in that language. $\mathcal{L}_G \subseteq \mathcal{L}$ is the set of all ground formulas from $\mathcal{L}$ and $\varphi, \psi \in \mathcal{L}_G$ formulas in it .*

A query operator $Query_{\mathcal{L}}$ associated with $\mathcal{L}$ is a mapping

$$Query_{\mathcal{L}} : \mathcal{L}_G \times 2^{\mathcal{L}} \rightarrow \{true, false\}; \langle \varphi, \tau \rangle \mapsto Query_{\mathcal{L}}(\varphi, \tau)$$

Similarly, corresponding update operator $Update_{\mathcal{L}}$ is a mapping

$$Update_{\mathcal{L}} : \mathcal{L}_G \times 2^{\mathcal{L}} \rightarrow 2^{\mathcal{L}}; \langle \psi, \tau \rangle \mapsto Update_{\mathcal{L}}(\psi, \tau)$$

In the case of a query, the result is truth value of φ w.r.t. τ. The result of an update operator application is a new theory $\tau' \subseteq \mathcal{L}$ which reflects an update ψ on τ.

Query and update operators $Query_{\mathcal{L}}$ and $Update_{\mathcal{L}}$ should be computable procedures evaluating formula $\varphi \in \mathcal{L}$ against theory $\tau \subseteq \mathcal{L}$. Especially in the field of logic programming and non-monotonic reasoning, there's a vast number of theories dealing with knowledge base updates (for overview see e.g. [10]). For many of them, there are even implementations of update operators. We can exploit capabilities and strengths of these approaches for implementation of various update operators in specializations of our architecture.

EXAMPLE 3. ***(running example cont.)*** *Query and update operators for the belief base, as they were introduced in Example 1, simply evaluate the given C++ expression against current state of the belief base*[1]*. The query is true, when the return value of the executed expression is also* true *(i.e. not equal* 0*).*

By the query formula 1 from Example 1, we consult the belief base to find out whether our crane agent beliefs that it is holding container No. 2 *and at the same time also believes that the cart, into which the container is to be put, is prepared for loading. After execution of the update formula 2, the crane agent should believe that it took the container No.* 3*, so now it holds it.*

In order to define the semantics of interaction rules in terms of queries and updates of BDI components, we first need to define a semantics of these query and update formulas. We do this by relating formulas of the form $Q_{\mathcal{L}}(\varphi)$ and $U_{\mathcal{L}}(\psi)$ to applications of corresponding operators $Query_{\mathcal{L}}$ and $Update_{\mathcal{L}}$.

DEFINITION 6. ***(semantics of ground query and update formulas)*** *Let $\mathcal{L}_1, \ldots, \mathcal{L}_4$ be a quadruple of BDI component languages and $\mathcal{L}_Q$ and $\mathcal{L}_U$ be query and update languages over union of these disjoint BDI component languages. Let also $(\tau_1, \tau_2, \tau_3, \tau_4)$ be a BDI agent configuration with $\tau_i \subseteq \mathcal{L}_i$ for $1 \leq i \leq 4$. Query operator is denoted by $\models$ and $\oplus$ denotes an update operator.*

The semantics of a ground query formula $\phi \in \mathcal{L}_Q$ is defined as follows

- *if $\phi = Q(\varphi)$ and $\varphi \in \mathcal{L}_i$ then $(\tau_1, \tau_2, \tau_3, \tau_4) \models \phi$ iff $Query_{\mathcal{L}_i}(\varphi, \tau_i) = true$,*
- *if $\phi = Q(\varphi_1) \wedge \cdots \wedge Q(\varphi_n)$ for $n > 1$, then $(\tau_1, \tau_2, \tau_3, \tau_4) \models \phi$ iff for each φ_i holds $(\tau_1, \tau_2, \tau_3, \tau_4) \models Q(\varphi_i)$ for $1 \leq i \leq n$.*

and for a ground update formula $\psi \in \mathcal{L}_U$

- *if $\psi = U(\varphi)$ and $\varphi \in \mathcal{L}_i$, then $(\tau_1, \tau_2, \tau_3, \tau_4) \oplus \psi = (\tau_1', \tau_2', \tau_3', \tau_4')$ iff $Update_{\mathcal{L}_i}(\tau_i, \varphi) = \tau_i'$ and $\forall j \neq i : \tau_j' = \tau_j$,*
- *if $\psi = U(\varphi_1) \circ \cdots \circ U(\varphi_n)$ for $n > 1$, then $(\tau_1, \tau_2, \tau_3, \tau_4) \oplus \psi = (\tau_1', \tau_2', \tau_3', \tau_4')$ iff there exists a chain of configurations $(\sigma_{1,1}, \sigma_{2,1}, \sigma_{3,1}, \sigma_{4,1}), \ldots, (\sigma_{1,n+1}, \sigma_{2,n+1}, \sigma_{3,n+1}, \sigma_{4,n+1})$, such that $(\tau_1, \tau_2, \tau_3, \tau_4) = (\sigma_{1,1}, \sigma_{2,1}, \sigma_{3,1}, \sigma_{4,1})$, $(\tau_1', \tau_2', \tau_3', \tau_4') = (\sigma_{1,n+1}, \sigma_{2,n+1}, \sigma_{3,n+1}, \sigma_{4,n+1})$ and for each i, $1 \leq i \leq n$, holds $(\sigma_{1,i+1}, \sigma_{2,i+1}, \sigma_{3,i+1}, \sigma_{4,i+1}) = (\sigma_{1,i}, \sigma_{2,i}, \sigma_{3,i}, \sigma_{4,i}) \oplus U(\varphi_i)$.*

Informally, an update formula $U(\varphi_1) \circ \cdots \circ U(\varphi_n)$ is evaluated from left to right, where each successive update is applied to the result of the previous one. Since different orders of updating a configuration can lead to different results, note that the operation of updates chaining $\circ$ is not commutative.

EXAMPLE 4. ***(running example cont.)*** *Assume a BDI agent configuration with the current state of the belief base as it was described in Example 2 and semantics of Query and Update operators from Example 3. The query formula 1 from Example 1 is true and after execution of the update formula 2 the agent should believe that it is holding container* 3*. I.e. the result of this update operation is a configuration in which the belief base of an agent is modified so that* m_nContId=3.

For evaluation of a query formula against a BDI component theory by *Query* operator, the formula should be ground. Similarly for update formulas. However, non-ground formulas provide a more concise form of programming and therefore we have to deal with them. Transformation of non-ground formulas to ground ones is provided by means of *variable substitution*. Variable substitution is a mapping $\theta \subseteq \{[V/T] | V \in Var_{D_i} \wedge T \in D_i \wedge 0 \leq i \leq n\}$, where $D_1, \ldots D_n$ are domains and $Var_{D_1}, \ldots, Var_{D_n}$ sets of corresponding domain variables. By $\varphi\theta$ we denote a ground formula with all occurrences of variable $V \in Var_{D_k}$ replaced by an element $T \in D_k$, such that $[V/T] \in \theta$ for some $0 \leq k \leq n$.

Finally, for a query formula $\phi \in \mathcal{L}_Q$ we denote by $\phi\theta$ a formula $Q(\varphi\theta)$ for $\phi = Q(\varphi)$. In the case that $\phi = Q(\varphi_1) \wedge \cdots \wedge Q(\varphi_n)$, then $\phi\theta = Q(\varphi_1\theta) \wedge \cdots \wedge Q(\varphi_n\theta)$. Analogically for update formulas.

We say that variable substitution θ is ground w.r.t. formula ϕ, when $\phi\theta$ does not contain any variables.

At each time point of a system life cycle, queries of only a subset of all interaction rules hold. We say that an interaction rule $\phi \longrightarrow \psi$ is *applicable* to a BDI agent configuration $(\beta, \delta, \iota, \kappa)$ iff there exists a ground variable substitution θ, such that $(\beta, \delta, \iota, \kappa) \models \phi\theta$.

An agent system moves from one configuration to another exclusively by the application of some currently applicable interaction rule. All possible agent configurations are connected to each other via transitions from an associated transition system induced by interaction rules. More formally

DEFINITION 7. ***(agent system transition)*** *Let $\phi \longrightarrow \psi$ be an interaction rule, $(\beta, \delta, \iota, \kappa)$ a BDI agent configuration and θ a ground variable substitution w.r.t. ϕ and ψ. Then*

$$\frac{(\beta, \delta, \iota, \kappa) \models \phi\theta, (\beta, \delta, \iota, \kappa) \oplus \psi\theta = (\beta', \delta', \iota', \kappa')}{(\beta, \delta, \iota, \kappa) \longrightarrow (\beta', \delta', \iota', \kappa')}$$

We say that the rule $\phi \longrightarrow \psi$ induces this agent system transition.

Although the semantics of interaction rules is defined for ground query and update formulas, a practical programming system has to handle also non-ground interaction rules. We therefore consider the concept of *grounding on-the-fly*. Non-ground rules are grounded at the time of their execution. For this, a mechanism of variable instantiation similar to the one provided by Prolog can be used. For other languages like C, C++, or Java, mechanism of returning a value to a variable passed as an argument by reference can be exploited.

As the execution of a BDI agent starts with some initial configuration, all other possible transitions are determined by the first one. Thus a BDI agent is formally defined as follows.

DEFINITION 8. ***(BDI agent)*** *A BDI agent is a tuple $(\beta_0, \delta_0, \iota_0, \kappa_0, \mathcal{IR})$, where $(\beta_0, \delta_0, \iota_0, \kappa_0)$ is the initial configuration of an agent and $\mathcal{IR}$ is a set of interaction rules.*

Given an initial configuration of an agent system, we can see its evolution as a path within the transition system. We call such a path *computation run*.

[1]Note, that we consider here an application of a C++ *interpreter*. Therefore a given expression can be executed at any time.

DEFINITION 9. ***(computation run)*** *A computation run $Comp(s_0)$ for a BDI agent $(\beta_0, \delta_0, \iota_0, \kappa_0, \mathcal{IR})$, where $s_0 = (\beta_0, \delta_0, \iota_0, \kappa_0)$, is a finite or infinite sequence $s_0, \ldots, s_n, \ldots$ of BDI agent configurations and $\forall i \geq 0 : s_i \longrightarrow s_{i+1}$ is an agent system transition.*

The semantics of a BDI agent system is the set of all possible computation runs. This corresponds to all possible evolutions of an agent system within its transition system.

Because of non-determinism there are more than one possible evolutions of an agent system. Basically, there are two sources of non-determinism in the BDI agent system:

internal: caused by multiple applicable interaction rules w.r.t. a single configuration, and

external: coming from non-determinism of agent's environment and uncertainty of results of agent's actions in it.

While external non-determinism of an agent system cannot be influenced by an agent itself, the degree of internal is handled by agent system's interpreter.

2.3 Interpreter

What exactly is the relation between the interpreter of an agent system and the set of interaction rules? While interaction rules secure the encoding of the dynamics of the system, the interpreter is responsible for their *selection* and *execution*. In order to achieve the highest possible flexibility, we have to provide a mechanism for the fine-tuning of the interpreter.

Tuning the mechanism of rule selection can be done by means of partial ordering over interaction rules. This gives a very high degree of flexibility and provides enough space for further extensions. It is even possible to remove internal non-determinism of an agent's transition system by applying a total ordering on interaction rules. Such a system would then resemble a standard Prolog interpreter which applies rules simply in order in which they were encoded in the source program. On the other extreme side, when no ordering on interaction rules is applied, the only mechanism governing the evolution of an agent system is the content of query formulas in query parts of interaction rules. Selection of a rule to execute is then arbitrary.

DEFINITION 10. ***(interpreted run)*** *Let $(\beta_0, \delta_0, \iota_0, \kappa_0, \mathcal{IR})$ be a BDI agent and $\prec$ be a partial ordering on $\mathcal{IR}$. We say that the computation run $Comp((\beta_0, \delta_0, \iota_0, \kappa_0))$ is an interpreted run iff for each agent system transition $(\beta_i, \delta_i, \iota_i, \kappa_i) \longrightarrow (\beta_{i+1}, \delta_{i+1}, \iota_{i+1}, \kappa_{i+1})$ induced by a rule $r = \phi \longrightarrow \psi$, r is some minimal rule applicable to configuration $(\beta_i, \delta_i, \iota_i, \kappa_i)$ w.r.t. partial ordering $\prec$.*

Considering only interpreted runs of BDI agent system, BDI agent's definition could be extended by including the ordering $\prec$ to it.

EXAMPLE 5. ***(running example cont.)*** *Consider an extension of the agent introduced in Examples 1, 2 and 3.*

Let the base of desires of this agent be implemented as a simple set of string identifiers {Load(ContID),Unload(ContID)}*, standing for loading and unloading the cart. The language of desires $\mathcal{L}_D$ is Prolog. Query and update operators correspond to Prolog query execution of predicates* isGoal/1*,* addGoal/1 *and* removeGoal/1 *with the obvious semantics.*

The base of intentions is implemented as a queue of string identifiers {PerformTake(ContID),PerformPut(ContID)} *standing for raising and putting down the container. Language of intentions $\mathcal{L}_I$ is also Prolog and query/update operations correspond to execution of predicates* currentInt/1*,* queueInt/1 *and* dequeueInt/1*.*

Finally the language of capabilities $\mathcal{L}_C$ is C and query/update are implemented as for beliefs by invoking the following routines:

```
int isContainerAtLoc(int nContID);
int isCartAtLoc();
void take(int nContID);
void put(int nContID);
```

Sample interaction rules for loading a container are

$$Q_D(\mathsf{isGoal}(\mathsf{Load}(\mathsf{ContID}))) \longrightarrow U_I(\mathsf{queueInt}(\mathsf{PerformPut}(\mathsf{ContID})))$$

$$Q_I(\mathsf{currentInt}(\mathsf{PerformPut}(\mathsf{ContID}))) \wedge Q_B(\mathsf{crane.isHolding}(\mathsf{ContID}) \;\&\&\; \mathsf{crane.isCartPrepared}()) \longrightarrow U_C(\mathsf{put}(\mathsf{ContID})) \circ U_I(\mathsf{dequeueInt}(\mathsf{PerformPut}(\mathsf{ContID})))$$

Considering a precedence ordering on the rules above, in one step of the interpreter's cycle, the upper rule will be evaluated as the first. If an agent has the goal to load a container (e.g. Load(2)*$\in$belief base), then this rule will be also executed, which will cause the term* PerformPut(2) *to be appended to the end of the queue of intentions. Then the interpreter will start the cycle all over again. If the query part of the first rule is false, the interpreter will proceed to considering the second interaction rule.*

Note, that in the second rule, we exploited the internal ability of C++ implementation of belief base component to evaluate conjunctions of expressions, instead of using query of the form $Q_B \wedge Q_B$.

By further extending this basic interpreter, by e.g. allowing changes of the ordering of interaction rules on-the-fly, we can implement a very dynamic behaviour of an agent system. However, this is not in the scope of this paper and we will investigate properties of such extensions in future work.

3. AGENT REASONING MODELS

The definition of a BDI agent system as given in the last section is quite abstract: it does not make any differences between individual BDI components. This uniformity is a direct implication of the requirement of independence of BDI agent's components w.r.t. applied knowledge representation technique.

However, we believe that crucial differences of BDI system components can be reflected in *constraints* on their interactions. By allowing, or enforcing certain interactions between components of a BDI agent, we can achieve various properties of the whole system. We will show that a wide range of agent reasoning models can be implemented in our framework by regulating types of interaction rules.

3.1 I-System

Implementations of rational agent reasoning model usually descend from the original I-system [14], which axiomatizes interactions within rational agents. Informally, an agent should adopt only goals it believes to be an option w.r.t. to its beliefs (AI1). An agent should adopt intentions only in order to achieve its goals (AI2). If an agent has an intention to perform a certain action, it will eventually also perform it (AI3). It should be aware of the fact that it committed itself to certain goals and intentions (AI4, AI5). If an agent intends to achieve something, it also has to have a goal to intend it (AI6). It should be aware of its actions, i.e. if it performs certain action, it should also believe that it already performed it (AI7). And finally an agent should never hold its intentions forever, i.e. each intention must be eventually dropped (AI8).

Out of these eight basic axioms, four (AI1-AI3 and AI7) enforce certain interactions between components. These correspond to interaction rules which, following the notation introduced in Example 1, look like $Q_B \longrightarrow U_D$ (AI1), $Q_D \longrightarrow U_I$ (AI2), $Q_I \longrightarrow U_C$ (AI3) and $Q_C \longrightarrow U_B$ (AI7). Axiom AI7 is implemented here indirectly, since agents can learn about their successful actions by perceiving changes caused by them in their environments. An alternative way to implement this axiom is to keep history of actions agent tried to perform in its belief base. We can achieve this by interaction rules of type $Q_I \longrightarrow U_C \circ U_B$ (AI3).

Axioms AI4 and AI5 are secured via accessibility of all BDI components for the agent reasoning mechanism. Interaction rules can examine desire and intention bases by means of queries, so agent reasoning mechanism is "aware" of the content of its components. Axiom AI6 is satisfied by simple execution of an interaction rule of the type $Q_D \longrightarrow U_I$. Finally axiom AI8 is very vaguely specified, since "eventually" can be arbitrarily long. Realisation of this axiom is more a matter of a particular implementation of agent's base of intentions, than a feature of software agent architecture. Finally, rational agents interact with their environment by rules of the form $Q_I \longrightarrow U_C$ for performing actions and $Q_C \longrightarrow U_B$ for perceiving events.

3.2 Extensions of I-System

A closer look at the flow of information in the rational reasoning model, described in the previous subsection, reveals that on the ground of events occurring in the environment, an agent adopts beliefs, which are again the basis for adopting desires. On the ground of desires, intentions are adopted which are finally the base for agent's actions in the environment. This information flow can be informally described as a cycle of BDI components through which the information flows $C \rightarrow B \rightarrow D \rightarrow I \rightarrow C$. By inserting additional links and shortcuts, we can achieve various different agent reasoning models.

In their original paper [14], authors provide examples of *blind*, *single minded*, and *open minded* agent. Informally, a blindly committed agent maintains its intentions until it actually believes that it had achieved them. Single minded agent maintains them as long as it believes they are still possible to achieve and finally open minded agent maintains its intentions only as long as these intentions are still its goals.

In our modular BDI architecture with appropriate implementation of BDI components, a blind agent would need interaction rules for removing intentions from the intention base once it recognizes that actions based on these intentions were successful in the environment. A single minded agent cancels certain intentions with preconditions φ exactly when φ does not hold anymore. Informally, for every rule $Q_B(\varphi) \wedge \ldots \longrightarrow U_I(+\varphi')$, which introduces certain intention into the base of intentions, also the interaction rule $Q_B(\neg\varphi) \longrightarrow U_I(-\varphi')$ must occur in agent's rule base. Similarly for an open minded agent, but instead of Q_B, it would query its base of desires Q_D.

Apart from rational agents, we can also model irrational[2] agent reasoning in our framework. Consider for example a *servant* agent, to which goals can be "implanted" from outside as commands which it should follow, although it doesn't believe they are an option w.r.t. its beliefs. This can be implemented by allowing rules of the type $Q_C \longrightarrow U_D$. Informally, such a rule can be interpreted as *"upon perceiving a command C, agent should carry out C"*. A slightly stricter version of servant agent, is a *slave* agent, to which intentions could be changed and added in a similar way by interaction rule of the type $Q_C \longrightarrow U_I$.

Slave agents resemble more software objects in their traditional meaning in object oriented programming. They simply execute a requested procedure without having a "free will" not to do so. However they are still able to freely decide on later canceling this intention. As an extreme case of irrational reasoning a *religiously fanatic* agent can be considered. Such an agent doesn't want to believe facts which are conflicting its goals, or intentions. According to its current intentions and goals, it is able to change its beliefs by executing rules of the type $Q_D/Q_I \longrightarrow U_B$.

Although purely irrational agents like slave agent lack autonomy and thus do not comply with classic definitions of an agent, mixing rationality with certain degree of non-rational behaviour (w.r.t. certain aspects of agent's functionality) can lead to more efficient implementations of software agent systems. However, this claim has to be yet experimentally demonstrated.

3.3 Modular BDI Programming Platform

As we already mentioned, the main disadvantage of our modular BDI architecture is its high degree of abstraction. On the other hand, we showed that it provides also a high degree of flexibility and a lot of space for customization to particular needs.

Implementation of a software development platform based on our proposal should be based on a plug-in architecture supporting development of BDI components in various programming languages. The interpreter of interaction rules serves only as a glue between them. Each plug-in should be an interpreter for a specific programming language able to evaluate queries and perform updates on the current operational state of the component. Since nowadays many interpreters for various programming languages ranging from C++ to Prolog, LISP or Java are available, such implementation is feasible.

Because of its high flexibility, a programming platform based on our modular BDI architecture could serve as a testbed for investigating applications based on combinations of various knowledge representation techniques. We will pay special attention to applications of logic programming

[2]In the sense of *not rational w.r.t. I-System*.

techniques and especially declarative non-monotonic knowledge representation approaches like Answer Set Programming (ASP) [7] (see also [6] for the relevance of ASP in agent programming). For ASP, there's a vast amount of research on its practical applications (see e.g. [1]) as well as knowledge base updates (e.g. [10]) a lot of which can be used and practically evaluated using our system.

4. RELATED WORK

Because of its legacy, 3APL agent programming language [8] is the closest relative to our modular BDI architecture. Modular BDI schema is rather a generalization of 3APL architecture than a parallel approach. 3APL uses fixed logic based languages for implementation of BDI components. In the 3APL platform [5] Prolog is used to implement the belief base. Goal base is realized as a set of Prolog terms, and plans in the plan base are stack resembling structures of Prolog terms. In the language of our framework, 3APL allows allows only certain types of interaction rules, namely goal rules of the form $Q_D \wedge Q_B \longrightarrow U_D$, plan rules $Q_I \wedge Q_B \longrightarrow U_I$ and interaction rules $Q_D \wedge Q_B \longrightarrow U_D$ [4]. Since belief base of a 3APL agent is implemented in Prolog, all other BDI components are therefore also limited to use structures of first order logic terms.

Another important representative of BDI agent programming systems is AgentSpeak(L) [13] and its incarnation in the agent development platform Jason [3]. AgentSpeak(L) is the original implementation of already discussed I-system in a logic based language. Similarly to 3APL, it uses language of first order logic terms for belief base and stack structures for implementation of intentions. The goal base is realized via direct event processing. Contrary to 3APL, AgentSpeak(L) is even more specific in terms of queries and updates of its components. Interaction rules, or plans, are of the type $Q_D \wedge Q_B \longrightarrow U_I$, or $Q_D \wedge Q_B \longrightarrow U_D$, where updating the base of desires means firing an event. Querying it is similar to processing events from event pool which is updated according to agent's perceptions.

We see the independence of implementation of an individual BDI component of knowledge representation technique as the main advantage of our modular architecture over 3APL and AgentSpeak(L). Because of their focus on rational agent reasoning model, both 3APL and AgentSpeak(L) limit design freedom of a system programmer and enforce particular software development methodology together with a specific knowledge representation technique. Use of proprietary programming language limits 3APL and AgentSpeak(L) w.r.t. exploitation of a wide range of standard libraries for software development and external code packages. This has a strong impact on possibilities of their integration with legacy systems. On the other hand, because of the clear specification of the architecture details, like implementation languages of BDI components, systems built using 3APL or AgentSpeak(L) have probably much clearer theoretical properties w.r.t. verification of an agent system.

The other extreme of the spectrum is represented by the second family of BDI inspired programming frameworks which includes systems like JACK [17] and Jadex [12]. These are focused on integration with a mainstream programming languages (Java in both cases) and provide a high degree of freedom w.r.t. software development techniques used. However, since they both provide a particular methodology for development of internal structure of components of BDI system, integration with other knowledge representation approaches is not straightforward. Finally, they do not provide a clear semantics of systems developed with them, therefore study of theoretical properties of their applications is even more difficult than in the case of our BDI architecture.

Our modular BDI architecture proposal is positioned somewhere between the two approaches to BDI agent programming. On one hand it provides a clear operational semantics and a simple technique for implementation of agent reasoning and on the other it allows high degree of integration with existing programming languages, standard libraries and external legacy code.

5. CONCLUSION AND FUTURE WORK

In this paper we presented a modular BDI architecture which is independent of the underlying knowledge representation approach used and provides a high degree of flexibility for implementation of rational and non-rational agent reasoning models. Its core, interaction rules, are specified as the connecting element between heterogeneous components of BDI agent system. We are convinced that by using such a flexible approach, it will be easier to step from agent system analysis to its implementation and exploit strengths of mainstream programming languages and wide range of libraries provided for them.

Since the proposed modular BDI architecture was conceived to provide support for various, particularly logic based, knowledge representation techniques, our future work will be focused in this direction. We are planning to implement the interpreter for the proposed modular BDI system and a set of generic plug-ins for various knowledge representation approaches. We are interested especially in exploitation of non-monotonic reasoning and incomplete information handling techniques like Answer Set Programming [6, 7]. We will develop a set of plug-ins for programming languages like SMODELS [16] and C++ in order to study properties of agent systems built with them.

The degree of abstraction, our architecture provides, allows embedding various agent reasoning models into it (including those of 3APL or AgentSpeak(L)) and thus provides a common base for their comparison and possibly also classification. Therefore we will also study properties of various agent reasoning models in our BDI architecture and extensions of it with concepts like role of an agent and agency.

ABSTRACT

For successful coordination and cooperation in a multiagent system, participants need to establish a sufficiently accurate awareness of the current situation. Awareness is understood here as a limited form of consciousness: in the minimal form, it refers to the state of an agent's beliefs about itself, about others and about the environment. When considered in the context of agents' mental states, this leads to distinguishing three levels of awareness: intra-personal (about the agent itself), inter-personal (about other agents as individuals), and group awareness.

Problems in modeling agents' awareness on all three levels are analyzed. It turns out that both the communication medium and agents' cognitive and computational limitations make the achievement of awareness difficult. Cognitive science is used to analyze and explain problems in human awareness, based on the concept of bounded rationality. The BDI framework, originally designed to formally define agents' informational and motivational attitudes, turns out to be also fruitful both for precisely formulating the problems concerning agents' awareness, and, even more importantly, for formulating and comparing possible solutions. Thus, the two fields of cognitive science and MAS mutually benefit from each other's viewpoints, especially in the light of the currently growing need for teamwork in which both computational agents and humans are involved.

In this paper, some possible avenues to solutions for defining and achieving appropriate levels of awareness are suggested. In some cases, these are concrete formal solutions, which have been adopted in our theory of collective motivational attitudes, presented in a number of conference and journal papers [5, 6, 7]. They give rise to more generic solutions that can be of use in any advanced BDI system, especially in those aiming to realize teamwork.

1. INTRODUCTION

Multiagent systems (MAS) as a research area have been created to enable solving of complex problems, that usually are beyond capabilities of individuals (agents or humans), and which usually need expertise and/or capabilities of many different kinds. Very often these problems need *teamwork* to be solved. In the first phase of designing multiagent systems, the emphasis was put on cooperating teams of agents, while nowadays there is a growing need for teams consisting of computational agents as well as humans [22].

For teamwork to be successful, the first need for the participants is to establish a common view of the environment, which can be built by communication, reasoning and various forms of observation, for example of other agents' behavior and changes in the environment. Then, the next steps of Distributed Cooperative Problem Solving (DCPS) need to be implemented. These phases include building the entire variety of individual, social and collective motivational attitudes, as described in [4, 5, 6, 7]. In this paper we will show that in these complex processes which together constitute teamwork, agents' *awareness* about others and the environment is a vital ingredient.

Awareness is understood here as a limited form of consciousness: in the minimal form, it refers to the state of an agent's beliefs about *itself*, about *others* and about *the environment*. These aspects, when considered in the context of agents' mental states, lead to distinguishing different levels of agents' awareness: *intra-personal* (about the agent itself), *inter-personal* (about other agents as individuals), and *group awareness*. For example, an agent's awareness of itself refers to its beliefs about sentences of the form "I (do not) believe φ". In general, an agent's awareness of φ certainly implies that it does not believe that φ is false, but in

many contexts, much stronger kinds of awareness are needed (see subsection 4.1).

In practice of MAS, agents' awareness is expressed in terms of *beliefs*. In the majority of applications, agents make do with belief instead of knowledge for at least the following reasons. First, agents' perception provides the main background for beliefs. In a dynamic unpredictable environment the natural (e.g. computational) limits of perception may give rise to false beliefs or to beliefs that, while true, still cannot be fully justified by the agent. Second, communication channels may be of uncertain quality, so that even if a trustworthy sender knows a certain fact, the receiver may only believe it. In the sequel, we will use the term of awareness in a generic way, sometimes pointing out by what means it is expressed. Usually, there will be different levels of beliefs (see subsection 4.1). However, we will not go into the phase of creating those beliefs, assuming generally that perception, communication and reasoning are basic steps in this process.

This paper is meant as a voice in the discussion on the general subject of formal specification of both static and dynamic aspects of teamwork. In our considerations we will address two issues. Firstly, we will argue that agents' awareness becomes a first class citizen in contemporary multiagent applications. Secondly, we will point out problems in modeling agents' awareness, suggesting some possible avenues to solutions. In some cases, we will present a concrete formal solution. These solutions have been adapted in our theory of collective motivational attitudes, that was presented in a series of journal papers [5, 6, 7] and [1]. However we will try to show that they give rise to more generic solutions, which can be of use in any advanced BDI system, especially in those aiming to realize teamwork.

Our postulates, even though they are formulated in logic, may be particularly interesting for system developers when tailoring a multi-agent system for a specific application, especially if both computational agents and humans are involved in teamwork. When looking for possible solutions, our aim has been to forge synergy between the viewpoints on awareness within teams from the fields of cognitive science and multi-agent systems. Cognitive science has been important in analyzing and explaining problems in human awareness. The BDI framework used in MAS turns out to be fruitful both for formulating the problems around agents' awareness in a very precise way, and, even more importantly, for formulating and comparing possible solutions. Thus, the two fields mutually benefit from each other's viewpoints.

The paper is structured as follows. Section 2 focuses on agents' awareness about their own mental states, and the effects of their bounded rationality. In section 3, attention is given to problematic aspects of agents' models of other individuals' mental states. These strands come together in section 4 where we show that awareness in groups is of vital importance. We show some pitfalls in achieving it, and some possibilities for system developers to flexibly adapt the type of group awareness in a multi-agent system to the environment and the envisioned kind of organization.

2. ON INTRA-PERSONAL AWARENESS

Intra-personal awareness, or consciousness of one's own mental states, also called meta-consciousness, plays an important role in an agent's thinking and reasoning. Such introspection has for long been held as totally unproblematic:

> Consciousness was often viewed as though it was *the* defining feature of human thought. The philosophical traditions that have had the strongest influence on psychology are those of Locke and Descartes, and while these two didn't agree on much, the one proposition they shared was that cognitive states are transparent to introspection [16].

In the second half of the twentieth century, however, cognitive scientists started to study phenomena like implicit cognition, where experimental subjects could correctly recognize well-formed strings of abstract languages by learning from examples, without being able to formulate the complex underlying rule [16]. Thus, humans are often not aware of their own knowledge and beliefs. In this section, we will see how the epistemic logics that are usually used in BDI systems to model agents' knowledge do not always form an accurate model of human cognitive abilities.

2.1 Problems of logical omniscience

The standard logic of beliefs is a modal logic with possible worlds semantics. The formula $\mathrm{BEL}(i, \varphi)$ stands for "agent i believes that φ", and it is defined to be true at a possible world w if φ is true at all worlds which are belief-accessible from w. In this paper, we do not go deeper into the semantics, but see [10, 17].

In order to represent beliefs, in our logical framework for teamwork in MAS [7], we adopt the standard $KD45_n$-system for n agents as explained in [10], containing axioms and rules for a n agents named $i = 1, \ldots, n$. Similar axioms hold in the standard epistemic logic for knowledge (KNOW), except that there, A6 is replaced by the stronger A3:

A3 $\mathrm{KNOW}(i, \varphi) \rightarrow \varphi$ (Veracity of knowledge)

Here follows the axiom system $KD45_n$, in which K refers to the basic modal logic (axioms A1, A2 and rules R1, R2), D refers to axiom A6, 45 refers to axioms A4 and A5, and the subscript n refers to the number of agents:

A1 All instantiations of propositional tautologies

A2 $\mathrm{BEL}(i, \varphi) \wedge \mathrm{BEL}(i, \varphi \rightarrow \psi) \rightarrow \mathrm{BEL}(i, \psi)$ (Belief Distribution)

A4 $\mathrm{BEL}(i, \varphi) \rightarrow \mathrm{BEL}(i, \mathrm{BEL}(i, \varphi))$ (Positive Introspection)

A5 $\neg\mathrm{BEL}(i, \varphi) \rightarrow \mathrm{BEL}(i, \neg\mathrm{BEL}(i, \varphi))$ (Negative Introspection)

A6 $\neg\mathrm{BEL}(i, \bot)$ (Belief Consistency)

R1 From φ and $\varphi \rightarrow \psi$ infer ψ (Modus Ponens)

R2 From φ infer $\mathrm{BEL}(i, \varphi)$ (Belief Generalization)

A first problem for modeling humans is that, as mentioned above, they often lack positive or negative introspection into their beliefs. As a counter-example to negative introspection, one may be completely unaware of a sentence φ that one doesn't believe, and thus not believe that one does not believe it. A counter-example to positive introspection is formed by the implicit cognition experiments mentioned above. (On introspection for humans, see also [25].) In multi-agent systems, in order for agents to model themselves

properly, the developer needs to take care that a modicum of (especially positive) introspection is present.

Another problem of systems based on epistemic logic is that we have the following theorems (similar ones hold for knowledge instead of belief):

$$\models \varphi \Rightarrow \models \mathrm{BEL}(i, \varphi) \qquad \text{(Belief of valid formulas)}$$

$$\models \varphi \rightarrow \psi \Rightarrow \models \mathrm{BEL}(i, \varphi) \rightarrow \mathrm{BEL}(i, \psi) \qquad \text{(Closure under valid implication)}$$

These are examples of *logical omniscience*: agents believe all theorems, as well as all logical consequences of their beliefs. Any modal logic with standard Kripke semantics in which belief is formalized as a necessity operator has this property. Logical omniscience definitely does not apply to humans nor to computational agents, who have only limited time available. It is unrealistic to assume that they believe every logical theorem, however complicated.

Two belief-related problems of logical omniscience are:

$$\mathrm{BEL}(i, \varphi) \rightarrow \neg \mathrm{BEL}(i, \neg\varphi) \qquad \text{(Consistency of beliefs)}$$

$$\mathrm{BEL}(i, (\mathrm{BEL}(i, \varphi) \rightarrow \varphi)) \qquad \text{(Belief of having no false beliefs)}$$

The first one is problematic because the agent may believe two sentences which are in fact (equivalent to) each other's negation without the agent being aware of it. The second one (which follows from A6 and A5) makes an agent too arrogant about its beliefs: it is not aware of its limitations.

There are several possible solutions to the problems of logical omniscience, involving non-standard semantics or syntactic operators for awareness and explicit belief. Good logical references to the logical omniscience problem and its possible solutions are [17, Chapter 2] and [10, Chapter 9].

2.2 Bounded rationality

According to Herbert Simon, who coined the term *bounded rationality*, "boundedly rational agents experience limits in formulating and solving complex problems and in processing (receiving, storing, retrieving, transmitting) information" [24]. We agree with Simon that models which present humans as logically omniscient or as perfectly rational in the sense of optimizing their own utility are problematic. Moreover, we would propose to extend this discussion to software agents, because they need to reason under bounded rationality as well as humans.

Another example where one needs to be aware of limitations on agents' information occurs in a quantified setting. The distinction de re / de dicto stems from the philosophy of language [21]. A sentence of the form

$$\exists x \mathrm{BEL}(j, A(x))$$

is a *de re* belief attribution which relates j to a *res*, an individual that the belief is about. On the other hand,

$$\mathrm{BEL}(j, \exists x A(x))$$

is a *de dictum* belief attribution, relating j to a *dictum*, namely the proposition $\exists x A(x)$. Luckily, here the distinction is easily modeled in quantified modal logic, where $\exists x \mathrm{BEL}(j, A(x))$ logically implies $\mathrm{BEL}(j, \exists x A(x))$, but not vice versa. For example, it usually takes the detective a whole novel to move from "I believe (or know) that somebody murdered the victim" to "I believe (or know) of a specific suspect that he/she murdered the victim", thus from general awareness that something is wrong, to a much more specific awareness. In subsection 5.3.2, we show that developers also need to take this distinction into account when deciding what kinds of awareness are appropriate for teamwork in the given circumstances.

3. ON INTER-PERSONAL AWARENESS

Bounded rationality plays a role not only in limiting intra-personal awareness, it also constraints agents' inter-personal awareness. Formal models of human reasoning, such as those in epistemic logic and game theory, assume that humans can faultlessly reason about other people's individual knowledge and beliefs, for example in card games such as happy families [23]. However, recent research in cognitive psychology reveals that adults do not always correctly use their theory of what others know in concrete situations [15, 13].

In Keysar's experiments, some adult subjects could not correctly reason in a practical situation about another person's lack of knowledge (first-order theory of mind reasoning of the form "a does not know p") [15]. Hedden and Zhang, when describing their experiments involving a sequence of dyadic games, suggested that players generally began with first-order reasoning. When playing against first-order co-players, some began to use second-order reasoning (for example, of the form "a does not know that I know that p"), but most of them remained on the first level [13].

In recent experiments by Lisette Mol, it turns out that humans *can* learn to play a version of symmetric Mastermind involving natural language utterances such as "some colors are right". After mastering the first task, namely to play the game according to its rules, many of them learn to perform a second task, namely to develop a winning strategy for the game by using a higher-order theory of mind: "Which sentences reveal the least information while still being true?" "What does the opponent think I am trying to make him think?" [18]. Thus, some awareness of others' mental states can be learned.

3.1 Inter-personal awareness in BDI systems

Inter-personal awareness, so crucial in BDI systems, can be modeled using multi-modal logics, but some drawbacks are inevitable. Here follows a theorem of the logic of knowledge and belief related to inter-personal reasoning:

$$\mathrm{KNOW}(i, \mathrm{KNOW}(j, \varphi)) \rightarrow \mathrm{KNOW}(i, \varphi) \quad \text{(Transparency)}$$

This is not realistic, for example a child may know that her father has proved Fermat's last theorem, without knowing the theorem herself (where knowing includes being able to justify it). The transparency problem has been treated by using an alternative semantics of "local worlds" [11]. Also the following theorem may be unrealistic:

$$\mathrm{BEL}(j, \mathrm{BEL}(i, \varphi)) \rightarrow \mathrm{BEL}(j, \neg \mathrm{BEL}(i, \neg\varphi))$$

(This theorem follows from A6 and R2.) The above and similar theorems with even higher stacks of belief operators unrealistically presuppose that agents are constantly aware

that other agents monitor the consistency of their beliefs (and follow other epistemic rules) as well as they themselves do, and that others are in their turn aware of still other agents following the logical rules.

4. ON GROUP AWARENESS

When analyzing different aspects of teamwork from the viewpoint of BDI systems, one of the first purposes is to define the scope and strength of motivational and informational attitudes needed for successful team action. These determine the strength and scope of the necessary awareness within a cooperating team.

4.1 Epistemic logic for group awareness

Knowledge, which always corresponds to the facts and can be justified by a formal proof or less rigorous argumentation, is the strongest and therefore preferred informational attitude. The strongest notion of knowledge in a group is *common knowledge*, which is the basis of all conventions and the preferred basis of coordination. Halpern and Moses proved that common knowledge of certain facts is on the one hand necessary for coordination in well-known examples, while on the other hand, it cannot be established by communication if there is uncertainty about the communication channel [10].

4.1.1 General belief and common belief

Common belief is the notion of group belief which is constructed in a similar way as common knowledge, except that a collective belief among a group that φ need not imply that φ is true. Here follows a short reminder of the axioms governing group beliefs. Let $G \subseteq \{1, \ldots, n\}$ be a group. The formula E-BEL$_G(\varphi)$ (group G has φ as a *general belief*) is meant to stand for "every agent in group G believes φ":

C1 E-BEL$_G(\varphi) \leftrightarrow \bigwedge_{i \in G}$ BEL(i, φ)

C-BEL$_G(\varphi)$ (group G has φ as a *common belief*) is meant to be true if everyone in G believes φ, everyone in G believes that everyone in G believes φ, etc. Let E-BEL$^1_G(\varphi)$ be an abbreviation for E-BEL$_G(\varphi)$, and let E-BEL$^{k+1}_G(\varphi)$ for $k \geq 1$ be an abbreviation of E-BEL$_G$(E-BEL$^k_G(\varphi)$). Thus, we have intuitively C-BEL$_G(\varphi)$ iff E-BEL$^k_G(\varphi)$ for all $k \geq 1$; it turns out that this seemingly infinitary property can be captured by the following (finitary) axiom and rule.

C2 C-BEL$_G(\varphi) \leftrightarrow$ E-BEL$_G(\varphi \wedge$ C-BEL$_G(\varphi))$

RC1 From $\varphi \rightarrow$ E-BEL$_G(\psi \wedge \varphi)$ infer $\varphi \rightarrow$ C-BEL$_G(\psi)$ (Induction Rule)

The system containing individual axioms of subsection 2.1 together with the above axioms and rule is called $KD45^C_n$ [10]. Although using common belief as the intended type of awareness puts less constraints on the communication media than common knowledge, it is still logically highly complex.

4.1.2 Degrees of beliefs important in teamwork

It is well-known that for teamwork, as well as for coordination, it often does not suffice that a group of agents has a general believe about something (E-BEL$_G(\psi)$), but they should collectively believe it (C-BEL$_G(\psi)$). An example is formed by collective actions where the success of each individual agent is vital to the result, for example, lifting a heavy object together or coordinated attack. It has been proved that for such an attack to be guaranteed to succeed, the starting time of the attack must be a collective belief (even common knowledge) for the generals involved [10].

One positive feature of collective belief is that if C-BEL$_G$ holds for ψ, then C-BEL$_G$ also holds for all logical consequences of ψ. The same is true for common knowledge. Thus, agents reason in a similar way from ψ and collectively believe in this similar reasoning and the final conclusions.

In cases in which only general belief E-BEL$_G(\psi)$ has been established, it is much more difficult for agents to maintain a model of the other team members with respect to ψ and its consequences. However, establishing E-BEL$_G(\psi)$ places much less constraints on the communication medium than C-BEL$_G(\psi)$ does. In short, one could say that common knowledge and collective belief are hard to achieve, but easy to understand. Thus, the system developer's decision about the level k of group belief (E-BEL$^k_G(\psi)$) to be established, hinges on determining a good balance between communication and reasoning for a particular application.

Parikh has introduced a hierarchy of levels of knowledge between individual knowledge and common knowledge and, together with Krasucki, proved a number of interesting mathematical properties. It turns out that, due to the lack of the truth axiom, the similarly defined hierarchy between individual belief and collective belief is structurally different from the knowledge hierarchy [20].

If even limited orders of theory of mind, as in inter-personal awareness, present such difficulties for humans, it seems that creating group awareness is impossible: reasoning about common belief and common knowledge apparently involves an infinitude of levels. From the time when these notions were first studied, there has been a puzzle about their establishment and assessment, the so-called *Mutual Knowledge Paradox*, most poignantly described in [3]. How can it be that to check whether one makes a felicitous reference when saying "Have you seen the movie showing at the Roxy tonight", one has to check an infinitude of facts about reciprocal knowledge, but people seem to do this in a finite, indeed short, time? Clark's solution for human communication was that such *common ground* (common knowledge) about a sentence can be created if a number of conditions is met, namely co-presence, mutual visibility, mutual audibility, co-temporality, simultaneity, sequentiality, reviewability and revisability. Most of these conditions do not hold in multiagent systems, where agents communicate over non-instantaneous and possibly faulty communication media.

Even though common knowledge cannot in general be established by communication, we have shown that common belief can. In [8] we presented a somewhat tricky procedure that, under some assumptions about the communication channels, trust among group members and temporary persistence of some relevant beliefs (e.g. the group should be aware of the procedure), establishes a common belief C-BEL$_G(\varphi)$. The idea is essentially that one initiator first broadcasts the message φ to all agents in the group, based on a standard low-level communication protocol such as TCP, ensuring that it knows at a certain point that E-BEL$_G(\varphi)$; then the initiator broadcasts the message that C-BEL$_G(\varphi)$ to all of them. We have discussed this procedure and the needed assumptions in [8]. Intuitively, the reason that this procedure can establish common belief, whereas common knowledge can never be established, is that common beliefs need not be true.

5. TUNING AS A METHOD TO EXPRESS DEGREES OF TEAM AWARENESS

The next part of this paper refers to a larger research program, aiming at investigating and, finally, understanding the role of collective motivational attitudes in Distributed Cooperative Problem Solving (DCPS). The analysis resulted, firstly, in a *static* characterization of DCPS, with collective intention and collective commitment as central notions. (A complete theory of collective motivational attitudes in teamwork was presented in [5, 7]). Secondly, an application of this theory in a dynamic and unpredictable environment led to the reconfiguration problem, formally treated in [6].

When building the static and dynamic parts of this theory we've experienced that our theory evolved in the course of the evolution of our thinking about awareness. Over a couple of years this resulted in a generalization and relaxation of some, previously rather strong, conditions. As the role of awareness in agents' setting became more and more clear, this led us to understanding the vital need of *explicitly* expressing awareness in these systems. This conclusion resulted in a tuning schema for collective commitments ([7]), further developed for social (bilateral) commitment and collective intention in the sequel.

While investigating the role of awareness within cooperating teams of agents and humans, let us turn to the commonsense meaning of teamwork. It is clear that there are different *gradations* of being a team. For example, in a group of researchers who jointly plan their research and divide roles, and who reciprocally keep a check on how the others are doing, all aspects of teamwork are openly discussed, and team members keep each other informed about relevant changes in the plan. This non-hierarchical teamwork may be contrasted with a group of spies who all work for the same (top secret) goal. In their case a plan is designed by one mastermind, who divides the roles and divulges to each participant *solely* the information that is absolutely necessary for him to do his own part. Thus, members may not know the main goal, nor even which other agents are included in the group. In the latter example, even though the connection between members is much looser than in the former one, we would still like to speak about DCPS, albeit a non-typical case.

These two examples, showing a different gradation of being a team, differ significantly as individual and collective awareness about the ingredients of DCPS (like the main goal and the plan to achieve it) ranges from very high in the first example to very low in the second. One way to express this subtle gradation of awareness is to *characterize* its different degrees, taking into account specific circumstances (e.g. the state of the environment), as well as the application in question. In the majority of applications, different degrees of awareness could be formally expressed in terms of different kinds of beliefs, defined in the previous section.

For efficiency reasons it is often important to minimize the degree of awareness between agents, which usually allows to minimize the level of communication among agents. This degree should be tuned to the circumstances under consideration. Thus in some situations individual belief may suffice, while in other situations, general belief (E-BEL$_G$ of a relevant proposition within a group G) ensures a proper level of awareness, and again in others the strongest notion of common belief is needed. This tuning mechanism is adopted below in our definitions of collective intention, social commitment, and collective commitment. As discussed in [5, 7, 1], collective intentions and collective commitments are the two essential team attitudes that allow teamwork to happen and be successful. While collective intention may be viewed as a sort of glue that holds a group together, collective commitment reflects the concrete manner to achieve the goal in question. Social commitments, finally, represent the concrete agent-to-agent "promises" to fulfill agents' individual actions that make up the team's social plan on which the collective commitment is based.

5.1 Tuning scheme for collective intentions

In strictly cooperative teams the notion of collective intention seems to be rather strong. A necessary condition for a collective intention is that all members i of the team G have the associated individual intention $\mathrm{INT}(i, \varphi)$ towards φ. (Note that individual intentions can be modeled using possible worlds semantics based on intention-accessibility relations similar to those for beliefs.) However, the combination of individual intentions is not sufficient. Imagine that two agents want to achieve the same goal but are in a competition about this, willing to achieve it exclusively. Therefore, to exclude the case of competition, all agents should *intend* all members to have the associated individual intention, as well as the intention that all members have the individual intention, and so on; we call such a mutual intention M-INT$_G(\varphi)$. In order to formalize this condition, E-INT$_G(\varphi)$ (standing for "everyone intends") is defined first:

M1 $\text{E-INT}_G(\varphi) \leftrightarrow \bigwedge_{i \in G} \mathrm{INT}(i, \varphi)$.

The mutual intention M-INT$_G(\varphi)$ is meant to be true if everyone in G intends φ, everyone in G intends that everyone in G intends φ, etc. As we do not have infinite formulas to express this, let $\text{E-INT}^1_G(\varphi)$ be an abbreviation for E-INT$_G(\varphi)$, and let $\text{E-INT}^{k+1}_G(\varphi)$ for $k \geq 1$ be an abbreviation of $\text{E-INT}_G(\text{E-INT}^k_G(\varphi))$. Thus again we have intuitively that M-INT$_G(\varphi)$ iff $\text{E-INT}^k_G(\varphi)$ for all $k \geq 1$.

M2 $\text{M-INT}_G(\varphi) \leftrightarrow \text{E-INT}_G(\varphi \wedge \text{M-INT}_G(\varphi))$

RM1 From $\varphi \rightarrow \text{E-INT}_G(\psi \wedge \varphi)$ infer $\varphi \rightarrow \text{M-INT}_G(\psi)$ (Induction Rule)

The resulting system is called $KD_n^{\text{M-INT}_G}$, and it is sound and complete with respect to Kripke models where all n accessibility relations are serial [5].

Furthermore, all members of the team need to be aware of this mutual intention. Adding this condition completes the definition of collective intention.

M3 $\text{C-INT}_G(\varphi) \leftrightarrow \text{M-INT}_G(\varphi) \wedge \mathit{awareness}_G(\text{M-INT}_G(\varphi))$

Instantiating the above schema corresponds to tuning the $\mathit{awareness}_G$-dials from $\emptyset$, through individual beliefs and different degrees of E-BEL^k_G, to collective belief, and/or analogously for degrees of knowledge.

Even though C-INT$_G(\varphi)$ seems to be an infinite concept, collective intentions may be established in practice in a finite number of steps. As defined by **M3**, collective intentions are appropriate to model those situations in which communication, in particular announcements, work, especially if one initiator establishes the team. We have showed in detail in [4] how team formation in such an ideal case may actually

work in terms of the first two stages of collective problem solving, namely potential recognition and team formation, and how at these stages the proper attitudes are established through dialogues consisting of the appropriate speech acts.

The degree of awareness in the definition of collective intention clearly depends on the circumstances, and varies from just recognizing the situation by perception when communication is difficult or impossible, through simply confirming what situation we deal with, to more complex cases. An example of a collective intention where $awareness_G$ is instantiated as E-BEL$_G$ occurs in a situation where two persons are needed to save a third one from disaster and have severely limited means to communicate (e.g. because of a storm), but can see each other act. In this case the fact that they see each other running toward the victim may be sufficient for them to conclude that the mutual intention is present, thus M-INT$_G(\varphi) \wedge$ E-BEL$_G$(M-INT$_G(\varphi)$) is achieved. Other examples of variants of collective intentions are discussed in [5].

5.2 Tuning scheme for social commitments

In teamwork, bilateral "promises" to execute one's allocated actions in order to achieve the main goal are very important. Such a *social commitment* is not as strong as a collective one, but stronger than an individual intention. If an agent commits to a second agent to do something, then the first agent should have the *intention* to do that. Moreover, the second one should be *interested* in the first one fulfilling its intention. These two conditions (inspired by [2]), need to be enhanced by the condition expressing the agents' awareness about the situation, i.e. about their individual attitudes. In our earlier papers, such awareness was expressed in terms of collective belief [7]. In order to relax the framework to be better adaptable to the environment, here follow the schemes for defining social commitments with respect to actions α and propositions φ:

$$\begin{aligned}&\text{COMM}(i,j,\alpha) \leftrightarrow \text{INT}(i,\alpha) \wedge \text{GOAL}(j, done(i,\alpha)) \wedge \\ &\quad awareness_{\{i,j\}}(\text{INT}(i,\alpha) \wedge \text{GOAL}(j, done(i,\alpha)))\end{aligned}$$

$$\begin{aligned}&\text{COMM}(i,j,\varphi) \leftrightarrow \text{INT}(i,\varphi) \wedge \text{GOAL}(j, \texttt{stit}(i,\varphi)) \wedge \\ &\quad awareness_{\{i,j\}}(\text{INT}(i,\varphi) \wedge \text{GOAL}(j, \texttt{stit}(i,\varphi)))\end{aligned}$$

Here $done(i,\alpha)$ means that agent i has just executed action α and $\texttt{stit}(i,\varphi)$ means that agent i sees to it (takes care) that φ is achieved. For a formal treatment of *done* and `stit`, see [6]. Instantiating the above schema again corresponds to tuning the $awareness_G$-dials from $\emptyset$, through individual beliefs and different degrees of E-BEL$_G^k$, to collective belief, and/or analogously for degrees of knowledge.

5.3 Tuning scheme for collective commitments

After a group is constituted on the basis of collective intention, as a next step a *collective commitment* between the team members may be established. While a collective intention may be viewed as an inspiration for team activity, the plan-based collective commitment reflects the concrete manner of achieving the intended goal by the team. This concrete manner is provided by planning, and hinges on the allocation of actions according to an adopted plan. The allocation is concluded when agents accept social commitments to realize their individual actions. We claim that it is important for system developers to make appropriate decisions about the type or gradation of teamwork, and consequently the type of agents' awareness, needed to achieve the goal in given circumstances. Thus, it is useful for them to have a mechanism that helps to choose the corresponding type of group commitment. See [1] for a thorough discussion on this matter.

5.3.1 General schema of collective commitment

Clearly, the two examples in the introduction to section 5 cannot be covered by *one* generic type of collective commitment. In [7], we give a generic method for the system developer to tune the type of collective commitment to the application in question, the organizational structure of the group or institution, and to the environment, especially to its communicative possibilities. This generic solution allows to provide a full range of types of collective commitments and weaker group attitudes covering the range from proper teams to more loosely connected groups involved in DCPS. In our generic description we define solely basic ingredients constituting collective commitments, leaving room for case-specific extensions. The obligatory ingredients are related to different aspects of teamwork:

1. Mutual intention M-INT$_G(\varphi)$ between a group of agents.

   The team is *based* on this attitude, and exists as long as the mutual intention exists. Thus, no teamwork is considered without a mutual intention among team members.

2. Social plan P on which a collective commitment will be based.

   The social plan provides a concrete manner for the team to collectively achieve the goal φ. The predicate $cons(\varphi, P)$ informally stands for "P is a correct social plan to achieve φ".

   For definitions of social plans and $cons(\varphi, P)$, see [6]. Here it is enough to say that social plan P consists of actions to be executed sequentially or in parallel.

3. Pairwise social commitments COMM(i,j,α) for actions from the plan.

   The group splits the tasks according to social plan P, and each agent takes on responsibility to do its part by accepting relevant social commitments (see 5.2).

Next to the above ingredients, different degrees of awareness about them may be present in a team. Thus, a general schema covering different types of collective commitment is the following, where the conjuncts between curly brackets may be present or not, according to the position of the awareness 'dial':

$$\begin{aligned}&\text{C-COMM}_{G,P}(\varphi) \leftrightarrow \\ &\quad \text{M-INT}_G(\varphi) \ \wedge \ \{awareness_G(\text{M-INT}_G(\varphi))\} \wedge \\ &\quad cons(\varphi, P) \ \wedge \ \{awareness_G(cons(\varphi, P))\} \wedge \\ &\quad \bigwedge_{\alpha \in P} \bigvee_{i,j \in G} \text{COMM}(i,j,\alpha) \wedge \\ &\quad \{awareness_G(\bigwedge_{\alpha \in P} \bigvee_{i,j \in G} \text{COMM}(i,j,\alpha))\}\end{aligned}$$

In words, group G has a collective commitment to achieve overall goal φ based on social plan P (C-COMM$_{G,P}(\varphi)$) iff all of the following hold. The group mutually intends φ (with or without being aware); moreover, successful execution of social plan P leads to φ ($cons(\varphi, P)$) (with or without the group being aware of this); and finally, for every one of the actions α from a plan P, there should be one agent in the group who is socially committed to at least one (mostly other) agent in the group to fulfil the action (COMM(i, j, α)) (with or without the group being aware of this).

Instantiating the above schema again corresponds to tuning the *awareness*$_G$-dials from $\emptyset$, through individual beliefs and different degrees of general belief, to collective belief, and/or analogously for degrees of knowledge.

5.3.2 Different aspects of agents' awareness

The notion of collective commitment, whatever strength of it is considered, combines essentially different aspects of teamwork: strictly technical ones related to social plans, as well as those related to agents' intentional stance. The latter concerns different aspects of awareness that appear in a group of agents in the course of DCPS. The degree of this awareness varies, as explained before. In the sequel, the strongest version is considered, namely collective belief about considered aspects of DCPS. For this reason it is justified to speak about *collective awareness* in this context, while in other circumstances, the degree of awareness can be weakened by using general belief E-BEL$_G$ (or another E-BEL^k_G) instead of collective belief C-BEL$_G$. Let us discuss the relevant aspect of building pair-wise commitments, where the notion of awareness plays a crucial role, more in detail. For extensive discussion of other aspects of commitments see [7].

When a plan P as a recipe is in place, then the particular actions α from it need to be allocated to particular team members (i, j) in order to create pairwise social commitments. This way a social team structure is built, and the plan acquires the property of being social. The type of awareness connected with this phase may be twofold.

- A *detailed* collective awareness of each social commitment:
  $\bigwedge_{\alpha \in P} \bigvee_{i,j \in G}$ C-BEL$_G$(COMM(i, j, α))
  This corresponds to the interpretation *de re*.
- A *global* collective awareness of the bare existence of social commitments:
  C-BEL$_G(\bigwedge_{\alpha \in P} \bigvee_{i,j \in G}$ COMM$(i, j, \alpha))$
  This corresponds to the interpretation *de dicto*.

Clearly, the distinction de dicto versus de re (of section 2.2) is also fruitful for complex epistemic operators such as collective belief. Note that C-BEL$_G$ in (a) and (b) distributes over conjunction ($\bigwedge_{\alpha \in P}$), so that only the position of C-BEL$_G$ with respect to $\bigvee_{i,j \in G}$ matters. The cognitive multi-agent distinction between both interpretations is the following. In the detailed collective awareness everybody knows every single detail, while in the global collective awareness everybody knows that all details are somehow arranged, and that things are under control.

The above aspects of awareness serve to distinguish different strengths of collective commitments. Exemplar definitions are produced by keeping the *awareness*$_G$-dial fixed to a choice between $\emptyset$ and collective belief. In [7], we started from the strongest form of collective commitment, fully reflecting the collective aspects of DCPS. Subsequently, some underlying assumptions were relaxed, leading ultimately to weaker notions of team and distributed commitment. In ongoing research, the interrelations between different forms of commitments and management theory are investigated.

6. DISCUSSION AND CONCLUSIONS

In this paper we have shown that agents working as a team depend, for good coordination and cooperation, on awareness of their own and others' mental states, as well as of the group attitudes. We have shown that both communicative possibilities and cognitive and computational limitations make the achievement of awareness difficult. Some examples showed that in BDI logics, used to make high-level specifications of MAS behavior, it is possible to show rather precisely where the limitations lie. It is important for system developers to keep these limitations in mind and to adapt to them.

Let us sum up some of the possible avenues of adaptation the system developer might choose. With respect to intrapersonal awareness, to enable agents' positive and negative introspection, it helps to restrict the language to a limited number of propositional variables, for which agents can easily check whether they believe in them (respectively know them) or not. In order to create a specification framework in which the problems of logical omniscience does not occur, the system developer may adapt a framework of non-normal modal logic as presented in [10] to the application at hand.

With respect to inter-personal awareness, a system developer designing a combined agent-human multiagent system should adapt to the fact that humans can only correctly reason about at most level two theory of mind ("you do not know that I know p"). Thus, it may be useful to model their reasoning about other individuals by a framework of local reasoning adapted from the proposal in [11].

Finally, in order to adapt to the problems in creating group awareness, a system developer may use the tuning mechanisms of section 5 to adapt the kind of awareness needed in collective intentions, social commitments, and collective commitments to one that is appropriate for the environment and kind of organization. This seems to be a rather sensitive mechanism allowing to calibrate the expressive power of the notion in question. Moreover, this is a very flexible method of defining various common-sense notions, as any case-specific extensions can be easily incorporated into the collective intention or collective commitment schema. Again, the resulting definition and its properties can be viewed as a high level specification of a system.

Emma Norling [19] also combines human modeling with BDI systems. She focuses on extending the BDI framework with characteristics of human reasoning such as timing, learning and memory, all understood in a *folk psychological* sense, in order to allow developers of training simulators to model human-like synthetic agents. We, on the other hand, remain within the scope of the BDI framework in that we focus on agents' informational and motivational attitudes, but pose the question where BDI models should be adapted to better model human and computational information processing constraints and cognitive limitations. Thus, we build on *cognitive science* studies of human awareness about themselves, others and the groups they are part of.

Software agents' bounded rationality is also intimately connected to the computational complexity of agent logics. The system defining collective intentions and collective commitments in [5, 7] is decidable, however it is highly complex. In order to decide whether a given formula is valid, one needs an amount of time that grows exponentially in terms of the length of the formula in question [9]. Thus, in general it is not feasible to give automated proofs of desired properties; at least there is no single algorithm that performs well on all inputs. As with other modal logics, the better option would be to develop a variety of different algorithms and heuristics, each performing well on a limited class of inputs. For example, it is known that restricting the number of propositional atoms to be used or the depth of modal nesting may reduce the complexity (cf. [12, 14]).

The outcome of our considerations on possible solutions can still be combined with some other, for example strictly technical, elements. Also, when creating teams in which humans and agents cooperate, system developers may divide roles in such a way that they make use of strong points of humans, such as common sense knowledge, as well as those of software agents, such as their memory, which enhances monitoring the team's activity.

ABSTRACT

We present a method for transforming the infinite interactive state space of interactive POMDPs (I-POMDPs) into a finite one, thereby enabling the computation of exact solutions. I-POMDPs allow sequential decision making in multi-agent environments by modeling other agents' beliefs, capabilities, and preferences as part of the interactive state space. Since beliefs are allowed to be arbitrarily nested and are continuous, it is not possible to compute optimal solutions using value iteration as in POMDPs. We present a method that transforms the original state space into a finite one by grouping the other agents' behaviorally equivalent models into equivalence classes. This enables us to compute the *complete* optimal solution for the I-POMDP, which may be represented as a policy graph. We illustrate our method using the multi-agent Tiger problem and discuss features of the solution.

1. INTRODUCTION

Interactive partially observable Markov decision processes (I-POMDPs) [8] provide a framework for sequential decision making in partially observable multi-agent environments. Along with the physical states of the environment they include other agents' computable models in the state space. The models encompass all information influencing the corresponding agent's behavior, which includes its preferences, capabilities, and beliefs. They are analogous to *types* in Bayesian games[10]. This augmented state space is called an *interactive state space*. Because beliefs in I-POMDPs are arbitrarily nested, the interactive state space is not the traditional one – it is a complex infinite space that contains beliefs over others' beliefs.

Traditional methods for solving POMDPs [4, 11, 16] focus on finite state spaces and exploit the piecewise linearity and convexity (PWLC) property of the value function. For POMDPs with infinite state spaces exact closed form solutions exist only in linear Gaussian systems [13, 17]. I-POMDPs, which generalize POMDPs to multi-agent domains, have a infinite state space as well, making it impossible to compute the exact solution by applying value iteration based methods in a straightforward manner.

In this paper, we present a method for computing the exact solutions to finitely nested I-POMDPs introduced in [8]. Our method transforms the infinite interactive state space into a finite space by grouping models of other agents into a finite set of behavioral equivalence classes. They are defined so that the optimal action(s) of the modeled agents are the same for all models inside a class. Given such behavioral equivalence classes, and the agents' optimal actions in these classes, we show that it is sufficient to reason about the other agents' equivalence classes, rather than the infinity of individual models, to compute a solution. When the set of actions and observations of each agent is finite, the set of behavioral equivalence classes for a finite horizon is also finite, and at most countably infinite for an infinite horizon. In practice though the number of behavioral equivalence classes will be finite for the infinite horizon because we usually settle for ϵ-optimal policies. Once we have transformed the interactive state space using the equivalence classes, we modify the I-POMDP belief update and value iteration to operate over the transformed interactive state space. Consequently, we can extend the exact POMDP solution methods in a straightforward manner to solve I-POMDPs exactly.

Related work in the area of multi-agent and multi-body planning like DEC-POMDPs [1, 2] and MTDP [12] only allow us to compute equilibrium based solutions under the assumption of common knowledge of the agents' prior beliefs. Further, dynamic programming approaches to find optimal solutions to DEC-POMDPs [9] are only possible in special co-operative cases where all agents share the same payoff function. In the context of state equivalence and aggregation, Given et al. [7] provide a nice discussion of using stochastic bisimilarity for model minimization in Markov decision processes and Poupart and Boutilier [14] propose an approach to get linear lossy compression of value function in POMDPs. Our method, in contrast, exploits the piecewise linearity and convexity of the value function of agent models to find the behavioral equivalence classes. Additionally, unlike [7, 14] our approach yields an optimal solution. Methods to solve I-POMDPs and DEC-POMDPs approximately have also appeared. In [5, 6], a sampling based approximation technique is presented, while in [3], bounded finite state controllers are used to derive the joint policy.

The rest of the paper is structured in the following manner. In Section 2 we give a brief overview of the I-POMDP framework. Section 3 introduces the idea of behavioral equivalence and its use in solving I-POMDPs exactly. In Section 4, we illustrate our method, using an example problem and discuss several solutions. We conclude in Section 5 and outline some avenues of future work.

2. OVERVIEW OF I-POMDP

Interactive POMDPs extend POMDPs to multi-agent settings by including other agents' models as part of the state space [8]. Since other agents might also be reasoning about others, the interactive

state space can be arbitrarily nested (belief about other agents' beliefs about other agents' beliefs and so on). For simplicity of presentation we will consider an agent, i, that is interacting with only one other agent, j.

DEFINITION 1 (I-POMDP$_{i,l}$). *A finitely nested interactive POMDP of agent i with a belief nesting level l referred to as I-POMDP$_{i,l}$ is defined as the tuple*

$$\textit{I-POMDP}_{i,l} = \langle IS_{i,l}, A, T_i, \Omega_i, O_i, R_i \rangle$$

where,

• $IS_{i,l}$ denotes a set of interactive states defined as, $IS_{i,l} = S \times \{\Theta_{j,l-1} \cup SM_j\}$, for $l \geq 1$, and $IS_{i,0} = S$, where S is the set of states of the physical environment, $\Theta_{j,l-1}$ is the set of computable *intentional models* of agent j at belief nesting level $l-1$: $\theta_{j,l-1} = \langle b_{j,l-1}, \hat{\theta}_{j,l-1} \rangle$ where the *frame*, $\hat{\theta}_{j,l-1} = \langle A, \Omega_j, T_j, O_j, R_j, OC_j \rangle$. Here, j is Bayes rational and OC_j is j's optimality criterion that influences its decision making process. SM_j is the set of sub-intentional models of j. We give a recursive bottom-up construction of the interactive state space below,

$$\begin{aligned}
IS_{i,0} &= S, \\
&\quad \Theta_{j,0} = \{\langle b_{j,0}, \hat{\theta}_{j,0} \rangle \mid b_{j,0} \in \Delta(IS_{j,0})\} \\
IS_{i,1} &= S \times \{\Theta_{j,0} \cup SM_j\}, \\
&\quad \Theta_{j,1} = \{\langle b_{j,1}, \hat{\theta}_{j,1} \rangle \mid b_{j,1} \in \Delta(IS_{j,1})\} \\
&\vdots \quad \vdots \\
IS_{i,l} &= S \times \{\Theta_{j,l-1} \cup SM_j\}, \\
&\quad \Theta_{j,l} = \{\langle b_{j,l}, \hat{\theta}_{j,l} \rangle \mid b_{j,l} \in \Delta(IS_{j,l})\}
\end{aligned}$$

• A is the set of joint actions of all agents in the environment, $A = A_i \times A_j$

• T_i describes the effect of the joint actions on the physical states of the environment, $T_i : S \times A \times S \rightarrow [0,1]$

• Ω_i is the set of observations of agent i

• $O_i : S \times A \times \Omega_i \rightarrow [0,1]$ gives the likelihood of the observations given the physical state and joint action

• $R_i : IS_i \times A \rightarrow \mathbb{R}$ describes agent i's preferences over it's interactive states. Usually only the physical states will matter

Agent i's policy is the mapping $\Omega_i^* \rightarrow \Delta(A_i)$ where Ω_i^* is the set of all observation histories of agent i. Since belief over the interactive states forms a sufficient statistic [8], the policy can also be represented as a mapping from the set of all belief's of agent i to a distribution over it's actions, $\Delta(IS_i) \rightarrow \Delta(A_i)$.

2.1 Belief Update

Analogous to POMDPs, an agent within the I-POMDP framework also updates its belief as it acts and observes. However, there are two differences that complicate a belief update in multi-agent settings when compared to single-agent ones. First, since the state of the physical environment depends on the actions performed by both agents, – in our example agents i and j – i's prediction of how the physical state changes has to be made based on it's prediction of j's actions. Second, changes in j's model have to be included in i's belief update. Specifically, if j is intentional then an update of j's beliefs due to its action and a new observation has to be included. In other words, i has to update its belief based on it's prediction of what j would observe and how j would update its belief. If j's model is sub-intentional, then j's probable observations are appended to the observation history contained in the model. Formally, following [8], we have:

$$\begin{aligned}
&Pr(is^t | a_i^{t-1}, b_{i,l}^{t-1}) = \beta \int_{IS^{t-1}: \widehat{m}_j^{t-1} = \widehat{\theta}_j^t} b_{i,l}^{t-1}(is^{t-1}) \\
&\times \textstyle\sum_{a_j^{t-1}} Pr(a_j^{t-1} | \theta_{j,l-1}^{t-1}) O_i(s^t, a_i^{t-1}, a_j^{t-1}, o_i^t) \\
&\times T_i(s^{t-1}, a_i^{t-1}, a_j^{t-1}, s^t) \textstyle\sum_{o_j^t} O_j(s^t, a_i^{t-1}, a_j^{t-1}, o_j^t) \\
&\times \delta_D(SE_{\widehat{\theta}_j^t}(b_{j,l-1}^{t-1}, a_j^{t-1}, o_j^t) - b_{j,l-1}^t) d(is^{t-1})
\end{aligned} \tag{1}$$

where β is the normalizing constant, δ_D is the Dirac-delta function, $SE(\cdot)$ is an abbreviation for the belief update, and $Pr(a_j^{t-1} | \theta_{j,l-1}^{t-1})$ is the probability that a_j^{t-1} is Bayes rational for the agent described by model $\theta_{j,l-1}^{t-1}$. When j's model is sub-intentional, the integration is over $IS^{t-1} : \widehat{m}_j^{t-1} = \widehat{m}_j^t$, $Pr(a_j^{t-1} | \theta_{j,l-1}^{t-1})$ is replaced with $Pr(a_j^{t-1} | m_{j,l-1}^{t-1})$, and $\delta_D(SE_{\widehat{\theta}_j^t}(b_{j,l-1}^{t-1}, a_j^{t-1}, o_j^t) - b_{j,l-1}^t)$ is replaced with $\delta_K(APPEND(h_j^{t-1}, o_j^t) - h_j^t)$. δ_K is the Kronecker delta, and $APPEND$ returns a string with the second argument appended to the first. If j is also modeled as an I-POMDP, then i's belief update invokes j's belief update (via the term $SE_{\widehat{\theta}_j^t}(b_{j,l-1}^{t-1}, a_j^{t-1}, o_j^t)$), which in turn could invoke i's belief update and so on. This recursion in belief nesting bottoms out at the 0th level. At this level, belief update of the agent reduces to a POMDP belief update. [1] For an illustration of the belief update, additional details on I-POMDPs, and how they compare with other multi-agent planning frameworks, see [8].

2.2 Value Iteration

Each belief state in a finitely nested I-POMDP has an associated value reflecting the maximum payoff the agent can expect in this belief state:

$$\begin{aligned}
&U^n(\langle b_{i,l}, \widehat{\theta}_i \rangle) = \max_{a_i \in A_i} \Big\{ \int_{is \in IS_{i,l}} ER_i(is, a_i) b_{i,l}(is) d(is) + \\
&\gamma \sum_{o_i \in \Omega_i} Pr(o_i | a_i, b_{i,l}) U^{n-1}(\langle SE_{\widehat{\theta}_i}(b_{i,l}, a_i, o_i), \widehat{\theta}_i \rangle) \Big\}
\end{aligned} \tag{2}$$

where, $ER_i(is, a_i) = \sum_{a_j} R_i(is, a_i, a_j) Pr(a_j | m_{j,l-1})$ (since $is = (s, m_{j,l-1})$). Eq. 2 is a basis for value iteration in I-POMDPs.

Agent i's optimal action, a_i^*, for the case of finite horizon with discounting, is an element of the set of optimal actions for the belief state, $OPT(\theta_i)$, defined as:

$$\begin{aligned}
&OPT(\langle b_{i,l}, \widehat{\theta}_i \rangle) = \operatorname*{argmax}_{a_i \in A_i} \Big\{ \int_{is \in IS_{i,l}} ER_i(is, a_i) b_{i,l}(is) d(is) \\
&+ \gamma \sum_{o_i \in \Omega_i} Pr(o_i | a_i, b_{i,l}) U^n(\langle SE_{\widehat{\theta}_i}(b_{i,l}, a_i, o_i), \widehat{\theta}_i \rangle) \Big\}
\end{aligned} \tag{3}$$

3. BEHAVIORAL EQUIVALENCE

The main idea in this paper is to aggregate interactive states into a finite number of equivalence classes using behavioral equivalence. Instead of reasoning over the infinite set of interactive states, we operate over the finite set of equivalence classes of interactive states (ECIS). In the next subsection, we introduce the concept of behavioral equivalence and show that reasoning over the equivalence classes preserves the optimal policy.

3.1 Defining the Equivalence Classes

In order to illustrate the construction of the behavioral equivalence classes we look at a simple example – the classical *tiger*

[1] The 0th level model is a POMDP: Other agent's actions are treated as exogenous events and folded into the T, O, and R functions.

problem introduced in [11]. The problem is that of an agent having to open either of two doors. Behind one of the doors is a tiger waiting to eat the agent and behind the other is a pot of gold. There is a reward of +10 to get the gold and -100 when the agent is eaten by the tiger. There are two states signifying the tiger's location behind the left (*TL*) door and the right (*TR*) door. The agent has three actions: open left door (*OL*), open right door (*OR*) and listen (*L*). Listening always incurs a cost of 1. When the agent listens, it can hear a growl on the left (*GL*) or right (*GR*) with 85% certainty. The

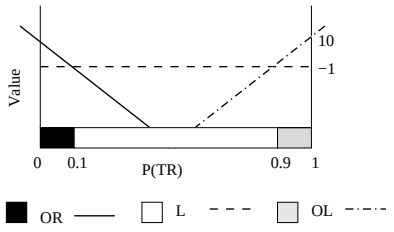

Figure 1: Horizon-1 value function in the tiger game and the belief ranges corresponding to different optimal actions.

value function gives the value of performing the optimal plan at any given belief. In Fig. 1, the value function is the envelope that provides the maximum value of any plan over all beliefs. We note that the agent opens the right door if it believes the probability that the tiger is behind the right door, *P(TR)*, is less than 0.1. It will listen if 0.1 < *P(TR)* < 0.9 and open left door if *P(TR)* > 0.9.

In Fig. 1 we observe that each of the optimal plans spans over multiple belief points. For example, opening the right door is the optimal action for all beliefs in the set [0–0.1), i.e. OPT(P(TR)= [0–0.1)) = OR. Thus, beliefs in the set [0–0.1) are equivalent to each other in that they induce the same optimal behavior. We call such beliefs *behaviorally equivalent*. [2] The collection of the equivalence classes (five of them in the example in Fig. 1) forms a partition of the belief space. For finite horizons, and a finite number of actions and observations, the number of distinct plans and therefore the equivalence classes is also finite. Note that each equivalence class is a node in the policy graph in a POMDP.

We use the above insight to discretize the infinite interactive state space of I-POMDPs into a finite one. The optimal value function in I-POMDPs, like POMDPs, is also piecewise linear and convex (PWLC) [8]. Recall that the interactive state space, $IS_{i,l} = S \times \{\Theta_{j,l-1} \cup SM_j\}$, where $\Theta_{j,l-1}$ is the set of intentional models of agent j that includes its beliefs, and all other parameters sufficient to determine its behavior. SM_j is the set of j's sub-intentional models. We transform the infinite space into a finite one by grouping together the behaviorally equivalent models into the equivalence classes. As we mentioned before, for a finite horizon and finite number of actions and observations, there exist a finite number of equivalence classes, thereby facilitating the application of standard POMDP solution methods for solving I-POMDPs.

We point out that the method scales well to higher levels of nesting. Since at each level of nesting we operate over the equivalence classes only, we need not concern ourselves with the complex space of beliefs over beliefs of other agents and so on. Of course, in deriving the equivalence classes we must solve all lower level models in a recursive manner. We formally define the equivalence classes below:

[2] It is possible that some plans may be optimal for only a single belief. In this case, the equivalence class would be a singleton set containing the single belief.

DEFINITION 2 (ECIS). *Equivalence classes of interactive states ($ECIS_{i,l}$) of an agent i is a* partition *of $IS_{i,l}$ such that the behavior of agent j is the same for all interactive states in a given subset.*

$$ECIS_{i,l} = \{ (s, M_{j,k}^{l-1}) \mid M_{j,k}^{l-1} \subseteq \{\Theta_{j,l-1} \cup SM_j\} and \forall_{m_{j,l-1}, m'_{j,l-1} \in M_{j,k}^{l-1}} OPT(m_{j,l-1}) = OPT(m'_{j,l-1}) \}$$

Here, $M_{j,k}^{l-1}$, is the kth equivalence class in the partition. Note that OPT(.) takes a model of the other agent as a parameter and gives the optimal action of the agent (see Eq. 3).

3.2 Belief Update and Value Iteration over ECIS

The main difference between the belief update as defined in Eq. 1 over the original interactive state space and the belief update over the transformed one is in the manner in which agent i updates j's models. Since j's model space is partitioned into equivalence classes, i must update j's equivalence class based on j's action and observation. To understand how this is done, let us consider the simple case where i is uncertain only about j's beliefs. In this case, each equivalence class is a disjoint subset of j's beliefs that induces identical optimal behavior.

As we mentioned before, the optimal solution to an I-POMDP (and a POMDP) provides a conditional plan or a policy graph that dictates the action(s) that agent j must perform given the equivalence class of its beliefs. Agent i updates j's equivalence class by locating the node for the current equivalence class in j's policy graph, and using j's predicted action and possible observation to trace to the next one. Before presenting the belief update equations, we note that i's belief over the transformed interactive state space forms a sufficient statistic.

PROPOSITION 1. *(Sufficiency) In a finitely nested I-POMDP, a probability distribution over $ECIS_{i,l}$, $\tilde{b}_{i,l} \in \Delta(ECIS_{i,l})$, provides a sufficient statistic for the past history of i's observations.*

We outline the proof of this proposition in the Appendix. We give the belief update over ECIS for an arbitrary belief nesting level l below:

$$\begin{aligned} & Pr(ecis^t | o_i^t, a_i^{t-1}, \tilde{b}_{i,l}^{t-1}) = \beta \sum_{ECIS^{t-1}} \tilde{b}_{i,l}^{t-1}(ecis^{t-1}) \\ & \times \sum_{a_j^{t-1}} Pr(a_j^{t-1} \mid M_{j,k}^{t-1})\, O_i(s^t, a^{t-1}, o_i^t) \\ & \times\ T_i(s^{t-1}, a^{t-1}, s^t) \sum_{o_j^t} \tilde{\tau}(M_{j,k}^{t-1}, a_j^{t-1}, o_j^t, M_{j,k}^t) \\ & \times\ O_j(s^t, a^{t-1}, o_j^t) \end{aligned} \quad (4)$$

where β is the normalizing constant. Agent i's update of j's equivalence classes is captured using the $\tilde{\tau}$ operator which returns 1 if $Pr(M_{j,k}^t | M_{j,k}^{t-1}, a_j, o_j) = 1$, and 0 otherwise. The $\tilde{\tau}$ operator uses j's policy graph to determine the updated equivalence class. Note that $M_{j,k}^{t-1}$ contains j's equivalent models before j performs it's belief update and $M_{j,k}^t$ contains models that are equivalent after j's belief update.

Since i's beliefs are now distributions over the transformed interactive state space, the value iteration, as shown in Eq. 2 is revised to include the value function defined over the transformed belief space:

$$\tilde{U}^n(\langle \tilde{b}_{i,l}, \widehat{\theta}_i \rangle) = \max_{a_i \in A_i} \Big\{ \sum_{ecis \in ECIS_{i,l}} ER_i(ecis, a_i) \tilde{b}_{i,l}(ecis) \times \gamma \sum_{o_i \in \Omega_i} Pr(o_i | a_i, \tilde{b}_{i,l}) \tilde{U}^{n-1}(\langle SE_{\widehat{\theta}_i}(\tilde{b}_{i,l}, a_i, o_i), \widehat{\theta}_i \rangle) \Big\} \quad (5)$$

In the next proposition, we show that the discretization of the interactive state space is a *lossless* one. In other words, for a given belief over the original interactive state space, the value of the optimal plan (and the optimal plan itself) remains unchanged for the corresponding belief over the discretized interactive state space. We define the concept of a value preserving transformation and formalize our result in Proposition 2.

DEFINITION 3 (VALUE PRESERVING TRANSFORMATION). *Define a transformation $F : B_1 \rightarrow B_2$, where B_1 is the space of original beliefs, and B_2 is the space of corresponding transformed beliefs. Let $Q : N \times B_1 \times A \rightarrow \mathbb{R}$ and $\tilde{Q} : N \times B_2 \times A \rightarrow \mathbb{R}$ be the N horizon action-value functions. F is said to be value preserving iff $\forall_{n \in [1,N], b \in B_1, a \in A} Q^n(b,a) = \tilde{Q}^n(F(b),a)$. In other words, the value of the transformed belief and action pair is same as the value of the original belief and action, for all horizons.*

PROPOSITION 2. *Define a mapping $CP : \Delta(IS_{i,l}) \rightarrow \Delta(ECIS_{i,l})$ in a finitely nested I-POMDP such that,*

$$\tilde{b}_i(s, M_{j,k}^{l-1}) = \int_{m_j \in M_{j,k}^{l-1}} b_i(s, m_j) dm_j \qquad (6)$$

where $b_i \in \Delta(IS_{i,l})$, $\tilde{b}_i \in \Delta(ECIS_{i,l})$, and $M_{j,k}^{l-1}$ is some equivalence class. The mapping CP is value preserving.

The proof of proposition 2 is given in the Appendix.

COROLLARY 1. *The optimal policy of the transformed finitely nested I-POMDP remains unchanged.*

PROOF. *Proof of this corollary is inductive, and involves a straightforward application of Proposition 2. From Proposition 2, CP is a value-preserving transformation. For the basis step – horizon is 1 – $\forall_{b_i,a_i} Q^1(b_i,a_i) = \tilde{Q}^1(CP(b_i),a_i)$. Therefore, the optimal single step action remains unchanged. The inductive proof then follows for any arbitrary horizon n. Since $\forall_{b_i,a_i} Q^n(b_i,a_i) = \tilde{Q}^n(CP(b_i),a_i)$, therefore $\forall_{b_i \in \Delta(IS_i)} OPT(b_i) = \tilde{OPT}(CP(b_i))$, the optimal policy remains the same.* □

4. MULTI-AGENT TIGER PROBLEM

To illustrate our method we use a slightly modified version of the multi-agent tiger problem discussed in [8] (based on [15].) The problem has two agents, each of which can open the right door (OR), the left door (OL) or listen (L). In addition to observing growls when they listen, the agents can also hear creaks (creak on the left (CL), creak on the right (CR) or silence (S), i.e no creaks) indicating the other agent's opening one of the doors. When any door is opened, the tiger's location is switched with a probability of 5%. The agent's preferences are as in the single agent game discussed in Section 3. The transition, reward and observation functions are shown in Table 1. From the observation functions we see that, in this case, agent i hears growls with a reliability of 65% and creaks with a reliability of 95%. Agent j, on the other hand, hears growls with a reliability of 95%. Thus, the setting is such that agent i can hear agent j opening doors more reliably than the tiger's growls. This suggests that i could use j's actions as an indication of the location of the tiger, as we discuss below.

For the sake of simplicity we assume agent i's I-POMDP to be singly nested and that agent i ascribes only intentional models to j. Additionally, we assume that i is uncertain only about j's beliefs and not j's frame. Note that in a general I-POMDP, i can be uncertain about all parameters of j's model. In Fig. 2(a) we give the optimal solution of the level 0 I-POMDP of agent j. Since

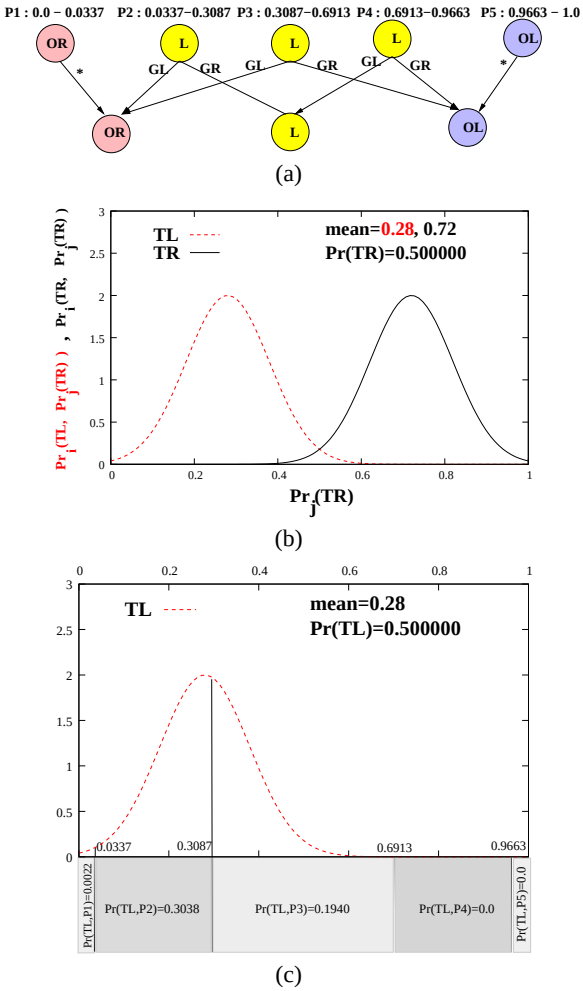

Figure 2: (a) Agent j's horizon 2 policy showing optimal plans given different prior beliefs. Since j's belief is not nested, its prior belief is given as the probability that the tiger is behind the right door. (b) An example of agent i's level-1 belief. Note that we have 2 distributions, one when the tiger is on the left and other when tiger is on the right. In the belief shown, i thinks that j is likely to be somewhat informed about the tiger's true location. (c) Shows how agent i's belief $b_{i,1} \in \Delta(IS_{i,1})$ (at 2 steps to go) is transformed into a belief $\tilde{b}_{i,1} \in \Delta(ECIS_{i,1})$. For example, the probability that the tiger is behind the left door and j's belief is in region $P2$ is given as $\tilde{b}_{i,1}(TL, P2) = \int_{0.0337}^{0.3087} b_{i,1}(TL, Pr_j(TR)) dPr_j(TR) = 0.3038$, where $b_{i,1}(TL, Pr_j(TR))$ is the Gaussian pdf describing i's belief about j's belief when the tiger is on the left. $\int_0^1 b_{i,1}(TL, Pr_j(TR)) dPr_j(TR)$ gives i's belief that the tiger is behind the left door. Similarly, $\tilde{b}_{i,1}(TR, P1), \tilde{b}_{i,1}(TR, P2) \ldots \tilde{b}_{i,1}(TR, P5)$ are computed from the Gaussian describing i's belief about j's belief when the tiger is behind the right door.

agent j's belief is not nested, j reasons about the tiger's location only and not about agent i's beliefs. Therefore, agent j's actions depend on hearing growls alone. The transformed horizon-2 interactive state space is: $ECIS_{i,1} = S \times \{P1, P2, P3, P4, P5\}$, where the classes $P1 - P5$ are shown in Fig. 2(a). Since $ECIS_{i,1}$ is finite, we can obtain the *complete* optimal value function using the modified value iteration shown in Eq. 5.

In the remainder of this section we visualize i's value function

(a) Transition function for i and j

Action <i,j>	State	TL	TR
<OL,*> , <*,OL>	TL	0.95	0.05

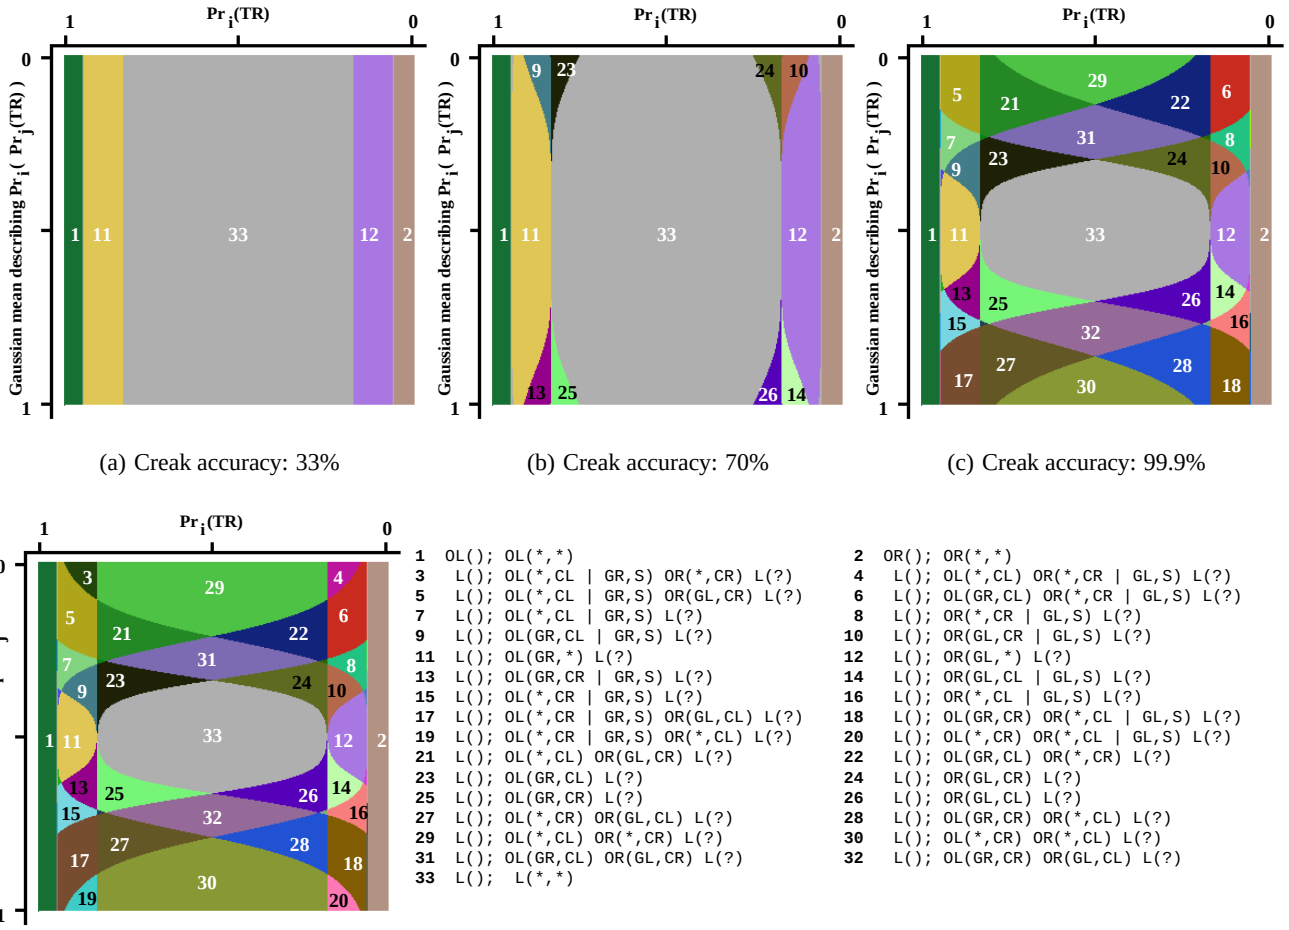
Table 1: The transition, reward and observation functions of agents i and j

and discuss i's behavior in the presence of j. The value function is defined over a ten dimensional space since agent j has five behavioral equivalence classes and there are two physical states. While we can compute the complete value function and policy, it is not possible to visualize it. Hence, here we plot agent i's value function for a subset of beliefs it has about agent j.

An example of agent i's belief about the location of the tiger and about j's belief is shown in Fig. 2(b). We represent agent i's belief about its interactive state as a pair of Gaussian densities with a variance of 0.01. One Gaussian captures i's belief about j's belief when the tiger is on the left, and the other captures i's belief about j's belief when the tiger is on the right (see [8] for a more detailed exposition on representing nested beliefs in I-POMDPs). To enable visualization, we capture i's belief about j's using a single parameter. To do this, we only look at those beliefs of i in which the mean of the two probability densities sum to 1, as do the densities shown in Fig. 2(b). The value function is plotted against agent i's belief about the tiger's location ($Pr_i(TR)$) and the mean of the probability density function (describing $Pr_i(Pr_j(TR))$ given the tiger is on the left. Note that in considering the particular form of i's beliefs, we have reduced the dimensions over which the value function spans in a non-linear fashion, and hence the value function plot is not linear.

Figures 3(a), 3(b), 3(c) and 3(d) show the projections of i's horizon 2 value functions on the belief space of agent i. We varied the reliability of the creaks, in order to explore its effect on i's policy. Figure 3(e) describes the optimal policies for the corresponding belief regions.

When creaks are not very reliable i's behavior is analogous to that of a single agent POMDP as seen in Fig. 3(a), as should be expected. Here, the agent uses only growls to reason about the location of the tiger.



When creaks become more reliable, it is possible for i to use them to reinforce the estimates made using the growls. For example, in the belief region 9 [*Policy: L(); OL(GR,CL|GR,S) L(?)*] shown in Fig. 3(b), agent i *supplements* the information from growl (GR) with either a creak from the left (CL) or silence (S). This is because a creak from the left or silence indicates that j likely did not open the right door. The fact that CL or S are not likely to be the outcome of noise is due to i's belief that j believes with a fairly large probability that the tiger is behind the right door. When agent i is less certain about the location of the tiger (in region 23 [*Policy: L(); OL(GR,CL) L(?)*]), it has to observe a creak from the left, in addition to the growl from the right, to open the left door.

In regions of the policy (Fig. 3(b)) where the Gaussian mean is closer to 1, it is possible to get misleading information and still make a decision of opening doors. For example, in the region 25 [*Policy: L(); OL(GR,CR) L(?)*], the agent opens the left door even though it hears a growl from the right and a creak from the right. Because in this region the mean is closer to 1, i thinks that j is misinformed. In other words, for the physical state that the tiger is on the right, i likely believes that j believes the tiger to be on the left. Hence, the creak from the right is interpreted to be a result of this misinformation, thereby reinforcing i's belief that the tiger is on the right.

As the reliability of the creaks increases to 99.90%, we see that agent i starts exhibiting a more complex behavior. Sometimes it is guided only by creaks (regions 29 and 30), when it knows that j's opening the doors is a good predictor of the tiger's location. Sometimes, however, when i is quite sure about the tiger's location and it thinks that j is misinformed, i can ignore the creaks and base its decisions only on growls (regions 1, 2, 11, and 12).

Let us now turn our attention to regions 5 and 17 and their symmetric counterparts – regions 6 and 18 in Fig. 3(c). We focus on only the region 5, but the arguments for the other regions are analogous. For region 5, i believes j is informed and it believes that the tiger is likely on the right. For this region, the agent opens the left door if it hears a creak from the left (since it was fairly certain that the tiger was behind right door and the tiger persists after opening doors) or on hearing a growl from the right and no creaks. It opens the right door only if it hears a growl from the left along with creak from the right. Since i believes j is informed, a creak from the right indicates that j likely opened the right door which means that j believed that the tiger was on the left. An observation of GL further reinforces i's belief that the tiger is indeed on the left, causing i to open the right door.

When the reliability of the creaks increases to 99.97%, the size of the regions that utilize only the creaks to guide the actions, increase

(a) Creak accuracy: 33%

(b) Creak accuracy: 70%

(c) Creak accuracy: 99.9%

(d) Creak accuracy: 99.97%

(e) Policy of agent i. ? indicates all other observations and * indicates all possible values

Figure 3: Figures (a-d) show the projections of the value functions of agent i, with varying creak reliabilities. The belief regions are marked with numbers that index into the list of policy trees in table (e)

(see regions 29 and 30), as should be expected. Additionally, new regions (3, 4, 19, and 20) appear as part of the policy.

5. CONCLUSION

We presented a method that exploits behavioral equivalence among other agents' possible models to exactly solve finitely nested interactive POMDPs. By aggregating the behaviorally equivalent models into equivalence classes, we transformed the infinite interactive state space of I-POMDPs into a finite one, thereby allowing the application of standard POMDP solution techniques for solving I-POMDPs. Our method works because the discretization of the state space preserves the value of the plans. We applied our method to the multi-agent tiger problem, and presented a series of policies for various values of the parameters of the problem. Our aim is to understand the interplay between an agent's belief about other agents' beliefs and its observations, in arriving at its optimal plan of action. As we demonstrated, an agent's optimal policy changes drastically as its capability about observing others' behaviors improves. We believe it may be possible to combine different behavioral equivalence regions together to approximately represent an agent's behavior and reason about them. This is one possible avenue of future work.

APPENDIX

PROOF OF PROPOSITION 1.

$$\tilde{b}^t_{i,l}(ecis^t) = Pr(ecis^t \mid o^t_i, a^{t-1}_i, \tilde{b}^{t-1}_{i,l}) = \frac{Pr(ecis^t, o^t_i \mid a^{t-1}_i, \tilde{b}^{t-1}_{i,l})}{Pr(o^t_i \mid a^{t-1}_i, \tilde{b}^{t-1}_{i,l})}$$

$$= \beta \sum_{ecis^{t-1}} \tilde{b}^{t-1}_{i,l} Pr(ecis^t, o^t_i \mid a^{t-1}_i, ecis^{t-1})$$

$$= \beta \sum_{ecis^{t-1}, a^{t-1}_j} \tilde{b}^{t-1}_{i,l} Pr(a^{t-1}_j \mid ecis^{t-1}) \times Pr(ecis^t, o^t_i \mid a^{t-1}_i, a^{t-1}_j, ecis^{t-1})$$

$$= \beta \sum_{ecis^{t-1}, a_j^{t-1}} \tilde{b}_{i,l}^{t-1} Pr(a_j^{t-1} \mid \langle s^{t-1}, M_{j,k}^{t-1} \rangle) \times Pr(ecis^t, o_i^t \mid a^{t-1}, ecis^{t-1})$$

$$= \beta \sum_{ecis^{t-1}, a_j^{t-1}} \tilde{b}_{i,l}^{t-1} Pr(a_j^{t-1} \mid M_{j,k}^{t-1}) Pr(o_i^t \mid ecis^t, a^{t-1}, ecis^{t-1}) \times Pr(ecis^t \mid a^{t-1}, ecis^{t-1})$$

$$= \beta \sum_{ecis^{t-1}, a_j^{t-1}} \tilde{b}_{i,l}^{t-1} Pr(a_j^{t-1} \mid M_{j,k}^{t-1}) O_i(s^t, a^{t-1}, o_i^t) \times Pr(\langle s^t, M_{j,k}^t \rangle \mid a^{t-1}, \langle s^{t-1}, M_{j,k}^{t-1} \rangle)$$

$$= \beta \sum_{ecis^{t-1}, a_j^{t-1}} \tilde{b}_{i,l}^{t-1} Pr(a_j^{t-1} \mid M_{j,k}^{t-1}) O_i(s^t, a^{t-1}, o_i^t) \times T_i(s^t, a^{t-1}, s^{t-1}) \sum_{o_j^t} \tilde{\tau}(M_{j,k}^t, a_j^{t-1}, o_j^t, M_{j,k}^{t-1}) \times O_j(o_j^t \mid a^{t-1}, s^t)$$

Thus belief at time t can always be expressed in terms of belief and actions at time $t-1$ and the observations at time t. $\square$

PROOF OF PROPOSITION 2 BY INDUCTION. To keep the proof short, we will assume that only the belief of the other agent is unknown, i.e. all other parameters of the model are known. Thus Eq. 6 can be written as $\tilde{b}_i(s, \mathbb{B}_{j,k}) = \int_{b_j \in \mathbb{B}_{j,k}} b_i(s, b_j) db_j$

Let b_i be an arbitrary belief of agent i. Let $\{\mathbb{B}_{j,1}, \mathbb{B}_{j,2}, ..., \mathbb{B}_{j,n}\}$ be the collection of equivalence classes of agent j's belief. Each class $\mathbb{B}_{j,k}$ is a set of beliefs of j such that the action a_j^k is optimal for each belief. Thus $\forall_{b_j \in \mathbb{B}_{j,k}} ER(s, b_j, a_i) = R(s, a_i, a_j^k)$, because a_j^k is optimal for all $b_j \in \mathbb{B}_{j,k}$.

Basis Step: We show that the horizon 1 value remains unchanged when i's original belief is replaced by its belief over the equivalence classes.

$$Q^1(b_i, a_i) = \int_{is_i} b_i(is_i) ER(is_i, a_i) = \sum_s \int_{b_j \in B_j} b_i(s, b_j) ER(s, b_j, a_i)$$

From the definition of equivalence classes,

$$Q^1(b_i, a_i) = \sum_s \left\{ \int_{b_j \in \mathbb{B}_{j,1}} b_i(s, b_j) ER(s, b_j, a_i) + ... + \int_{b_j \in \mathbb{B}_{j,n}} b_i(s, b_j) ER(s, b_j, a_i) \right\}$$

Note that $ER(s, b_j, a_i) = \sum_{a_j} R(s, a_i, a_j) Pr(a_j | b_j)$, and for all $b_j \in \mathbb{B}_{j,n}$ the $Pr(a_j|b_j)$ will be 1 for some a_j^n (assuming a deterministic policy) and 0 for others. Therefore,

$$Q^1(b_i, a_i) = \sum_s \left\{ \int_{b_j \in \mathbb{B}_{j,1}} b_i(s, b_j) R(s, a_i, a_j^1) + ... + \int_{b_j \in \mathbb{B}_{j,n}} b_i(s, b_j) R(s, a_i, a_j^n) \right\}$$

$$= \sum_s \left\{ R(s, a_i, a_j^1) \int_{b_j \in \mathbb{B}_{j,1}} b_i(s, b_j) + ... + R(s, a_i, a_j^n) \int_{b_j \in \mathbb{B}_{j,n}} b_i(s, b_j) \right\}$$

Using Eq. 6,

$$Q^1(b_i, a_i) = \sum_s \Big\{ R(s, a_i, a_{j,1}) \tilde{b}_i(s, \mathbb{B}_{j,1}) + ... + R(s, a_i, a_{j,n}) \tilde{b}_i(s, \mathbb{B}_{j,n}) \Big\} = \sum_{s,k} \tilde{b}_i(s, \mathbb{B}_{j,k}) R(s, a_i, a_{j,k}) = \tilde{Q}^1(\tilde{b}_i, a_i)$$

Because the Q values remain unchanged, maximizing over them will also yield identical values.

Inductive Hypothesis: Let us assume that $\forall a_i, b_i \; Q^n(b_i, a_i) = \tilde{Q}^n(\tilde{b}_i, a_i)$ where $\tilde{b}_i$ is related to b_i using Eq. 6. Because the Q values are identical, the N horizon value function also remains unchanged.

Inductive Proof:

$$Q^{n+1}(b_i, a_i) = \int_{is_i} b_i(is_i) ER(is_i, a_i) + \gamma \sum_{o_i} Pr(o_i | b_i, a_i) V^N(SE(b_i, a_i, o_i)) = Q^1(b_i, a_i) + \gamma \sum_{o_i, is_i} Pr(o_i | is_i, a_i) \times b_i(is_i) U^n(SE(b_i, a_i, o_i))$$

From the basis step,

$$Q^{n+1}(b_i, a_i) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, is_i, a_j} Pr(o_i | is_i, a_i, a_j) \times Pr(a_j | b_j) b_i(is_i) U^n(SE(b_i, a_i, o_i)) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, s} \int_{b_j} \sum_{a_j} Pr(o_i | is_i, a_i, a_j) \times Pr(a_j | b_j) b_i(s, b_j) U^n(SE(b_i, a_i, o_i))$$

From the definition of equivalence classes,

$$Q^{N+1}(b_i, a_i) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, s, \mathbb{B}_{j,k}} \int_{b_j \in \mathbb{B}_{j,k}} \sum_{a_j} Pr(o_i | is_i, a_i, a_j) \times Pr(a_j | b_j) b_i(s, b_j) U^n(SE(b_i, a_i, o_i))$$

Using the BNM and BNO assumptions of the I-POMDP framework [8],

$$Q^{n+1}(b_i, a_i) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, s, \mathbb{B}_{j,k}} \int_{b_j \in \mathbb{B}_{j,k}} Pr(o_i | s, a_i, a_j^k) \times b_i(s, b_j) U^n(SE(b_i, a_i, o_i))$$

From Eq. 6,

$$Q^{n+1}(b_i, a_i) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, s, \mathbb{B}_{j,k}} Pr(o_i | s, a_i, a_j^k) \times \int_{b_j \in \mathbb{B}_{j,k}} b_i(s, b_j) U^n(SE(b_i, a_i, o_i)) = \tilde{Q}^1(\tilde{b}_i, a_i) + \gamma \sum_{o_i, s, \mathbb{B}_{j,k}} Pr(o_i | s, a_i, a_j^k) \times \tilde{b}_i(s, \mathbb{B}_{j,k}) U^n(SE(b_i, a_i, o_i))$$

Using $Pr(o_i|s,a_i,\mathbb{B}_{j,k}) = \sum_{a_j} Pr(o_i|s,a_i,a_j,\mathbb{B}_{j,k})Pr(a_j|\mathbb{B}_{j,k}) = Pr(o_i|s,a_i,a_{j,k})$ and the inductive hypothesis,

$$\begin{aligned} Q^{n+1}(b_i,a_i) &= \tilde{Q}^1(\tilde{b}_i,a_i) + \gamma \sum_{o_i,s,\mathbb{B}_{j,k}} Pr(o_i|s,a_i,\mathbb{B}_{j,k}) \\ &\quad \times \tilde{b}_i(s,\mathbb{B}_{j,k})\tilde{U}^n(SE(\tilde{b}_i,a_i,o_i)) \\ &= \tilde{Q}^1(\tilde{b}_i,a_i) + \gamma \sum_{o_i} Pr(o_i|a_i,\tilde{b}_i) \\ &\quad \times \tilde{U}^n(SE(\tilde{b}_i,a_i,o_i)) \\ &= \tilde{Q}^{n+1}(\tilde{b}_i,a_i) \end{aligned}$$

Because the Q values are identical under the mapping, the values of the beliefs over the equivalence classes of interactive states remain unchanged. We have assumed in the proof that agent j's policies are deterministic, i.e., for every class $\mathbb{B}_{j,k}$ there is one optimal action $a_{j,k}$. The proof extends in a straightforward manner when there is more than one optimal action for a class. □

ABSTRACT

Goals are an important concept in intelligent agent systems, and can take a variety of forms. One such form is *maintenance goals*, which, unlike *achievement goals*, define states that must remain true, rather than a state that is to be achieved. Maintenance goals are generally restricted to acting as trigger conditions for goals or plans, and often take no part in any deliberation process. These goals are *reactive* and are only acted upon when the maintenance conditions are no longer true. In this paper, we study maintenance goals that are *proactive*, in that the agent system needs to not only react when the maintenance conditions fail, but also anticipate the failures of these conditions, and act in order to avoid them failing. This can be done by performing actions that prevent the condition from failing, or suspending goals that will cause the maintenance conditions to fail. We provide a representation for maintenance goals that captures both their reactive and proactive aspects, algorithms that identify in advance where maintenance conditions may not hold, and mechanisms for enabling preventative actions in such situations. We also provide some experimental results on an implementation of these ideas.

1. INTRODUCTION

Goals are a crucial concept in agent programming languages. Agent properties such as proactiveness, reactivity, autonomy and social ability can be described in terms of the goals of the agent. A *proactive* agent is required to actively work towards achieving its goals, while a *reactive* agent is required to adapt to environmental changes in order to maximise its ability to achieve its goals. An *autonomous* agent is free to choose how to achieve its goals, how to resolve conflicts between its goals and whether to drop goals which appear to be unachievable. A *social* agent may choose to adopt a goal on a request from another agent, or to request another agent to adopt one of its goals. Accordingly, there are a number of agent systems in which goals are a central concept, such as 3APL[5], KAOS[4], and Tropos[7].

Goals can hence be seen as a link between the agent's reasoning and its actions; actions are only undertaken in order to achieve one or more of the agent's goals, and changes in the status of the agent's goals are reflected in changes in its actions.

For the most part, goals in agent systems are *achievement goals*, i.e. goals which are not currently true, and which the agent, by means of pursuing the appropriate actions, acts to make true. However, the agent has no obligation once the goal becomes true, in that there is no requirement to act to ensure that goal remains true.

There are some systems (such as Jadex[9] and JAM[8]) which include *maintenance goals* as well as achievement goals. In such systems, a maintenance goal is one which is initially true, and if it becomes false, the agent will take action to make it become true. Hence such goals act as a trigger, in that it is only when they become false that any action is taken. We refer to such goals as *reactive maintenance goals*, as no action is taken for such goals until the goal becomes false.

In this paper we extend the notion of maintenance goals to include *proactive* behaviour as well. In other words, an agent may take action not only to bring about an achievement goal or in response to a maintenance goal becoming false, but also to ensure that a maintenance goal will remain true. Hence the agent reasons about possible future events, and perform actions to avoid maintenance goals becoming false (as well as possibly taking actions if any such goals do become false).

For example, consider an agent controlling a Mars Rover, which has a number of target locations it is required to visit (the agent's achievement goals), while ensuring that certain conditions related to the safe operation of the rover are maintained (the agent's maintenance goals). A typical

example of a maintenance goal could be to ensure that the rover has sufficient battery charge to perform its activities, recharging when it has less than 20% of its battery remaining [1]. The rover knows several locations where it can recharge its battery. The process of moving consumes charge, and the electrical usage of the rover may be predictable in some cases (for example, where the rover has visited some location before). In such a case, the rover can determine how much charge it will use, and the expected battery level it will have upon reaching its destination. It would appear rational for a rover to anticipate that its maintenance condition may be unsatisfied if it attempts to move towards the location immediately – instead, it should take the opportunity to recharge its battery whilst it is near the charger, prior to moving to a distant location.

A second example can be found in the domain of *autonomic computing*. An intelligent operating system may be given the goal to maintain the availability of a cluster of machines by preventing all machines being shut down at once. There is no obvious mechanism that would allow a reactive maintenance goal to ensure that all machines are active, without first allowing all machines to be shut down, recognising that the maintenance condition is violated, and restarting a machine to re-establish the maintenance condition. On the other hand, a proactive maintenance goal would prevent the last machine from being shut down. We believe that the domain of autonomic computing is a rich one for proactive maintenance goals.

A final example consists of a boiler that produces some output power. An agent is able to control the output power by increasing or decreasing the temperature of the boiler. This example can be used to illustrate how maintenance goals can be made to interact. As a safety measure, the agent may have a maintenance goal to ensure that the boiler's temperature never exceeds some amount. There may also be a second maintenance goal that the output power always be greater than some minimum value. The agent may have several achievement goals, such as providing power for several devices, which require the agent to increase the temperature to produce enough power. A rational agent may limit the number of devices that can concurrently be powered, to ensure that the temperature required is not too elevated. The rational agent may also choose to ensure that there is always some device being powered by the boiler, to avoid wasted energy.

Hence, achievement goals drive the agent to perform actions to produce a desired state; maintenance goals either trigger corrective actions to be taken, or constrain the choice of actions so that the maintenance goals will not be violated.

This paper is organised as follows. In Section 2, we provide background material to a number of elements concerning the agent framework support for proactive maintenance goals. Next, in Section 3 we provide a detailed explanation of the requirements and mechanisms an agent system should incorporate to support our ideals of proactive maintenance goals. A discussion of mechanisms for implementing proactive behaviour follows in Section 4. We have done some preliminary experiments to evaluate our work which we present in Section 5. We conclude with possible future directions in Section 6.

2. MAINTENANCE GOALS

The earliest examples of maintenance goals (such as [6]) are purely reactive, i.e. they act as triggers to adopt an extra achievement goal, and only when the stated condition becomes false. In the Mars rover example, a reactive maintenance goal of maintaining a battery level of at least 20% will only cause the agent to act once the level drops below this amount. Hence the maintenance goal can be completely characterised as a trigger which adds an achievement goal such as "recharge the battery". In a system such as JACK[2], this is not very different from adding the negation of the maintenance goal as a context condition for the plan which fills the tank.

The life cycle of such reactive maintenance goals is discussed in some detail in [1]. As discussed in that paper, "a maintenance goal is introduced to observe and maintain some world state as long as the goal exists". Whilst the discussion of goal types and the way in which goals are managed during the execution cycle is quite comprehensive, their use of maintenance goals remains reactive.

A more active approach to maintenance goals includes not only triggering some recovery action once the goal is violated, but *taking actions in anticipation of the maintenance goal becoming false*. As mentioned above, this will presumably lead to more rational behaviour, such as the battery-charging activity of the robots discussed in [1] taking place shortly before the low power threshold is reached, rather than just after it. However, there is no point in recharging the robot too often, such as when the battery is 85% charged, just because the robot happens to be nearing a charging point. In other words, the agent has to have a reasonable expectation that the maintenance goal is likely to be violated in the near future; action is then taken to ensure that it is not violated.

In some sense, this approach assumes that it is important to prevent the maintenance goal from becoming false. For example, consider a maintenance goal to maintain the pressure of a gas cylinder at no more than a certain amount. Whilst emergency action is clearly needed if the pressure exceeds this value, rational management of this property would also include actively preventing the pressure from getting too close to the limit.

Hence the proactive approach takes action not only when the maintenance goal is violated, but also when the agent anticipates that it will be violated in the near future. In order to perform such reasoning, the agent needs to be aware of the effects of other goals on the maintenance condition. This can be of the form of altering the belief of an agent, or consuming or producing some resource involved in the maintenance condition. Therefore, we require the effects and required resources of goals to be explicitly represented in the structure of the agent goals, as well as having these structures utilised in the agent execution cycle.

It should be noted that maintenance goals are a means of improving the rationality of the agent by using a richer class of goals. Hence they can be seen as a way of more closely approximating perfectly rational behaviour whilst remaining intuitively simple. The main thrust of this paper is to show that the extra subtlety gained comes at a cost of comparatively little efficiency.

3. REPRESENTATION

Our agents are based on standard implementations of the Belief-Desire-Intention (BDI)[11]. In particular, our central notions are *beliefs*, *goals* and *plans*.

The agents we develop have a pre-defined set of plans that are utilised at run-time to satisfy goals. The agents also have belief-bases which contains facts about the world known to the agents. In this section we describe a representation for an agent's beliefs, plans, achievement goals and maintenance goals. We build on some of our earlier work to provide a representation for achievement goals and plans [12, 13], and provide a new structure for maintenance goals.

Beliefs can be represented in many different forms. For example, in AgentSpeak [10] they are represented in first order logic. In our framework, we present a restricted form of beliefs in order to better explain the reasoning mechanisms in later sections. We represent a belief as a tuple, ⟨ *Name, Type, Value* ⟩, where *Name* is an alphanumeric string which allows the agent's beliefs to be uniquely referenced, *Type* defines the type of object the Value attribute represents, and *Value* is the actual data representing the belief. Some examples of beliefs are:

⟨FuelLevel, Number, 60⟩
⟨GripperEmpty, Boolean, True⟩
⟨RoverID, Text, Rover1⟩

Plans are lists of instructions an agent can follow to potentially establish a desired state with respect to some goal. A plan is a tuple of the form ⟨*Type, Pre-Condition, Effects, Plan Body*⟩. *Type* is an alphanumeric string which identifies the type of the plan. The *Pre-Condition* is an expression over the agent's beliefs which must be satisfied before this plan can be executed. If it is not satisfied, this plan cannot be instantiated. In systems like JACK, pre-conditions are represented as *context conditions*. The *Effects* denote the changes to the agent's belief set that will occur if the plan is executed successfully.

The *Plan Body* consists of sub-goals and actions, which can be combined by either sequencing them (denoted by ;), or by executing them in parallel (denoted by ‖). Sub-goals are treated like top-level goals. Actions can be any arbitrary code specified by the user.
An example of a plan is as follows:

Type *RefuelRoverPlan*
Pre-Condition $FuelLevel \geq 50$
Plan Body {*FindRefuelPoint ; MoveToRefuelPoint ; Refuel*}
Effects {*Update(FuelLevel,100)*}

Achievement goals are states of the world that the agent works toward establishing. We follow the definition of [15] and represent them as follows.
⟨*Type, Success Condition, Failure Condition, Plans*⟩
Type is an alphanumeric string that uniquely identifies a goal. *Success Conditions* are the desired outcomes of the goal and when true indicates the goal has been successfully achieved. The *Failure Condition* when true indicates the goal cannot be achieved by the agent by any means possible, and hence the agent should no longer pursue it.

The *Plans* attribute is a set of plan names which achieves the success condition. When an instance of an achievement goal is created, the agent selects a plan from this set and if its pre-condition is satisfied, begins executing it. If the plan fails, then another plan from the plan set is selected and tried. If no applicable plan exists, the goal is dropped. This mechanism is typical of BDI agent systems.
An example of an achievement goal is:

Type: GatherSoilSample
Success Condition: $ObtainedSoilSamples = true$
Failure Condition: $GripperBroken = true || RoverImmobile = true$
Plans: $\{GatherSoilAtXPlan, GatherSoilAtYPlan\}$

This example describes a goal whose purpose is to obtain a soil sample, and it has two options in terms of the location which has soil (X and Y), hence two plans. If either plan succeeds, the rover will have obtained said sample, and the agent's belief of $ObtainedSoilSample == true$ will be satisfied. The goal can (and should) be abandoned if the gripper, used to gather soil, is broken, or if the rover is incapable of moving.

As discussed earlier, our representation of maintenance goals needs to support both proactive reactive aspects.

Maintenance goals are tuples of the form
⟨*Type, Maintenance Condition, Failure Condition, Recovery Plans, Preventative Goal* ⟩.
The *Type* and *Failure Condition* is similar to that of an achievement goal indicating the type of the goal and the condition which when true makes the goal no longer applicable.

The condition (belief) the goal requires the agent to maintain is given by *Maintenance Condition*. If this condition becomes false, the agent selects an applicable plan (i.e., one whose pre-condition is currently true) from *Recovery Plans*, in order to re-establish the maintenance condition.

In contrast to purely reactive maintenance goals, if the agent determines that the maintenance condition is currently true, but is anticipated to become false in the future, it will select and execute an applicable goal from *Preventative Goal*. These goals are designed to ensure that the maintenance condition remains true.

An example of a maintenance goal follows, which aims to ensure that the rover has an adequate battery level, recharging if the level drops below a certain threshold.

Maintenance Condition: $BatteryLevel \geq 20\%$
Failure Condition: $ChargerBroken = True$
Recovery Plans: {*RechargeBatteryPlan*} (Move a robot to a charging station and allow it to recharge its battery)
Preventative Goal: {*RechargeBatteryGoal*}

A second example of a maintenance goal ensures the speed of the rover does not exceed a maximum operating speed.

Maintenance Condition: $Speed \leq 100km/hr$
Failure Condition: {}
Recovery Plans: {*ReduceSpeedPlan*} (Slow down vehicle)
Preventative Goal: {}

A third example of a maintenance goal originates from the domain of robot soccer. An agent controls the behaviour of a 'defender' robot player, whose role is currently to prevent a opposition 'forward' from obtaining the ball.

Maintenance Condition: $OpponentHasBall == false$
Failure Condition: {}
Recovery Plans: {*TackleOpponentPlan*}
Preventative Goal: {*BlockOpponentGoal*}

In such a case, the maintenance goal behaviour of the defender differs depending on who has control of the ball. If its opponent has the ball, the agent must 'recover' its maintenance goal of preventing this, and so must tackle the opponent to cause it to lose control of the ball. However, if the opponent does not have control of the ball, one approach is to block the opponent, by moving to a location between the opponent and the ball, ready to intercept a pass or prevent the attacker from moving to the ball. In this example, the behaviour of the agent is different depending on if the agent is recovering from or preventing maintenance goal failure.

In addition to the above attributes, at run-time plan and goal instances will further require an *instance name* which is a label that provides a unique handle to them.

4. REASONING ALGORITHMS

In the BDI theory [11], goals of an agent are required to be consistent. Thangarajah et al.[12, 13, 14] provide mechanisms for ensuring this property holds for achievement goals. We build on this work to incorporate maintenance goals into the set of goals an agent may pursue, and provide mechanisms that ensure that all goals (maintenance and achievement) that an agent pursues are consistent with each other.

We consider two aspects in which an agent's maintenance goal may conflict; conflicts due to resource limitations, and conflicts due to the effects that goals produce. Our aim is to ensure that maintenance goals remain consistent with other goals with respect to these aspects.

In BDI-like systems, a goal can be decomposed into plans (that achieve the goal) and sub-goals. Often, there are several ways in which a goal can be realised, represented by a number of different plans and sub-goals. When a plan fails, a new plan is selected and tried. It is only when there are no applicable plans left that the agent declares a goal has failed. This leads to a natural tree structure which is termed a *goal-plan* tree [14], which indicates the possible ways in which the top level goal can be established. Every goal or sub goal in the tree has at least one plan as a child, and each plan may have a number of sub-goals. The plan nodes of a goal can be viewed as an "OR" since only one of the plans need to succeed for the goal to succeed, and the sub goal nodes can be viewed as "AND" nodes as they all must succeed for the plan to succeed.

Since there are a number of paths that an agent may take to satisfy a goal, the agent cannot be certain as to the resources consumed and the effects that are produced as a result of a goal. In [12, 13, 14], the notion of summary information is used to capture at an abstract level the resource requirements and the effects of executing a goal.They do this by requiring that each plan and goal in a goal-plan tree have information pertaining to the effects that the plan brings about, as well as the resources that each plan requires[1].

They use the goal-plan tree structure and the notion of summary information [3] to provide detailed algorithms that derive the *necessary* (but not sufficient) and *possible* resources for a goal [14], as well as the *definite* and *potential* effects of a goal [13].

Necessary resources are the resources that are common to all possible paths in achieving the top level goal. *Possible resources* are the maximum set of resources that may be required for an agent to achieve its goal, given any path through the goal-plan tree. The possible resource takes plan failure into consideration, and is often an exaggeration, but provides a clear upper bound. The necessary resources are a subset of the possible resources, which indicates that all necessary resources are possible resources as well. We refer to the combination of necessary and possible resources as *resource summaries*.

The *definite effects* of a goal are the effects that are certain to come about no matter which path through the goal-plan tree the agent follows in achieving a goal. Note that this process ignores the possibility of a goal becoming satisfied by some external process. The *potential effects* of a goal are a set of all the effects that could potentially occur, given that any plan could be selected, and that plan may fail and another be selected and so on. We refer to the combination of definite and potential effects as *effect summaries*.

The summary information is initially derived at compile time and then later dynamically updated as the agent completes goals and plans (or if they fail). With respect to resources, they also distinguish between *consumable* and *reusable* resources which are resources that once used are no longer available and those that once used can be re-used again respectively. Their algorithms consider these resource types as the behaviour varies between them.

In our work, we will use these notions of *resource summaries* and *effect summaries*, to determine if a maintenance goal is in conflict with an achievement goal. We rely on the methods developed in [13, 14] to obtain this summary information, and also on the conflict detection mechanisms between achievement goals. We do not reproduce these algorithms here, but show how they are incorporated into our own algorithms ahead.

If we consider an agent that supports proactive maintenance goals, several factors are required beyond that found in most agent systems. As described in Section 3, we require that each plan be tagged with additional information describing the effects the plans bring about, as well as the resources they use. The success condition of achievement goals defines the effects of the goal.

We assume that each agent has set of currently active goals $\mathcal{G}$ which includes both the set of maintenance goals ($\mathcal{G}_m$) and the set of achievement goals ($\mathcal{G}_a$) (i.e. $\mathcal{G} = \mathcal{G}_m \cup \mathcal{G}_a$). The list of goals which are waiting for another goal/plan to complete before it can be pursued, are stored in a *Suspended Goals (SG)* set, where each entry is the suspended goal and the list of goals/plans that it is waiting on. Finally, the agent requires a resource table to determine the current resources available for its goals. We call this resource table $\mathcal{R}$, containing tuples which are name, value pairs describing the current availability of its resources.

Goals are added to the agent system one at a time[2]. Of course once the goals have been added, when possible, the agent will execute goals in parallel. Section 4.1 looks at the mechanisms for ensuring that the goals are consistent when a new achievement goal is added to the system and section 4.2 investigates the addition of a new maintenance goal.

4.1 Adding Achievement Goals
