Before an agent can pursue a new achievement goal, G_a, it must determine if it can be executed without causing any of the agent's other goals to fail. Four elements must be checked to ensure that this is the case – an agent must determine if a conflict can occur over (a) the effects the goal can cause, and (b) the resources that a goal requires. In each of these cases, the agent must check if conflicts arise between the new goal and existing achievement goals as well as existing maintenance goals.

The agent's first step is to determine the effects of G_a. This can be done using the algorithms developed in [13]. This algorithm results in the identification of two sets of effects – the *definite* effects(DE) of a goal, and the *potential*

[1]Note that the resources and effects that are the result of child-nodes are not included at the parent level.

[2]A goal set maybe given to an agent but it processes them one after the other.

effects(PE) of a goal. Using the algorithms in [13] this information can be used to determine if a conflict can arise between G_a and any achievement goals in $\mathcal{G}_a$. We then provide an algorithm to check for conflict between G_a and the set of maintenance goals $\mathcal{G}_m$.

G_a must be checked for consistency with every maintenance goal in $\mathcal{G}_m$. This requires the identification of the definite and potential effects of G_a. The effects of G_a are combined with the effects of $\mathcal{G}_a$, producing the set of definite and potential effects for the agent's current goals, and the new achievement goal. This set is represented as $< DE_A\prime, PE_A\prime >$. A maintenance goal is consistent if the definite and potential effects that the goal brings about, does not cause the maintenance condition of the maintenance goal to fail. A maintenance goal is inconsistent with the achievement goal if the definite effects alone cause the maintenance condition to fail. In situations where the definite effects do not cause the maintenance condition to fail, but some potential effects do cause failure, the agent is uncertain if the addition of G_a will cause the maintenance goal to become inconsistent.

function *check-effect-consistency* ($\mathcal{G}_m$, $< DE_A\prime, PE_A\prime >$)
```
    number of maintenance goals := 0
    number of maintenance goals satisfied := 0
    number of maintenance goals unsatisfied := 0
    for each maintenance goal mg in G_m
        mc := mg.maintenance condition
        if mc is consistent with DE_A' + PE_A' then
            number of maintenance goals satisfied ++
        if mc is ¬ consistent with DE_A' then
            number of maintenance goals unsatisfied ++
        number of maintenance goals ++
    if number-of-maintenance-goals-satisfied ==
        number-of-maintenance-goals then
        // all maintenance goals are definitely consistent
        return consistent
    else if number of maintenance goals unsatisfied > 0 then
        // some or all maintenance goals are not consistent
        return inconsistent
    else
        return uncertain
```

Goals can also conflict over the resources they require to execute successfully. The work in [12] provides a mechanism for determining the *necessary* (N) and *possible* (P) resource requirements of a goal. The necessary and possible resources of G_a (which is a tuple, $< N_a, P_a >$), are combined with the necessary and possible resources of all achievement goals in $\mathcal{G}_a$ ($< N, P >$), producing $< N_a\prime, P_a\prime >$ which describes the minimum and maximum resource needs if G_a is added to the goal set.

The agent must now determine if the maintenance goals in $\mathcal{G}_m$ are consistent with $< N_a\prime, P_a\prime >$ and the current set of available resources, $\mathcal{R}$. The achievement of all the goals in $\mathcal{G}_a$ will lead the reduction of $\mathcal{R}$ by *at least* $N_a\prime$, but *no more* than $P_a\prime$. These represent the upper and lower bounds to the resources consumed by the set of goals. It is rational for an agent to ensure that its maintenance goals will still hold after the achievement of its goals, i.e. after $\mathcal{R}$ has been reduced by at least $N_a\prime$, but no more than $P_a\prime$, the maintenance conditions in $\mathcal{G}_m$ still hold.

If a maintenance condition holds after $\mathcal{R}$ is reduced by $P_a\prime$, this indicates that the maintenance condition will still hold no matter which method of achieving the goals is selected by the agent. If the maintenance condition does not hold after $\mathcal{R}$ is reduced by $N_a\prime$, this indicates that the maintenance condition cannot be satisfied, no matter which method of achieving the goals are selected, i.e. the maintenance goal is inconsistent with $\mathcal{G}_a\prime$. A third alternative occurs when neither of the first two cases are met – this identifies a case where $\mathcal{R}$ is insufficient to ensure that $\mathcal{G}_m$ remains consistent after achieving all goals in $\mathcal{G}_a$, yet there are sufficient resources such that the goals may be achieved with the maintenance condition valid. All maintenance goals are required to be checked for consistency in this manner, and the results are aggregated in the following function. A set of maintenance goals that are inconsistent are also produced as a result of this function.

function *check-resource-consistency* ($\mathcal{G}_m$, $< N_A\prime, P_A\prime >$, R)
```
    number of maintenance goals := 0
    number of maintenance goals satisfied := 0
    number of maintenance goals unsatisfied := 0
    CFG := ⟨⟩
    for each maintenance goal mg in G_m
        mc := mg.maintenance condition
        if mc is consistent with R − P_A'
            number of maintenance goals satisfied ++
        if mc is ¬ consistent with R − N_A'
            number of maintenance goals unsatisfied ++
            CFG := ⟨ CFG ∪ mg ⟩
        number of maintenance goals ++
    if number-of-maintenance-goals-satisfied ==
        number-of-maintenance-goals then
        // all maintenance goals are definitely consistent
        return consistent
    else if number of maintenance goals unsatisfied > 0 then
        // some or all maintenance goals are not consistent
        return ⟨ in-consistent, CFG ⟩
    else
        return unknown
```

There are three possible outcomes of checking for consistency using the methods described above:

Case 1 *Consistent with all maintenance goals*

In the case that if after adding G_a
(a) the maximum possible resource requirements ($P_a\prime$) are consistent with the current maintenance goals; and
(b) the potential effects of all goals ($PE_a\prime$) are also consistent with the current maintenance goals,
then it is *safe* to add G_a as a goal to the system.

Case 2 *Not consistent with some or all maintenance goals*

In the case where after adding G_a if either
(a) the necessary resource requirements ($N_a\prime$); or
(b) the definite effects ($DE_a\prime$)
of the new goal set is not consistent with one or more maintenance goals then there will be a definite conflict if G_a is added to the system. To prevent this conflict, we can use the *preventative goal* associated with each maintenance goal as follows:
(1) For each maintenance goal G_m that is in conflict with G_a add the preventative goal of G_m to the system.
(2) Add the goal G_a to the suspended goals list with entry (G_a, {PG_1, ..., PG_i}) where PG_1, ..., PG_i are the preventative goals added in the previous step.

This method would then allow G_a to begin execution only after all the necessary preventative measures are taken.

In the case where there is no preventative goal prescribed for a conflicting maintenance goal then G_a has to wait until that maintenance goal is no longer in the system. We assume that maintenance goals take priority over achievement goals. Naturally, we could enforce any reasonable scheme for resolving such conflicts..

Case 3 *It is uncertain if there will be a conflict*

The *uncertain* case occurs when either:
(a) the resource requirements to be maintained are greater than the necessary resource requirements and less than the possible resource requirements; or
(b) the definite effects of the goal do not violate any maintenance condition but the potential effects do.

In this case we cannot determine for certain if there will be a conflict or not as it depends on the path chosen by the agent to achieve its goals.

In such situations it would appear rational for the agent to pursue G_a without performing additional actions, as there is a possibility that the appropriate path is chosen such that no conflicts occur. However, it may also be rational for an agent to execute some preventative goals that may make (more) certain that the agent's goals will be achieved successfully.

In [13], a process of *dynamic updates* was used to update the resource summaries of goal as the agent committed to certain plans (and sub-goals) at run-time. A more sensible approach for an agent would be to execute G_a when it is uncertain but monitor for situations, by dynamically updating the summary information and checking for inconsistencies, when the status changes to either definitely conflicting (case 2) or safe (case 1) and act accordingly.

There may be times, however, when the agent does not (or cannot) anticipate the future violation of its maintenance goals due to its pursuit of its achievement goals, and in these cases, the maintenance goals could be unsatisfied. The reactive nature of maintenance goals are still supported by our system. Hence, in such cases where the maintenance goal of the agent is spontaneously violated, the agent will trigger its recovery goal, which has the goal of re-establishing the maintenance condition of the goal.

We make a note here that preventative goals will most likely not be used in the case when an achievement goal conflicts with maintenance goals due to the effects that it brings about, rather than its resources. While our framework supports such a mechanism, we could not identify any cases where a preventative goal would be of use in avoiding conflicts over effects.

4.2 Adding Maintenance Goals

In the previous section, we have shown how achievement goals can be added whilst maintaining consistency between existing goals. We now look at the process of adding a maintenance goal to an agent system such that it is consistent with all other goals that the agent is pursuing. Maintenance goals present several challenges that separate them from the addition of achievement goals, as they do not achieve any effects per se but require conditions to be maintained.

The first step in adding a new maintenance goal G_m is to determine if it is consistent with the set of existing maintenance goals $\mathcal{G}_m$. This is done by simply checking the maintenance condition of each maintenance goal in $\mathcal{G}_m$ against the maintenance condition of G_m. If G_m conflicts with any other maintenance goals, then it is not added to the system. If the application demands it, G_m may be placed in the suspended goals list, waiting on the conflicting goals.

If G_m is consistent with $\mathcal{G}_m$ then the next step is to check if it is consistent with the current set of achievement goals $\mathcal{G}_a$. This is done by combining G_m with $\mathcal{G}_m$ and check that no achievements goal will violate the new set of maintenance goals, using the methods described in the previous section.

If there is no conflict then G_m is added to the system. In cases where adding G_m causes conflict, we prevent G_m from being added to the system, as it is difficult to determine the correct subset of achievement goals that are compatible with the set of maintenance goals. There may be a subset of achievement goals from the agent's current goal set that is consistent with the agent's maintenance goals (and current resources), but identifying such a subset can be difficult. It may be feasible, however, if there is a goal preferencing mechanism in place.

In these algorithms, we have assumed that the goal that is being added to the system is preferred less than the existing goals – that is, the agent does not drop goals that it is currently pursuing if a new conflicting goal is added. Further work is required in this area, and in the area of selecting between goals. itemize

5. EXPERIMENTAL EVALUATION

We have performed some preliminary experiments to quantify the benefits of proactive maintenance goals. X-JACK is an extension to JACK Intelligent Agents[3] developed in [14, 13] for evaluating their work. We further extend X-JACK to incorporate reactive and proactive maintenance goals and the algorithms developed in this work.

Our experimental test bed is that of a Mars rover capable of moving about a 2 dimensional environment, consuming energy from its battery as it moves. For simplicity, we assume that each unit of distance drains the battery by 1 unit and that there is a refuelling depot located in the middle of this environment.

A *goal* within the system is a particular location that the agent must visit. To test our system we created a number of goals with randomly generated locations. The agent was then given goals varying from a set of 10 to 100 for simulating an agent's typical workload. Each set was run a 20 times and the results mentioned below are the average of these runs.

Our experiments were conducted in 3 cases as follows:

- No maintenance goal (NMG) - In the first case, we assume that the rover's movements did not consume battery power, therefore, the rover had no need to recharge. This allows us to determine a baseline in our experiments.

- Reactive maintenance goal (RMG) - The second case involves a rover with a maintenance goal that is *reactive* to ensure that there is always enough charge in the battery to be able to reach the recharging station. Therefore, as the rover moves about, it will periodically compare its current distance from the recharge station with the amount of charge remaining in its battery. If there is not enough charge to continue, the rover must first head to the recharge station and recharge, prior to pursuing any other goal.

- Proactive maintenance goal (PMG) - The third case is when the rover has the same maintenance goal as case 2, but it is *proactive* in this case. This requires the

agent, when commencing a new goal, to anticipate its resource usage in achieving that goal. If the resources consumed in achieving this goal violate the agent's proactive maintenance goal, a preventative goal will be activated. The agent determines how much battery power will be left after achieving this goal, and if it is an insufficient amount, the recharge goal is executed first. In our experiment, to simulate the possible inaccuracies with estimating resource usage, the rover is able to estimate its resource usage to an accuracy of 10%.

The total time taken for the set of goals to complete in all 3 cases are shown in table 1. As expected, the case where the rover never needs to refuel (NMG) is the fastest. Note that there is little difference here between the reactive and proactive maintenance goals. In some instances the proactice maintenance is actually faster, due to less distance being travelled. As shown in Table 2, the total distance travelled by the rover in each of the cases is less for proactive maintenance than for reactive maintenance.

Tables 3 and 4 provides a breakdown of the rover's movements for the reactive and proactive cases respectively. They show the distance the rover spent successfully pursuing a goal (*total distance*), the distance the rover spent to refuel (*backtrack*), and the distance the rover spent trying to accomplish a goal that failed due to insufficient fuel (*waste*). The *excess* column is the sum of the waste and backtrack distance. Where this value is small indicates that the rover did not spend many resources on movement that was not directly attributable to achieving one of its goals. Therefore, smaller values are better. The comparison of the excess column shows that the excess amount for the proactive case is always less than that for the reactive case. This is because the proactive maintenance goal avoids consuming resources for goals that it can anticipate will fail. The reactive maintenance goal can only determine that the goal will fail once it has already consumed some resources in trying to achieve it.

Goals	Total Distance	Waste	Backtrack	Excess
10	439	120	69	189
20	946	282	151	433

Table 3: Distance breakdown for Reactive Maintenance Goals

Goals	Total Distance	Waste	Backtrack	Excess
10	341	0	91	91
20	797	0	259	259
30	1034	0	280	280
40	1587	43	524	567
50	1812	92	510	602
60	2112	127	546	673
70	2350	48	685	733
80	3086	158	887	1045
90	3717	93	1181	1274
100	3925	140	1075	1215

Table 4: Distance breakdown for Proactive Maintenance Goals

If we compare the waste and backtrack values for the reactive and proactive cases, it is observed that often the reactive case has less backtrack than the proactive. This is because in the reactive case, some movement that becomes waste actually brings the rover closer to the refuelling point – hence, reducing the backtrack distance.

We also note that the value of waste for the proactive case is often much less than that for the reactive, because the objective of the proactive maintenance goal is to eliminate waste, by anticipating the failure of its maintenance condition at an earlier point than the reactive goal. For the first goal sets (10,20,30) for the proactive case, this works perfectly. However, some waste still occurs as the number of goals increases. This is because the estimation of resource usage was not 100% accurate. Our results show that even with inaccurate estimation, proactive maintenance goals can offer a reduction in resource consumed.

When resource estimation is perfectly accurate, there would be no waste at all for proactive maintenance, as it will never attempt to achieve a goal unless it is certain that it will be successful. In other words, the only way that waste gets introduced in the proactive case is by the inaccurate estimate of resources.

6. DISCUSSION AND FUTURE WORK

We have seen how the use of proactive maintenance goals can improve the rational behaviour of BDI agent systems. In particular, the ability to anticipate the failure of maintenance goals (rather than merely reacting to their failure) can result in some significant improvements in the decision-making ability of the agent. We see this as the first step towards providing a richer variety of goal types for agent systems, resulting in greater rationality for the agents concerned.

By utilizing existing techniques for reasoning about achievement goals, we are able to smoothly integrate proactive versions of maintenance goals, together with reactive maintenance goals and achievement goals. This provides a richer programming environment which can be readily developed as a plug-in for existing systems such as Jadex.

A line of further work that we intend to pursue is that of passive maintenance goals. A reactive maintenance goal leads to action only when the goal is violated. As we have seen, proactive maintenance goals may also lead to action in anticipation of violation. A passive maintenance goal is one that does not lead to actions per se, but is one that is never allowed to be violated. Such goals act purely as constraints on other actions; for example, if the Mars rover is currently travelling at its maximum speed and there is a passive maintenance goal to this effect, then there is no point in considering any action which will increase the rover's speed.

An extension of this idea is to prioritise maintenance goals, possibly via their urgency. For example, a maintenance goal of keeping the temperature of a gas tank below 100° will becoming increasingly urgent as the temperature climbs above 90°. This kind of rational behaviour is particularly important for safety-critical systems.

The relationship between achievement goals and maintenance goals also raises some questions, such as under what circumstances an achievement goal can trigger a maintenance goal. For example, the Mars rover may have to arrive at a particular location with at least 50% batter power (to perform a particular experiment), and doing so will require it to travel at a lower maximum speed than normal.

A further direction is to explore the ways in which violation of maintenance goals can be predicted. When the goals are about resources, it is inevitable that they will be exhausted; the key issue is to determine the optimal point of replenishement and to see how this can be specified by proactive maintenance goals. Clearly the system's ability to utilize maintenance goals is a direct function of its predictive power.

ABSTRACT

In this paper we describe the initial results of an investigation into the relationship between Markov Decision Processes (MDPs) and Belief-Desire-Intention (BDI) architectures. While these approaches look rather different, and have at times been seen as alternatives, we show that they can be related to one another quite easily. In particular, we show how to map intentions in the BDI architecture to policies in an MDP and vice-versa. In both cases, we derive both theoretical and related algorithmic mappings. While the mappings that we obtain are of theoretical rather than practical value, we describe how they can be extended to provide mappings that are useful in practice.

1. INTRODUCTION

Markov decision processes (MDPs) can be regarded as an ideal approach to the implementation of intelligent agents provided that one can either assign utilities to states and probabilities to transitions between states, or that it is feasible to learn such values. Once these values are known, algorithms such as value iteration [10] will yield an MEU-optimal *policy*, that is a mapping from every state into the best action to execute in that state. Such a policy is a complete specification of what the agent should do in *every* state, based on the probable outcomes of *every* action possible in that state.

However, the very nature of these algorithms, and in particular the need to establish the outcome of every possible action in every state, means that finding policies is intractable in many practical cases. This has led to the search for approximate solutions to MDPs [1], but even state of the art approaches like those in [8] are not able to handle particularly large or complex problems.

A contrasting approach to building agents is the use of the BDI architecture [3, 12, 23]. Agents constructed in this way have a set of *belief*s about the state of the world and a set of *desire*s which, broadly speaking, identify those states of the world that the agent has as goals. From its beliefs and desires, and via a process of *deliberation*, and agent formulates one or more *intention*s. The precise semantics of an intention vary across the literature, but intentions can be broadly considered to be states that the agent has committed to bringing about. The agent then constructs a plan to achieve its intentions, typically through some form of *means-ends reasoning*, and executes it.

This is a heuristic approach, and naturally enough agents built using it are outperformed by the those programmed using MDPs when the full MDP solution is tractable [19]. However, the BDI model can scale to handle problems that are beyond the scope of a full MDP solution, and can outperform approximate MDP models [19] for some relatively small problems (such as a simplified Tileworld [9]).

Given this trade-off, we are interested in the formal relationship between the two approaches, and that is our subject in this paper. In particular we investigate the following questions:

1. Given a policy that is a solution to an MDP, how can we extract a BDI description that can be used to approximate the solution to the MDP?
2. Given a complete BDI description, how can we obtain a *policy* that an MDP-based agent can use to control its actions?

We start by briefly summarizing how actions, states, and transition functions for BDI and MDP descriptions can be related. Drawn from [16] this summary considers the formal descriptions provided by the BDI and MDP frameworks. Both descriptions consists of a state space S, a set of actions A, and a a state transition function T which depends on the current state and the action performed. In addition, an MDP description includes:

- a reward function R,
- a probability distribution P over the set of states, and
- a set of policies Π, each member of which identifies the best action to take in each state.

We will denote an MDP description as a tuple

$$\langle S, A, T, R, P, \Pi \rangle$$

An agent that uses an MDP description to decide how to act will be called an MDP agent.

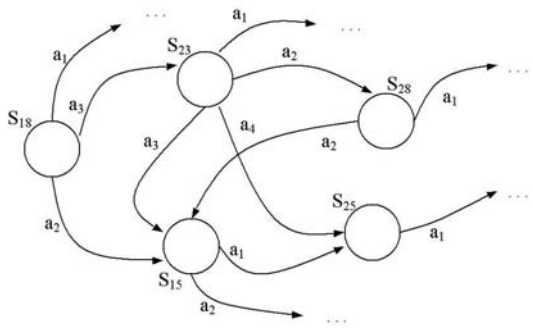

Figure 1: Part of a state-space

A BDI description consists, in addition to the state space, actions, and transition function, of:

- A set current beliefs B, desires D, and intentions I;
- a deliberation component Del; and
- a means-ends reasoning component M

We will denote a BDI description as a tuple:

$$\langle S, A, T, B, D, I, Del, M \rangle$$

An agent that uses a BDI description to decide how to act will be called a BDI agent.

For a given agent in a given environment, it is clear that the S, A and T will be the same for both the BDI and MDP descriptions. Furthermore, we will consider that P, the probability distribution in the MDP description and B in the BDI description do exactly the same thing — they identify which state in S the agent is currently in. While we deal with fully observable worlds, we can imagine both pick a single state (and we will revisit this when we talk about partially observable worlds).

With these equivalences in place, we can see that answering the two questions posed above comes down to relating rewards and policies, on the one hand, to desires, deliberation, means ends reasoning and intentions on the other hand. In fact, since rewards are merely a means of determining policies, and desires a step on the way to determine intentions, these components can be effectively ignored. Indeed, the relation we have to consider in detail is that between policies and intentions.

2. INTENTIONS, PLANS AND POLICIES

As mentioned above, the precise semantics for an intention varies across the literature. An intention is often taken to be "the agent's current focus", that a state that the agents is committed to bring about (for example by [23]). An intention can also be taken (as in PRS [5]), to be a linear plan that an agent has adopted to reach a state that the agent is committed to bring about. Here we will use the term *intention* to denote a state that an agent has committed to bring about, and use the term *intention-plan* (i-plan) to denote a sequence of actions built to reach a specific state, or, in other words, to achieve a specific intention. Since the precise sequence of actions selected will vary depending on what state the agent was in when it deliberated, an i-plan will depend on both state and intention — an agent will, in general, create different i-plans to achieve the same intention from different states, and will, in general, create different i-plans to achieve different intentions from the same state.

The reason that we are interested in i-plans is that they are key in the development of BDI agents. In practical implementations like PRS, once an agent has adopted an intention, it rifles through a pre-compiled set of plans (confusingly also called intentions, and hence i-plans in our terminology) to determine how to achieve the intention it has adopted. Building an efficient BDI system hinges on having a good plan library, and such a library will contain a set of i-plans tailored for the environment in which an agent operates. Thus, in order to answer our motivating questions, we need to relate i-plans to policies. We are interested in both establishing i-plans by solving MDPs, and using a set of i-plans to solve MDPs (hence the two questions we posed in the previous section).

We will adopt the following notation. An i-plan will be denoted by a lowercase Greek letter such as ψ, indexed $\psi^{i,s}$, where necessary, to denote the state s and intention i it relates to. I-plans are sequences of actions and ψ_i denotes the i-th action in ψ, while s_i^ψ denotes the i-th state that the agent plans to visit while executing ψ. Thus, for an i-plan ψ of length p, the agent starts at state s_0^ψ and plans on subsequently visiting states $s_1^\psi, s_2^\psi, ...s_p^\psi$. Of course, the agent may deviate from this sequence of states thanks to nondeterministic actions or changes in the environment. For example, in the case of the state-space in Figure 1, an agent in s_{18} might adopt an i-plan $\psi^{s_{18}}$:

$$s_{18} \xrightarrow{a_3} s_{23} \xrightarrow{a_4} s_{25} \xrightarrow{a_1} s_{79}$$

but find that executing a_4 in s_{23} takes it to s_{28}, where executing a_1 will take it back to s_{18} rather than on to s_{79}.

When such a deviation occurs, then execution of an i-plan will not have exactly its desired effect, though it may still help to bring the agent towards its goal. When the agent realizes that a deviation from the sequence of states laid down in the i-plan has occurred, then it needs to decide if it needs a new intention (which would typically require a new i-plan). This process of *intention reconsideration* [14, 15, 24] identifies whether or not the agent should keep its current intention, or whether it should deliberate to determine a new intention. Clearly if a new intention is adopted, the agent will need to create a new i-plan, and it may need a new i-plan even if it doesn't change intention.

Deliberation, reconsideration and the generation of i-plans can be done decision theoretically. Such approaches to intention reconsideration are explored in [17, 18]. The expected utility of an i-plan can be obtained exactly as one obtains the expected utility of a policy when solving MDP models — by establishing the expected value of executing each action in the state in which it is executed. The difference, however, is that in evaluating an i-plan in this way we only consider a single trajectory through the state-space rather than, as for policy evaluation, consider executing an action in *every* state. Typically, though, this is not the way that deliberation is done. Indeed, the BDI model was developed largely because it was felt [3] that decision-theoretic approaches were intractable (though see [11] for an example of a decision-theoretic approach to deliberation).

Whether reconsideration and deliberation are carried out decision theoretically or not, a BDI agent will have the same approach to traversing a state-space such as that in Figure 1. It will select an intention, identify an i-plan to achieve that intention, and execute that i-plan until it either it realizes that the current i-plan will no longer achieve its intention or until it realizes that the current intention is no longer achievable (or no longer the best possible intention). At such a point the agent will generate a new i-plan, or choose a new intention and generate an i-plan to achieve it, and the process will repeat.

We can contrast this process to that of an MDP agent in the same

state-space, which will always know, from its policy, what is the best action to take. The policy cannot fail to provide a suitable action — it is a universal plan [13] — and will eventually take an agent to its goal. The price paid by the MDP agent is that it has to compute the policy to begin with, a computation that is expensive compared with establishing a simple linear plan. The price paid by the BDI agent is that it has to compute what to do online (while the MDP agent can compute what to do offline) and has to suffer the sub-optimality of likely deviation from its chosen path through the state-space (though the loss of utility can be reduced by effective approaches to intention consideration [18]).

Now, despite the differences between the BDI and MDP models, we can establish a broad equivalence between them by considering how they work on the same state-space. Informally this can be done as follows. Given a policy, we have an action selection for every state, and so can establish one or more i-plans that summaries trajectories through the state-space from a given state to the goal. Thus such a policy incorporates a set of i-plans. Conversely, consider a set of i-plans, each of which captures a trajectory through a set of states. This set of i-plans identifies what action to take in all the states on the trajectory, and if one adds to that the null action for all states not on a trajectory, then one has a policy (albeit not a very good one).

The main contribution of this paper is to make this informal relationship between policies and i-plans more precise. In particular, Section 4 describes how i-plans can be used to create policies, and Section 3 details how policies can be used to derive i-plans.

3. FROM POLICIES TO I-PLANS

Assume we have a policy π that is the solution to a fully specified MDP. For now we assume that π is optimal — the results we obtain depend on this assumption — but we will see that this assumption can be dropped. From any π, it is possible to extract utility values for states that will induce π, and these can be used to establish i-plans.

For the purposes of this section, we shall consider the policy π to be the result obtained by the convergence of an algorithm such as Q-learning [20, 22] which gives a value for every state/action pair. BDI agents can also map states and actions into values. These values can be computed by assigning a value to each i-plan. Let ψ be an i-plan of length p, and ψ_i the i-th action involved in ψ. One way of assigning a value to ψ is:

$$V(\psi) = \sum_{i=1}^{p} \frac{R(s_{i-1}^{\psi}, \psi_i)}{i}$$

where $V(\psi)$ is the value of i-plan ψ, s_o^{ψ} is the initial state of ψ, s_{i+1}^{ψ} is the state to which the agent *expects* to arrive after executing action ψ_i, and $R(s_{i-1}^{\psi}, \psi_i)$ is the reward received for taking action ψ_i in state s_{i-1}^{ψ}. Therefore, the value assigned to an i-plan is the sum of rewards that will be achieved if all of the actions have the desired effect; the division of the reward by i in the above formula captures time discounting — rewards gained early are more valuable than the ones gained in the future.

It is important to note that this is only one of many possible ways of assigning a value to an i-plan. In general, we only require that for an i-plan ψ, every action that is added to the plan has a non-negative cost[1], and that these values depend on the rewards of the states that the agent plans to visit. For example, for a simple environment, the reward function could be defined by:

$$R(s_{i-1}^{\psi}, \psi_i) = \begin{cases} 1 & \text{if } \psi_i \text{ leads directly to a goal} \\ 0 & \text{otherwise.} \end{cases}$$

and $R(s, a) = 0$ for every other state/action pair.

We will now formally define the concepts of *i-plan* and *i-plan length*, and what it means for an i-plan to *obey* a given policy.

DEFINITION 1. *A sequence of actions $\psi = \psi_0, \psi_1, ..., \psi_p$ is called an* i-plan *if the ψ_i's ($0 \leq i \leq p$) were selected with the objective of executing them in turn in order to reach a given goal.*

DEFINITION 2. *Given an i-plan $\psi = \psi_0, \psi_1, ..., \psi_p$, we say that p is the* length *of ψ.*

DEFINITION 3. *An i-plan ψ of length p* obeys *a policy π if, and only if, $\forall i, 1 \leq i \leq p$, $\pi(s_{i-1}^{\psi}) = \psi_i$, where s_i^{ψ} is the state to which the agent is planning on arriving after executing action ψ_{i-1}, and s_0^{ψ} is the initial state.*

Definition 3 simply states that an i-plan obeys a policy if, and only if, the actions prescribed by the i-plan are the same as those prescribed by the policy through the i-plan's intermediate states. Remember that we are assuming that i-plans are *linear* plans, that is no considerations are made for unexpected outcomes of actions (which is typical for BDI implementations).

The dual of the notion of obedience is the notion of conformance:

DEFINITION 4. *A policy π* conforms *to an i-plan ψ of length p if, and only if, $\forall i, 1 \leq i \leq p$, $\pi(s_{i-1}^{\psi}) = \psi_i$ where s_i^{ψ} is the state that results from executing action ψ_{i-1} in state s_{i-1}^{ψ}, and s_0^{ψ} is the state in which the first action is executed.*

Since an i-plan is indexed by the intention that it will achieve when executed, we can extend the notions of obedience and conformance to intentions. A policy π conforms to an intention i if for all i-plans $\psi^{i,s}$, π conforms to $\psi^{i,s}$, and an intention i obeys a policy π if all i-plans $\psi^{i,s}$ obey π.

With the concepts that we have now introduced, we can state the following claim:

CLAIM 1. *Given a* BDI *agent and an* MDP *agent with an optimal policy π, if the* BDI *agent is in state s_i, then the i-plan ψ with the highest utility value will be such that ψ obeys π, starting at s_i.*

The remainder of this section explores this claim.

In general, the claim will only hold if states with the same reward are considered in the same order by both MDP and BDI approaches. Otherwise, even though the utilities are equivalent, the actions might not be exactly the same because the order in which states with the same reward are considered can affect the selection of actions. The proof of the claim can be made with respect to progressively more complex scenarios.

Our initial result relating policies to intentions and i-plans is established for the deterministic, fully accessible case (in other words the simplest):

PROPOSITION 1. *Let $\langle S, A, T, R, P, \Pi \rangle$ be an* MDP *agent, and let $\pi \in \Pi$ be a policy that is optimal under the maximum expected utility criterion. Let $\langle S, A, T, B, D, I, Del, M \rangle$ be a* BDI *agent. Let Del always select the intention with the highest reward and M select the i-plan with the highest reward. If the environment is observable and deterministic, so $\forall s \in S, \forall a \in A, |T(s, a)| = 1$, then $\forall i \in I$, $\forall s \in S$, it holds that $\psi^{i,s}$ obeys π.*

[1] This restriction, basically the same restriction that is required of the path cost function to ensure the optimality of A* search, means that the agent can follow a value gradient to the goal state.

```
Intention policyToIplan(Policy π, MDP m){
    Iplan i;
    s = getCurrentState(m);
    g = getGoalState(s,π,m);
    p = obtainPath(s,g,m);
    while not empty(p) do {
       i.addAction(p);
       p.deleteAction();
    }
    return i;
}
```

Figure 2: Pseudocode for mapping policies into intentions

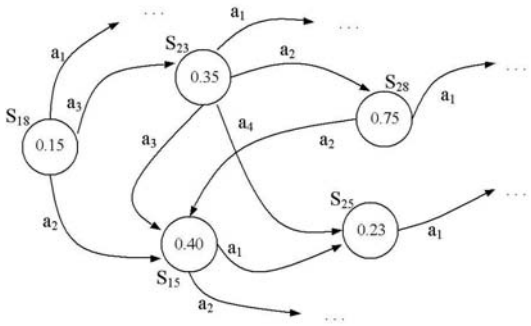

Figure 3: Part of the state space of an MDP

PROOF. *The result follows directly from the fact that we are assuming that D is optimal and that actions are completely deterministic in the environment. Because π is* MEU*-optimal, it will always select actions that take the agent to the best goal state in the best possible way. Because D picks the intention with the highest reward, and actions are deterministic, it will select the same intention/goal that π takes the agent to. Similarly since M picks the i-plan with the highest rewards it will pick an i-plan that traces the same path through the state space (from whichever state the agent is in) as π. Therefore, if we assume that states with equal rewards are considered in the same order by π and M, it is clear that the i-plans generated by M will obey π.* □

If actions are not deterministic, the utility of i-plans is not so clearly defined. Instead of a simple summation of rewards along the path of the plan, the *failure* of actions must be considered. Therefore, we must now assume that the deliberation and means-ends reasoning components are MEU-optimal as opposed to being able to pick the intention and i-plan (respectively) with the highest rewards.

PROPOSITION 2. *Let $\langle S, A, T, R, P, \Pi\rangle$ be an* MDP *agent, and let $\pi \in \Pi$ be a policy that is optimal under the maximum expected utility criterion. Let $\langle S, A, T, B, D, I, Del, M\rangle$ be a* BDI *agent where M and Del are* MEU*-optimal. If the environment is observable and non-deterministic, so $|T(s,a)| \geq 1$, then, then $\forall i \in I$ $\forall s \in S$, it holds that $\psi^{i,s}$ obeys π.*

PROOF. *Because we are now assuming that D is picking* MEU*-optimal intentions and that M is building* MEU*-optimal i-plans, the same argument as in Proposition 1 tell us that every i-plan will obey π even though actions are now non-deterministic.* □

This result also encapsulates the reason why the BDI approach struggles to generate optimal behavior. If we stick with the classic BDI model in which deliberation selects an intention and means-ends analysis then builds a plan to achieve it, in order to pick an optimal set of actions (which is what Proposition 2 is all about), the deliberation component has to be able to pick an intention that is MEU-optimal *before* means-ends analysis picks out a suitable i-plan (and thus before the agent has considered the cost and likelihood of achieving the intention it is selecting).

Now we turn to the case where the environment is not fully observable — in other words the agent doesn't know which state in S it is in, and must rely on its estimates of the current state of the environment [7]. MDP models (technically POMDP models under these conditions) handle this kind of situation by extending the notion of state. Rather than dealing (as we have until now) with a state that is some $s \in S$, the state space describing all the states of the environment, a state becomes a probability distribution across all the s. If we imagine enumerating all these possible distributions s'_i, then we can think of the policies and i-plans as being concerned with a new state space $S' = \cup_i s'_i$. If we call S' the *partially observable counterpart* to S and consider this new state space to be the space in which our BDI and MDP agents operate — so that both B and P identify some $s' \in S'$ as the current state that the agent is in — we can carry forward Proposition 2 as:

PROPOSITION 3. *Let $\langle S, A, T, R, P, \Pi\rangle$ be an* MDP *agent, and let $\pi \in \Pi$ be a policy that is optimal under the maximum expected utility criterion. Let $\langle S, A, T, B, D, I, Del, M\rangle$ be a a* BDI *agent where M and Del are* MEU*-optimal. If the environment is partially-observable, with S' the partially-observable counterpart of S, and non-deterministic, so that $|T(s,a)| \geq 1$, then $\forall i \in I$ $\forall s' \in S'$, it holds that $\psi^{i,s'}$ obeys π.*

PROOF. *This result generalizes the previous one because we are now considering a partially observable environment. However, because we have just expanded S into S' on both the* BDI *and* MDP *sides, the result follows directly from Proposition 2.* □

Thus it turns out that there is a simple formal correspondence between policies and i-plans, similar to the one informally discussed in Section 2. This correspondence holds under rather restrictive assumptions, in particular the optimality requirements, but ensures that the i-plans generated reflect an optimal policy. If we are willing to relax the requirement for a set of i-plans to correspond to an optimal policy, we can create i-plans under fewer restrictions.

Now, these formal results, though they tell us that we *can* extract i-plans that obey a policy don't tell us *how* we might do so. We consider how to do this next. We can obtain an i-plan from any policy in practice by means of a simple search through the state space, following policy π until a local maximum is reached — this state is then selected as the intention. In order to select a unique intention using this process, we assume that the agent's actions always have the most likely outcome; otherwise, a tree would result instead of a simple path. Figure 2 outlines an algorithm `policyToIplan` that can do this in a Java-like pseudocode.

By following policy π in this manner, we are able to obtain as many i-plans as desired: after reaching a intention state, simply continue following the policy from the state that results after achieving the previous intention. For example, in Figure 3 we illustrate this using a fragment of the same state space we considered before. Assume the agent is currently in state S_{18}, $\pi(S_{18}) = a_3$, and $\pi(S_{23}) = a_2$, and that state S_{28} is an intention for the agent. The i-plan that can be extracted in this situation is the linear plan $\langle a_3, a_2\rangle$. In this case, the i-plan that arises is obtained as the result of only one iteration of the process. The same is true in the case of the simplified TileWorld considered in [19], where agents only build plans for reaching one hole, not multiple hole tours.

The process that we have outlined here will construct a set of i-plans that obey an *arbitrary* policy. Such a policy will not necessarily be optimal, and so nothing can be inferred about the optimality or otherwise of the set of i-plans that are established, but the members of the set of i-plans will obey the policy.

With the procedure `policyToIplan`, and the fact that we can determine intentions from i-plans — intentions are, by definition, the states that i-plans lead to — we have answered the first of the questions that we set ourselves at the start of the paper.

4. FROM I-PLANS TO POLICIES

In this section, we will look to answer the second question. We consider how to use a set of i-plans to assign rewards to states in order to provide a policy for the underlying MDP that will mimic the behavior of an agent with the given i-plans. Such an approach makes it possible to use domain knowledge to solve problems that are intractable for existing MDP solution techniques (at the cost of providing sub-optimal solutions) — we use domain knowledge to construct i-plans and then use these i-plans to obtain a policy. Indeed, we can use intentions to construct i-plans and then i-plans to construct policies.

4.1 A single i-plan

We will start off by showing how rewards can be assigned in the state space in order to map *one* i-plan into a policy. Later on, we will see how the process is generalized to an arbitrary set of i-plans.

Assume the agent is currently in state s_a, and has adopted some i-plan ψ of length p. Then, we can assign a value to each state-action pair according to the following formula:

$$val(s^{\psi}_{i-1}, \psi_i) \stackrel{def}{=} i \cdot U(\psi)$$

$\forall i, 1 \leq i \leq p$, s^{ψ}_i is the i-th state involved in ψ, and ψ_i is the i-th action in ψ. In any other case, we have

$$val(s_j, a_k) \stackrel{def}{=} 0$$

$\forall s_j \neq s^{\psi}_i$, for any s^{ψ}_i such that $1 \leq i \leq p$, $\forall a_k$.

These values can be used induce a policy by selecting the action with the highest value given the current state. This process identifies a path through the state space assuming that nothing will go wrong. Such a policy only considers what to do in states that are involved in ψ, and therefore allows for no deviation from the path.

This mapping of states into values is then used as the reward function, which will clearly "mark the path" that the agent must follow in order to reach the goal, and executing the actions along this path will constitute a policy that conforms to the i-plan ψ and hence achieves the intention that ψ was constructed to achieve. In Figure 4, we show this assignment of values to states for the fragment of state space from Figure 3. The agent is initially in state S_{18}, and has formed the intention of reaching state S_{25} by executing actions a_2 and a_1. Therefore, if we assume that the intention has unit value, state S_{18} is given the value 1.0, S_{15} is given 2.0, and the goal is given 3.0; the rest of the states are assigned the value 0.

What we have so far is a mapping that turns an i-plan into its "equivalent" in terms of policies. That is, we have only obtained a correspondence from states to actions similar to the one described in Section 2, which doesn't consider what to do in cases in which the agent *drifts from the path* of its initial i-plan because of the failure of some action to reach the state that was planned for. To obtain a full policy — one that considers *every* possible state — we can extend the partial policy obtained from the i-plan using value iteration to establish a value for every state from the values that have been assigned to states that were part of the intention. The

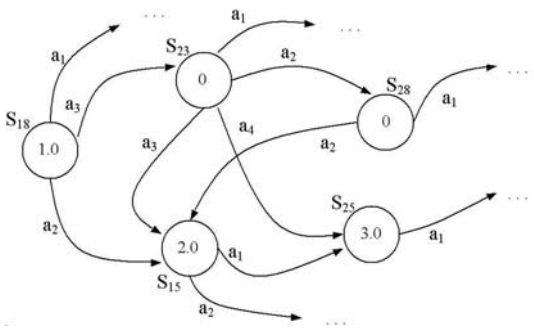

Figure 4: Part of a state space, with values assigned to the states leading to a goal.

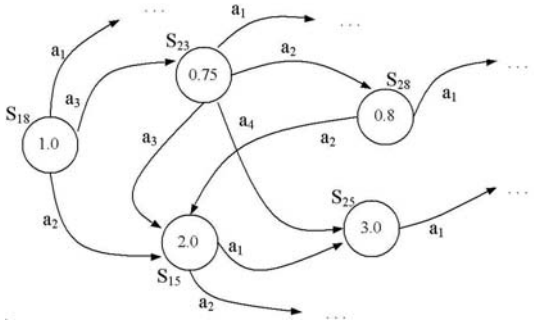

Figure 5: The state space from Figure 4, with values assigned to every state.

example in Figure 5 illustrates how doing this will assign the rest of the states an associated value, with value iteration working in exactly its normal fashion [10], assigning a state a value by suitably discounting the value of states to which it is connected by an action (with the discount determined by the expected cost of the action relating the two).

4.2 Sets of i-plans

So far we have only considered how to build a policy from a single i-plan. In order to use the same technique when an agent has more than one i-plan, only a minor change needs to be made. We must now take into account that the i-plan being considered is not necessarily the first. Therefore, we must keep count of the number of actions involved in the i-plans that have already been processed, which will be represented by the letter κ. When the process starts, we set $\kappa = 1$, indicating that the action to be considered is the first. The function val is now defined as:

$$val(s^{\psi}_{i-1}, \psi_i) \stackrel{def}{=} \kappa \cdot U(\psi)$$

$\forall i, 1 \leq i \leq p$, s_i is the i-th state involved in ψ, and ψ_i is the i-th action in ψ. After each action is considered, the value of κ is increased by 1. After all intentions have been processed, we have

$$val(s_j, a_k) \stackrel{def}{=} 0$$

$\forall s_j \neq s_i$, for any s_i involved in some i-plan, $\forall a_k$. Suppose, for example, that the agent has two i-plans ψ and φ, of lengths p and q, respectively. After processing ψ, κ will have the value $p + 1$ and, after processing φ, its value will be $p + q + 1$.

The process just described is captured by the algorithm `iplanToPolicy` outlined in the form of JAVA-like pseudocode in Fig-

```
Policy iplanToPolicy(IplanSet I, BDI A){
    MDP m; Policy π;
    ValueFunction val; int κ, j = 0;

    val.initialize(0); m.initialize(A);
    orderedIplan = I.obtainOrdering();
    for each i in orderedIplan do {
       j = 0;
       for each action a in i do {
          s = i.obtainInvolvedState(j++);
          val.setState(s,a) = κ*i.getUtil();
          κ++;
       }
    }
    π = valueIteration(m,val);
    return π;
}
```

Figure 6: Pseudocode for mapping i-plans into policies

ure 6. The following proposition formalizes the relationship between a set of i-plan and a policy as established by this algorithm:

PROPOSITION 4. *The algorithm* `iplanToPolicy` *obtains a policy which conforms to the given set of i-plans.*

PROOF. *The algorithm considers each i-plan in the set in turn, assigning a value to each state-action pair that is involved in the i-plan. The value that is assigned is the product of the current i-plan's utility and a monotonically increasing succession of integers. Therefore, each state-action pair will receive a monotonically increasing value with respect to the one before it. Up to this point we have an assignment of monotonically increasing values to the state-action pairs that the given set of intentions dictates, which allows us to obtain a straightforward policy using these values. If we feed the value iteration algorithm with these value assignments, the rest of the state-action pairs (not involved in the set of intentions) will receive values according to this assignment. The value iteration algorithm ensures us that the resulting policy will be* MEU *with respect to the input values.* □

`iplanToPolicy` generalizes the process described above for single i-plans, and to do so requires the i-plans to be ordered — the order in which the i-plans are processed. As we have seen above, i-plans can be assigned utilities in relation with how their execution will reward the agent by reaching certain goals, and this provides a suitable ordering.

Using `iplanToPolicy` to assign rewards to states, we can use value iteration as an *anytime* algorithm to construct a policy. With each iteration, more and more states will receive non-zero values, making the plan more universal. The example in Figure 7 shows how the policy evolves through three iterations of the algorithm on a specific state space.

Of course value iteration always works like this — with values backing-up across the state space from states with rewards — but it is not usually considered an anytime algorithm. That is because in early iterations most states have zero values, and so no useful policy can be extracted. However, in this case, an initial useful policy is provided by the values established by an i-plan. That policy can be used "as is". The worst that will happen is that whenever an agent strays off the "path" marked by states with non-zero values, it will try immediately to get "back on" that path by the shortest route rather than taking the optimal route that would be visible if all states had values. As more states have values filled in by value

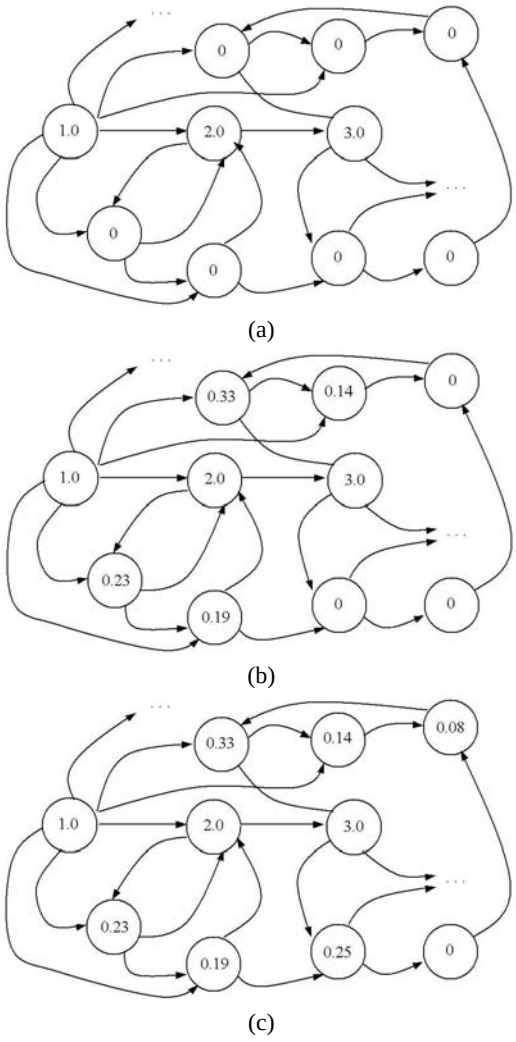

Figure 7: State values after the (a) first, (b) second, and (c) third iterations

iteration, the less likely this is to happen, and thus the better the policy that is computed.

4.3 Practical reasoning and policies

Up to now, we have only been considering the problem of how to map a single i-plan or a group of i-plans into a policy. Even though we have established a relationship between the most important components of the BDI and MDP models, the mapping is not yet complete because a policy obtained using the methods developed in the previous section corresponds to a "snapshot" of the BDI agent's state. If the agent switches intention (for example, due to reconsideration performed in order to profit from a change in the environment), the policy might no longer be valid.

It is possible to map the *complete* set of possible i-plans (all the i-plans for all its possible intentions) into a single policy by considering what intention, and hence what i-plans, the BDI agent would adopt in every possible state. If deliberation is performed in *every* state, followed by means-ends reasoning, a policy can be built by assigning actions to states corresponding to what the BDI planner dictates. It is clear that this process need not be initiated in every state in practice — if a state already has an action assigned to it

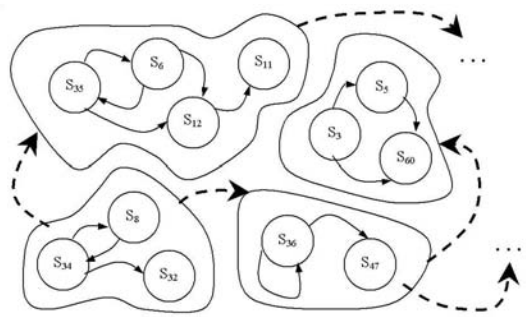

Figure 8: Grouping of states into "envelopes".

(because a previously built plan runs through it), then there is no sense in performing the same computations again.

The fact that we can do this, and that we can establish a set of i-plans from a set of intentions, gives us an answer to the second question we posed at the start of the paper.

It is interesting to point out that such a policy can be built in this way without considering rewards. Rewards played a fundamental role in previous sections because they were the basis for the construction of *contingencies* — once the main plans were laid, the actions performed in the rest of the states were based on these rewards. However, because we are now considering how the BDI agent behaves in every state, such an assignment of rewards is no longer necessary.

We should also point out that this mapping is initially of theoretical interest only, and its sole purpose is to show that a relationship exists between the universal behavior of a BDI agent and a policy for an MDP agent. The computational costs of constructing such a policy would be just as high as (or higher than) the actual process of solving the MDP directly.

5. TOWARDS HIERARCHICAL POLICIES

The analysis in the previous section established a relationship between BDI and MDP models based on the existence in the BDI agent's plan library of i-plans that lay out a precise sequence of actions that the agent has to carry out. It turns out that the i-plans that a BDI agent are typically equipped with aren't quite so detailed.

What happens in a typical BDI implementation is that the deliberation process decides *what* is to be achieved — what intention to adopt. Once a decision is made, the means-ends reasoning process then decides *how* this will be achieved — what i-plan will be used — picking from a set of relatively abstract i-plans and instantiating it to fit the specific situation. The result is to effectively groups states into "envelopes" which contain sets of states that are equivalent as far as the current intention of the agent is concerned but which might differ in detail. For example, considering Figure 8, imagine that each state represents an agent location. The agent is currently at s_{34} and needs to get to s_{60}, and its environment is split into a series of rooms that group states together — s_{34} with s_8 and s_{32}, all in the same room but at different locations within the room, say — and so on. Now the important thing as far as the agent is concerned, while navigating around, is which room it is in, so it can construct an i-plan at the "room level", figuring that it needs to get to the $\langle s_{36}, s_{47} \rangle$ room first, then to the $\langle s_3, s_5, s_{60} \rangle$ room.

The idea of this kind of state aggregation is not a novel one. In fact, much work has been dedicated to the grouping of states in MDPs and POMDPs, as can be seen in [2, 4, 6, 21], with the aim of improving the tractability of solving problems with ever larger state-spaces. However, it does tie in very neatly with the BDI model, and we can easily see that it will be possible to establish similar results to those we have obtained above, but where the correspondence is not between whole-environment policies and i-plans at the level of individual states, but between i-plans and policies at the state-aggregation level.

Now, being able to construct policies at the state-aggregation level is a useful thing to do. Open questions in work on state-aggregation are how to aggregate states, what level states should be aggregated at, and which states should be grouped with which states. The methods we have developed here potentially provide answers — i-plans identify what states to group together, and these can then be turned into high-level policies for a partial MDP solution that can then be refined, filling in policies that tell the agent how to act within grouped states (which is a smaller, and hence more tractable problem than determining a whole-world policy).

6. DISCUSSION

The BDI model was established at least in part [3] because it was felt that decision-theoretic models were too computationally intractable to use in practice. This has led to a perception that the two models are somehow cast in opposition with one another, that one adopts the BDI model only if one believes that decision theoretic models are somehow wrong or impractical, and that to use the BDI is to somehow settle for less than perfect performance (it is, after all, a heuristic approach). Our aim in this work is to steer a middle course.

We have previously shown [19] that on a particular task there are cases where using an MDP model provides the best solution, while in other cases an BDI approach works best — as the task grows in size beyond the range of problems that can be optimally solved using an MDP, the BDI approach outperforms the best one can do with an MDP. This suggests that some aspects of the BDI approach may be worth considering in more detail. Here we provide some of that detail.

The results from Section 3 show that the BDI model is not inherently sub-optimal. If we can, as the results there show we can in theory, construct a set of intentions that obey an optimal policy, then the BDI model will give us optimal performance. That it doesn't in practice, is because intentions are constructed not from optimal policies but from domain knowledge, and it is because of the mismatch of the two that sub-optimality creeps in.

The results in Section 3 don't help us in practice since there is no need to build intentions from an optimal policy — if we have an optimal policy we can just execute it directly. However, the results in section Section 4 can help us in practice. They show us how to construct policies from i-plans, and we can (as in [19]) create i-plans in situations where the state-space is so large that it isn't possible to generate anything like an optimal policy from first principles.

Finally, the discussion in Section 5 suggests that we can use the relationships we have developed to construct policies at a sufficiently abstract level that we can gain some computational advantage over directly solving an MDP. Of course, so far we have only demonstrated that it is possible to do this in theory. Some practical demonstration will be necessary to be completely convincing, and providing empirical results that do demonstrate this, using the same Tileworld testbed as we used in [19], is what we are currently working towards.

7. SUMMARY

In this paper, we have presented a series of relationships that exist between certain components of the BDI model and those of

MDPs. We have extended the work of [16] by exploring how *i-plans* on the BDI side and *policies* on the MDP side can be related to one another. To our knowledge, this is the first time that such a relationship has been proposed.

We have mapped from policies to i-plans by proving that the i-plans derived from an optimal policy are those adopted by a BDI agent which selects i-plans with the highest utility, and an optimal reconsideration strategy; furthermore, we presented a computational version of this mapping, by means of a search algorithm based on following the given policy through the state space. The other part of the mapping, obtaining policies from i-plans and thus intentions, was also characterized both theoretically and algorithmically. First, we established the mapping declaratively, by assigning rewards to states in such a way as to induce the selection of actions in the same way as they are selected by the intentions. This allows the derivation of a policy by means of any of the MDP solution algorithms. A simple algorithmic version of this mapping was also presented, indicating that one possible solution is a policy that simply follows the actions as dictated by the i-plan, and says nothing about the rest of the possible states. The use of value iteration as an anytime algorithm which refines and completes the policy with each i-plan was also proposed as an alternative way of deriving a policy.

This work constitutes the first steps in a line of research that aims to unify the two approaches. In the future we will test these findings empirically in pursue of the development of agent design methodologies that make use of the best of both the BDI and MDP models.

Agent and multi-agent architectures; Frameworks, infrastructures and environments for agent systems

1. INTRODUCTION AND MOTIVATION

BDI agent systems and languages such as PRS, JAM, JACK, 3APL, and AGENTSPEAK have been widely used in developing robust and flexible applications in dynamic domains. However, one criticism of these systems is that the modelling of how agent reasoning progresses is too reliant on the rather low level notion of individual *events*. In our own work in a number of application areas, we have consistently noticed a need for a more abstract concept, which we call a *situation*. Recognition by the agent that it is in a particular situation may affect the goals that it has, may place overarching constraints on how it operates, or may influence the way that it chooses to achieve its goals.

Work on "situation awareness" [1] also supports the position that aggregation of lower level perceptions into meaningful chunks allowing for understanding is a crucial part of intelligent agent systems. Work on "situation spaces" [2] collects together information about the environment into a set of meaningful high-level abstractions that provide the context for the agent's cognitive activity (in this case planning). Situation awareness has also more recently been proposed as a means of interpreting pro-active behaviour in agents [3].

While situations can in a sense be captured simply as a collection of beliefs, there is an advantage in introducing them as a conceptual entity which can be modelled declaratively.[1] Firstly, this allows for developing a semantics that directly captures the meaning of situations within the agent architecture (for example, we shall require that the reasoning about situations takes priority over all other agent reasoning.) Secondly, it allows for domain experts to more readily specify the characteristics of the situations particular to the domain. Thirdly, it can allow for general purpose infrastructure which supports the recognition of situations and the appropriate adjustment of agent attitudes.

As an initial step in capturing and reasoning about situations, we provide an operational semantics describing the agent's reasoning when it recognises that a particular situation exists, or ceases to exist. We do this within the context of the previously presented BDI agent language CAN (**C**onceptual **A**gent **N**otation) [4], which is similar in style to AGENTSPEAK, 3APL, and other BDI languages. The distinguishing feature of CAN is its goal construct and its account of failure handling typically found in implemented BDI systems, which provides goal persistence.

Although our initial work is assuming situations will be recognised by individual agents, the work is generalisable to multi-agent systems also.

2. SITUATION RULES

We define the rules for managing situations as an addition to the CAN language defined in [4]. As previously indicated, situations are (conceptually) at a coarser level of granularity than individual events, and the agent's reaction to a situation may involve changing its mental attitudes and focus of attention, rather than directly producing behaviour. Consequently, we introduce the notion of a *meta* program/plan (MP) whose objective is not to produce behaviour (directly), but to change such things as attitude, focus, understanding, and priorities of an agent. It is possible to conceive a range of things a meta plan could do, such as change the agent's goals; drop active intentions; change the plan library; start protecting certain conditions; or engage in specialised reasoning such as diagnosis or prediction. For the purpose of the current work, though, we shall restrict meta plans to add goals and to set and release system constraints.

In the CAN language, an *agent configuration* is a tuple $\langle \mathcal{N}, \Pi, \mathcal{B}, \mathcal{G}, \Gamma \rangle$ where $\mathcal{N}$ is the agent name, Π is a plan library, $\mathcal{B}$ is a belief base, $\mathcal{G}$ is a goal base, and Γ is the

[1] We note that plan types in the BDI plan library can also be modelled simply as beliefs, However, it is well accepted that there is both a computational and semantic advantage in modelling plans as special kinds of beliefs. We claim the same is true of situations.

set of current intentions. The belief base of an agent often contains ground belief atoms in the form of first-order relations. However, CAN makes no commitments about the form of the belief base; sophisticated logics and reasoning about action formalisms can be used to model more expressive belief bases. We simply require that well-defined operations exist to check whether a condition follows from a belief set ($\mathcal{B} \models \phi$), to add a belief b to a belief set ($\mathcal{B} \cup \{b\}$), and to delete a belief b from a belief set ($\mathcal{B} \setminus \{b\}$). Observe that, in order to capture interesting situations, a temporal formalism for beliefs is likely to be desirable. We will discuss this below when talking about the implementation.

Next, we introduce a *constraint* construct, $\mathsf{Constraint}(\alpha, P)$, with the intended meaning that no action is to be performed if it would make the agent not believe α. If at some point α does not hold, initially or due to some factor beyond the agent's control (e.g., other agent's actions), then plan P ought to be executed. Program P is intended to encode a recovery procedure to re-establish α. We denote the set of constraints in the system as $\mathcal{C}$.

In the CAN language, actions are primitives that always succeed. In order to reason about constraints we require this notion of actions to be extended, as we want to restrict an agent from performing any action that violates any system constraint. To that end, we assume that agents are equipped with a STRIPS-like *action description library* Λ containing rules of the form: $act : \psi_{act} \leftarrow \overset{-}{}_{act}; \overset{+}{}_{act}$, one for each action type in the domain, where ψ_{act} is the pre-condition of the action, and $\overset{+}{}_{act}$ and $\overset{-}{}_{act}$ are the add and delete lists of atoms, respectively. Figure 1 shows the derivation rules for actions. Note that rule *act* ensures that the agent only performs an action if the system constraints are not violated. If the action does violate a system constraint, then the action does not fail but is not allowed to execute. This means that the action in question would be re-considered later on. Hence, actions only *fail* if the pre-conditions are not met.

So, we next define a *meta plan* MP as follows:

$$MP ::= +\mathsf{Goal}(\phi_s, P, \phi_f) \mid +\mathsf{Constraint}(\alpha, P) \mid \\ -\mathsf{Constraint}(\alpha, P) \mid MP_1; MP_2 \mid true$$

where P is a CAN plan-body and MP_1, MP_2 are meta plans.

A *situation library* Π_{Sit} contains all the situations the agent knows of. Concretely, Π_{Sit} includes *situation tuples* of the form $\langle N, \phi_a, MP_a, \phi_e, MP_e \rangle$, where N is the name of the situation, ϕ_a and ϕ_e are *entry* and *exit conditions* respectively, and MP_a and MP_e are the meta plans that the agent executes on situation entry and exit.

We extend the notion of an agent configuration to be $\langle \mathcal{N}, \Pi, \Lambda, \Pi_{Sit}, \mathcal{B}, \mathcal{G}, \mathcal{C}, \mathcal{S}, \Gamma \rangle$, where Π_{Sit} is a situation library, $\mathcal{C}$ is the set of current system constraints, and $\mathcal{S}$ is the set of situations that the agent currently believes to be active. Each entry in $\mathcal{S}$ is the name of the situation and the object bindings that enabled the entry condition of the situation to be true. Figure 2 depicts the derivation rules for capturing when a particular situation becomes active and when a situation ends (Sit_{active} and Sit_{end}), as well as for handling meta-plans. Rule Sit_{active} states that for any situation $\langle N, \phi_a, MP_a, \phi_e, MP_e \rangle$, the situation becomes active when: (a) ϕ_a is true with the bindings ; and (b) the situation in question is not already active (that is, N is not already in $\mathcal{S}$.[2] When a new situation becomes active, then the agent: (a) creates an entry N in the active situations set; and (b) executes the steps of the meta plan MP_a with the corresponding bindings to ensure that the plan acts upon the same object instances that formed the situation.

The Sit_{end} rule states that for any situation that is currently active, if the exit condition is true, then the agent: (a) removes the relevant entry from the active situations set; and (b) executes the exit meta plan with the object bindings that enabled the exit condition to hold. We shall require that the Sit_{active} and Sit_{end} rules take precedence over all other rules of the agent, i.e., they must be applied whenever applicable in every BDI execution cycle.

3. REPRESENTING AND MONITORING

We have indicated that situations will be characterised by some sort of belief-set formulae indicating entry to and exit from a situation, along with meta plans which will be executed on entry and exit. Situations often include a recognition of trends and changes that have occurred over a period of time such as "the thunderstorm's intensity has been increasing steadily in the last 30 minutes" or "the thunderstorm has been moving towards the fire." In order to support this kind of reasoning, we choose to maintain a temporal database. The challenge then is to know what should be stored in this temporal database in order to support the relevant belief-set queries, and when we should query this database.

Noting that the temporal queries we encounter generally have to do with *appearances* of objects over time, we choose to explicitly identify those objects which are involved in temporal relations in the recognition of the entry or exit condition of some situation. We refer to this set of objects as the *core* of a situation as it contains the core objects which require monitoring over time for situation recognition. This identification enables us to maintain historical information regarding only the relevant object types, and to query the temporal database at selected points to recognise entry to and exit from a situation.

The entry condition for the situation is then specified as a *temporal entry formula* (TEF) and a *current entry formula* (CEF). If the TEF is true with some bindings, the CEF will then also be checked with these same bindings. These are conceptually part of the same formula, but are separated out to facilitate using the temporal database only where necessary, if that is desired. The exit condition for a situation is specified in a similar manner. Along with the entry and exit conditions, we specify the meta-plans that ought to be executed when these conditions hold.

We also introduce the notion of a set of *active situations*, which are those situation instances where the entry condition has been true, and the exit condition has not yet become true. Situation instances are added to and removed from this set dynamically. This set is important to ensure that the agent does not repeatedly act upon the same situation instance, and to keep track of which situation instances the end condition should be monitored for.

During execution we need to ensure that relevant temporal (and other) information is stored, while also ensuring that there is not a blow-out in space consumption. We then need to use this information to recognise when a situation starts and ends. We chose to use a temporal database

[2]This is necessary to avoid the agent repeatedly reacting to the very same situation.

$$\frac{a: \quad \leftarrow \quad {}^{+}; \quad {}^{-} \in \Lambda \quad a\theta = act \quad \mathcal{B} \models \quad \theta \quad \forall \mathsf{Constraint}(\alpha, P) \in \mathcal{C} : (\mathcal{B} \setminus \quad {}^{-}\theta) \cup \quad {}^{+}\theta \models \alpha}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, act\rangle \longrightarrow \langle (\mathcal{B} \setminus \quad {}^{-}\theta) \cup \quad {}^{+}\theta, \mathcal{G}, \mathcal{C}, true\rangle}\ act$$

$$\frac{a: \quad \leftarrow \quad {}^{+}; \quad {}^{-} \in \Lambda \quad a\theta = act \quad \mathcal{B} \not\models \quad \theta}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, act\rangle \longrightarrow \langle \mathcal{B}, \mathcal{G}, \mathcal{C}, fail\rangle}\ act_f$$

$$\frac{\langle N, \phi_a, MP_a, \phi_e, MP_e\rangle \in \Pi_{Sit} \quad \mathcal{B} \models \phi_a\theta \quad (N, \theta) \notin \mathcal{S} \quad \langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, MP_a\theta\rangle \stackrel{*}{\Longrightarrow}_{Sit} \langle \mathcal{B}', \mathcal{G}', \mathcal{C}', \Gamma', true\rangle}{\langle \Pi_{Sit}, \mathcal{B}, \mathcal{G}, \mathcal{C}, \mathcal{S}, \Gamma\rangle \longrightarrow \langle \Pi_{Sit}, \mathcal{B}', \mathcal{G}', \mathcal{C}', \mathcal{S} \cup \{N, \theta\}, \Gamma'\rangle}\ Sit_{active}$$

$$\frac{\langle N, \phi_a, MP_a, \phi_e, MP_e\rangle \in \Pi_{Sit} \quad \mathcal{B} \models \phi_e\theta\theta' \quad (N, \theta) \in \mathcal{S} \quad \langle \mathcal{B}, \mathcal{G}, \Gamma, \mathcal{C}, MP_e\theta\theta'\rangle \stackrel{*}{\Longrightarrow}_{Sit} \langle \mathcal{B}', \mathcal{G}', \Gamma', \mathcal{C}', true\rangle}{\langle \Pi_{Sit}, \mathcal{B}, \mathcal{G}, \mathcal{C}, \mathcal{S}, \Gamma\rangle \longrightarrow \langle \Pi_{Sit}, \mathcal{B}', \mathcal{G}', \mathcal{C}', \mathcal{S} \setminus \{N, \theta\}, \Gamma'\rangle}\ Sit_{end}$$

$$\frac{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, MP_1\rangle \Longrightarrow_{Sit} \langle \mathcal{B}', \mathcal{G}', \mathcal{C}', \Gamma', MP_1'\rangle}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, (MP_1; MP_2)\rangle \Longrightarrow_{Sit} \langle \mathcal{B}'', \mathcal{G}'', \mathcal{C}'', \Gamma'', (MP_1'; MP_2)\rangle}\ ;_1 \qquad \frac{}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, (true; MP_2)\rangle \Longrightarrow_{Sit} \langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, MP_2\rangle}\ ;_2$$

$$\frac{}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, +\mathsf{Constraint}(\alpha, P)\rangle \Longrightarrow_{Sit} \langle \mathcal{B}, \mathcal{G}, \mathcal{C} \cup \{\mathsf{Constraint}(\alpha, P)\}, \Gamma, true\rangle}\ +\mathsf{Constraint}$$

$$\frac{}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, -\mathsf{Constraint}(\alpha, P)\rangle \Longrightarrow_{Sit} \langle \mathcal{B}, \mathcal{G}, \mathcal{C} \setminus \{\mathsf{Constraint}(\alpha, P)\}, \Gamma, true\rangle}\ -\mathsf{Constraint}$$

$$\frac{}{\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, +\mathsf{Goal}(\phi_s, P, \phi_f)\rangle \Longrightarrow_{Sit} \langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma \cup \{\mathsf{Goal}(\phi_s, P, \phi_f)\}, true\rangle}\ +\mathsf{Goal}$$

Figure 2: Rules for situations and meta plans. $\Longrightarrow_{Sit}$ is a transition relation between situation configurations of the form $\langle \mathcal{B}, \mathcal{G}, \mathcal{C}, \Gamma, MP\rangle$ ($\stackrel{*}{\Longrightarrow}_{Sit}$ stands for the usual reflexive transitive closure of $\Longrightarrow_{Sit}$.)

to store object information, as they provide an infrastructure for storing and retrieving objects with temporal data. The particular temporal database system that we are currently investigating is RapidBase[3] [5]. There are a number of reasons for this choice, some of which we outline below. The RapidBase Query Language (RQL) is based on SQL, which allows programmers with sufficient SQL skills to be able to write RQL queries. RapidBase allows tables to be defined with history columns, such that only histories of those columns will be maintained. This helps in avoiding redundant data and keeping the size of the database to a minimum.

We use RapidBase to store and track objects over time. For efficiency reasons, we only record objects whose types are part of the *core* of some situation known to the agent. Objects are stored by creating a table for each object type and specifying the attributes that require histories to be stored, as history columns.

When specifying a known situation, entry and exit conditions are expressed as RQL temporal queries. If a query returns an empty result set, then the condition in question is false; otherwise, when the result set is not empty, the answer set will contain the bindings for the objects for which the corresponding condition is true. These bindings are necessary for the entry condition, because, as mentioned previously: (a) the same bindings must be used to check the exit condition for that situation instance; and (b) the meta-plan that executes on activation should also use the same bindings as they should reason about the same object instances that formed the situation. The manner in which the object bindings are obtained is another useful and convenient feature of using a temporal database.

4. DISCUSSION AND CONCLUSION

We have introduced a notion of a situation as a special type of entity of which agents should be aware. We have added some rules to a previously developed agent specification language which provide for some initial aspects of responding to situations. We have also presented a representation for situations at the application programming level using a temporal database to capture the important temporal comparisons that commonly occur. We have currently only addressed a small number of things to be done upon recognition of a situation. This is an area where future work is required.

ABSTRACT

BDI-based agent architectures have proven their usefulness in building MASs for complex systems - their explicit attention for coping with dynamic environments is one obvious explanation for this. One large and quite interesting family of MAS applications is characterized (1) by their large scale in terms of number of agents and physical distribution, (2) by their very dynamic nature and (3) by their complex functional and non-functional requirements. This family includes a.o. manufacturing control, traffic control and web service coordination. In this paper, we present an innovative approach to BDI agents which alleviates agent complexity through "delegate MASs". Delegate MASs consist of light-weight agents, which are issued either by resources for building and maintaining information on the environment, or by task agents in order to explore the options on behalf of the agents and to coordinate their intentions.

1. INTRODUCTION

The term "coordination and control applications" can be coined to refer to a large family of applications which share a number of characteristics. First, in the applications, one can distinguish (1) an underlying physical or software environment, and (2) a software system that is connected to this environment. The underlying environment contains fixed entities or "resources" capable of performing particular operations, as well as mobile entities which can move in the environment. Second, the coordination and control software system is able to observe and direct the entities in the underlying environment. Third, the purpose of the application is to execute "tasks". Executing a task requires moving through the environment and performing operations by resources. The purpose of the software system is to manage the underlying environment by controlling entities that live in the environment, and coordinating the collective behavior of these entities. Fourth, the underlying system evolves several orders of magnitude slower than the coordination and control software. This allows the software to observe the environment and to plan ahead. Fifth, the environment itself is highly dynamic. Resources may crash, new resources may be added, connections between resources may be added, lost, or their characteristics (e.g. throughput, speed) may change. Members of this family of coordination and control applications include manufacturing control, traffic control and web service coordination. As an example, in manufacturing control, the environment is the physical world equipped with resources such as machines and conveyor belts, and the tasks are the client orders for fabricating particular products. The software in manufacturing control is responsible for controlling the resources and for guiding the orders through the factory floor. Both the mobile entities (partially fabricated products, vehicles, client software) and the fixed entities or resources in the environment (machines or conveyor belts, roads and intersections, web services) are obvious candidates to be represented as agents - which we call task agents and resource agents respectively.

In this paper, we propose a particular BDI-based approach [1, 4] that aims to avoid part of the internal agent complexity by exploiting the environment [6]. In the approach, so-called "delegate MASs" are issued by the different agents. Delegate MASs consist of light-weight agents (called ant agents). These ant agents explore the environment and bring relevant information back to their responsible task agent, evaluate optional paths, and put the intentions of their task agent as information in the environment. This allows delegate MASs of different agents to coordinate by aligning or adapting the information in the environment according to their own tasks.

2. BASIC COMPONENTS

The basic architecture comprises the task agents, resource agents, and the environment. The environment of the targeted applications is a dynamic directed graph. The nodes in the graph correspond to the resources in the environment and the edges represent connections between different resources.

A resource agent represents a resource in the environment and contains an information processing part for controlling the resource. In manufacturing control systems, a resource agent is an abstraction of the production means such as machines, conveyors, tool holders, material storage or even personnel. A resource can abstractly be described as a set of capabilities, i.e. the operations that the resource is able to perform. Resource agents need to be able to make schedules based on requests from task agents, and must be able to answer "what-if questions": a task agent may ask a re-

source agent when and according to what quality standards a particular operation could be performed if the task would arrive at a particular moment in the future.

A task agent represents and controls a task in the coordination and control application, and resides on a (physical or virtual) mobile entity in the environment. A task agent is responsible for performing its task by guiding its mobile unit through the environment, and communicating with resource agents in order to perform operations on the unit. Every task agent is aware of the schemes or plans that can be followed in order to reach its goal. For manufacturing control, the task agents represent (unfinished) client orders and are associated with the pallets with partially fabricated products. The production schemes describe possible sequences of operations on the product in order to obtain the final product. Task agents are obvious candidates to be modeled as BDI agents. Task agents need to deal with the observations of the environment and its entities (beliefs), consider possible options on how to proceed (desires), choose a particular option (intention) and communicate and coordinate this with the other task agents.

Both resource and task agents control the entities in the environment, and obviously need to interact to achieve the goal of the application. A typical interaction amongst these agents goes as follows. When a new "task" enters the system, a task agent is created and connected to the appropriate unit. The agent is aware of the initial state of the task and investigates possible next operations that can be performed. The agent searches and selects a combination of a next processing step and a suitable resource that has the capability to execute the step. When the selected processing step is executed by the resource, the resource reports on the new state of the task. This may or may not be the expected outcome of the operation. Based on this state, the task agent investigates possible next steps. The process repeats until the task is finished.

3. DELEGATE MULTI-AGENT SYSTEMS

A typical approach would be to use direct communication protocols, knowledge engineering and means-ends reasoning to achieve the required coordination. Here, we use delegate MASs for (1) obtaining feasibility information, (2) exploration and (3) propagation of intentions toward the resource agents. The following interesting principles are recognized in "ant-like multi-agent systems": (1) make the environment part of the solution to handle a complex environment without being exposed to its complexity - ants are quite simple agents; (2) place relevant information as signs in the environment ensuring that locally available data informs about remote system properties; (3) limit the lifetime of this information (evaporation) and refresh the information as long as it remains valid - this allows the system to cope with changes and disturbances. We exploit these principles in our approach and define three types of light-weight agents, which each represent a different delegate MAS and which share a common environment for indirect communication. To distinguish them from task and resource agents, we call the light-weight agents "ant agents" or ants further on. Delegate MASs consist of ant agents that reside in a virtual software environment which reflects the application environment, and in which ant agents can navigate.

Feasibility Ants. Feasibility ants form a delegate MAS that is issued by resource agents. Their purpose is to roam

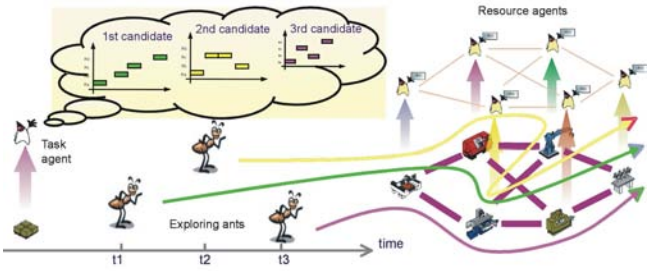

Figure 1: ***Exploration ants scout feasible paths***

the environment and, at each node they pass, drop information on feasible paths that start from this node. Resource agents which have not seen a feasibility ant passing by for a particular period will create new feasibility ants themselves at a certain frequency. The behavior of a feasibility ant is as follows. A feasibility ant communicates with the resource agent at its current node, and asks for its capabilities. The ant observes the environment locally and finds out from which other nodes the current node can be reached. The ants can be seen as moving upstream. When arrived at the new node, the ant asks the local resource agent for its capabilities, and merges this information with information of previous nodes. Now this ant knows that from this node, a sequence of operation that requires a capability from the current node followed by an operation that can be performed at its previous node is currently feasible. This information is dropped at the local information space of the current node, as a kind of road sign. Then the ant clones itself for every node upstream, and the process repeats itself. A feasibility ant dies if there are no nodes upstream. The information that is stored in local information spaces is time-stepped, and if not refreshed by another feasibility agent in time, that information disappears.

Exploration Ants. Using the feasibility information available locally, a task agent is able to find out which paths are physically or virtually feasible for achieving the goal of its task. A task agent generates exploration ants at a certain frequency which explore feasible paths. These exploration ants are scouts that each explore a feasible route through the underlying system and evaluate this route. To make the evaluation, an exploration ant follows a path through the environment, and interacts with the resource agents at the different nodes by asking the resource agent *what* the timing, quality or costs would be *if* a task in a particular state would arrive at a particular moment in time. The exploration ant collects this information, and then proceeds to the next node in the path, in which this behavior is repeated. When arrived at the end of the path, the exploration ant returns and reports back to its base, i.e. the task agent that created the exploration ant. Figure 1 illustrates this process for a simple factory (see right-hand side of figure, cf. www.mech.kuleuven.be/benchmarking). The task agent on the left hand side creates three exploration ants for scouting feasible paths.

The list of candidates get refreshed regularly as exploration ants are sent out regularly. Candidates that are not refreshed are removed over time, assuming that these candidates have become invalid or infeasible because of changes in the environment.

Intention Ants. Exploration as described above requires the resource agents to possess an adequate estimate of their future workload. To serve this purpose, task agents generate intention ants, which propagate the intention of task agents through the environment. When a task agent has constructed a set of valid paths to follow, the task agent selects one candidate path to become its intention. The criteria used for this selection depends on the requirements of the task, and is application-specific. Then, the task agent creates intention ants, at a certain frequency, to inform the resource agents that are involved in this intended path. The intention ants follow the selected path, and virtually execute the routing and processing of their selected candidate solution. On their virtual journey, the intention ants acquire travel, queuing, and processing times from the resource agents on their path. Similar as exploration ants, intention ants report back to their task agent to inform the agent about the schedule and performance of the bookings.

The intention information at the resource agent - the booking - evaporates. Task agents must create intention agents to refresh their intention at a frequency that is sufficiently high to maintain their bookings at the resources. While refreshing, a task agent observes the evolution of the expected performance of its current intentions through the reports on the estimated performance that intention ants bring back. This performance estimate is compared to the estimates of the candidate solutions that are found and refreshed by the exploration agents. When the estimated performance of the current intention drops significantly below the estimated performance of other candidate solutions, the task agent may revise its intention. When the task of a task agent reaches the point where a decision needs to be executed, the task agent triggers the action in the underlying system in accordance with the intention.

Task and Resource Agents. Let us now list the responsibilities of task and resources agents. These lists should guide a developer of a coordination and control application to define a concrete software architecture for these agents.

A resource agent is responsible for (1) answering what-if questions from exploration ants, (2) making schedules based on requests for bookings by intention ants - the schedules must obviously respect resource constraints as well as follow a predefined policy for re-scheduling, e.g. when high-priority tasks make a booking, this may reject earlier reservations, (3) keep an up-to-date view on the resource that the resource agent is managing (e.g. observe operation quality and status), and (4) send out feasibility ants if no feasibility ants have contacted this resource agent for a while. These guidelines should suffice to produce a concrete architecture according to the requirements of a concrete application. The resource agent could execute each of these responsibilities in sequence, or one may opt to define concurrent execution of some of these responsibilities.

The responsibilities of the task agents are the following. First, a task agent must have knowledge about its task, about the initial state of the task, and about task schemes. Task schemes describe one or several plans to achieve the goal of the task, and given any intermediate state of the task, the task scheme should provide one or more sub-plans to fulfill the task. Second, a task agent must manage its beliefs. Beliefs on feasibility are readily available from the information space in the environment. Beliefs about explored paths are gathered by exploration ants. Third, this information needs to be filtered out, yielding valid paths - the agents desires. Fourth, based on the beliefs about the task and the options, a task agent then chooses or revises its intention. Fifth, at appropriate times and frequency, exploration ants as well as intention ants are sent out. Finally, a task agent is responsible for interacting with resource agents in order to perform operations on its task. Again, these responsibilities are either executed as a sequence, or one may choose for concurrent execution of some of these responsibilities.

4. EVALUATION AND CONCLUSION

In the approach we propose, we stick to the basic philosophy of belief-desires-intention agents, but exploit the environment and delegate MASs, inspired by ant behavior, to realize beliefs, desires and intentions. Based on simulation experiments for a real-world case of manufacturing control, we can state that this innovative approach yields very interesting results for the targeted application domains, both in terms of the reduction of the agent software complexity and in overall performance in a highly dynamic environment [5].

One important difference between an approach using delegate MAS and traditional BDI approach for coordination and control systems is that a delegate MAS design extends Brooks concept of having the world as its own best model, while traditional BDI approaches rely on maintaining world models. The basic idea of having the "world as its own best model" only discusses the present state of the world. In contrast, the delegate MAS approach in this paper extends this idea toward the future state, using exploration and intention ants, while keeping modeling efforts acceptable. Indeed, resource agents only need to be knowledgeable and intelligent about their own small section of the world. Known scalable MAS coordination and control developments are myopic [2, 3], while our approach allows to take future state into account.

ABSTRACT

An agent needs to balance its time between reflecting on its past behaviors, the execution of its current behaviors and the recognition of opportunities for future action. The optimal strategy to achieve this balance is heavily dependent on the environment in which the agent is situated. In this paper we extend a BDI agent programming language called AgentSpeak(L) in two ways. Firstly we refine the use of execution monitoring to enable agents to reflect on their past endeavors. Secondly, we extend the semantics and syntax of the language to allow for user defined monitoring strategies. This allows agent designers to utilize execution monitoring in a way that balances the focus of an agents behavior in a way that is appropriate for its application domain.

Keywords: Agent and Multi-Agent Architectures, Agent Programming Languages

1. INTRODUCTION

For an intelligent agent, behaving in complex and real-time environments is a balancing act. There are three primary tasks that must be managed in order to achieve this balance. An agent must be able to recognize opportunities for future conduct. Simultaneously, the agent must devote resources, including its cognitive abilities, towards the execution of its current behaviors. All the while the agent must be watchful to collate its perceptions with the outcomes of its previous behaviors so as to maintain an accurate view of its progress towards its goals. This must all be done while remaining responsive to real-time constraints on its behavior.

This paper proposes the use of execution monitoring to allow BDI systems to correlate their perceptions with their previous behavior. More specifically we argue that providing the ability for agent developers to integrate user defined monitoring strategies is the only way to do this efficiently given the variety of domains for which BDI systems are applicable. AgentSpeak(L) was chosen as the prototypical BDI system for reasons outlined in Section 3 and it is the framework into which we have integrated execution monitoring. However, prior to providing an overview of AgentSpeak(L) and our extensions (Section 4) we describe the execution monitoring problem for BDI systems.

2. THE MONITORING PROBLEM

Monitoring is the mental act of validating expectations through the inspection of ones world model. There are three main things that a BDI system should be monitoring for: success, validity and failure. In dynamic and complex environments, monitoring for one cannot be reduced to monitoring for another[5]. Ideally an agent should continuously monitor the environment to determine the outcomes of its behaviors. However, in resource-bounded practical agents the monitoring process has a cost. Therefore an agent needs to schedule the times at which it monitors. This way an agent makes a trade-off between its introspection capabilities and the time constraints imposed upon it by the environment in which it is embedded. Thus, an agent needs to minimize the cost of monitoring. Be it the cost resulting from not monitoring when monitoring would have been beneficial or the cost of the monitoring process itself when the monitoring process has no effect on the agent's behavior.

3. WHAT IS AGENTSPEAK(L)?

AgentSpeak(L)[9] is an abstract architecture and programming language that aims to embody the BDI philosophy[4] and logic[10] in a computationally attractive way. It has a number of semantics ranging from the Z specification language [7] to structural operational semantics [8, 3, 1] and a sub-set of the language has been demonstrated, through model-checking, to satisfy a number of specifications expressed in BDI logic formula[2]. Due to its simplicity and elegance, AgentSpeak(L) is easy to extend and is designed in such a way that customizing the architecture and language to suit the application domain is straight forward.

4. MONITORING IN AGENTSPEAK(L)

Recently, the AgentSpeak(L) language and architecture was extended to facilitate the specification of and reasoning with success and failure conditions of plan execution[5, 6]. However, one significant drawback of the approach proposed was that the architecture utilized a naïve approach to monitoring execution. Each success and failure condition of each intended means in each intention stack was checked once each reasoning cycle. This results in significant proportions of the agents cognitive faculties being devoted to the monitoring process at the expense of its other activities. In order to balance the monitoring process with action execution, opportunity recognition and belief revision an agent needs to be able to make decisions as to when to monitor for the success and failure of its

plans. We believe that the optimal strategy is dependent on both the application domain and the deployment environment. To cater for this we incorporate monitoring strategies by way of an additional user function in the architecture of the agent. We build upon the structural operational semantics and syntax developed in [1] and extended in [5, 6]. The primary contribution of this paper required no modification to the extended syntax of the language. However it was necessary to add new definitions, auxiliary functions and rules to the semantics of the interpreter.

4.1 Definitions

We extend the definition of an agent to include two new user defined functions: $F_M$and F_{ConRes}. $F_M$encapsulates the agents monitoring strategy. Given that both implemented BDI systems and BDI logic[10] represent time discreetly, this function takes the current state of the agent, a mental attitude to monitor and maps them to true or false ($M : S \times At \mapsto [\top, \bot]$). True indicates the agent needs to check the condition this reasoning cycle and false indicates the agent need not. $F_{ConRes} : \xi \times B \mapsto [\top, \bot, \dashv]$defines the agents conflict resolution strategy. $F_{ConRes}$is necessary because the agent may come to believe evidence for both the success and failure of an effect of a plans execution. It is used to alleviate the ambiguity of whether to conclude success or failure in these cases. $F_{ConRes} : \xi \times B \mapsto [\top, \bot, \dashv]$maps an effect ($\xi$) of a plan and the current beliefs (B) of the agent to one of three values: $\top$ if the agent should conclude true given this ambiguity, $\bot$ if the agent should conclude false under uncertainty and $\dashv$ if the agent can conclude nothing this cycle and should continue monitoring this effect.

One additional temporary data store is also required: η. During each reasoning cycle, this set is generated based on the user function $F_M$to include all the effects that the agent needs to check for either success or failure. Being temporary (the contents do not persist across reasoning cycles), this data store is referred to in the semantics as T_η.

4.2 Auxiliary Functions

Here we define the filtering function ($\mathbf{FilterInt} : C_I \mapsto \{\pi\}$). It returns the sub-set of the current set of intentions (C_I) such that each included intention has elements remaining in the body. This function is used to prevent intentions that have completed from executing but have effects outstanding from being candidates for processing on this reasoning cycle.

$$\mathbf{FilterInt}(C_I) = \{\pi | \pi = \pi'[l \rightarrow te : c \leftarrow \{i\}h.e] \wedge h \neq \emptyset\}$$

This function ($\mathbf{GenEff} : T \times C \times AG \mapsto \{\langle \pi, \varrho, \xi \rangle\}$) generates the set of effects that should be monitored this reasoning cycle. This is achieved by iterating over each intention in the set of intentions ($\forall\pi$), each plan on each intention stack ($\forall\varrho$) and each effect within each plan ($\forall\xi$). This combination, in addition to the current state of the agent (T, C), is passed onto the user defined effect monitoring strategy function ($F_M(T, C, \pi, \varrho, \xi)$). This function defines whether this effect should be checked in this cognitive cycle. The return value of this function is the set of tuples $\langle \pi, \varrho, \xi \rangle$ for which the ($F_M(T, C, \pi, \varrho, \xi)$) function returns true ($\top$).

$$\mathbf{GenEff}(T, C, AG) = \left\{ \langle \pi, \varrho, \xi \rangle \;\middle|\; \begin{array}{l} \forall \pi \varrho \xi \text{ s.t. } \pi \in C_I \wedge \varrho \in \pi \wedge \\ l \rightarrow te : c \leftarrow \{i\}h.e = \varrho \wedge \\ \xi \in e \wedge AG_{F_M(T,C,\pi,\varrho,\xi)} = \top \end{array} \right\}$$

Because we regenerate the set of effects to monitor each reasoning cycle, we need to remove those effects that have sufficient evidence for the agent to conclude their success from their encompassing plan. Otherwise, the agent will continue to monitor for these effects and the plan will never be considered complete. We do this using the update effects function ($\mathbf{UpdEff} : \pi \times \varrho \times \xi \mapsto \pi'$). This function maps an intention, plan and effect into a new intention. Because an agent can monitor for and consequently conclude the success of an effect in any level of an intention stack, this function retrieves the input plan ($l \rightarrow te : c \leftarrow \{i\}h.e$) from the intention ($\pi$)[1], removes the input effect (ξ) from the input plan ($l \rightarrow te : c \leftarrow \{i\}h.e$) and reconstructs the intention stack (π') to be returned.

$$\mathbf{UpdEff}(\pi, l \rightarrow te : c \leftarrow \{i\}h.e, \xi) = \pi'$$

where: $\pi = \pi''[l \rightarrow te : c \leftarrow \{i\}h.e\backslash\xi]\pi'''$ s.t. $\pi''[l \rightarrow te : c \leftarrow \{i\}h.e]\pi''' = \pi$

4.3 Rules

The first rule that we must alter from the original is that of **SelInt**. We do so in order to integrate the intention filtering function (as described above) into the intention selection process. The first rule is applicable in the case where there are intentions for which further processing is required. The second handles the case where there are not.

$$\mathbf{SelInt}\frac{\mathbf{FilterInt}(C_I) \neq \emptyset \qquad F_I(\mathbf{FilterInt}(C_I))) = T_\iota}{\langle AG, C, T, \mathbf{SelInt}\rangle \longrightarrow \langle AG, C, T', \mathbf{ExecInt}\rangle}$$

$$\mathbf{SelInt}\frac{\mathbf{FilterInt}(C_I) = \emptyset}{\langle AG, C, T, \mathbf{SelInt}\rangle \longrightarrow \langle AG, C, T, \mathbf{GenEff}\rangle}$$

We do not repeat the rules for executing the top most plan of the selected intention as they remain identical to those in [3]. The next process is that of generating the set of effects to check. We employ two rules to do this. The first handles the case where the set of intentions is empty. If the set of intentions is empty then there can be no effects to be monitoring for and we skip the procedure and transition to clearing the intentions.

$$\mathbf{GenEff}\frac{C_I = \emptyset}{\langle AG, C, T, \mathbf{GenEff}\rangle \longrightarrow \langle AG, C, T, \mathbf{ClrInt}\rangle}$$

However, should there be elements in the set of intentions the second rule passes the current set of intentions as a parameter to the effect generation function and stores the result in the set of effects to be checked (T_η).

$$\mathbf{GenEff}\frac{C_I \neq \emptyset \qquad \mathbf{GenEff}(T, C, AG) = T_\eta}{\langle AG, C, T, \mathbf{GenEff}\rangle \longrightarrow \langle AG, C, T', \mathbf{UpdEff}\rangle}$$

Four rules are required to process the current effects. The first three are repeatedly applied until there are no elements left in the effect set. The first is applicable when there are outstanding effects to be checked($T_\eta \neq \emptyset$) and the selected effect is deemed successful ($\top = F_{ConRes}(\xi, B)$) by the conflict resolution strategy (F_{ConRes}). It removes the effect from the set of effects awaiting monitoring and from the plan from which it originated. It also updates the intention using the ($\mathbf{UpdEff}$) function.

$$\mathbf{UpdEff}\frac{T_\eta \neq \emptyset \qquad \langle \pi, \varrho, \xi \rangle \in T_\eta \wedge \top = F_{ConRes}(\xi, B)}{\langle AG, C, T, \mathbf{UpdEff}\rangle \longrightarrow \langle AG, C', T', \mathbf{UpdEff}\rangle}$$

where:

$T'_\eta = T_\eta \backslash \langle \pi, \varrho, \xi \rangle$

$C'_I = (C_I \backslash \pi) \cup \mathbf{UpdEff}(\pi, \varrho, \xi)$

[1]producing $\pi''[l \rightarrow te : c \leftarrow \{i\}h.e']\pi'''$ where π'' and π''' represent the elements of the intention both below and above the required plan respectively

The second rule is also applicable when there are outstanding effects to be checked, but requires the conflict resolution strategy to judge the selected effect to have failed. This rule creates the appropriate failure event and adds it to the event set. Then the intention is removed from the set of intentions to prevent its further processing until the failure is handled.

$$\mathbf{UpdEff}\frac{T_\eta \neq \emptyset \qquad \langle \pi, \varrho, \xi\rangle \in T_\eta \wedge \bot = F_{ConRes}(\xi, B)}{\langle AG, C, T, \mathbf{UpdEff}\rangle \longrightarrow \langle AG, C', T', \mathbf{UpdEff}\rangle}$$

where: $C'_E = \begin{array}{ll} C_E \cup \{(+g, \pi)\} & \text{if } te = -g \text{ (where g is a goal)} \\ C_E \cup \{(-g, \pi)\} & \text{if } te = +g \text{ (where g is a goal)} \end{array}$

$C'_I = C_I \backslash \pi$

$T'_\eta = T_\eta \backslash \langle \pi, \varrho, \xi\rangle$

The third rule handles the case where there are effects to audit, one of these is selected, yet the conflict resolution strategy can not conclude that the effect has been satisfied or invalidated. All that must be done in this case is to remove the effect from the effect set so that it will not be tested again.

$$\mathbf{UpdEff}\frac{T_\eta \neq \emptyset \qquad \langle \pi, \varrho, \xi\rangle \in T_\eta \wedge \dashv = F_{ConRes}(\xi, B)}{\langle AG, C, T, \mathbf{UpdEff}\rangle \longrightarrow \langle AG, C, T', \mathbf{UpdEff}\rangle}$$

where: $T'_\eta = T_\eta \backslash \langle \pi, \varrho, \xi\rangle$

Finally, the last (**UpdEff**) rule handles the case where there are no elements in the set of effects to review.

$$\mathbf{UpdEff}\frac{T_\eta = \emptyset}{\langle AG, C, T, \mathbf{UpdEff}\rangle \longrightarrow \langle AG, C, T, \mathbf{ClrInt}\rangle}$$

There is only one primary modification required to the original (**ClrInt**) function and that is to retain plans that have outstanding effects. This prevents the continued processing of these intentions until all the effects have been realized or demonstrated to have failed.

$$\mathbf{ClrInt}\frac{C_I \neq \emptyset}{\langle AG, C, T, \mathbf{ClrInt}\rangle \longrightarrow \langle AG, C', T', \mathbf{SelEv}\rangle}$$

where: $C'_I = \begin{cases} C_I \backslash T_\iota & \text{if } \begin{array}{l} T_\iota = [l \rightarrow te : c \leftarrow \{i\}h.e] \\ \wedge i = h = e = \emptyset \end{array} \\ (C_I \backslash T_\iota) \cup \{T'_\iota\} & \text{if } \begin{array}{l} T_\iota = \pi[l \rightarrow te : c \leftarrow \{i\}!at; h.e] \\ [l' \rightarrow te' : c' \leftarrow \{i'\}h'.e'] \wedge \\ i' = h' = e' = \emptyset \end{array} \\ C_I & \text{otherwise} \end{cases}$

$T = \emptyset$

5. CONCLUSION

In conclusion, through our studies of existing BDI systems we discovered that these systems do not have strong capabilities for monitoring the outcomes of their behaviors. Particularly, existing systems have no methodology for utilizing user defined monitoring strategies that facilitate effective balance of the time an agent spends monitoring and doing its other activities. We chose as our prototypical BDI implementation, AgentSpeak(L), and made extensions to its semantics in an attempt to address this issue. Due to the sensitivity of the performance of an agent to the environment in which it is situated, utilizing user defined strategies that are tuned to the particular application domain is essential. We believe that agents utilizing these extensions will perform better due to their ability to better balance the time spent correlating their current beliefs with their past behaviors, the time spent recognizing opportunities and executing current behaviors.

MDP, transition-independent decentralized MDP, piecewise linear approximation, mixed integer linear programming

1. INTRODUCTION

Markov decision process (MDP) provides a framework for computing optimal policies for individual agents operating in uncertain environments. However, extending single-agent MDP techniques to multiagent problems is not straightforward. Previous complexity analyses have shown that the general decentralized Markov decision process (Dec-MDP) is NEXP-complete, which means that optimally solving a Dec-MDP is extremely difficult. The class of problems studied in this paper is a subclass of Dec-MDP in which two or more cooperative agents are tied together through the rewards of completing joint tasks but the actions taken by one agent do not impact other agents' transitions. Although this reduces the complexity class to NP-complete [4], efficiently solving such transition independent Dec-MDPs is still nontrivial.

Optimal algorithms, such as the coverage-set algorithm [2], slow down dramatically as the size of the problem increases. Approximation algorithms, such as the JESP algorithm [5], can quickly find a locally optimal joint policy, but the solutions usually lack quality guarantees. Other collaborative multiagent research often makes the simplifying assumption that each agent has the same (complete) world view. Thus, there remains a critical need for new algorithms that can efficiently build optimal or near-optimal policies for transition independent Dec-MDPs. In this paper, we present a novel mathematical programming algorithm for this purpose.

2. MDPS AND LINEAR PROGRAMMING

A classical MDP can be defined as a four-tuple $\langle S, A, P, R\rangle$, where S is a finite state space, A is a finite action space, $P = \{p_{i,a,j}\}$ is the state transition probability where $p_{i,a,j}$ is the probability that the agent reaches state j if it executes action a in state i, and $R = \{r_{i,a}\}$ is the reward function where $r_{i,a}$ is the reward that the agent receives if it executes action a in state i.

One approach to solving MDPs is based upon linear programming (LP) [1]. Let $x_{i,a}$ represent the expected number of times action a is executed in state i. Then the objective function $\sum_i \sum_a x_{i,a} \times r_{i,a}$ represents the total expected reward. Now, consider the linear program shown in Eq.1.

$$\max \sum_i \sum_a x_{i,a} \times r_{i,a} \left| \begin{array}{l} \sum_a x_{j,a} = \alpha_j + \sum_i \sum_a p_{i,a,j} \times x_{i,a} \\ x_{i,a} \geq 0 \end{array} \right. \quad (1)$$

where α_j is the probability that the system is initially in state j. The constraint $\sum_a x_{j,a} = \alpha_j + \sum_i \sum_a p_{i,a,j} \times x_{i,a}$ indicates that the expected number of times state j is visited must equal the initial probability distribution at state j plus the expected number of times state j is entered via all possible transitions.

If we solve Eq.1, it is trivial to derive the optimal policy. Specifically, assigning a probability of executing action a in state i as $\pi_{i,a} = \frac{x_{i,a}}{\sum_a x_{i,a}}$ will maximize the total expected reward.

3. ALGORITHM

In the class of problems studied in this paper, multiple cooperative agents aim to maximize their total expected reward in a stochastic environment where actions taken by one agent cannot impact other agents' transitions. Each agent can fully observe its own local state but can only have a partial view of the global environment. An agent receives rewards by completing its individual tasks. Agents can also work together to complete joint tasks. The accomplishment of a joint task needs participation from multiple agents. That is, if every (relevant) agent completes its subtask of the joint task, then the group receives a joint reward; otherwise they get zero reward for that joint task. Since agents might not be able to complete all available tasks due to limitations (such as time), they need to determine the subset of tasks they should pursue, and align their policies.

Let $p^m_{i,a,j}$, $r^m_{i,a}$, and α^m_j, respectively, represent the transition probabilities, rewards (or costs) for individual activities, and initial probability distribution for agent m, let $p^{m,k}_{i,a}$

represent the probability that agent m completes its subtask of joint task k when executing action a in state i, and let R^k represent the reward for accomplishing joint task k (i.e., $R^k > 0$). Our problem can then be formulated as

$$\max \sum_m \sum_i \sum_a x_{i,a}^m \times r_{i,a}^m + \sum_k \rho^k \times R^k$$
$$\left| \begin{array}{l} \sum_a x_{j,a}^m = \alpha_j^m + \sum_i \sum_a p_{i,a,j}^m \times x_{i,a}^m \\ \rho^{m,k} = \sum_i \sum_a p_{i,a}^{m,k} \times x_{i,a}^m \\ \rho^k = \prod_m \rho^{m,k} \\ x_{i,a}^m \geq 0 \end{array} \right. \quad (2)$$

where $x_{i,a}^m$ is the expected number of times that action a is executed in state i for agent m. $\rho^{m,k} = \sum_i \sum_a p_{i,a}^{m,k} \times x_{i,a}^m$ is the expected number of times agent m completes its subtask of joint task k. Note that it is generally not difficult to restrict an autonomous agent from completing a particular task more than once, either through an additional bit in the state representation or through a fixed acyclic ordering for completing the tasks, and so $\rho^{m,k}$ can also represent the probability of agent m completing its subtask of joint task k. $\rho^k = \prod_m \rho^{m,k}$ is the probability that the group successfully completes joint task k.

The term $\sum_m \sum_i \sum_a x_{i,a}^m \times r_{i,a}^m$ in the objective function of Eq.2 is the total expected reward (or cost) of individual activities, and the term $\sum_k \rho^k \times R^k$ is the total expected reward from accomplishing joint tasks. The constraint $\sum_a x_{j,a}^m = \alpha_j^m + \sum_i \sum_a p_{i,a,j}^m \times x_{i,a}^m$ is a multiagent version of the constraint in Eq.1.

It is important to emphasize that, unlike an LP formulation (e.g., Eq.1), Eq.2 uses nonlinear constraints to represent cooperative activities of agents (instead of using the joint state space) and thus avoids exponential increase in the size of the mathematical formulation. In the following two subsections, we present discretization and piecewise linear approximation techniques, and then reformulate Eq.2 into a mixed integer linear program (MILP) that can be efficiently solved by state-of-art algorithms [3].

3.1 Discretization

We now introduce a discretization technique that, although it cannot eliminate the nonlinearities in Eq.2 by itself, paves the way for using piecewise linear approximation technique presented in Section 3.2.

Let $\mathbb{H}$ denote an ordered set of constants (named *thresholds*) in which $0 \leq h_1 < h_2 < \ldots < h_i < \ldots \leq 1$, and define binary variables Θ_h^k. Then, with additional constraints Eq.3,

$$\left| \begin{array}{l} \frac{\rho^k}{h} \geq \Theta_h^k \\ \sum_h \Theta_h^k \leq 1 \\ \Theta_h^k \in \{0,1\} \end{array} \right. \quad (3)$$

the objective function of Eq.2 can be approximated as

$$\sum_m \sum_i \sum_a x_{i,a}^m \times r_{i,a}^m + \sum_k \sum_{h \in \mathbb{H}} h \times \Theta_h^k \times R^k \quad (4)$$

The constraint $\frac{\rho^k}{h} \geq \Theta_h^k$ is equivalent to $\Theta_h^k = 0$ when $\rho^k < h$, and $\Theta_h^k \in \{0,1\}$ when $\rho^k \geq h$. The constraint $\sum_h \Theta_h^k \leq 1$ guarantees that, for each joint task k, there is at most one nonzero integer in the set $\{\Theta_h^k \mid h \in \mathbb{H}\}$. These two constraints work together to make $\sum_{h \in \mathbb{H}} h \times \Theta_h^k \leq \rho^k$. Since rewards of joint tasks are always positive, $\sum_{h \in \mathbb{H}} h \times \Theta_h^k$ equals the largest h in the set $\{h \mid h \in \mathbb{H}$ and $h \leq \rho^k\}$ when Eq.4 is maximized. That is, $\sum_{h \in \mathbb{H}} h \times \Theta_h^k$ can nicely approximate ρ^k when the maximum gap between two adjacent thresholds in $\mathbb{H}$ is sufficiently small.

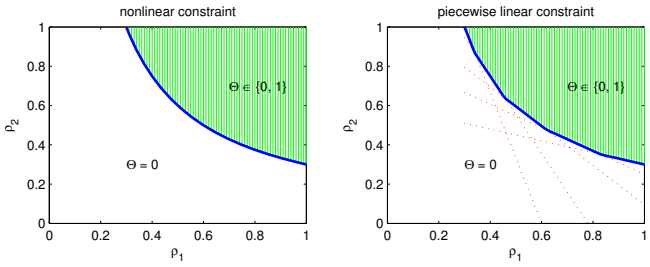

Figure 1: An example of piecewise linear approximation ($h = 0.3$, two agents).

3.2 Piecewise Linear Approximation

With the discretization technique, we are ready to remove the nonlinearities. Note that, in our new formulation (i.e., adding Eq.3 into Eq.2, and replacing Eq.2's objective function with Eq.4), ρ^k are trivial variables, which can be taken away by combining constraints $\rho^k = \prod_m \rho^{m,k}$ and $\frac{\rho^k}{h} \geq \Theta_h^k$ into a new constraint $\frac{\prod_m \rho^{m,k}}{h} \geq \Theta_h^k$.

In general, the nonlinear constraint $\frac{\prod_m \rho^{m,k}}{h} \geq \Theta_h^k$ can be closely approximated with a sufficient number of linear constraints. Figure 1 shows a simple example where a nonlinear constraint $\frac{\rho^1 \times \rho^2}{h} \geq \Theta_h$ ($h = 0.3$) is approximated by five linear constraints.

Explicitly, for M agents, we can build a piecewise linear matrix for threshold h as:

$$\mathbb{A}_h = \begin{bmatrix} \frac{1}{\varrho_1^1 \times M} & \cdots & \frac{1}{\varrho_1^m \times M} & \cdots & \frac{1}{\varrho_1^M \times M} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \frac{1}{\varrho_i^1 \times M} & \cdots & \frac{1}{\varrho_i^m \times M} & \cdots & \frac{1}{\varrho_i^M \times M} \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ \frac{1}{\varrho_n^1 \times M} & \cdots & \frac{1}{\varrho_n^m \times M} & \cdots & \frac{1}{\varrho_n^M \times M} \end{bmatrix}$$

where $\overrightarrow{\varrho_i} = \langle \varrho_i^1, \ldots, \varrho_i^M \rangle$ represents a point on the function $\prod_m \rho^m = h$.[1] $\frac{\prod_m \rho^{m,k}}{h} \geq \Theta_h^k$ can then be approximated as $\mathbb{A}_h \times \overrightarrow{\rho}^k \geq \Theta_h^k$, where $\overrightarrow{\rho}^k = \langle \rho^{1,k}, \ldots, \rho^{M,k} \rangle$.

3.3 MILP-HCS Algorithm

Using the approximation techniques presented above, a transition-independent Dec-MDP problem can then be formulated as the following mixed integer linear program.

$$\max \sum_m \sum_i \sum_a x_{i,a}^m \times r_{i,a}^m + \sum_k \sum_{h \in \mathbb{H}} h \times \Theta_h^k \times R^k$$
$$\left| \begin{array}{l} \sum_a x_{j,a}^m = \alpha_j^m + \sum_i \sum_a p_{i,a,j}^m \times x_{i,a}^m \\ \rho^{m,k} = \sum_i \sum_a p_{i,a}^{m,k} \times x_{i,a}^m \\ \mathbb{A}_h \times \overrightarrow{\rho}^k \geq \Theta_h^k \\ \sum_h \Theta_h^k \leq 1 \\ x_{i,a}^m \geq 0 \\ \Theta_h^k \in \{0,1\} \end{array} \right. \quad (5)$$

[1] In this work, we use a greedy algorithm to find n points $\overrightarrow{\varrho_i}$ for $\mathbb{A}_h$.

We can then use state-of-art MILP solvers for it, and derive a joint policy in a similar way to that described in Section 2. That is, agent m executes action a at state i with probability $\pi^m_{i,a} = \frac{x^m_{i,a}}{\sum_a x^m_{i,a}}$.

Not surprisingly, with the approximation techniques, our MILP-based algorithm cannot guarantee optimal solutions. However, we can prove that, in the worst case, the algorithm suffers a loss of $\sum_k (e + g) \times R^k$ from the optimal total expected reward, where g denotes the maximum error caused by the discretization, which can be reduced by increasing the size of $\mathbb{H}$, and e denotes the maximum error caused by the piecewise linear approximation, which can be reduced by using more points $\overrightarrow{\varrho_i}$ in $\mathbb{A}_h$.

To further improve performance, we integrate the MILP algorithm with hill-climbing search, and iterate MILP and hill-climbing search with gradually increasing approximation accuracy. The details are presented in Algorithm 1.

Algorithm 1 MILP algorithm integrated with hill-climbing search (MILP-HCS)

```
1: Initialize approximation accuracy parameters e, g, and
   randomly choose a joint policy randomSol
2: initSol ← HillClimbSearch(problem, randomSol)
3: repeat
4:    milp ← CreateMILP(problem, e, g)
5:    nearOptimalSol ← SolveMILP(milp, initSol)
6:    sol ← HillClimbSearch(problem, nearOptimalSol)
7:    initSol ← sol
8:    e, g ← ImproveAccuracy(e, g)
9: until computational time uses up or user interrupts
10: return sol
```

4. EMPIRICAL RESULTS

In this section, we give a preliminary empirical evaluation of our algorithm through comparing its performance with two other well-known approaches: the coverage-set algorithm [2] and the random restart JESP algorithm [5].

We evaluate these algorithms on problem instances with two cooperative agents where each autonomous agent has a ordered set of 40 tasks, half of which (randomly chosen) are its individual tasks and the others are its subtasks for joint tasks. The rewards for the individual tasks are evenly distributed in the range $[0, 1]$ and the rewards for the joint tasks are evenly distributed in the range $[0, 3]$. The cooperative agents try to maximize their total expected reward within 20 time steps. The state for each agent is composed of its current task and the remaining time before the deadline. At each state, each agent can choose to execute the current task or to skip it. If the agent chooses to skip, then it moves to the next task immediately. The uncertainty in the problem is in the time required to execute the tasks. In this paper, we assume that, if an agent decides to execute a task, it has 25% probability of accomplishing it within one, two, three, and four time steps respectively.

We ran experiments on a Pentium IV machine, and used *cplex* 9.1 (www.ilog.com) as our MILP solver. The empirical results shown in Figure 2 were collected from 100 randomly generated test problems. Figure 2 illustrates anytime performance of these three algorithms, in which we can see that MILP-HCS is able to find good solutions much faster than the other two algorithms.

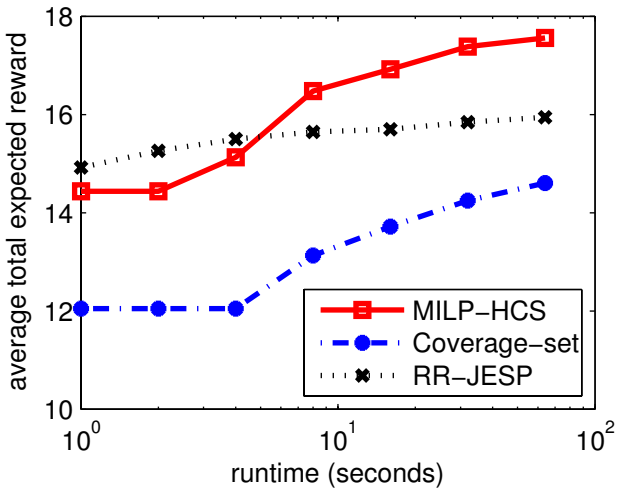

Figure 2: Anytime performance of three algorithms.

5. CONCLUSION

We have described a novel MILP-HCS algorithm for solving transition-independent Dec-MDPs, and shown through experiments that this algorithm is able to find a satisfactory solution much faster than previous approaches. This work links transition-independent Dec-MDPs with mixed integer linear programming, and lays the foundation for further efforts of exploiting established MILP techniques.

ABSTRACT

Recently we had proposed two untraceability protocols for mobile agents and began investigating their quality. We believe that quality evaluation of security protocols should extend a sole validation of their security and cover other quality aspects, primarily their efficiency. Thus after conducting a security analysis, we wanted to complement it with a performance analysis. For this purpose we developed a performance evaluation framework, which, as we realised, with certain adjustments, can be applied to evaluate performance of a whole class of security protocols for mobile agents. This class contains the protocols in which each host on the agent's route is responsible for providing a security function, and, inter alia, includes a big variety of integrity checking schemas and accountability mechanisms for mobile agents such as Lee's Partial Results Authentication Codes or family of Karjoth's et al protocols for protection of computation results of free-roaming agents. Finally, we used the framework to evaluate efficiency of our Untraceability Protocol I. In this paper we present the framework and the results of the evaluation.

1. INTRODUCTION

We proposed two security protocols for untraceable migration of mobile agents [1, 2] which have this advantage over other existing untraceability protocols for agents, that they support agents' autonomy in choosing their route [1, 2]. We performed a basic security analysis of the protocols [1, 2] by checking their resistance to known generic and traffic analysis attacks, and currently we are working on extending this analysis. We also applied the protocols to an e-health service to verify their applicability to real IT services [3].

Although in [2] we had presented some implementation suggestions aiming at improving performance of the protocols, the general question of their performance was left open. In this paper we present the results of our recent work aiming at comprehensive coverage of the issue.

To evaluate performance of our protocols we developed a framework. The framework is composed of three modules: an analytic study, related to computation of time complexities; a performance benchmark based on standard performance testing; and a protocols' target environment overhead estimation. The objective of the first part was to obtain the indicator of the protocols' performance, independent of a concrete computer architecture, agent environment and implementation details [4]. The empirical part aims at complementing the analytical results with validation of the simplifying assumptions of the analytical model which was introduced to derive the final complexity equations; and providing a direct view on the protocols' efficiency in a real context. The third module is to obtain a picture of the overhead which will be brought in by the protocols to their target architecture.

In the next sections we will describe the framework and we will present the results of evaluation of our Untraceability Protocol I performed on its basis. Because the description of the framework often refers to our real case, we decided to precede it with a brief presentation of the protocols.

2. UNTRACEABILITY PROTOCOLS

Anonymity is the property that ensures that a user may use a resource or a service (the items of interest) without disclosing his/her identity [5]. *Untraceability* is a subclass of communication anonymity [6] assuring that the identities of the message sender and the receiver can not be inferred (and linked) by tracing the message. In case of mobile agents this

means that the agent's owner and the target (a particular location or just a statement of the goal) can not be identified by tracing the agent.

Anonymity plays a crucial role for various activities conducted in the Internet. Gülcü et al [7] describe four categories of the activities[1]. These are: discussion of sensitive and personal issues, information searches, freedom of speech in intolerant environments and polling/surveying. For some of these uses, the anonymous access was an enabler and contributed to increasing the popularity of the Internet.

To support anonymity in agent environments we proposed an untraceability protocol for mobile agents – the *Protocol I* which has this advantage over the solutions of Westhoff et al and Enzmann et al [8, 9] that it does not constrain agents' autonomy of choosing a migration path.

In brief, the concept of the protocol is that an agent, while migrating, at each visited host encrypts the identifier of the last visited host (using the public key of the present host) and puts it in the LIFO queue stored in its state. Then, after achieving a goal, when the agent wishes to come back to its base host, it uses the queue to find its way back. Down the route back the identifiers are subsequently decrypted using each host's private key [2].

We investigated security [1] of the protocol and figured out that the protocol, while being effective, is prone to the costly, nonetheless possible to perform – *cordoning-off attack* – i.e. the attack in which the attacker compromises all hosts surrounding the source one [1]. Consequently we introduced the *Protocol II* which eliminates this vulnerability at the cost of addition of some computation workload to the source host and restriction of the agent's autonomy at the beginning of its route [3]. Hereby we gave choice to the users: they can use more effective but slightly less secure Protocol I, or choose the Protocol II, to receive stronger protection.

Because we do not refer to the second protocol in this article, we decided to skip its details. An interested reader may find them in the [3].

3. FRAMEWORK

The framework consist of three modules: an analytic study, a performance benchmark and a target environment overhead estimation.

The first module, aiming at estimation of performance of protocols which abstracts of any underlying technological architecture [4], focuses on calculation of time complexity of a protocol as a function of the length of the agent's route.

The second, provides a practical view at the performance of the protocols, allowing to confront the analytic results with the figures obtained during the tests performed in a testing architecture.

The third module gives an image of the overhead brought in by the protocols to their target architecture.

We developed the framework to evaluate performance of our untraceability protocols but we believe it can be applied to the whole class of security protocols for mobile agents.

This class contains the protocols in which each host on agent's route is responsible for providing a security function. For example in case of our Protocol I, each host has to compute the hash value of a concatenation of the preceding container identifier $\mathsf{ID}_{\mathrm{m}-1}$, the own identifier and the successor identifier; then it has to encrypt the $\mathsf{ID}_{\mathrm{m}-1}$, the hash value and a nonce with its secret key; so the agent could add it to the end of its queue of encrypted platform identifiers [3].

Another example is the Simple Partial Results Authentication Codes (Simple PRAC) schema of Lee et al [10]. In the schema a digital signature (and optionally a hash function) has to be computed at each host to assure that the partial results collected at the host are not-repudiable and undeniable.

To the group also belong other variations of Yee's PRAC such as MAC-based PRAC with One-Way Functions [10], and techniques presented by Karjoth et al [11] as well as the Vigna's tracing schema [12]. Apparently most of the methods aiming at detection of tampering with data gathered by a mobile agent will fall into the category since they are based on the similar concepts.

Thus, our framework, although primarily targeting our untraceability protocols, eventually may become very useful to evaluate performance of various other security protocols for mobile agents.

4. ANALYTIC STUDY

The analytic study focuses on calculation and comparing time complexities of security protocol -enabled (protected) and -disabled (plain) agent's migrations. These complexities are calculated as sums of partial times spent on each involved host. Because specific protocols may differ from each other with relation to numbers of these hosts between protected and plain migration (e.g. in our case untraceable migration needs twice as many nodes as plain migration) or other than Java environments might be required to serve as a reference, the study should be performed individually for a particular protocol. For this reason, we do not provide any common template, yet instead, we present derivations corresponding to our untraceability protocol, which we encourage to use as a reference point.

Since Java is the most popular environment for implementation of agent platforms [13] the Java-founded migration mechanisms served as a reference for our analysis. Relying on our experience, we claim that the general code-transfer principles of Java are equally applicable to other environments, and where they are not, they differences are just slight.

In the next subsection we present the reasoning for the protected (untraceable) migration and then the results of adequate deduction applied to the plain migration. Comparing the results will allow us to derive the equation for the overhead induced by employing our security protocol which we present in section 4.3. Implications of this specific formula we will discuss in further part of the paper.

In this section, the term 'time' is used interchangeably with 'time complexity'.

4.1 Protected migration

During the initialisation of its migration, the Untraceable Agent (UA) is given a route to be traversed in order to achieve its goal. Let N be a length of the route. The total migration of UA is composed of $2N$ steps since, according to the Protocol, during the actual migration, the given route is covered twice – first when the agent performs its task, and second when the agent is coming back to the source location. If time of each step performance is denoted as $\dot{t}[i]$ then the

[1]This is important to note that the authors don't claim this set to be exhaustive.

total migration time of UA $\ddot{T}[N]$ is specified as:

$$\ddot{T}[N] = \sum_{i=1}^{2N} \ddot{t}[i] \ . \tag{1}$$

A single migration step roughly involves – suspension of the execution, then serialization of the agent's state and code, and finally sending the resulting data package to the new location where it is de-serialized and the execution resumes. This implies that the time $\ddot{t}[n]$ is the combination of the following times:

$\ddot{t}_T[n]$ – time of UA's transfer (T) to the container n (from the container $n-1$) through the communication channel,

$\ddot{t}_S[n]$ – time of UA's serialization and de-serialization (S) on the container n,

$\ddot{t}_{TR}[n]$ – time of UA's task realization (TR) on the container n,

$\ddot{t}_{UO}$ – time of UA's untraceability operations (UO) on one container.

The time $\ddot{t}_{UO}$ does not depend on N and is fixed since the untraceability operations always operate on fixed amount of data. The other times can vary: the agent can perform a different task on each location, the agent transfer time depends on characteristics of a transmission medium and the agent (de-)serialization may last longer or shorter proportionally to size of the agent's state. While the first two times are the N-independent, the third includes a component which depends on N – the information about agent's route is maintained in the agent's state.

Because the migration times while heading to the target location and returning to the source can differ significantly, the time $\ddot{t}[i]$ distinguishes between them as follows:

$$\ddot{t}[n] = \begin{cases} \overrightarrow{t}_{UA}[n], & \text{if } 1 \leq n < N; \\ \overleftarrow{t}_{UA}[n-N], & \text{if } N < n \leq 2N; \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

where $\overrightarrow{t}_{UA}[n]$ denotes the step performance while going ahead and $\overleftarrow{t}_{UA}[n]$ represents step performance while going backwards.

The time $\ddot{t}_S[n]$ is a combination of the two components:

$$\ddot{t}_S[n] = \ddot{t}_{RS}[n] + \ddot{t}_{RESS}[n] \ , \tag{3}$$

where $\ddot{t}_{RS}[n]$ is the time of UA's route serialization (RS) and $\ddot{t}_{RESS}[n]$ – the time of UA's route excluded state serialization (RESS).

The time $\ddot{t}_{RS}[n]$ can be expressed by the times of atomic serialization operations:

t_{LS} – time of one location serialization (LS),

t_{ELS} – time of one encrypted location serialization (ELS),

– and distinguished between $\overrightarrow{t}_{UARS}[n]$ – the time of route serialization (RS) while UA is heading the target location and $\overleftarrow{t}_{UARS}[n]$ – the time of route serialization (RS) while the UA is coming back to the source:

$$\overrightarrow{t}_{UARS}[n] = [N-n]t_{LS} + nt_{ELS} \ , \tag{4}$$

$$\overleftarrow{t}_{UARS}[n] = [N-n]t_{ELS} \ . \tag{5}$$

Consequently:

$$\begin{aligned} \overrightarrow{t}_{UA}[n] = \ddot{t}_{TR}[n] + \ddot{t}_{RESS}[n] + (N-n)t_{LS} \\ + nt_{ELS} + \ddot{t}_{UO} + \ddot{t}_T[n] \ , \end{aligned} \tag{6}$$

$$\overleftarrow{t}_{UA}[n] = \ddot{t}_{RESS}[n] + (N-n)t_{ELS} + \ddot{t}_{UO} + \ddot{t}_T[n] \ , \tag{7}$$

$$\ddot{T}[N] = \sum_{i=1}^{N} \overrightarrow{t}^{UA}[i] + \sum_{i=1}^{N} \overleftarrow{t}^{UA}[i] \ , \tag{8}$$

and the final expression for $\ddot{T}[N]$ is:

$$\begin{aligned} \ddot{T}[N] = N^2 t_{ELS} + 2N\ddot{t}_{UO} + \frac{N(N-1)}{2} t_{LS} \\ + \sum_{i=1}^{N} \ddot{t}_{TR}[i] + \sum_{i=1}^{2N} \ddot{t}_{RESS}[i] + \sum_{i=1}^{2N} \ddot{t}_T[i] \ . \end{aligned} \tag{9}$$

4.2 Plain migration

After applying the analogous reasoning and notation to the Traceable Agent (TA), and keeping in mind that TA needs only to cover a one-way route (N locations), after which it moves back directly to the source location (1 migration step), the following equations describe the relevant times for TA:

$$\dot{T}[N] = \sum_{i=1}^{N} \overrightarrow{t}_{TA}[i] + \overleftarrow{t}_{TA} \ , \tag{10}$$

$$\overrightarrow{t}_{TA}[n] = \dot{t}_{TR}[n] + \dot{t}_{RESS}[n] + (N-n+1)t_{LS} + \ddot{t}_T[n] \ , \tag{11}$$

$$\overleftarrow{t}_{TA}[n] = \dot{t}_{RESS}[n] + \ddot{t}_T[n] \ . \tag{12}$$

And from the above we can convert (10) into:

$$\begin{aligned} \dot{T}[N] = \frac{N(N+1)}{2} t_{LS} + \sum_{i=1}^{N} \dot{t}_{TR}[i] \\ + \sum_{i=1}^{N+1} \dot{t}_{RESS}[i] + \sum_{i=1}^{N+1} \dot{t}_T[i] \end{aligned} \tag{13}$$

4.3 Overhead

The overhead introduced by the untraceability protocol can be calculated as a ratio:

$$\frac{\ddot{T}[N] - \dot{T}[N]}{\dot{T}[N]} \cdot 100\% \ . \tag{14}$$

where the value of $\ddot{T}[N] - \dot{T}[N]$ is given as following:

$$\begin{aligned} \ddot{T}[N] - \dot{T}[N] = N^2 t_{ELS} + 2N\ddot{t}_{UO} \\ + (N-1)\ddot{t}_{RESS} + \sum_{i=1}^{N-1} \dot{t}_T[i] - Nt_{LS} \end{aligned} \tag{15}$$

It is assumed that the parameters not related to untraceability are equal, i.e. n: $\dot{t}_{TR}[n] = \ddot{t}_{TR}[n]$ and $\dot{t}_T[n] = \ddot{t}_T[n]$ and $\dot{t}_{RESS}[n] = \ddot{t}_{RESS}[n] = t_{RESS} = const.$

5. PERFORMANCE BENCHMARK

The testing module is composed of a testing architecture and a series of tests to be performed upon it.

5.1 Testing architecture

To obtain meaningful test results, tests should be performed either directly in the target environment or in an environment that is sufficiently close to the target one. Since at security protocols' design and validation stages authors of protocols usually do not know the target environment, and yet because security protocols are usually designed to cover various areas of problems (both cases applied to us), only the second option remains available.

To reach the feature of sufficient proximity between testing and possible target environments, when designing our testing architecture, we paid particular attention to its flexibility and configurability. In other words, we aimed at providing an architecture, which with one setting of 'switches' would be similar to one predicted target environment, while with another setting it would become close to another target environment.

For this reason, firstly we had to identify the characteristics of computational environments which have the strongest impact on performance of the environments.

Each agent environment is composed of three layers: the agents layer, comprising agents of any type; the underlying containers layer – a middleware allowing agents' operation; and the hosts layer which aggregates hosts interconnected via a computer network.

When extracting the characteristics of interest we examined each of the three layers respectively. Results of the study are listed in the table 1[2].

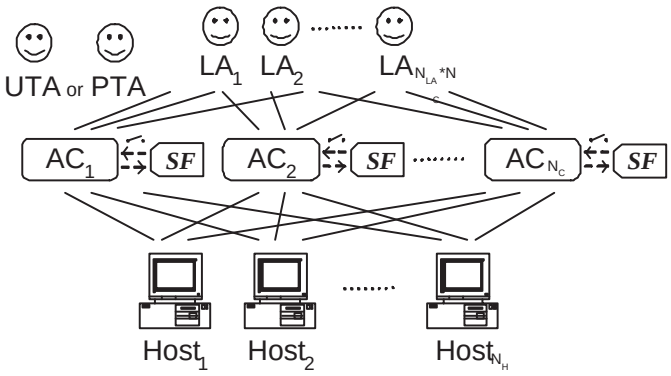

Figure 1: Benchmarks architecture.

After receiving the above characteristics we developed a three-layered testing architecture (Figure 1) in which we can control a subset of the characteristics. The architecture is realised in Java Agent DEvelopment Framework (JADE – `http://jade.tilab.com/`) since it appears to be most popular agent middleware [13].

In our architecture, the agents layer is composed of Load Agents (LAs), amount of which is flexibly adjustable. As the name indicates, the main aim of LAs is to load the environment and consume its resources. This must be done quite similarly to as original agents would do. Thus, each LA actively operates in the system – it migrates and 'realises tasks'. The task realisation is simulated by stopping LA on a container for a random period in time. Despite the fact that the container resources are not consumed directly in sense of being utilised by a working agent, the LA's presence on a container requires reservation of an execution space for LA. The stay-time is chosen with equal probability from the range between 10 milliseconds and 10 seconds – corresponding to various kinds of agent tasks. Another type of diversity of agents' behaviours, is simulated by introducing two types of LAs – Protected LAs (PLAs) and Unprotected LAs (ULAs), what allows to examine the behaviour of the environment depending on the level of use of protection (usually only a certain subset of agents requires protection).

Since our untraceability protocols do not involve any agent intercommunication and a user-control we decided not to include these characteristics of agents layer into our architecture. We also did not examine nuances of implementation since our protocols straightforwardly follow specifications and do not leave a space for performance-focused improvements.

In the containers layer we can configure a number and deployment of containers and to enable or disable protection. Originally we used untraceability but it may be conveniently replaced by any other measure by means of JADE add-ons. We can also enable another services, which could consume (or provide) additional resources of environment.

The hosts layer is very independent of the actual implementation of our architecture and can be flexibly configured according to the hardware resources available to testers.

In such simulated environment test agents are run. Each such agent can be either an Unprotected Test Agent (UTA) or a Protected Test Agent (PTA). They are identical except that the first one utilises and the second one does not utilise the untraceability service.

During a test each test agent has to follow the route of N_{IC} length N_R times. The UTAs and PTAs are following the same routes. The time of passing every round is measured and recorded as well as the time of passing all N_R rounds. The precision of time measurements is 10 milliseconds [3].

5.2 Tests

The objectives of the tests were to:

- examine if and to which extent enabling protection affects performance of agents which do not use it,
- compare performance of protected agents (PAs) and unprotected agents (UAs),
- analyse performance of PAs as a function of length of the agent route and the agent environment load.

While comparing performance of UAs and PAs the two most common agent migration scenarios were taken into consideration[4]:

Agent Migration Scenario I – the agent has its goal formulated in general terms so the it has to traverse mul-

[2]It is important to note that the authors do not claim this set to be exhaustive.

[3]We have used java `System.currentTime()` – being the most precise of the program execution measuring methods which do not require hardware devices [14].

[4]In figures we use the notation: N_C – total number of containers, N_{IC} – number of Intermediate Containers (IC).

layer	characteristics
Agents Layer	number of agents present in the environment, diversity of agents behaviours (including agent relocation), agents intercommunication, agents implementation, agents resources, agents control (autonomous agents, user-controlled agents etc)
Containers Layer	number of containers, containers deployment, services resources
Hosts Layer	number of hosts, hosts efficiency, inter-host communication (communication protocols, communication medium)

Table 1: Characteristics of agent environments of the strongest influence on performance of the environments.

tiple locations in order to satisfy the goal (e.g. web crawling)

Agent Migration Scenario II – the agent goal is to visit its target location and to perform its task there (e.g. bandwidth conservation scenarios – in which an agent is sent to a remote host in order to reduce multi-host communication)

Figures 2 – 5 illustrate the scenarios applied to our untraceability protocol.

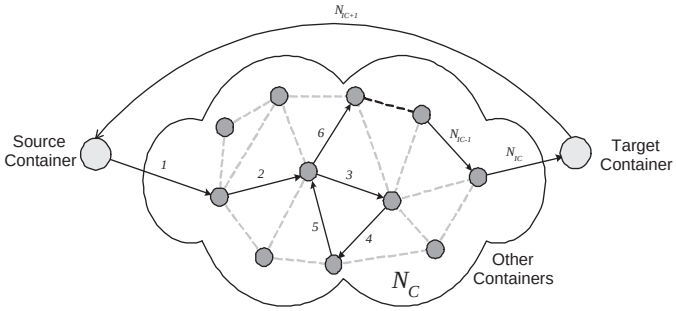

Figure 2: Agent Migration Scenario I realized by TA: TA traverses N_{IC} containers and in N_{IC+1} step returns to the source container.

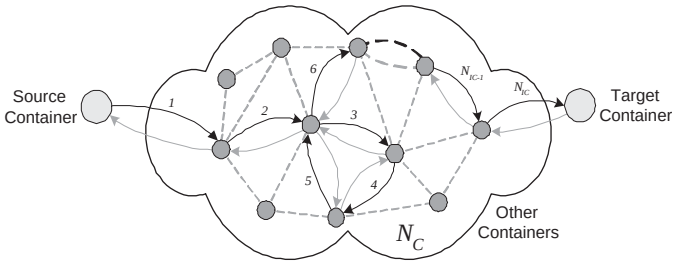

Figure 3: Agent Migration Scenario I realized by UA: UA traverses N_{IC} containers and then has to cover the traversed route again (in reversed order) to return to the source container.

In each case, after achieving the goal the agent returns to the source container.

6. TARGET ENVIRONMENT OVERHEAD ESTIMATION

As a third module of the evaluation framework we propose estimation of overhead brought in by a security protocol to the foreseen target environment.

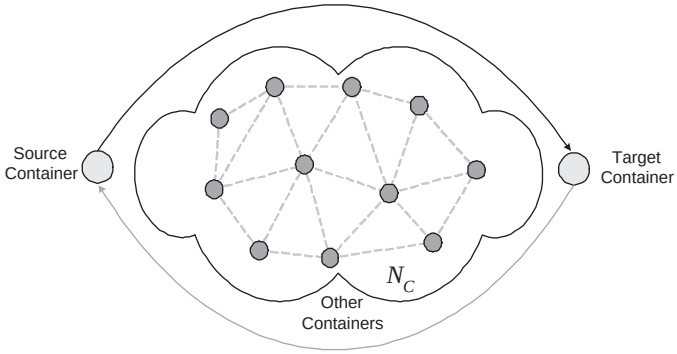

Figure 4: Agent Migration Scenario II realized by TA: TA simply 'jumps" directly to the target container and after realizing its task returns to the source container.

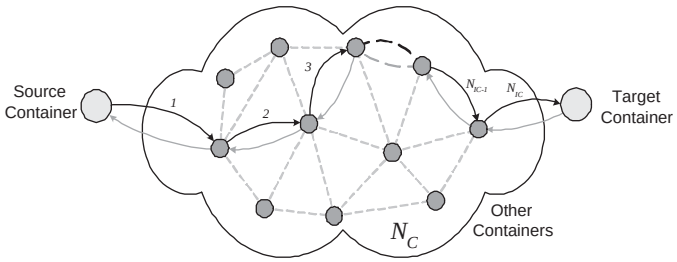

Figure 5: Agent Migration Scenario II realized by UA: Before reaching the target container the UA has to cover an intermediate route of a length N_{IC} in order to hide a migration trace. This route must be traversed again by the UA when returning to the source container.

At this stage it is necessary to obtain the specification of the target environment allowing the most precise determination of functional types of agents required in the environment and their quantitative proportions. With these figures it is possible to assess the amount of the agents actually utilising the security protocol, and on its ground, to evaluate the real overhead which the security protocol will bring to the environment.

We will illustrate this on the example of our protocols.

One of the applications where users anonymity (so untraceability) plays crucial role is anonymous e-health counselling. Anonymous e-health counselling is a service allowing IT-based provision of health related advices on an anonymous basis. Another words, it provides all functionalities for performing the scenarios where a patient using an IT system asks for a health advice, yet wishes to do it anonymously (because, for example, they suffer from an embar-

rassing disease or from an addiction) [15].

This application, which for the first sight seems to be quite dedicated, in reality it represents a large area of (often used) applications in which the schema of agent-based accessing multiple knowledge sources in order to obtain a comprehensive information is implemented [3].

Thus we developed an experimental application providing the e-health counselling service [3] which takes advantage of untraceable agents – to provide ourselves the opportunity to observe how our protocols behave in a real settlement.

And the e-health environment we treated as the target environment when estimating the level of the total untraceability overhead brought in by enabling the untraceability service.

The target health environment involves many stakeholders participating in the process of medical service delivery: patients, health professionals, pharmacists, dietitians etc. In the technological e-health platform, a stakeholder is represented by an agent, – its *Virtual Ego*. Apart of Virtual Ego agents, various other agents are present in the platform [3]: Knowledge Discovery Agents (KDA), Information Agents (IA) and a compound group of Auxiliary Agents (AA) – encompassing different types of agents responsible for performing supportive tasks (Figure 6).

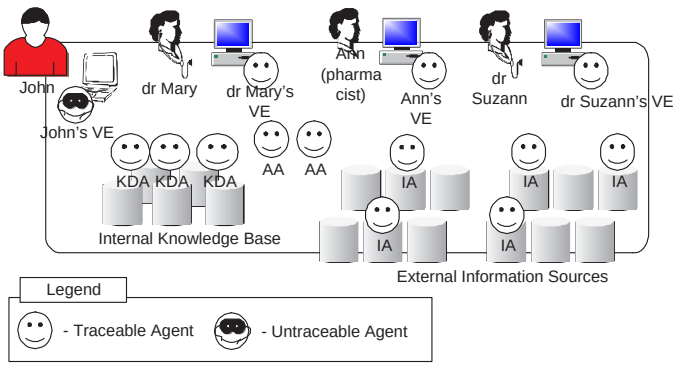

Figure 6: Mobile agent based health platform.

For such platform we estimated the proportion of active (running) agents in the system as a function of N_{PU} – the number of patients using the system at a particular moment ($N_{PU} \leq N_P$, where N_P is the number of all agents registered in the system). It is worth to note that besides these active agents also temporarily suspended agents exist in the system, which wait for dispositions of their owners. Our prognoses are based on the report of Royal College of Physicians of London [16] saying that average number of practising physicians per 1000 inhabitants in Europe equals 3.4 and the surveys conveyed under the International Network Health Policy & Reform project indicating average 6.19 health consultations per person taking into account ten European countries [17]; and our experience in design of IT systems.

The results (assuming $N_{PU} = 10000$) are presented in the table 2.

With the figures we estimated the overhead. The results of the estimation we present in the next section.

7. EVALUATION RESULTS

7.1 Analytic study

The equation (15) for the overhead introduced by the untraceability protocol, indicates polynomial (quadratic) dependence of $\ddot{T}[N] - \dot{T}[N]$ on N. The Untraceability-Related Component (URC) ($N^2 t_{ELS} + 2N\ddot{t}_{UO}$ – with a higher significance of the first component of the sum) grows faster than the Migration-Related Component (MRC) ($(N-1)\ddot{t}_{RESS} + \sum_{i=1}^{N-1} \dot{t}_T[i]$). However the real value of t_{ELS} is at least four orders of magnitude smaller than the value of MRC, which means that not until N reaches very high values ($N \geq 10000$), the influence of URC becomes visible. In practical agent applications, agents scarcely (if ever) have to cover routes of such lengths. It must be also remembered that assigning a route of that large length to a traceable agent, leads to dominance (because of the quadratic growing with reference to location serialization) of the route-storage component as well.

7.2 Performance benchmarks

The following benchmarks were performed basing upon our testing architecture:

Test I – Comparing the non-protected agent (the traceable agent – TA) performance in the untraceability enabled and untraceability disabled environments, $N_{IC} = N_C = 100$, the random stay-time is turned off,

Test II – Comparing migration times of the traceable agent (TA) and the untraceable agent (UA) as the function of N_{IC}, $N_{IC} = NC \in 20, 40, 60, 80, 100, 120, 140$ (refers to Migration Scenario I),

Test III – UA performance dependent on N_{IC}, $1 \leq N_{IC} \leq 64$, $N_C = 150$ (refers to Migration Scenario II),

Test IV – Comparing UA performance in variably loaded environments. Due to identified problems with JADE this test was performed for $N_C = 60$ and only three $N_L A$ values – $N_L A \in 60, 120, 180$.

At the current stage of our research all benchmarks were performed on one host[5], but we consider extending them to a higher number of hosts in the future.

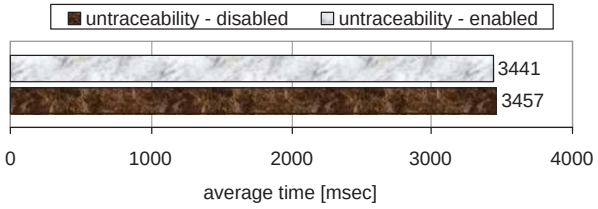

Figure 7: Test I – Comparing TA performance in untraceability enabled and untraceability disabled environment, $N_{IC} = N_C = 100$.

The results of Test I (see Fig. 7) empirically prove that enabling the untraceability service does not influence the per-

[5]Intel®Pentium®4, 3 GHz, 1.5 GB RAM. Java™2 Runtime Environment, Standard Edition (build 1.4.2_01-b06), Java HotSpot™Client VM (build 1.4.2_01-b06, mixed mode) – run with default settings.

active patients	patients VE	health physicians VE	KDA	IA	AA
10000	10000	34	5000	5000	30000

Table 2: Numbers of different mobile agents running (active) in the health system for 10000 active patients.

formance of traceable agents[6]. This is not surprising since the mobile agents do not use any functions from the service. However the question was if the fact that the service is enabled on the containers (and takes some resources) might affect the performance.

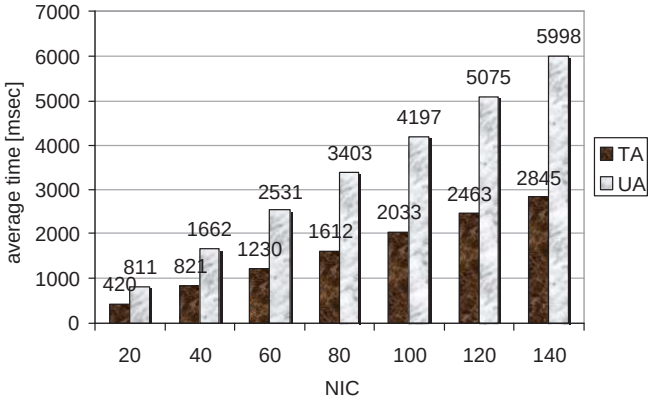

Figure 8: Test II – Comparing migration times of TA and UA dependent on N_{IC} (refers to Migration Scenario I).

The results of Test II (Figure 8) confirm the intuition, that for realistic values on N_{IC}, the dominant factor influencing the performance is agent migration – the approximately linear growth of time consumption in dependence on N – practically the same for TA and UA (the linearity coefficient is roughly equal to 1 – to cover two times longer route agent needs approximately two times more of time) – as it could be inferred from the estimation of complexity. Consequently, the dominant role of the migration factor affected the overhead, which oscillates on the level of around 100% – UA must again cover the already traversed route whereas TA just 'jumps' from the target location back to the source.

The meaningful result is obtained from Test III – when sending UA the user has to be conscious that its performance is directly proportional to the length of untraceability route (Figure 9).

Test IV confirms the intuition that if the number of the load agents approaches the limit resulting from the capacity of the agent environment, the performance falls significantly (as the result of the shortage of the operational resources) (Figure 9).

7.3 Target Environment Estimated Overhead

Assuming that every tenth patient want's to take advantage of a medical service untraceably, only 1000 of total 50034 active agents will introduce the overhead related to untraceability to the platform. Having in mind that each

[6]The slight difference of values (this time, surprisingly –) in favour of the untraceability enabled environment is in the range of standard deviation which is equal to 110 [ms].

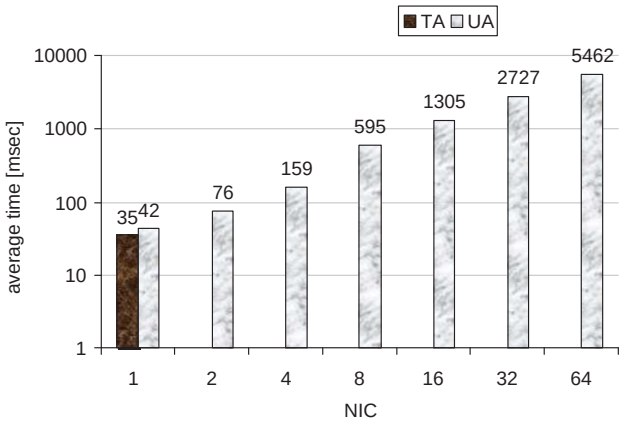

Figure 9: Test III – UA performance dependent on N_{IC} (refers to Migration Scenario II).

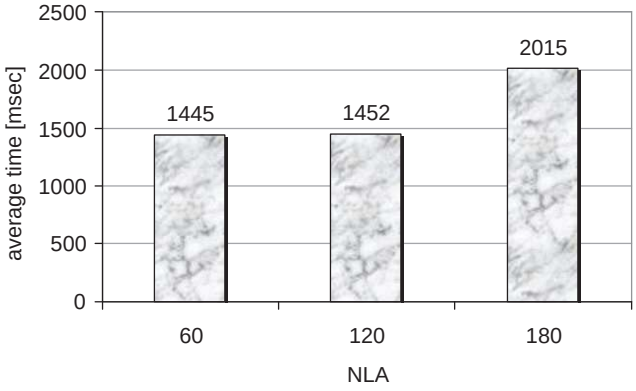

Figure 10: Test IV – Comparing UA performance in variably loaded environments.

individual UA introduces around 100% of the TA overhead, and representing a performance of each TA as 1 Unit of Performance (UP), for 50034 UP's – related to the presence of 50034 agents in the system – the 1000 UA's will induce additional 1000 UP's. Consequently the total overhead (we must underline that the overhead is related solely to a time of migration and not with any other agent activities) will be almost 2%.

8. SUMMARY

The paper presented a performance evaluation framework which although originally designed for our untraceability protocols, may be applied to a much wider category of security protocols for mobile agents. This category include all the protocols where during migration of agent, a security function is computed at each host passed. The framework is based on three modules. The first, analytic module aims

at deriving a mathematic formulae for the overhead imposed by the employment of the protection, and involves computation of time complexities of standard and protected agents. In the empirical part we provide a testing architecture and a series of tests to be performed upon it, in order to obtain 'real' performance characteristics of protected and unprotected agents. The third module requires forecasting the structure of the environment to which the protection will be added and it results in estimation of the overall overhead brought in by the protection.

With the architecture, we carried out the evaluation of our Untraceability Protocol I. We derived the universal (not tied to any implementation) symbolic equation for the overhead as a function of the length of the agent's route. Then we performed the tests, results of which confirm the analytical estimates and provide more concrete data related to the Java enabled agent platforms. The general result is that untraceability cost (in terms of time overhead resulting from traversing a given route) is twice as much as the cost without untraceability. A good news is that this cost does not depend on the tasks performed by the agent. It should be also remembered that the real agent applications would likely be composed of both – traceable and untraceable – agents, so the resulting total overhead would be relatively small (see Section 7.3).

ABSTRACT

This paper studies scalable data delivery algorithms in mobile ad hoc sensor networks with node and link failures. Many algorithms have been developed for data delivery and fusion in static microsensor networks, but most of them are not appropriate for mobile sensor networks due to their heavy traffic and long latency. In this paper we propose an efficient and robust data delivery algorithm for distributed data fusion in mobile ad hoc sensor networks, where each node controls its data flows and learns routing decisions solely based on their local knowledge. We analyze the localized algorithm in a formal model and validate our model using simulations. The experiments indicate that controlled data delivery processes significantly increase the probability of relevant data being fused in the network even with limited local knowledge of each node and relatively small hops of data delivery.

1. INTRODUCTION

The mobile ad hoc sensor networks of the near future are envisioned to consist of hundreds of UAVs (unmanned aerial vehicles) or robots. These networked mobile sensors play strong roles in military and civilian operations, e.g., battlefield surveillance, disaster search and rescue [9, 15, 13]. One phenomenon in mobile sensor networks is that the raw data from each sensor usually has low confidence. The raw data cannot be used directly for team coordination and has to be fused with other relevant data [11]. Various statistical inference techniques have been studied for distributed data fusion in mobile sensor networks, but these approaches do not have any control on the data flows [12]. Uncontrolled data flows may cause large amount of conflicting plans and have severe effects on the performance of the whole network when mobile sensors work together to conduct high-level tasks. Thus, how to optimize communication strategies for team coordination is an important problem for mobile ad hoc sensor networks [18]

Many protocols have been developed for data delivery and fusion in microsensor networks with small and battery-powered "motes", where a node, called a sink, attempts to gather data from a number of data sources [21]. For example, in directed diffusion, the sink floods a query toward the sensor nodes in a specific area [7]. The source nodes within the specific area then send data back to the sink along the best path. In other words, a source node will not send any data back to the sink until it receives the query. For this reason, these routing protocols are called *reactive protocols*.

Reactive protocols are mainly designed for microsensor networks, where the sensors are stationary after deployment. They are not appropriate for mobile sensor networks for the following two reasons:

- Heavy traffic: Since locations of collected data are not correlated with existing positions of mobile sensors, effective routing of either query or data is usually infeasible. Sinks have to flood the queries to the whole network when they need the data each time for a specific area. This could overload one or more sinks and cause a lot of traffic in the network.

- Long latency: Sinks usually do not know when source nodes will have the data in mobile sensor networks. If the source nodes follow reactive protocols, they have to wait for the queries from sinks to send the data. This causes long latency and cannot meet the requirements of time-critical missions in many defense and civilian applications for mobile sensor networks [2].

In this paper we present a scalable and reliable approach to data delivery in mobile ad hoc sensor networks with failures. While failures could happen at either team coordination level or data communication level, our approach focuses on communication failures for sensor data delivery among

mobile sensors [8]. We assume these mobile sensors such as UAVs are "blind" in some sense and they cannot monitor the activities of other sensors directly.

In our approach there is no querying process and each node proactively forwards the data to one of its neighbors. The constraint here is that nodes have no global knowledge of network topology. Each node has to intelligently deliver data solely based on the knowledge about itself and its neighbors. Moreover, the data delivery processes need to be survivable to failures. The challenge is, with various decisions made by individual sensors, how to minimize the communication overhead and maximize the probability of relevant data being fused in the network.

We propose an efficient and failure-resistant localized algorithm over mobile ad hoc networks, where each node learns routing decisions from its history of data delivery via *Q-learning*. We study the process of neighbors selection for each sensor node and the emergence of a spanning tree in the network for reliable data delivery. Moreover, we analyze the probability of relevant data being fused in a random network in a formal model and validate our model using simulations. The experimental results show that controlled data flows significantly increase the probability of relevant data being fused, where the probability is improved by two to five times for the same hop of data propagation.

The rest of this paper is organized as follows. Section 2 summarizes the relevant literature. Section 3 briefly describes the background of mobile ad hoc sensor networks. Section 4 investigates the design of protocols and localized algorithms for data delivery and fusion. Section 5 provides a formal analysis of the data delivery algorithm in mobile sensor networks. Section 6 presents some experimental results for the algorithms. Section 7 discusses the main themes and some directions for future research.

2. RELATED WORK

Mobile sensor networks have been studied by Howard et al. [6], but their work focuses on the coverage problem of a multi-robot system, and does not consider the effective data delivery for fusion. Q-learning and ants algorithms have been studied by [1, 19] for network routing problem. Routing problem is different from ours since the sensor data does not have explicit destination during the data delivery processes. Moreover, we need not consider alternative paths for surplus sensor data. The data propagation paths are deterministic in our approach, while paths in ants algorithms are probabilistic.

Multisensor data fusion has been studied for a long time, where both the data fusion and control algorithms are centralized [3, 4]. We will not discuss the literature on multisensor data fusion since they fall outside of the scope of this paper.

Distributed data fusion in sensor networks has been focused on statistical inference techniques. For example, Niu et al. investigate an optimum local fusion detection threshold for binary hypothesis testing by local sensors [14]; Rosencrantz et al. present a Bayesian technique for decentralized state estimation using particle filters [16]; and Durrant-Whyte et al. consider distributed data fusion as a state estimation problem using information filter (a variant of Kalman filter) [11, 12]. These approaches focus on detection and tracking performance of distributed sensor networks. They do not have any control on the data flows in the network. In this paper we propose an efficient data delivery algorithm for distributed data fusion. Moreover, we study the tradeoff of the efficiency and fusion probability in a network with node and link failures.

3. BACKGROUND

This section provides some background on mobile ad hoc sensor networks.

We assume mobile sensors communicate on a point-to-point basis [17]. A network of these mobile sensors is modeled as a connected undirected graph $G = (V, E)$, where $V = \{a, b, \ldots\}$ is a set of sensor nodes and E consists of edges between any two nodes a and b that can communicate directly. $N(a)$ is the set of a's neighbors and $b \in N(a)$ is any neighbor of node a. Note that neighbors in mobile sensor networks need not be in the proximity and they are neighbors only in the logical sense.

There are two types of communication failures in a mobile ad hoc sensor network: *node failure* (the loss of sensor nodes) and *link failure* (unreliable communication channels). Link failure is temporary and is modelled as a fixed probability for any two nodes in our scenario. Node failure is permanent and cannot be recovered once the node is dead. Following [5], we model the reliability $R_a(t)$ of a node a as a Poisson distribution

$$R_a(t) = e^{-\lambda_a t} \tag{1}$$

where λ_a is the failure rate of the sensor node and t is the time period. $R_a(t)$ captures the probability of not having a failure within the time interval $(0, t)$. $1 - R_a(t)$ describes the probability of a node failure. The higher the failure rate λ_a, the lower the reliability of a sensor node.

Specifically, we consider a UAVs network for target detection, tracking, and classification in the battlefield. We assume there are multiple stationary or moving targets $T_1, T_2, \ldots, T_M$ on the ground. A target $T_K (1 \leq K \leq M)$ may be detected by multiple UAVs at the same time, but each UAV cannot initialize its plans based on its own raw sensor data about the target, e.g., engagement of its missile with a target. The reason is that the raw sensor data from a UAV is uncertain and noisy. Sometimes, a UAV with SAR (Synthetic Aperture Radar) may even confuse friendly targets ($T80$ tanks) with enemy targets ($M1$ tanks). Hence, the low quality sensor data cannot be used directly for high-level plans and has to be delivered to other nodes for fusion in the network [4].

If sensor a detects a target T_K, it will generate an event e_i about target T_K. An event e_i about T_K can be denoted as a tuple $\langle sender, identity, location, TTL, pedigree \rangle$, where

- *sender* is the ID of the sensor that detects the target.
- *identity* is the decision about the target from the sensor. For example, the target could be classified as $\langle T80, 0.4 \rangle$, where $T80$ is the possible vehicle type and 0.4 is the confidence level.
- *location* is the location of the target T_K being detected.
- *TTL (time-to-live)* is the maximal number of hops allowed for the event propagation in the network.
- *pedigree* is the list of nodes event e_i has been visited, denoted as L. Note that pedigree is used to avoid cycles during event propagation.

The processes of sensor data delivery can be described as follows. When sensor a receives or generates an event e_i about T_K, it first tries to fuse e_i with its previous events about target T_K using statistical inference techniques. [1] If the confidence of fused events meets a threshold, sensor node a will stop the propagation of event e_i and become a sink node for relevant events of T_K. Otherwise, sensor a will choose one of its neighbors to continue the delivery unless its TTL is zero. Note that, sensor a will create an information token about target T_K when it becomes a sink for target T_K. Information tokens are then used for high-level team coordination [18].

4. ALGORITHMS

Obviously, an event does not need to visit all sensor nodes to meet with other relevant events. However, visiting too few sensors can lead to low probability of relevant events being fused. Here two events e_i and e_j are relevant if and only if they are referring to the same target, denoted as $rel(e_i, e_j) = true$. The key is how to minimize communication overload and maximize the probability of relevant data being fused. In this section, we discuss the efficiency and robustness of three algorithms: *random walks*, *path reinforcement* algorithm and *path learning* algorithm.

Random walks are a simple data delivery technique in mobile sensor networks. In random walks, sensor node a with event e_i first decides if it will stop the propagation of e_i. If not, sensor node a just forwards the event e_i to one randomly chosen neighbor $b \in N(a)$. Once the neighbor receives the data, it repeats the same process until the event is successfully fused with other relevant events or the TTL of the event reaches zero.

Obviously, random walks are not efficient for data delivery, since they do not consider the relationships of events and just pass events randomly in the network. Hence, we design other two algorithms — path reinforcement algorithm and path learning algorithm.

4.1 Path Reinforcement Algorithm

The intuition behind path reinforcement algorithm is that relevant events are likely to be fused earlier if they will follow the same path after they meet. Specifically, if sensor node a has sent an event e_i to one of its neighbors b before, it will send b any events e_j if $rel(e_i, e_j) = true$.

Figure 1 shows an example of data flows in the network using path reinforcement algorithm. The solid lines correspond to directed communication channels between sensor nodes. The arrows in dashed lines represent information flows of relevant events e_i, e_j, and e_k. Event e_i and e_j meet at node b and then they follow the same path (event e_j reinforces the path $\langle b, c\rangle$). As shown in Figure 1, the three events are fused at node c.

From the figure it is easy to understand why path reinforcement algorithm is more efficient than random walks for data delivery. For example, if event e_i and e_j meet at node b and they continue to walk randomly in the network, there will be a very small chance that they can meet again and be fused with event e_k at node c.

[1]Commonly used frameworks for processing uncertain sensor data fusion are Bayesian inference method and Dempster-Shafer theory, but the details are outside of the scope of this paper. Readers may refer to [3] for more information.

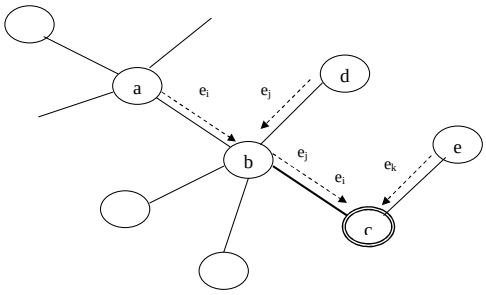

Figure 1: An example of data flows in the network using path reinforcement algorithm, where e_i, e_j, and e_k are three relevant events.

4.2 Path Learning Algorithm

Path reinforcement algorithm is quite efficient when there is no failure in the network. One phenomenon in path reinforcement algorithm is that a sensor never checks if its neighbor has successfully received the data. This will cause severe data loss problem and decrease the probability of relevant data being fused when node or link failures happen.

To remedy to the problem we can allow each node to retransmit the data to another neighbor when a failure is detected. Path reinforcement algorithm with retransmission is robust, but it is not efficient when failures happen. The reason is that sensor a may choose a failed neighbor again when a selects its neighbor randomly. Hence, the key is how to model the reliability of each neighbor, so we can reduce the number of retransmission. Here we describe another algorithm, called path learning algorithm, where each node keeps track of statistics on which neighbor leading to successful data delivery.

Formally, the probability of successfully passing events to a neighbor $b \in N(a)$ at time t is defined as $Q^t(a, b)$ and $0 < Q^t(a, b) < 1$. For any neighbor $b \in N(a)$, $Q^t(a, b)$ is initialized as 0.5 when $t = 0$. Given an event e_i, node a will send e_i to a neighbor $b \in N(a)$ with maximal Q value. Node a will randomly choose a neighbor for e_i if there are any two neighbors b, $c \in N(a)$ and both have maximal Q value at time t, e.g., $Q^t(a, b) = Q^t(a, c)$.

After node a sends out an event e_i to b, a waits for a feedback from b in a period of $\mathcal{T}$. The feedback from b can be defined as

$$feedback = \begin{cases} 1 & \text{if } b \text{ is a sink node for } e_i \\ 0 & \text{if no feedback} \\ max_{z \in N(b)} Q^{t-1}(b, z) & \text{otherwise} \end{cases}$$

where $Q^{t-1}(b, z)$ is the feedback from b and z has the maximal probability from the point of b at time $t - 1$. Here a sink node means b successfully fuses e_i with other relevant events.

The probability to deliver event e_i is updated as

$$Q^t(a, b) = (1 - \alpha)Q^{t-1}(a, b) + \alpha * feedback \qquad (2)$$

where α is the learning rate and $\alpha = 0.5$ in this paper if not specified otherwise. In the case of no response, node a will decrease the value of $Q^t(a, b)$ and choose another neighbor

Algorithms	Efficiency	Robustness
Random walks	bad	bad
Path reinforcement algorithm without retransmission	good	bad
Path reinforcement algorithm with retransmission	average	good
Path learning algorithm	above average	good

Table 1: The comparison of four data delivery algorithms.

to resend the event. The adjusted possibility reduces the chance of choosing b in the future.

Algorithm 1 presents the path learning algorithm, where e_i is an event for target T_K from either node a or other nodes and $\Theta_a(T_K)$ is the set of events about T_K that node a has. Other parameters include: L the pedigree of event e_i and $N(a)$ the set of neighbors of sensor a. The algorithm has two basic parts: (1) deciding if node a will stop propagating event e_i (line 2-4); (2) choosing a reliable neighbor $z \in N(a)$ to deliver e_i and z is not in e_i's pedigree L (line 6-19). Finally, sensor a updates its Q value about neighbor z if $feedback \neq 0$ (line 24).

Algorithm 1 The path learning algorithm

```
1: Suppose sensor a receives or generates an event e_i and
   Θ_a(T_K) is the set of events about T_K at t − 1.
2: Θ_a(T_K) = Θ_a(T_K) ∪ e_i
3: if Θ_a(T_K) has high confidence then
4:    Return success
5: else
6:    repeat
7:       Choose z ∈ N(a) with maximal Q^t(a, z) and z ∉ L
8:       TTL = TTL − 1
9:       L = L ∪ {z}
10:      Send event e_i to neighbor z
11:      if No response from z within time T then
12:         Q^t(a, z) = (1 − α)Q^{t−1}(a, z)
13:         if Q^t(a, z) < ε then
14:            N(a) = N(a) − z
15:         end if
16:         TTL = TTL − 1
17:         L = L − {z}
18:      end if
19:   until feedback ≠ 0 or |N(a)| = φ
20: end if
21: if |N(a)| = φ then
22:    Return fail
23: else
24:    Q^t(a, z) = (1 − α)Q^{t−1}(a, b) + α ∗ feedback
25:    Return success
26: end if
```

Path learning algorithm also helps to maintain the topology of the network when node failures happen. Node a will remove the dead node z from its neighbors when $Q^t_{z \in N(a)}(a, z) < \epsilon = 0.1$ (line 12-13). Intuitively, node a cannot locally distinguish a link failure from a node failure for one time data loss, but it can recognize a neighbor b as a dead node if sensor b continuously fails to deliver data for several times. Also, in order to avoid network partition, node a needs to pass a request in the network when $N(a)$ is small. Any node with small number of neighbors can accept the request and become a neighbor of node a.

4.3 Spanning Tree

From the local view of node a, the feedback from b seems only reinforces the path $\langle a, b\rangle$. But, if we look at the data delivery processes in the whole network, we can find that data flows generate multiple trees, where each tree represents a successful data delivery process for a set of relevant events. The probability $Q^t(a, b)$ serves as the gradient of the path $\langle a, b\rangle$ and controls the direction of data flows.

Once we have multiple trees in the network, there will be two cases for sensor a to deliver an event: (1) if node a is on a tree and is not the root node, it just forwards the event according to the gradient of the path; (2) otherwise, node a just chooses a neighbor with maximal Q value to pass the event. The latter may extend the existing tree or connect the tree with another one.

An important question is how to avoid cycles when a tree connects with another one. A simple way is to check the pedigree of each event before it was sent out. For example, if node x attempts to send event e_i to node a and a already appears in the pedigree of event e_i, x will first reset the gradient between them to 0.5, e.g., $Q^t(x, a) = 0.5$ and then pass e_i to another neighbor y with the highest Q value, where $y \in N(x)$ and $y \neq a$.

Multiple trees will evolve and merge with each other and finally one spanning tree may emerge in the network. The advantage of a spanning tree is that the tree keeps track of the node and link failures and connects most of nodes for reliable data delivery. Note that, in mobile sensor networks, any node on the spanning tree can fuse relevant events and stop the data delivery processes. Hence, our approach is different from other work on building spanning trees in static microsensor networks, e.g., [10], in which nodes on the spanning tree transmit all data to a single sink node and only the sink node has the fusion function.

Table 1 summarizes the properties of four algorithms in terms of efficiency and robustness. Here efficiency denotes the number of messages for data delivery, including both data and feedbacks. The efficiency of path reinforcement algorithm with retransmission is worse than that of path learning algorithm since the former randomly chooses a neighbor, which may be found as a dead node before. Robustness denotes the data loss rates when failures happen. Both random walks and path reinforcement algorithm are vulnerable since they do not have retransmission mechanisms. They do not check if a neighbor has received the data or not.

In the experiments we will evaluate only three of them: random walks, path reinforcement algorithm (without retransmission) and path learning algorithm (only for the spanning tree).

5. ANALYSIS OF FUSION PROBABILITY

In this section we analyze the probability of relevant events being fused in a random network using random walks.

For simplicity, we do not consider link and node failures in the formal model. We assume there are some relevant events e_1, e_2, ..., e_F generated by multiple sensors at the same time. For any sensor node a, the probability that node a knows e_i at hop 0 is $P_a(e_i, 0)$, where $1 \leq i \leq F$.

The probability that sensor node a knows event e_i at hop h as $P_a(e_i, h) \rightarrow [0, 1]$. In a random network with homogeneous sensor nodes, we can model the probability that any sensor node a knows event e_i at hop 0 is

$$P_a(e_i, 0) = 1/|V| \tag{3}$$

where $a \in V$ and $|V|$ is the total number of sensor nodes. Given the relevant events e_1, e_2, ..., e_F, the probability that sensor node a has all these events at hop h is

$$P_a(\Delta, h) = P_a(e_1, h)P_a(e_2, h) \dots P_a(e_F, h) \tag{4}$$

where Δ is the fused result of events e_1, e_2, ..., and e_F.

The probability of all relevant events being fused by any member of the network V is,

$$P_V(\Delta, h) = 1 - ((1 - P_a(\Delta, h))(1 - P_b(\Delta, h)) \dots) \tag{5}$$

where $P_V(\Delta, h)$ is called the probability of fusion and $V = \{a, b, \dots, \}$. We assume the condition $P_a(\Delta, h) = P_b(\Delta, h) = \dots$ holds in a homogeneous logical network, and we can rewrite the probability that the team can do the fusion at hop h as,

$$P_V(\Delta, h) = 1 - (1 - P_a(\Delta, h))^{|V|} \tag{6}$$

Figure 2: The relationships of three probabilities in the formal model

Figure 2 gives relationships among three probabilities in the formal model: $P_a(e_i, h)$, $P_a(\Delta, h)$, and $P_V(\Delta, h)$. From Equation 4 and Equation 6, we can find that the computation of the probability of fusion $P_V(\Delta, h)$ is trivial once we have the value of $P_a(e_i, h)$. Next we will describe how to compute the probability $P_a(e_i, h)$ for random walks.

Initially we have $P_a(e_i, 0) = 1/|V|$ for any sensor a. Its probability of knowing event e_i at hop 1, $P_a(e_i, 1)$, depends on the follows,

- Its probability of knowing event e_i at hop 0, $P_a(e_i, 0)$,
- The probability of being told e_i from its neighbors at hop $h = 1$.

The latter depends on two parts: (1) the probability of knowing e_i for one of its neighbors b at hop zero ($h = 0$), $P_b(e_i, 0)$; and (2) the probability of whether sensor a can get e_i from any neighbor b, denoted as $\delta(a, h)$.

The challenge is how to estimate $\delta(a, h)$ for random walks. Intuitively, random walks can be viewed as a random walker moving around in the network. If the walker's position is on node b, then it has $1/m$ probability to visit one of its neighbor. If not, sensor b cannot pass e_i to sensor a even when b knows e_i. Figure 3 shows an example of random walks for event e_i in the network, where the random walker visits node c, b, j, and g and its existing position is at g.

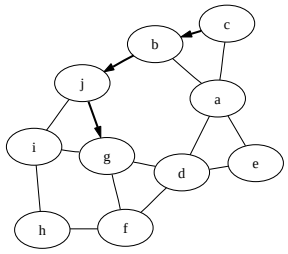

Figure 3: A example of random walks in the network, where the random walker visits nodes c, b, j, and g.

In this case, b cannot pass event e_i to a, although a is b's neighbor and b knows event e_i.

In other words, the event can be propagated from b to one of its neighbors a only and if only the walker's position is on b. For a random walk of e_i with $h - 1$ hops, b is one of the nodes that e_i visits, then we have $\delta(a, h) = 1/h$ for a $h - 1$ hops random walk.

Now let's estimate the probability being told e_i from its neighbors at hop h. Obviously, we have $\delta(a, 1) = 1$ when $h = 1$. Assume b has m neighbors, where m is the average degree of the network. The probability that b will forward e_i to a at hop one is $\delta(a, 1) * 1/m$. The probability of being told e_i by one of the neighbor at hop one is $P_b(e_i, 0) * \delta(a, 1) * 1/m$. If sensor node a has m neighbors, the probability a knows e_i from any of its neighbors is

$$P_b(e_i, 0) * \delta(a, 1) * 1/m * m = P_b(e_i, 0)$$

Similarly, the probability a knows e_i from its neighbors at hop h is $P_b(e_i, h - 1) * \delta(a, h)$, where $\delta(a, h) = 1/h$ refers to the probability of the random walker on node b.

The probability a knows e_i at h is

$$P_a(e_i, h) = P_a(e_i, h - 1) + \frac{(1 - P_a(e_i, h - 1))P_b(e_i, h - 1)}{h} \tag{7}$$

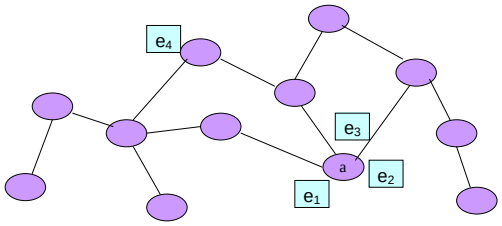

Figure 4: A subset of relevant events in the network

Up to now we consider to fuse all of the relevant events in the network. Fusing all relevant events is infeasible, since, sometimes, we may only the range of F for a given target and we do not know the exact number of F. It is also unnecessary when the confidence of fused data is already high. Therefore, we may only need to fuse a subset of the events if the number of relevant events F is big,, e.g., f out of F events and $f \leq F$. We will try to stop the propagation of the rest of relevant events in the network. As illustrated in Figure 4, sensor a will stop propagating event e_4 if it already fused other three relevant events e_1, e_2, and e_3.

For the rest of this paper, we simply choose $f = 3$ and $P_a(e,h)$ as the probability of fusing three events at hops h. If $F = f = 3$, we need to fuse all three of them and it can be described as $f/F = 3/3$. If $F > 3$ and $f = 3$, we may only fuse any three of them together.

Now we try to derive the relationship between $P_a(e,h)$ and $P_a(\Delta,h)$. The probability of fusion for 3/4 case is

$$P_a(e,h)+(1-P_a(e,h))P_a(e,h)+\ldots+(1-P_a(e,h))^3P_a(e,h) \quad (8)$$

When $F > f = 3$, the equation can be generalized as

$$P_a(e,h)(1+(1-P_a(e,h))+\ldots+(1-P_a(e,h))^{c_1-1}) \quad (9)$$

where $c_1 = C_F^f$. We can find that the value of $P_a(e,h)$ is still very small when we increase h to 10, e.g., $P_a(e,10) = 0.001$. Hence, we have

$$1+(1-P_a(e,h))+\ldots+(1-P_a(e,h))^{c_1-1} \approx C_F^f$$

The probability of fusing any three of them can be estimated as

$$P_a(\Delta',h) = c_1 P_a(e,h)$$

where $c_1 = C_F^f$.

The probability of fusion for $F > f = 3$ can be estimated as

$$P_V(\Delta',h) = 1-(1-P_a(\Delta',h))^{|V|}$$

Obviously, we have $P_V(\Delta',h) \geq P_V(\Delta,h)$ when we only need to a subset of relevant events.

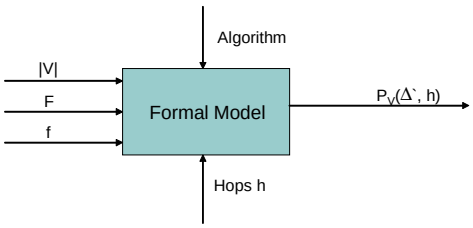

Figure 5: The inputs and outputs of the formal model

Figure 5 describes the inputs and outputs of our formal model. Given the size of networks $|V|$, two values F and f, we can easily compute the probability of fusion for random walks at hop h.

Figure 6 visualizes the outputs of the formal model — the probability of fusion $P_V(\Delta',h)$ — for a network with 100 nodes, where $f = 3$. While we may not use random walks in practice, the results here provide a baseline to test our proposed algorithms and estimate the low bound of TTL for a given network and the number of relevant events F.

6. EXPERIMENTAL RESULTS

In this section, we empirically study the data delivery algorithms. We use a random network of 100 nodes and each of them has, on average, four neighbors. Nodes are randomly chosen as the source of relevant events and they propagate the events according to different algorithms.

The experiments here serve as two purposes in this paper. First, we would like to validate our formal model for random walks using simulation results. For example, in the formal model, we assume each node has the same probability of knowing event e_i at hop h. This is not always true in practice. Second, we would like to study the robustness and efficiency of our algorithms.

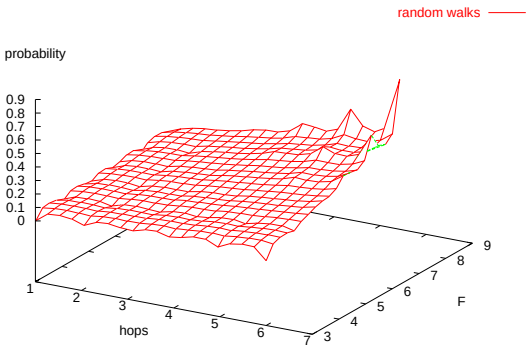

Figure 6: Probability of fusion for random walks for a sensor network with 100 nodes (f = 3).

6.1 Probability of Fusion

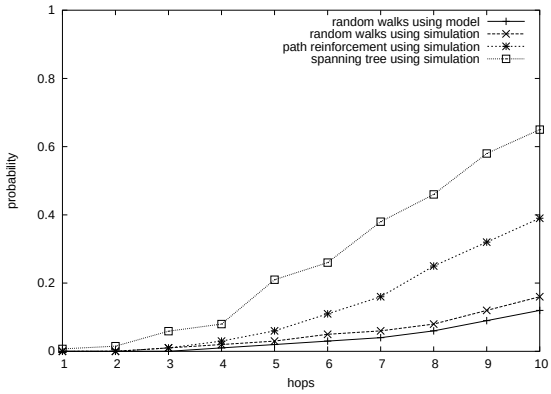

Figure 7: Probability of fusion for random walks, path reinforcement algorithm, and spanning tree (3/3 case).

We first study the probability of fusion for random walks, path reinforcement algorithm (without retransmission) and spanning tree when there is no failure. The probability of fusion from simulations is computed as $\frac{\sum s_i}{Num}$, where $s_i = 1$ if f events are successfully fused at iteration i. Otherwise, $s_i = 0$. The probability is averaged over 1000 iterations, e.g., $Num = 1000$.

Figure 7 and Figure 8 compare the probabilities of fusion for 3/3 and 3/5 cases using our formal model (only for random walks) and simulations. We can find that the results for random walks are consistent with those from the formal model. Also, random walks are quite easy to beat since they do not consider the relevance between events. For both 3/3 and 3/5 cases, path reinforcement algorithm performs better than random walks.

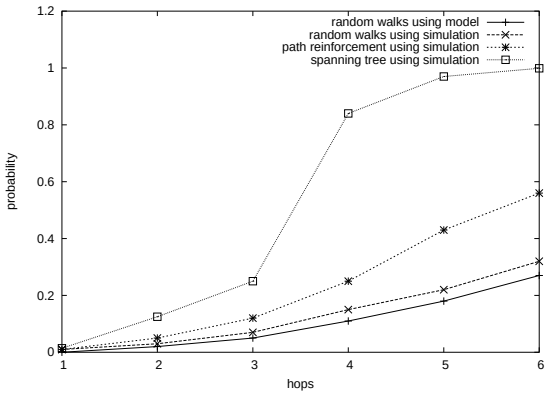

Figure 8: Probability of fusion for random walks, path reinforcement algorithm and spanning tree (3/5 case).

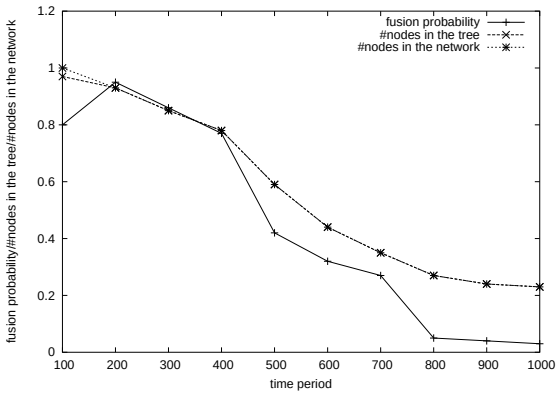

Figure 9: The fusion probability, percentages of active nodes in the tree and in the network (the line for #nodes in the tree is overlaid by the line for #nodes in the network).

We also study the effects of spanning tree for data delivery and fusion in the network. We use the first eight sets of relevant events to train the spanning tree and then we test the probability of fusion for the spanning tree. The results indicate that learning is quite effective for sensor data delivery. For the 3/5 case, the local learning scheme at least doubles the probability of fusion for path reinforcement algorithm when the hop of events is greater than three. The probability of fusion for 3/5 is guaranteed to be high if we allow the set of events to be propagated 6 hops in the network with 100 nodes.

6.2 Robustness

In this section and next section, we study if our localized algorithm is robust to failures in the network. We choose a random number between 0 and 0.01 as failure rate λ_a for any sensor a. We introduce a random number between 0 and 0.01 as the link failure rate between a node and any of its neighbors.

Figure 9 describes the fusion probability and percentages of active nodes in the tree and the network when $F = 5$. The dead nodes are detected after every 100 time periods. The figure tells us that trees evolve and merge and quickly one spanning tree covers most of the sensor nodes. Moreover, the tree always connects the nodes in the remained network. Another result is the probability of fusion decreases when the size of the network decreases. The reason is that the number of relevant events for fusion F becomes small, e.g., $F < 5$.

We consider the worst case of a mobile sensor network, where more than 50% nodes are destroyed after 500 time periods. In the hostile environments like this, e.g., a battlefield, we probably need to reduce the necessary number of events for fusion f . For example, if we reduce f from 3 to 2 ($F = 5$ on the network of 100 nodes), we can still reach the fusion probability of 70% after 500 time periods (Figure 10). Another solution is to incrementally deploy more sensor nodes to the sensor networks, as suggested by [6]. Figure 10 shows that, if we add 5 nodes to the network after every 100 time periods, we can still keep pretty high probability of fusion.

One concern of node failures is whether fused events can

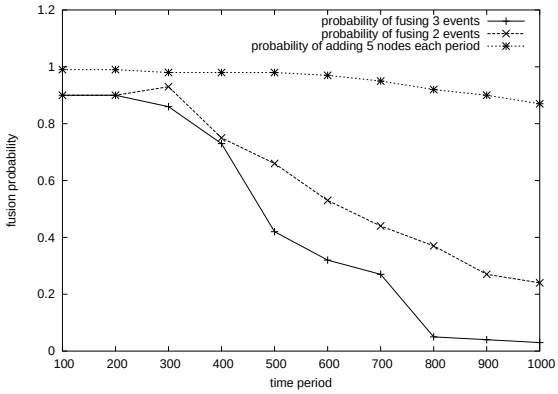

Figure 10: The fusion probability in the network when adding more nodes.

be lost when the fusion node happens to be destroyed. We study the fusion process and find this is not a problem when F is relatively big. For example, there are multiple copies of fused events at different nodes for 3/5 case when each event is propagated to 6 hops. The redundancy of fused events increases the survivability of the information and success rates of coordinating plans and actions for the network.

6.3 Efficiency

One question we did not answer in the formal model is if path learning algorithm is more efficient than path reinforcement algorithm. Since a node using path learning algorithm needs the feedback from its neighbors to learn their reliabilities. This will at least double the traffic in the network.

From Figure 11 we can find that if the events are allowed to propagate longer in the path reinforcement algorithm, both algorithms have very high probability of fusion. However, path reinforcement algorithm is vulnerable to node and link failures. Its probability of fusion becomes low when node failures happen. One reason is that the events are lost during information delivery in path reinforcement algorithm. In path learning algorithm we maintain the reliable

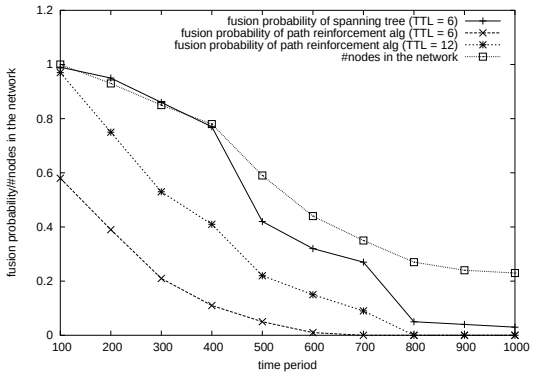

Figure 11: Probability of fusion and efficiency for path reinforcement algorithm and spanning tree.

data delivery of events through a retransmission mechanism, where an event is delivered to another neighbor if a node or link failure is found.

7. CONCLUSION

This paper studies localized data delivery algorithms for mobile ad hoc sensor networks with failures. The empirical results show that our path learning algorithm significantly increases the probability of fusion in a sensor network with node and link failures.

In future work we will develop methods for tuning system parameters, such as learning rate α in path learning algorithm, for different numbers of relevant events F, and node and link failure rates. Moreover, we have previously shown that small-world networks are more efficient than random networks for passing tokens in large teams [20, 18]. We plan to study the effects of different network topologies on probabilities of fusion, especially when both node and link failures happen in the network.

ABSTRACT

Numerous domains ranging from distributed data acquisition to knowledge reuse need to solve the cluster ensemble problem of combining multiple clusterings into a single unified clustering. Unfortunately current non-agent-based cluster combining methods do not work in a distributed environment, are not robust to corrupted clusterings and require centralized access to all original clusterings. Overcoming these issues will allow cluster ensembles to be used in fundamentally distributed and failure-prone domains such as data acquisition from satellite constellations, in addition to domains demanding confidentiality such as combining clusterings of user profiles. This paper proposes an efficient, distributed, agent-based clustering ensemble method that addresses these issues. In this approach each agent is assigned a small subset of the data and votes on which final cluster its data points should belong to. The final clustering is then evaluated by a global utility, computed in a distributed way. This clustering is also evaluated using an agent-specific utility that is shown to be easier for the agents to maximize. Results show that agents using the agent-specific utility can achieve better performance than traditional non-agent based methods and are effective even when up to 50% of the agents fail.

1. INTRODUCTION

Clustering is a difficult problem in numerous fields including machine learning, multi-agent systems, data management and bioinformatics [13, 19, 10]. The central concept of clustering is that data points should be partitioned into separate clusters so that data points within a cluster are "close" to each other, while data points from different clusters are "far" from each other. A set of clusters with these properties is a clustering. The goal of the clustering problem is to find good clusterings. While the clustering problem is typically an NP-complete optimization problem, there are numerous heuristic clustering algorithms including k-means, expectation-maximization and Metis [12, 9, 2, 7]. Note that even though clustering is often used within multi-agent systems (e.g. to group similar agents), agents are not typically used to solve the clustering problem itself. This is as much due to the traditional view of a cluster as a passive label, rather than an active agent, as to the difficulty in decoupling the interactions among the agents representing the labels.

This paper focuses on using agents for an important subset of the clustering problem known as the *cluster ensemble* problem (Figure 1) [15]. In the cluster ensemble problem one needs to combine multiple clusterings, formed from different aspects of the same data set, into a single unified clustering. Cluster ensembles are particularly useful when all of the original data points are not available to create a clustering, but separate clusterings of the data still exist. This situation occurs:

1. When some of the data points come from proprietary sources, where the data owners are willing to reveal their clustering of the data, but not the data itself.
2. When the original data points are simply lost, or have been thrown away, but the much smaller summery cluster data is saved.
3. When all of the original data is available, but it may be too big to store in one site of computation. In this case, it may be desirable to make separate clusterings of different parts of the data and combine them later.
4. When we want to inject prior knowledge into learning systems or re-use information since new clusterings can be combined with older clusterings without needed to know all the information used in the previous clusterings or how they were derived.

Currently the best algorithms for cluster ensembles are graph-theoretic methods [14]. These methods treat the clus-

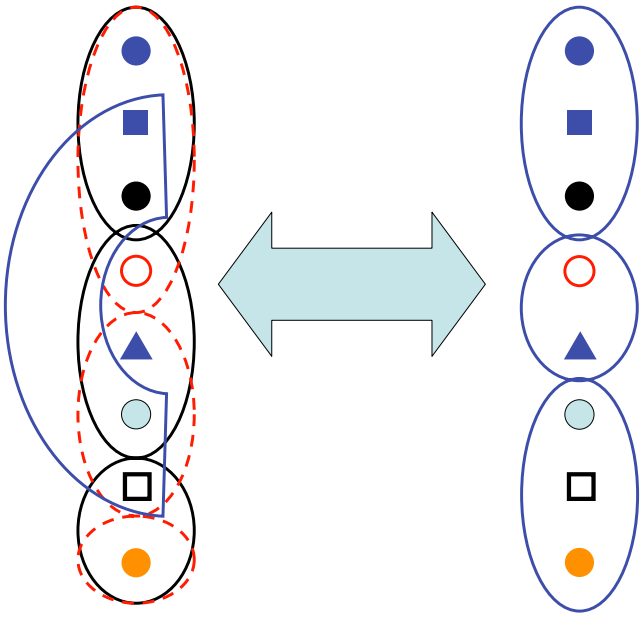

Figure 1: Cluster Ensembles. Shown on left are three different clusterings for eight data points. The goal of the cluster ensemble is to create a unified clustering (shown on right) that preserves the most information from the original clusterings.

ter ensemble problem as a global static problem, examining the entire data set and producing a single result. While these methods have shown to have good results on certain information theoretic measures, they tend to be inflexible [15]. The graph-based methods require the cluster combining to happen on a single node of computation. This requires all the data to be centrally available, creating a single point of failure. This centralization makes them inappropriate for domains that are inherently distributed, and have a potential for high component failure such as in space-based operations.

Instead of graph-based cluster ensemble methods, this paper proposes using learning agents to solve the cluster ensemble problem. In this approach each agent contributes to the final clustering and uses reinforcement learning to learn to maximize a utility function based on the clustering. Unlike graph-based methods, the multi-agent approach treats the cluster-ensembe problem as a dynamic system, where agents continually attempt to create a unified clustering that maximizes a utility. This dynamic agent-based approach is more flexible and robust in the following ways:

- Agents are robust against noisy data sources.
- Agents naturally adapt to loss of data sources.
- Computation is distributed.
- There is no single point of failure, so performance gracefully degrades with the number of failures.
- Computation can be stopped at any time when performance is adequate.
- Data sources do not have to be revealed.

These advantages allow multi-agent cluster ensembles to be used more effectively in more domains than their non-agent-based counterparts.

Despite these advantages, multi-agent systems have not been used in the cluster ensemble problem due to coupling between the cluster assignments. The utility the agents attempt to maximize is highly non-linear, limiting the independence assumptions that can be made. This non-linearity prevents many multi-agent techniques from being applicable. In addition if an agent attempts to maximize the utility directly, it faces a difficult signal-to-noise problem in that it does not know the effect of its actions on the utility, among the effects of the actions of all the other agents. To address this issue, this paper shows how agents can instead use agent-specific utilities that are much easier to maximize, yet are still aligned with the original utility.

In Section 2, this paper gives a formal description of the cluster ensemble problem as well as a brief overview of a graph-based and simple greedy solutions to the cluster ensemble problem. In Section 3 this paper presents an agent-based approach. Finally in Section 4 the paper shows results for the performance of agent-based cluster ensemble methods, and how they are robust against agent failure.

2. CLUSTER ENSEMBLE PROBLEM

In clustering problems a set of data points are grouped into clusters, so that data points in the same cluster are "closer" to each other than data points from different clusters. The closeness between data points is typically measured with a domain dependent distance metric. This metric is influenced by the type of data, the goal of the clustering and even the "scale" of the clustering depending on the amount of clusters desired [16, 15, 4]. Given a distance metric, a "soft-clustering" can be performed where data points belong to different clusters with varying probability, or hard clustering where each data point is part of only one cluster [6]. This paper will focus only on hard-clustering. This type of clustering problem is equivalent to creating a non-overlapping partition of the data. In this paper we refer to a particular partition as a *clustering*. In general there can be many different clustering for the same data, depending on the clustering algorithm used [11, 5, 7]. In addition there can be sets of related clusterings that are formed with overlapping subsets of the data [15]. The goal of the cluster ensemble problem is to create a single clustering that best characterizes a set of clustering, without using the original data points used to generate the clusterings [1].

To formalize the clustering ensemble problem, we need a way to compare two clusterings. In this paper, this is done through an information theoretic measure previously used in the clustering community called *normalized mutual information* (NMI) [15]. This measure is based on the sizes of the clusters within the clusterings (a formal justification for this is presented in [14]). To compute this measure we

[1]Note that sometimes the clustering problem includes computing an "optimal" number of clusters in addition to assigning data points to these clusters. However, finding the correct number of clusters is ill-defined, and changes depending on the context. All the algorithms in this paper assume that the final number of clusters is known ahead of time. If the number of clusters is not specified ahead of time, meta-algorithms can be used, where the number of clusters is varied until a good number is found.

first define a clustering X, where each cluster $x_i \in X$ is a set of data points. We now define the mutual information between clusterings X and Y as:

$$I(X,Y) = \sum_{x \in X} \sum_{y \in Y} \frac{|x \cap y|}{n} log_2 \left(\frac{n|x \cap y|}{|x||y|} \right) \quad (1)$$

where there are n data points and $|\cdot|$ and $\cap$ are the set cardinality and intersection operators respectively. The intersection operation $x \cap y$ returns the data points that are common to both clusters x and y. Next we define the entropy of a clustering, X, as:

$$H(X) = -\sum_{x \in X} \frac{|x|}{n} log_2 \left(\frac{|x|}{n} \right) \quad (2)$$

Now we can define the normalized mutual information (NMI) between two clusters, X and Y as:

$$\text{NMI}(X,Y) = \frac{I(X,Y)}{\sqrt{H(X)H(Y)}} \quad (3)$$

which has the desirable property of being bounded by [0, 1] and having $\text{NMI}(X,X) = 1$.

The normalized mutual information between two clusters measures how much information they have in common. If two clusterings are similar they will have an NMI close to one. If two clusterings are completely different then they have an NMI of zero. In this case knowing one clustering would not help one predict the clusters within the second clustering. If we had a "true" clustering of the data we would want our ensemble clustering to have as high as possible NMI with respect to this true clustering. However, typically all we have to compare our ensemble clustering with is the original clusterings used to create the ensemble. In this case our goal is to create an ensemble clustering that shares as much information as possible with the clusterings it was created from. This can be measured by averaging the normalized NMI between the original clusterings and the ensemble. Formally we define the ANMI between a clustering X and a set of clusterings $\overline{Y}$ as:

$$\text{ANMI}(\overline{Y}, X) = \frac{1}{|\overline{Y}|} \sum_{Y \in \overline{Y}} \text{NMI}(X,Y) \ . \quad (4)$$

When an ensemble clustering X has more information in common with the original clusterings $\overline{Y}$, $\text{ANMI}(\overline{Y}, X)$ will have a higher value. Therefore the goal of the agents is to find the clustering, X^*, that maximizes the ANMI between X^* and the set of available clusterings $\overline{Y}$.

2.1 Graph-based Approaches

The graph-based approaches to the cluster ensemble problem involve representing the data points as nodes in a hypergraph, and the clusters as undirected hyperedges of the hypergraph. This paper will compare cluster ensemble performance with three of these algorithms, which are described in detail in [15]. Note that these methods are only heuristics and are not optimal, since similar to clustering methods, the graph methods tend to be NP-complete. However the methods described here have been shown to have high performance in practice. The first algorithm called CSPA (Cluster-based Similarity Partitioning Algorithm) provides moderate performance, but requires significant computation. CSPA works by creating a similarity measure between data points. Within a clustering, all data points in the same cluster have a similarity of 1, and data points from different clusters have a similarity of 0. If the similarities between data points are averaged over different clusterings, a new single clustering can be made with a similarity based clustering algorithm, such as METIS [7].

The second clustering algorithm is called HGPA (HyperGraph Partitioning Algorithm) and is simpler to compute than CSPA. This method creates the final combined clustering for the ensemble by using HMETIS [8] to perform hypergraph partitioning on the hypergraph that represents the clusterings. The objective of this method is to create clusters that break the least number of hyperedges. The final method, called MCLA (Meta-CLustering Algorithm), provides better performance than HPGA and retains its low computational complexity. This algorithm works by collapsing a group of related hyperedges into a single hyperedge. This can be seen as clustering clusters.

2.2 Simple Greedy Optimization

Simple greedy optimization approaches have been applied to the cluster ensemble problem in [15]. In this method, one starts with a single representative clustering, X, which is usually the clustering that has the highest ANMI with respect to all the other clusterings:

$$X = argmax_{X' \in \overline{Y}} \text{ANMI}(\overline{Y} \backslash X', X') \quad (5)$$

where $\overline{Y}$ is the set of clusterings, and $\backslash$ is the set difference operator. For each data point, a new clustering is created from the previous clustering by moving the data point to a new cluster at random. If this new clustering has a higher ANMI than the previous one, then it is preserved, otherwise it is thrown away. The algorithm is repeated for each data point. When it has gone through all the data points, the algorithm stops if all of the new clusterings where thrown away. Otherwise it repeats through all the data points. This algorithm can be seen as a form of serial simulated annealing with zero exploration or as greedy hill-climbing. Unlike the graph-based methods, this algorithm is dynamic as it continually tries to maximize utility. However, this algorithm has a number of difficulties. Since the exploration is zero, the system will only reach a local maximum. Also since for each loop, the ANMI has to be computed for every data point, the computationally burdensome when there are many data points.

3. AGENT-BASED APPROACH

Similar to the greedy optimization approach, the agent-based approach treats the cluster ensemble problem as a dynamic optimization problem, with the agents striving to create a final combined clustering with the highest utility. However, the agent-based approach requires significantly less computation and is naturally distributed. In this approach agents are assigned a set of data points and vote on which cluster in the final clustering the data points should belong to. Through reinforcement learning, the agents learn how to vote in a way that leads to the best final clustering.

3.1 Assigning Agents and Voting

In this paper, the cluster ensemble problem is approached by assigning one or more agents to each cluster in the original set of clusterings. If m agents are assigned to each

cluster, then the multi-agent sytem for r clusterings with k clusters each would have mrk agents. The action of an agent is to vote on the cluster in the combined clustering, to which the data points it is responsible for should belong. A data point will then belong to a final cluster that received the most votes from agents that were responsible for the cluster containing the data point. This process is shown in Figure 2. The global utility of the system is the ANMI of the combined clustering with respect to the original clusterings. Agents can then try to maximize the ANMI, by using their private utilities to help them choose the best actions. In this example, the top two points are in the same clustering in two of the three clusterings (agents 1 and 4). Similarly, the second and third data points are in the same clustering in two of three clusterings (agents 1 and 8). In the final clustering, all three data points belong to the same cluster, as this clustering minimizes the mutual information between the original clusterings.

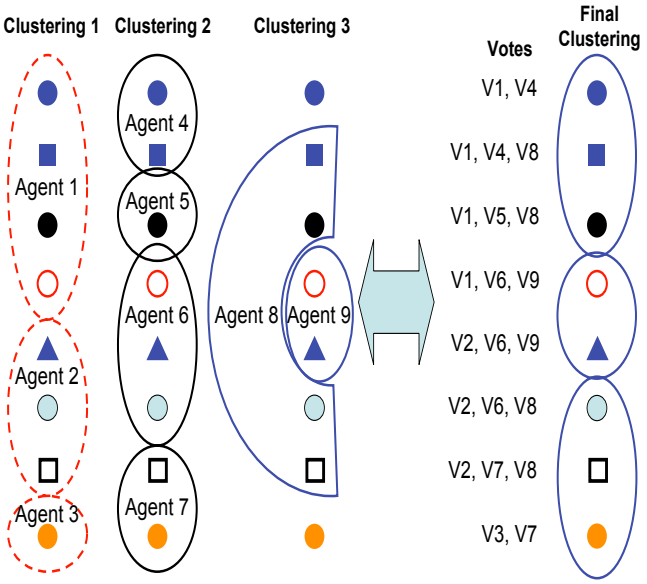

Figure 2: Agent-Based Cluster Ensembles. An agent is assigned to a cluster in each clustering. Agents then vote on the final cluster to which the data points within their current cluster belong.

Formally the votes by the agents for a combined clustering Z can be represented by a two dimensional array of sets indexed by agents and clusters. If agent i chooses cluster $z \in Z$, then $V_{i,z}$ equals the set of data points in agent i's assigned cluster. If agent i did not choose z then $V_{i,z}$ equals the empty set. The number of votes for data point p to be put in cluster z can be formulated as follows:

$$N_{p,z} = \sum_i I_{p \in V_{i,z}} \tag{6}$$

where I is an indicator function. The assignments of data points to a cluster in the combined clustering can now be expressed as:

$$z = \{p | N_{p,z} = max_{z'} N_{p,z'}\} \tag{7}$$

Tie votes are broken randomly.

3.2 Global Utility

The global utility that the agents ultimately try to maximize is the ANMI between Z and the initial set of clusterings $\overline{Y}$:

$$G(\overline{Y}, V) = \text{ANMI}(\overline{Y}, Z(V)) \; . \tag{8}$$

Note that the global utility can be computed in a distributed way when the votes V are broadcasts to all agents. Each agent can compute the final clustering $Z(V)$ and compute its own normalized mutual information NMI(Y, Z(V)). The NMIs can then be broadcasts and all the agents can compute ANMI and therefore G on their own. While this process requires a fair amount of communication, it is usually considerably less than broadcasting the entire data set, depending on the size of the clusters. While an agent can compute the global utility, it is difficult for an agent to maximize the global utility directly since this utility is a function of the actions of all of the other agents. If an agent takes an action and the global utility increases, the agent does not know if the increase is due to its action or the actions of other agents. As a consequence, when there are many agents, it will take a large number of learning steps for an agent to discern the effects of its actions from the actions of all the other agents.

Note that while the computation of G ultimately uses information derived from all of the data points, these data points are never assembled into a central data set. Instead the computation of G involves the agents broadcasting what they believe the final clustering should be, not what their current clusterings are. In this distributed framework the original clusterings do not have to be revealed. This decentralized computation allows the agent-based approach to be used in domains where the owners of individual data sources do not want their data set to be made fully available to the other data owners.

3.3 Agent-Specific Utility

Instead of maximizing the global utility directly, an agent can learn more quickly if it maximizes an agent-specific "private" utility that is more influenced by its own actions than the actions of all the other agents. We call this relative influence an agent has on its utility, the "learnability" of the utility [17]. Learnability for a private utility g_i for agent i can be informally defined as the ratio of agent i's influence on g_i to all other agents' influence on g_i. Generally if a utility is more learnable for an agent, the faster an agent will be able to maximize it. However, having all the agents being able to maximize their private utilities is not useful if this does lead to the maximization of the global utility. For the maximization of private utilities to lead to the maximization of the global utilities, each private utility should be "factored." A private utility is factored when any action an agent takes to increase its private utility also increases the global utility [17, 20].

A utility that has been shown to have high learnability while being factored is the difference utility, defined as:

$$D_i(z) = G(z) - G(z_{-i}); \tag{9}$$

where z are the actions of all the agents and z_{-i} are the actions of all the agents other than agent i. The second term of the difference utility is a counterfactual, computing the value of the system without agent i. Subtracting this counterfactual from the global utility therefore computes an agent's

contribution to the global utility. This utility is factored since the second term is not a function of the agent's actions, therefore it can only influence the utility by changing the value of the first term, the global utility. Furthermore, this utility usually has far better learnability than does $G(z)$ because the second term of D_i removes a lot of the effect of other agents (i.e., noise) from agent i's utility [17]. This utility has proven effective in many multi-agent system domains including network routing, rover control, job scheduling and congestion games [1, 18, 17].

Using the global utility defined in 8 we can define the difference utility for the cluster ensemble problem as:

$$\mathrm{D_i}(\overline{Y}, V) = \mathrm{ANMI}(\overline{Y}, Z(V)) - \mathrm{ANMI}(\overline{Y}, Z(V')) \quad (10)$$

where V' is the same as V, except that all of the elements of V' that are indexed by i are equal to the empty set. Since this utility is factored, agents maximizing $D_i(\overline{Y}, V)$ will tend to maximize $G(\overline{Y}, V)$, though they can learn more quickly since each agent has more influence over its own difference utility than over the global utility. Note that when an agent's vote does not influence the final clustering Z(V') the difference utility does not have to be computed since its value is zero. In large systems, this case will occur often. If an agent's vote is a deciding vote, then all the agents will have to compute and broadcasts their NMIs for the counterfactual $Z(V')$. In the worst case when all the votes are deciding votes, the amount of computation grows linearly with the number of agents. However, this system is still distributed and an agent can simply not average in NMIs from other agents that fail to respond. This distribution is critical to robustness as agents can still try to maximize their utilities even when some of the agents are not working properly.

4. RESULTS

The performance of the multi-agent approach to cluster ensembles relative to other methods was tested with three data sets. The first data set was artificial, while the other two came from real-world problems. These data sets showed different aspects of the cluster ensemble problem. In the first data set, the "true clustering" was known since it was artificially generated. The second data set involved clustering images of hand-written images, where the true number of clusters was known, but the correct clustering was subject to interpretation. The final data set involved groupings in the Yahoo! web site, where both the correct number of clusters and the correct clustering was subject to interpretation. The experiments showed that the multi-agent approach often achieved superior performance to the best existing centralized cluster ensemble algorithms, while being able to recover from a number of types of agent failures.

All agents learned with a simple single-time-step reinforcement learner. This learner was equivalent to an Q-learner with infinite reward discounting ($\gamma = 0$) so that only the immediate reward was processed. At every time step, each agent would choose one of k clusters based on its estimates of the utility for that choice. These estimates were stored in a utility table of size k. This process was done in an ϵ-greedy fashion (with $\epsilon = 0.005$) where the highest valued cluster would be chosen with probability $1 - \epsilon$ and a random cluster would be chosen with probability ϵ. After all the agents chose their cluster, each agent would compute their private utility and use it as the reward to update their reinforcement learner.

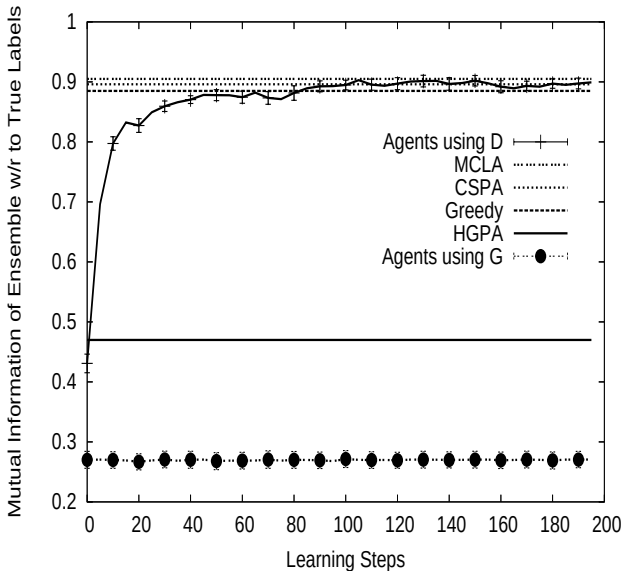

Figure 3: Results of Ensemble Methods with Artificial Data. Eight clusterings are created by adding 40% noise to the original cluster labels. The ensemble tries to recover the original labels from the eight clusterings. The decentralized algorithm using the difference utility performs as well as the best graph-based algorithm, which requires centralization.

4.1 Artificial Data

In the first experiment, four hundred data points where randomly placed into ten clusters to form an initial clustering. From this initial clustering, eight variants were created. Each variant was made by first duplicating the original clustering and then adding random noise by moving a random subset of the data points to new clusters (for each data point in the subset, the cluster it was moved to was chosen independently over a uniform distribution over all the clusters). The amount of random noise was specified by B, the fraction of all the data points contained in the subset. These noisy variant clusterings were used as the ensemble clusterings and experiments were performed with B ranging from 0.0 to 1.0. The performance of the algorithms were determined by the NMI between the clustering produced by the algorithm and the initial clustering. Since this is an artificial data set we have "ground truth" about what the true clusterings should be. A better cluster ensemble algorithm should produce a clustering as close to possible to the initial clustering in which the eight ensemble clusterings were derived. Figure 3 shows the results with $B = 0.4$ for agents using D_i or G as their utility along with results obtained from the graph-based methods and the simple greedy method.

The results show that the agent-based method using the difference utility performed as well as the best graph-based method, MCLA and considerable better than the lowest performing graph-based method, HGPA. In noisy domains HGPA had particular poor performance as compared to MCLA because MCLA could reduce noise by collapsing similar edges. In addition to performing as well as the best

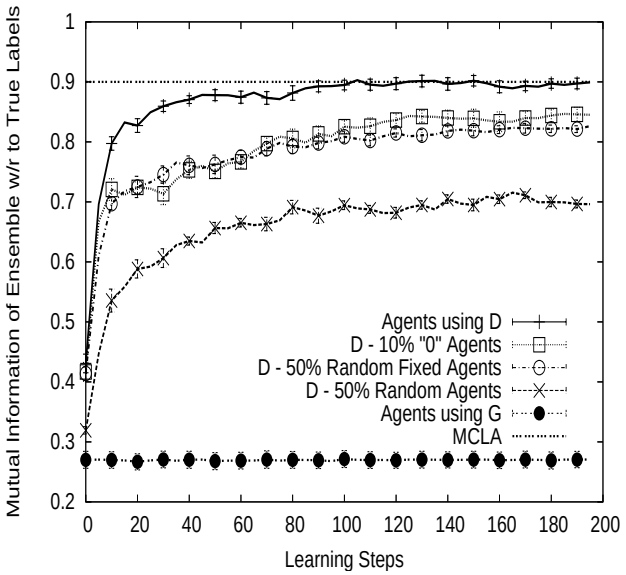

Figure 4: Results of Ensemble Methods with Artificial Data with Faulty Agents. Systems with agents using D generally perform well when some of the agents fail. Top curve shows performance when all agents are working properly. Second curve shows performance when 10% of the agents always choose cluster 0 as their action. Third curve shows performance when 50% of the agents always choose the same random cluster as their action. Fourth curve shows performance when 50% of the agents always choose a different random action at every time step.

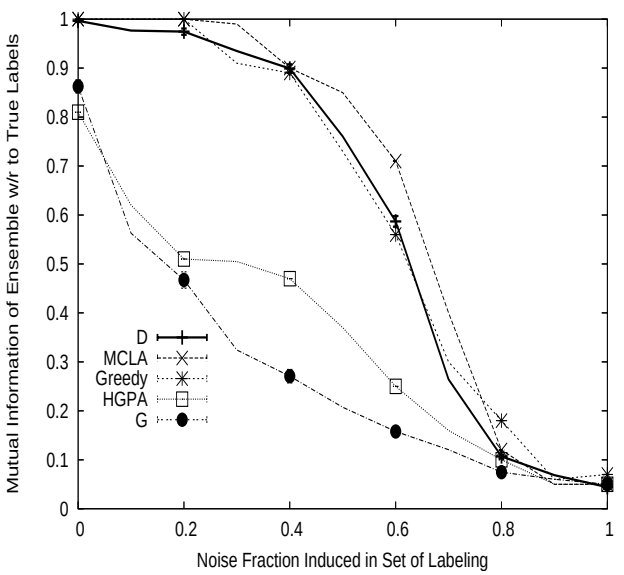

Figure 5: Results of Ensemble Methods on Artificial Data. Eight clusterings are created by adding variable amounts of noise to the original cluster labels. The ensemble tries to recover the original labels from the eight clusterings. Relative performance of methods is consistent across noise levels (CSPA performance is almost identical to greedy method, but not shown to reduce clutter).

graph-based methods, the agent-based method using the difference utility performed about the same as the simple greedy method. However this performance was achieved with much less computation. The greedy method was reported to take an hour on a 1Ghz PC [15]. The agent-based method took only 45 seconds on a similar computer. In contrast to agents using the difference utility, agents using the global utility performed very poorly. This poor performance can be attribute to the large number of agents in this problem (eighty). When an agent choose a cluster and the value of the global utility changed, the agent did not know whether the change was caused by its action or the action of one of the seventy nine other agents. This very low performance of the global utility is likely the reason why agent-based cluster ensembles have not been pursued until now.

In addition to testing the agents under normal conditions, we tested the case where some of the agents fail. In this test three agents were used for every cluster to provide redundancy. This redundancy was tested under three failure scenarios. In the first scenario 50% of the agents were faulty. These faulty agents (called "random agents" in the figures) chose a random cluster at every time step. In the second scenario 50% percent of the agents (called "fixed random agents") chose a random cluster at the beginning of a trial and kept making the same choice throughout the trail. In the final scenario 10% of the agents always chose the first cluster (these are called "0" agents). The results shown in Figure 4, reveal that agent-based cluster ensembles can perform well in a number of adverse conditions. Even when half of the agents were faulty, the system could still perform well. Note that the agent-based system in the first scenario performed worse than the one in the second scenario, even though the same number of agents were faulty. This can be explained by the adaptivity of the agents. In the second scenario the faulty agents always took the same wrong move, so the working agents could adapt to overcome the adversity. In the first scenario, the faulty agents simply added random noise to the system, which could not be easily adapted to. Despite the inherent failure tolerance of the multi-agent system, there was still a possibility of catastrophic failure if too many of the agents failed in the same way. While the system was able to recover when 10% of the agents choose the same wrong cluster, the performance drops to zero if 50% percent of the agents choose the same wrong cluster (not shown in the graphs). This failure is caused by the voting scheme, since when 50% percent of the agents vote for the same cluster, that cluster will always win. In this case, the final clustering will always have just one cluster.

The previous experiments were done with the noise parameter, B, used to generate the noisy clusterings from the initial clustering, set to 0.4. To show that the relative performance of all the methods was not dependent on this choice of noise parameter, we tested the performance of the methods on a wide range of values shown in Figure 5. The results show that for a wide range of noise parameters that the agent-based methods perform well, and the relative performances of the other methods is about the same. Averaged over all of the noise parameters, the NMI of MCLA, D, Greedy and HGPA are 6.4, 6.0, 6.1 and 3.5 respectively.

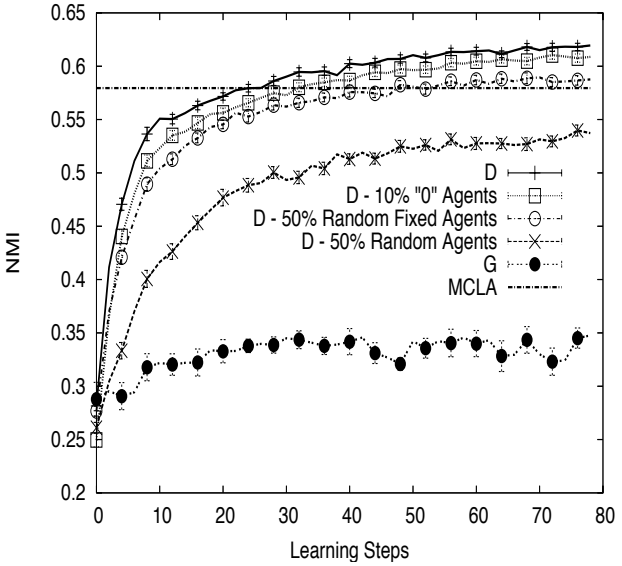

Figure 6: Results of Ensemble Methods for the Pendig Data Set. Agents using difference utility perform better than the best graph-based algorithm. Even when up to 50% of the agents fail, the system performs well.

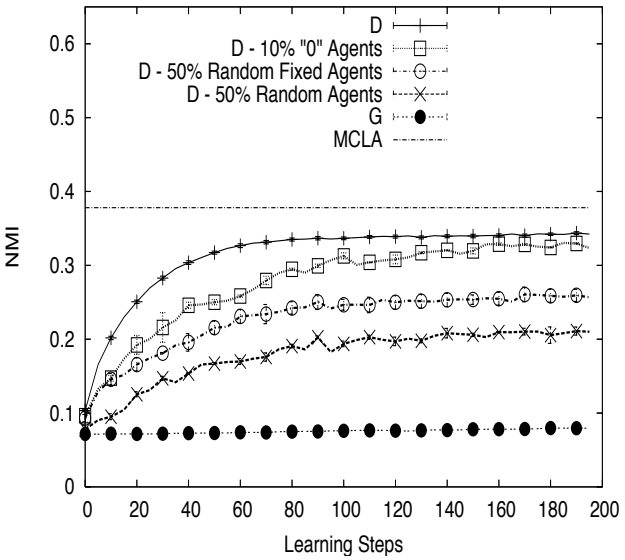

Figure 7: Results of Ensemble Methods for the Yahoo Data Set. Agents using difference utility slightly under-perform the best graph-based algorithm, but still perform adequately when up to 50% of the agents fail.

4.2 Pendig Data Set

The Pendig data set contained one thousand data points, with each data point having sixteen features. Each data point represented a processed handwritten digit. The data points were clustered into ten clusters, with each cluster representing a digit from '0' to '9.' While this data set is known to have precisely ten clusters, the true clustering is subjective since some of the images could be ambiguous. From the original Pendig dataset we produced ten different clusterings (by coincidence, each with ten clusters) by partitioning the data into ten data sets. Each point in the new data sets contained four features sampled from the original sixteen. Ten clusterings were then produced by clustering each of the new data sets with METIS. Using these clusterings for the ensemble, agents using the difference utility were able to perform better than the best centralized graph-based algorithm, MCLA (see Figure 6). Again the results show that agent-based cluster ensembles can perform well in a number of adverse conditions. Even when half of the agents were faulty, the system could still out-perform the graph-based methods. Only in the case when half the agents choose random actions at every time step, did the performance drop below that of the MCLA. Though even in this case the agents using the difference utility with 50% failure were able to perform better than agents using the global utility when there are no failures.

4.3 Yahoo Data Set

In this experiment a processed version of the Yahoo! data set was used. This data set has also been used in [16] and [3]. The data set contained 2340 data points, with each data point having 2903 features. Each data point represented a document and the features were a pruned set of word frequencies contained in the document. The data set was clustered into twenty clusters, based on which Yahoo! news category they were originally placed in. Note that both the correct number clusters and the true clusterings were subjective for this data sets. More or less news categories could have been used, and many documents could have been placed in different categories.

In the experiment we created twenty clusterings (coincidentally, each clustering having twenty clusters) by splitting the full data set into twenty separate data sets. Each new data set contained all of the 2340 data points, but each data point only had a 128 element subset of the original features. Each new data set was then clustered using METIS, forming twenty clusterings. These new clusterings were then used for the ensemble in the experiment. The output of the ensemble algorithm was then compared to the original Yahoo! clustering using NMI. Figure 7 shows the results between an agent-based method using D_i as its utility, an agent-based method using G as its utility and the best performing graph-based method, MCLA.

The results show that agents using the global utility were unable to produce an adequate clustering. This is not surprising since there were 400 agents in the system. In this case, the learnabity of the global utility was very poor since an agent cannot easily see the contribution of its action on the global utility, amongst the 399 actions of the other agents. In contrast the agents using D_i were able to do much better. While these agents were not able to do as well as the MCLA algorithm [2], they did exhibit a high level of fault tolerance. This reduced performance level of the

[2]Note that we could not generate the exact clusterings used in the papers [15, 14], due to the randomness in the Metis algorithm. Our results for MCLA and the agent methods were based on a set of clusterings that turned out to be slightly harder, therefore our results cannot be directly compared to the results in this paper.

agent-based solution compared to the graph-based solution here can be attributed to having to combine clusters that were not good representatives of the "true" labels. While the agent-based approached performed well at maximizing ANMI, the agents had no way of knowing if they were also maximizing NMI with respect to the true labels. Here the heuristics in the graph-based approach happened to produce a result that more closely matched the true labels. However, the agent-based solution was able to maintain high levels of performance with a high number of agent faults. When 10% of the agents were not working properly, the system still managed to achieve nearly the same performance as the fully operational system. Even when 50% of the agents were taking random actions, agents using the difference utility were still able to learn to compensate, and achieve much better performance than the system using the global utility.

5. DISCUSSION

Using the difference utility, the results show that agent-based cluster ensembles can perform comparably to the best existing cluster ensemble methods. In addition they are able to achieve this level of performance with relatively little computation as compared to simple greedy optimization methods. Also agent-based method also allow the cluster ensemble problem to be treated as a dynamic optimization problem, significantly increasing the robustness of the system. The agent-based cluster ensembles exhibit a high level of fault tolerance and are able to retain high performance even when 50% of the agents fail. This property allows them to be used in domains that have a high component failure rate, such as in space-based systems or domains with unreliable communication. In addition the agent-based cluster ensembles have the flexibility to be stopped early in domains where a fixed level of performance is needed. This ability can save computational costs, even when the difficulty of the ensemble problem is not known ahead of time.

The implementation presented in this paper assigned an agent to a single cluster and the agent vote involved all the data points in that cluster. However, this way of mapping agents to data points is not necessary to the framework. Depending on the performance requirements one agent could be assigned several clusters or multiple agent could be assigned to different parts of the same cluster. Having alternative agent to cluster mapping may be beneficial if the owners of the clustering sources do not want to reveal their exact clusterings, but still want to collaborate with other data owners to create unified clusterings.

ABSTRACT

We present a performance analysis of an agent-based middleware system we have developed based on "reAgents," remotely executing agents that enhance the performance of client/server-based Internet applications. ReAgents simplify the use of mobile agent technology by transparently handling data migration and run-time network communications, and provide a general interface for programmers to more easily implement application-specific logic. This is made possible through the use of *behaviors*, i.e., common patterns of actions that exploit the ability to process and communicate remotely. We model the performance of each of the primary behaviors, and provide an experimental evaluation of reAgent performance.

1. INTRODUCTION

ReAgents support the remote processing of client/server application requests and responses via dynamically deployed mobile code, which carries out work tailored to the particulars of the client device. A reAgent acts as an intermediary between client and server, but maintains the client/server model (Fig. 1). As a simple example, an application running on a client device with a small, limited display would benefit from a remote agent operating at or near the server that filters the rich server data into a spartan response.

Our system is designed with the following goals:

1. Provide the programmer a better way to handle the client's needs and limitations

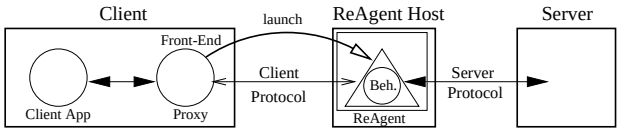

Figure 1: Client-ReAgent-Server Model

2. Be transparent to servers (i.e., do not require modifications to servers)

3. Be easy to program and use

To meet these goals, we propose a remote code mechanism that is more flexible than proxies but less complicated than fully-general mobile agents. We achieve this compromise by adopting a form of "one-shot" mobile agents, simply called a *reAgent* (for "remotely executing agent"). Unlike a general mobile agent, which can move to multiple machines during its computation and retain its state and identity, a reAgent moves exactly once: before it begins execution. The reAgent cannot move after it has begun execution, or even launch other reAgents (only the user may launch reAgents). These restrictions simplify the requirements of the underlying remote code execution mechanisms and reduce the potential for malicious behavior, while still deriving many of the benefits of remote execution.

A reAgent is launched to operate at a remote location because there is an advantage in doing so, such as superior computing or network resources. This location is known as the *reAgent host* (Fig. 1). The reAgent then acts as a customized dynamic proxy for that particular client, and returns the server response to it. This allows for extending the capabilities of the client in a customized fashion. By moving its own provided code to a better location, the client gains extra power to better deal with its limitations and needs. And, the client can represent itself to the server as a standard client via its reAgent, thereby keeping the server code unchanged.

A novel aspect of our approach is that reAgent code is strictly derived from a template library of *behaviors*. Behaviors are useful patterns of processing and communication that are the result of restricting and simplifying the form of movement of reAgents. Examples of general behaviors include filters, monitors, cachers, and collators. Once a general behavior is selected for a reAgent, it is then *specialized* for specific application needs via code parameters.

For the reAgent code to migrate to and run on the reAgent host, some middleware system that supports remote execution must be available. Our reAgent architecture does not specify its own remote execution mechanism. Instead, we leverage existing work in mobile code by translating the launch procedure into the appropriate code movement calls for each system. These movement calls

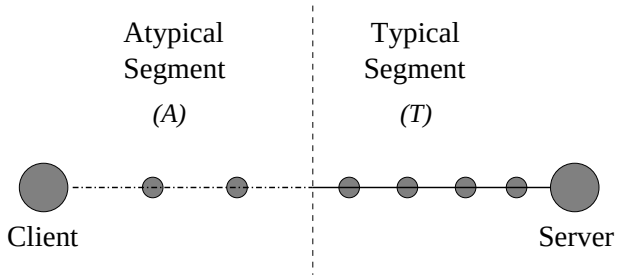

Figure 2: Operative network environment

are translated at run-time when the agent is launched, when the type of middleware on the target reAgent host is specified in a configuration file. The underlying mobile code middleware system is completely transparent to the programmer, who must only understand the simplified reAgent interface. For example, to experiment with reAgents we used a locally-developed and stand-alone Java-based mobile code system [16].

Our experience to date with reAgents has been in the context of Web-based applications [10], and mobile-computing applications [11]. In this paper, we go beyond these studies and analyze the micro-performance of each individual behavior using analytical models, and we present a set of experiments that demonstrate the macro-performance of ReAgents.

The rest of this paper is organized as follows. Section 2 presents a model of the network environment which allows us to reason about the advantages of reAgent location and execution. Section 3 analyzes the general behaviors that are the building blocks of ReAgents. Section 4 presents experimental results. Section 5 describes previous work in this area. Finally, Section 6 presents our conclusions.

2. SYSTEM ENVIRONMENT MODEL

In this section, we present a model of a system environment where an advanced remote code mechanism would be useful.

2.1 Definitions and Assumptions

We define the network environment as a traditional client/server environment, with the network conceptually divided into two segments, *the typical segment* T and the *atypical segment* A (Fig. 2).

T consists of physical network link(s) whose levels of performance and reliability are typically what is observed in the core of the Internet, in general. A, which represents the client device's connection to the Internet, contains links less predictable in their attributes and possibly significantly different from most links in T.

Each network segment is a conceptual unification of its individual composite links, and has gross characteristics of performance and reliability that can be abstracted from the finer-grained characteristics of its individual links. For example, on a link-level basis, the reliability of a segment is only as strong as its weakest physical link. When there is only one route between the client and server, the bandwidth of a segment cannot exceed the least bandwidth of its physical links. Finally, the latency of a segment is at least the sum of the latencies of its physical links.

Within this environment, we make the following assumptions:

- The server, when communicating with a client, assumes clients to be generally powerful devices that communicate with the server through links similar to those in the typical segment. If a client device deviates from this expectation, the server is not expected to handle it.
- The server expects the client to communicate with a predefined protocol P_S, which we refer to as the *server protocol*.
- The client knows the above server protocol P_S.
- The client knows its network limitations and how it deviates from the server's model of a standard, powerful, well-connected client.

2.2 Regions

A *region* is an encapsulation of part of the environment that incorporates the above assumptions into our model. All machines in a region (and the code that runs on those machines) possess knowledge of any deviations from the standard Internet environment. For simplicity, deviations are assumed to be static. In particular, a wireless network is only considered atypical if its operation is distinguishable from that of a wired network.

In addition, machines outside of a region lack any knowledge of any environmental deviations that operate within that region. Note that unlike a firewall, a region does not preclude the ability to communicate with machines in different regions — it merely expresses the boundary of environmental awareness.

Our model defines two regions: the client region and the server region. The client region consists of the client device and the atypical segment, to model the assumption that the client developer knows its deviations (and possibly, where necessary, how to measure them). Examples of such deviations include:

- Physical limitations of client device (small display, inadequate memory)
- Atypically low bandwidth in connection to Internet
- Atypically unreliable communications
- Atypically insecure communications
- Excessive latency between client and server

Meanwhile, the server region consists of the server machine(s) and the typical network segments that connect them to the atypical segment. This models the server's lack of knowledge about any client problems. (For purposes of simplicity and clarity, we limit the subsequent discussion to a server region containing a single server, but multiple servers are also supported by this model.)

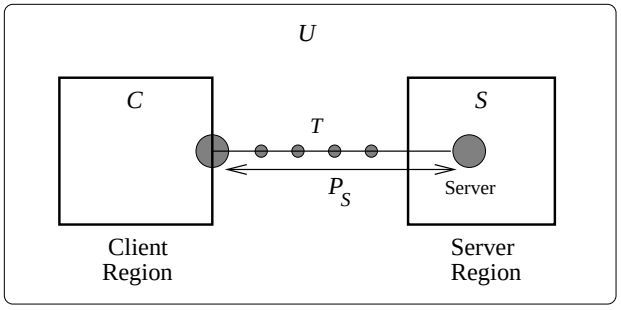

Figure 3: Server view of environment

Code in the server region operates as if the network environment were as depicted in Fig. 3. This view consists of the exterior of the client region, $U-C$ (which contains the server region S), and the physical network links between C and S that make up the client-server network connection (which is categorized as a typical network segment). Thus, server code is only required to assume that

there is a client, operating on a machine remote to the server, that connects and makes requests to the server using the server protocol P_S. It does not know about the atypical network segment at all.

In contrast (Fig. 4), code operating in the client region operates in an environment consisting of the exterior of the server region $U-S$ (which contains the client region C). The code developer is not required to understand either the implementation of the server architecture or the details of the typical segment, but only the server protocol P_S and the point of communication where the server can communicate with the client using P_S.

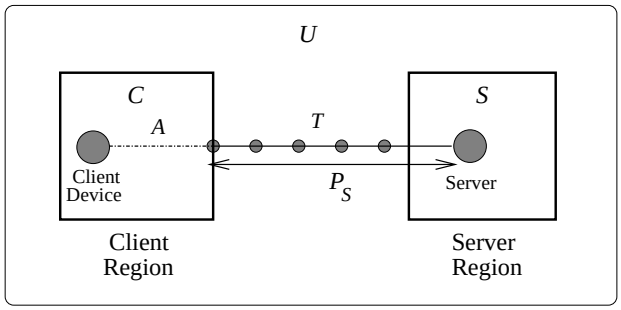

Figure 4: Client view of environment

2.3 Location of Customizing Logic

Given this model, and the concept of using remote code for customizing application performance, it is important to decide where the customizing logic should be placed. There are three possible areas where such customizing logic is based. They are:

- Within the client region
- Within the server region
- Within the network somewhere in between the client and server regions

Each of these three regions has been used in previous solutions for customizing performance. If the customizing logic is placed within the network, both client and server will have to deal with this change in their world view, making it hard to deploy. Also, the overhead of the mechanisms supporting the customizing logic is potentially incurred by all applications, regardless of whether they use them or not, thus lowering efficiency.

Meanwhile, if the customization logic is based at the server, then each change in a client causes a change in every server. This solution does not scale well: as the heterogeneity of client devices (represented by the addition of different client regions) increases, support required in the server universe also increases, as each server must add customization logic to handle each new client region.

Thus, we have chosen to base the location of the customizing logic, as a **reAgent**, in the client region. The reAgent is originated by the client and placed on a machine that resides in the typical segment, beyond the atypical segment. Once the reAgent is placed, we bound the client region to have the client device at one end and the customizing logic at the other end, so that the atypical segment is masked from the server. (Fig. 5)

From the model, we can see that the reAgent, being in the client region, is exposed to the problems of the client region, but that the server is not. Instead, the server treats the reAgent as the actual client, as they are both part of the opaque client region. Thus, the server need not change when new client problems arise, promoting deployability and scalability. Meanwhile, the client is still able

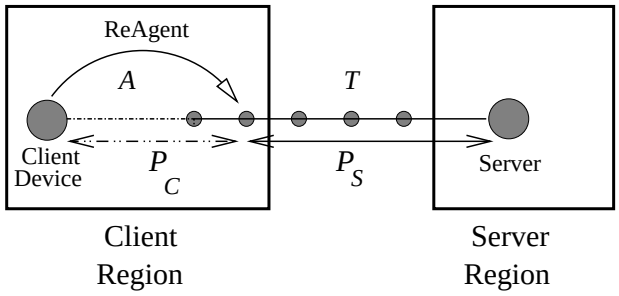

Figure 5: Bounding of Client Region

to communicate with the server by providing the reAgent with an understanding of the server protocol P_S. Moreover, with the addition of the reAgent as an intermediary between client and server, the client can now communicate with the reAgent using a custom *client protocol* P_C. Such a protocol could be used to ameliorate communication problems over the atypical segment, or provide the client with run-time control over the reAgent.

3. BEHAVIORS

We developed the definition of behaviors based on their usefulness in the design of reAgents. A behavior is "useful" if it exhibits benefits that are derived from a reAgent's ability to operate remotely. These benefits come from some combination of, but not limited to, the following: (1) use of remote computational resources; (2) avoiding or minimizing the effects of a problematic portion of the network (high delay, low bandwidth, low reliability, etc.); (3) ability to act autonomously on behalf of the client in a customized fashion.

The following sections catalog the useful behaviors we have identified. For each behavior, we present a description of the behavior, an outline of its base logic, an example of its use, and an analysis of its performance.

3.1 Filter

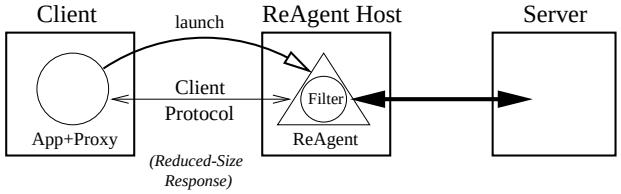

Figure 6: The Filter Behavior

Description. The Filter behavior (Fig. 6) is used whenever a server response needs to be reduced (in size) before reaching the client. The reAgent interposes itself between the client and server, filters the server responses into a smaller, possibly more suitable format for the client, and sends this filtered result back to the client. The CL (customizing logic) is the application-specific algorithm that defines *how* to reduce the data.

Base Logic. The reAgent passes the request through to the server, runs the filtering algorithm on the server response, and sends the new response back to the client.

Application. The Filter behavior is designed for scenarios where the server data is too large for the client. A common scenario involves browsers on clients with limited capabilities, such as small battery-powered wireless devices (e.g., PDAs). General features of such a device include limited network bandwidth as well as low-fidelity rendering of data, so filtering by removing extraneous or unusable data before sending it to the browser would reduce required bandwidth and reduce delay without significantly impacting the perceived quality of the data.

Analysis. In this analysis and those that follow, we assume that network latency (i.e., propagation time) and network message processing overhead are negligible (relative to the other factors we consider). All overheads that are attributable to the the reAgent itself, e.g., its launching time, are encapsulated as a single variable (λ).

One way a filter is effective is if it reduces end-to-end server-to-client delay. In straight client/server, the delay (D_{cs}) to return a file of size $\mathcal{S}$ is the transmission time given by file size divided by client-server bandwidth (B_{cs}):

$$D_{cs} = \frac{\mathcal{S}}{B_{cs}}$$

The delay as a result of using reAgents is equal to the the transmission time between the the server and reAgent ($\frac{\mathcal{S}}{B_{rs}}$) plus the processing time for the filter ($\mathcal{P}_{filter}$), plus the overhead of using the reAgent (λ), plus the transmission time between the reAgent and the client ($\frac{\alpha\mathcal{S}}{B_{cr}}$), where α is the percentage of original data left over from the filter:

$$D_{crs} \quad = \quad \frac{\mathcal{S}}{B_{rs}} + \mathcal{P}_{filter} + \lambda + \frac{\alpha\mathcal{S}}{B_{cr}}$$

To compare D_{cs} and D_{crs}, we calculate the *speedup*, which represents the percentage improvement of the reAgent approach. When the speedup is positive, reAgents are superior; when the speedup is negative, traditional client/server implementations are superior.

The speedup is derived from the following equation:

$$speedup = 1 - \frac{D_{crs}}{D_{cs}} \tag{1}$$

Plugging in the values of D_{crs} and D_{cs} into the speedup equation above, and setting B_{cr} equal to B_{cs} (assuming that the bandwidth of a set of links is equal to the bandwidth of the slowest individual link) results in a speedup of

$$speedup = \frac{(1-\alpha)\mathcal{S}/B_{cs} - (\mathcal{S}/B_{rs}) - \mathcal{P}_{filter} - \lambda}{D_{cs}}$$

If we express the ratio of the bandwidths as $\rho = \frac{B_{cs}}{B_{rs}}$, then $speedup > 0$ when

$$(1 - \alpha - \rho)\frac{\mathcal{S}}{B_{cs}} - \mathcal{P}_{filter} \quad > \quad \lambda$$

Thus, reAgents become more advantageous as

- α decreases (the filter reduces more data)
- ρ decreases (the bandwidth ratio of the client/reAgent to reAgent/server network segments becomes much smaller)
- $\mathcal{P}_{filter}$ decreases (the filtering algorithm processes more quickly)
- B_{cs} decreases (the overall bandwidth is small)
- $\mathcal{S}$ increases (there is more data to filter)
- λ decreases (overhead of using reAgent decreases)

So if client-reAgent bandwidth drops, or original data size gets larger, the filtering reAgent becomes more effective.

3.2 Monitor

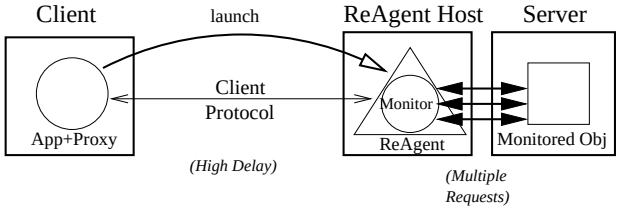

Figure 7: The Monitor Behavior

Description. The Monitor behavior (Fig. 7) is designed for use in applications that have a need to frequently examine the state of a remote object (on a far-away server) until a certain state is observed. The calculation of the next monitor attempt, plus the response evaluation function, forms the CL.

A reAgent that uses the monitor behavior is placed on a site close to the object that is being monitored, for the purpose of reducing the time of receiving a critical state change and sending the trigger action to the server. This is important for applications that require a real-time response to sudden changes in environment, such as a stock ticker or online bidding auction.

Base Logic. The behavior repeatedly calculates the next time to query the server, queries the server at that time, and then checks to see if a trigger state has been reached. Once the trigger state is reached, monitoring is terminated and the response that triggered the state change is returned.

Application. A simple example of an application for a Monitor involves intelligent auto-refresh of a Web browser. Many pages auto-refresh at fixed intervals. A Monitor can bypass the automatic refresh and refresh at its own customized rate. This can be advantageous when the Monitor is sensitive to network conditions and adjusts the rate depending on the amount of traffic. More importantly, the intelligent auto-refresh only updates the client when the server changes, and will not force a refresh when the data remains unchanged, saving bandwidth.

Analysis. To evaluate the monitor, we assume that the monitor will send a message to the server n times before the trigger condition is satisfied.

Under straight client/server, the total delay between sending a request to the server and processing its reply is

$$T_{cs} = n \times D_{cs}$$

where n = the number of queries before the trigger condition is satisfied.

With a reAgent, the total delay is

$$T_{crs} = D_{cr} + nD_{rs} + \lambda$$

as the delay between client and reAgent is only paid once. Equation 1 gives a reAgent speedup of

$$speedup = 1 - \frac{D_{cr} + nD_{rs} + \lambda}{nD_{cs}}$$

Solving for $speedup > 0$, we find that reAgents are better for monitoring when

$$(n-1)D_{cr} > \lambda$$

Thus, reAgents become more advantageous as

- n increases (more queries before trigger state is reached)
- D_{cr} increases (more delay between client and reAgent that is avoided)
- λ decreases (overhead of using reAgent decreases)

Therefore, many queries, or high delay between the client and the reAgent, points to using a monitor reAgent to gain a performance advantage.

3.3 Cacher

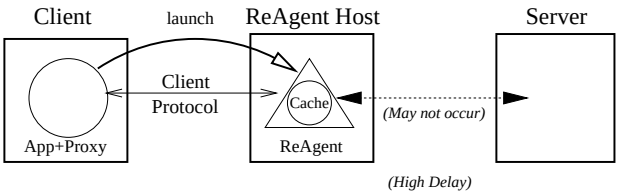

Figure 8: The Cacher Behavior

Description. The Cacher behavior (Fig. 8) is used for storing recently retrieved server data at a nearby location with the expectation that it will be accessed again, thus improving future performance. When previously retrieved data is requested again, the nearby stored copy is retrieved instead of the distant original. The cache replacement policy forms the CL. This behavior is especially useful for applications that have frequent yet identical requests to remote servers, such as occurs in Web browsing.

Base Logic. This behavior uses customized logic on the request input to decide whether or not to pass along the request to the server. If the request has not been made recently, the behavior generates a *key* that gets associated with the request, and then uses the request to contact the server. When the server responds, the behavior associates the data in the response to the key of the request and stores both items in a database, i.e., the cache, before outputting the response data. When a request is made that matches a key in the cache, the behavior will bypass sending the request to the server and immediately return the associated cache data.

The behavior is in charge of inserting, removing, and retrieving data contained within the cache. Insertion of data into the cache happens whenever the server sends the behavior a response. Cached data and its corresponding key are removed whenever the amount of storage allocated to the cache begins to run out, or by special order of the client. Data is retrieved from the cache when the client request key matches a key within the cache. While the behavior defines these general actions, particulars regarding cache policy (such as which cache entries to replace first when the cache is full) are supplied as part of the CL.

Application. Caching of frequently accessed Web pages is so beneficial to performance that most major Web browsers support some form of caching. With no intermediate hosts, the server data is stored on the client device. While storing the cached data on the client device is optimal for minimizing network delay, some client devices have such small amounts of memory that cache performance is seriously degraded by running locally. These resource-poor clients would benefit greatly from moving the cache from the client device to a nearby location with sufficient resources.

In such situations, a reAgent with a Cacher type of behavior can be created, along with a client-specified cache replacement policy and size, and launched to the nearby machine to effectively operate a cache for the browser.

Analysis. To evaluate the cacher in both scenarios, end-to-end delays are compared.

Under straight client/server, the delay between sending a request to the server and processing its reply is simply D_{cs}. Under a caching reAgent, the delay between sending a request to the server and receiving its reply depends on whether the item requested is in the cache. A delay between client and reAgent is always incurred. When the item is not found in the cache, a delay is also incurred between the reAgent and server. This can be expressed as

$$D_{crs} = D_{cr} + pD_{rs} + \lambda$$

where p is the probability of a cache miss.

The speedup of a reAgent Cacher over client/server is

$$speedup = 1 - \frac{D_{cr} + pD_{rs} + \lambda}{D_{cs}}$$

and $speedup > 0$ when

$$(1-p)D_{rs} > \lambda$$

So caching is better when

- D_{rs} increases (the delay from the network segment skipped by the cache is higher)
- p decreases (fewer cache misses)
- λ decreases (overhead of using reAgent decreases)

Thus, a reAgent cache outperforms client/server when the delay between reAgent and server is high enough, or the miss rate is low enough to overcome reAgent overhead.

3.4 Collator

Description. The Collator behavior (Fig. 9) transmits the same message to multiple servers from a remote location, and waits until a wait condition, specified by the client, is satisfied. Afterwards, the responses are sent to an application-specific function that produces a result for the client (collating).

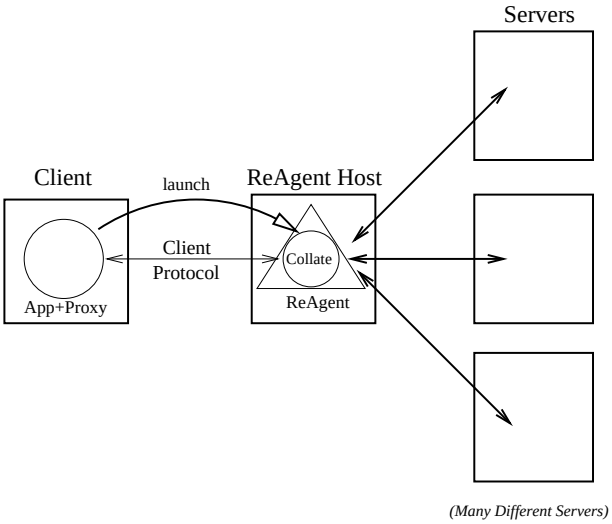

Figure 9: The Collator Behavior

Base Logic. The message is sent once to the reAgent, which then transmits it multiple times, once for each server. The reAgent then waits for responses from the servers in an application-specific fashion. For example, the reAgent may only wait for the first response from any server, or for some bounded number of responses, or even wait for responses from the servers within a timeout period. After waiting is completed, the server responses are collated in an application-specific way (as part of the CL), and the result is sent to the client.

Application. A typical Web application that exhibits this behavior is a comparison agent that queries different servers with the same question and returns the "best" result. While many services for finding the best price of an item already exist on the Web, they do not perform correctly if a server is not known or supported by the query service, or if the user is more concerned about some other attribute, such as delivery time or seller reputation, that the service does not support.

Analysis. For ease of analysis, the following assumes that the messages are sent serially, not in parallel.

Under straight client/server, the delay for completing requests to n servers is

$$D_{cs} = n \times d_{cs}$$

where d_{cs} = the average delay between client and server.

Under a collating reAgent, the time is

$$D_{crs} = nd_{rs} + \lambda$$

where d_{rs} = the average delay between reAgent and server.

Applying the speedup equation (1) gives a speedup of

$$speedup = 1 - \frac{nd_{rs} + \lambda}{nd_{cs}}$$

and a performance win for reAgents when

$$(n-1)d_{cr} > \lambda$$

where d_{cr} = the average delay between client and reAgent.

Thus, for any advantage to be gained, $n > 1$ (confirming the obvious). For each n beyond 1, a collating reAgent reduces delay by d_{cr}, which logically corresponds to traversing the network segment between the client and the reAgent, per additional server. If this amount is greater than the overhead from using the reAgent, the reAgent performs better than client/server.

4. EXPERIMENTS

Previous papers[10, 11] quantified the low overhead and utility of reAgents used for data compression and image filtering, based upon the Filter behaivor. Here, we describe an experiment that validates the theoretical advantages of the Monitor behavior.

A primitive stock server and client application were developed. The server outputs a ticker, showing the fluctuating price of a stock, and is programmed to accept only the first buy order it receives per run (i.e., only 1 share is available at this listed price).

The Monitor behavior was then used as the basis for a reAgent that would connect via network sockets to the stock server to watch stock prices and issue a buy order. The Monitor behavior was chosen because this application requires multiple communications between the reAgent and stock server. The reAgent monitors the ticker and sends a buy request when the price of a certain stock falls to a certain value (both chosen by the user as input arguments). The decision-making component is a custom algorithm that acts as the CL for the Monitor behavior.

In the following experiments, the performance metric used was the time it took for the server to receive a "buy" command after the stock hit the target price, essentially a measure of the total latency between the decision-maker and the server, plus the CPU time alloted to the decision-maker.

4.1 Response Time

The first experiment was to evaluate the relative response-time performance of three network application paradigms :

1. Traditional RPC
2. ReAgent-based computing
3. Service-based customization

To introduce a non-trivial latency, the client machine, *federation*, a Sun Ultra 1, was stationed at CMU in Pittsburgh, approximately 2500 miles away from the stock server machine, *ursus*, a Sun Ultra 10, in San Diego. The results, after 10000 iterations for each paradigm, are summarized in the following table:

Table 1: Comparison of Response Time for Various Paradigms

Paradigm	Response Time (*ms*)			95% Confidence Interval
	Min	Max	Mean	
Traditional	71	3474	79.6	$\pm$ 1.8 ms
reAgent	1	14	1.161	$\pm$ 0.008 ms
Service	0	11	0.051	$\pm$ 0.005 ms

The confidence intervals show that the averages are statistically significant. These results say, not surprisingly, that the best performance occurs if the server can be hard-wired with the action that the client requests. While this might be true for simple operations like limit-order stock purchases, in practice, not all servers will be able to anticipate every need of the client, such as when the user has an unusual stock-trading algorithm to implement.

Comparing the non-hardwired methods of traditional vs. reAgent, the traditional method suffers severe performance penalties as well as a highly variable response time. The high variance is a result of intermittent network congestion and timeouts, which the reAgent, running near the server, can ameliorate.

From this experiment, it can be concluded that a Monitor-based reAgent application achieves similar, although slightly inferior, performance when compared with a server-customized service. Of course, the cost of building applications with a similar level of performance with reAgents is much smaller than requiring all servers to hardwire their services for each user. Attempts to create flexible applications without reAgents result in highly variable and inferior performance due to the high-latency communications between the decision-making algorithm and the server.

4.2 Application Performance Comparison

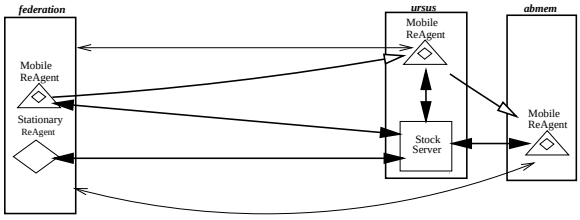

Figure 10: Stock Traders Setup

An application-based comparison was performed as a supplement to the previous experiment. The comparison centered on the Monitor-based stock trading reAgent described in the previous section. This reAgent was run in sets of two. In each set, one reAgent remains at the client (the stationary reAgent), while the other reAgent (the mobile reAgent) is potentially launched to a different host to improve application performance. Each Trader's goal is to wait until the stock hits a pre-determined low price, and then buy it before their opponent.

The experiment was conducted with three sets of reAgents. The first set has both reAgents begin at *federation* (the client), to demonstrate the worst case of no supporting reAgent servers. The next set has the mobile reAgent moves to *ursus*, the stock server itself, and results are compared. The final set has the mobile reAgent move to *abmem*, a machine on *ursus*'s LAN that acts as a reAgent host. The last experiment is important because it highlights the deployable nature of reAgents; one can neither assume that every server in the world will support reAgents, nor that servers will always have the capacity to host reAgents. However, it is reasonable to assume that an independent reAgent host will be nearby.

The experiment showed that the mobile reAgent beat the stationary reAgent every time when operating from a closer location. The full results can be seen in Table 2.

Table 2: Mobile vs. Stationary ReAgent

Mobile reAgent Host	Mobile reAgent Success Rate	95% Confidence Interval
client	50.8%	$\pm$ 1.4%
server	100.0%	$\pm$ 0.0%
reAgent host	100.0%	$\pm$ 0.0%

The 100% success rate in the cases where the reAgent migrated closer demonstrated that the mobile reAgent could parlay the theoretical performance benefits of reAgents into a superior, flexible application. In the worst-case scenario with no supporting reAgent servers, the reAgent still functioned on a relatively equal footing with a normal, traditional trader (represented by the stationary reAgent). However, the mobile reAgent was able to use its ability to move when closer reAgent hosts were available, allowing it to improve its performance along with its location. The reAgent allows this improvement to be easily customizable, merely by changing its destination (a line of text). As users have different requirements — for example, running directly on the server may be significantly more expensive, so a grad student's trading application may only give a destination of a cheaper reAgent server — reAgents allow users to scale the performance effectiveness to a level appropriate with their needs and abilities.

5. RELATED WORK

The idea of enhancing client applications with remote code is not new, but previous efforts have been divided on how and where to provide this functionality. The *active networks* approach [23] argues for putting customizing logic at the network level. While various active networks [26, 19, 1] are able to effectively support a wide variety of client devices, they do so at the expense of deployability [6].

Another customization solution lies in the use of proxies, which act as intermediaries between client and server. While traditional proxy applications concentrate on caching and firewalls [14], some have focused on actively customizing application behavior (dynamic proxies) [4, 24, 15].

Another approach is to attempt to have servers adapt to the specifics of each individual client. Server-provided CGI scripts/forms, and the group of technologies bundled into the Open Mobile Alliance (OMA) [17] are two examples of this type of approach, where the server programmer is responsible for anticipating common client problems and catering to them. To be less dependent on the server, researchers have developed customizers with more client-side support [28, 22, 3].

A significant area of past research in client-based customization has been based upon *mobile agents* [5]. Mobile agents are pieces of customizing logic that have a persistent identity, moving around the network to multiple sites [25]. The D'Agents project [8] and IBM Aglets Workbench [13] are prominent examples from industry and academia, respectively, of systems that support the execution of mobile agents. A fuller description of these and other important agent systems can be found in [9].

Our reAgent approach is a middle-ground solution, based on a one-shot remote code mechanism that is more flexible than proxies but less complicated than fully-general mobile agents. This model is similar to that of remote evaluation [21]. Several advantages arise from limiting movement to one hop. By avoiding some of the security issues introduced by code that can roam from site to site, infrastructural support is simplified. Also, with a stationary remote agent acting on its behalf, the client gains the benefits from remote execution without adjusting its client/server architecture: the reAgent acts as a server by taking requests and returning responses. Finally, technical problems associated with maintaining and updating program state during migration are avoided, without losing much functionality, a view supported by [12].

Finally, behavior templates are similar to the idea of "design patterns." In [27], the authors describe problems facing the development and deployment of mobile agent (and mobile code) applications. Consequently, there has been some work attempting to extend the idea of design patterns to mobile code [7]. Design patterns have previously been proposed for use in designing mobile agent applications [2, 18, 20].

6. CONCLUSION

In this paper, we described the behavior-based architecture and performance of reAgents. ReAgents are especially applicable to situations where clients are resource limited in their computing or network access capabilities. A reAgent effectively extends the client's reach into the network, and derives its power by performing remote operations that (1) minimize the effects of a problematic network path (2) gain an advantage by operating close to one or more servers, (3) take advantage of remote resources (e.g., computational, memory) that are relatively more powerful than those locally available at the client, and (4) act autonomously on behalf of the client in a customized fashion.

The use of reAgents allows us to derive benefits of mobile agent systems — specifically their support for dynamically-located remote execution, limited to one-shot movement — in what we believe to be an easy-to-program form. Key to this simplicity is the transparent handling of data migration and run-time network communications. This is a direct result of the reAgent programming model: reAgents are composed of one or more behaviors, i.e., abstractions for common remote patterns of action, each of which can be specialized with custom logic that allows reAgents to be tailored to their applications. We presented four such general behaviors — filtering, caching, monitoring, and collating — and using analytical models showed the conditions under which performance will improve when compared to the straight client/server model. We also presented empirical results from experiments that provide evidence of the performance benefits of reAgents.

ABSTRACT

Security systems can observe and hear almost anyone everywhere. However, it is impossible to employ an adequate number of human experts to analyze the information explosion. In this paper we present an autonomous multi-agent framework which, as an input, obtains biometric information acquired at a set of locations. The framework aims in real-time to point out individuals who act according to a suspicious pattern across these locations. The system works in large-scale scenarios. We present a scenario to demonstrate the usefulness of the framework. The goal is to point out individuals who visited a sequence of airports using face recognition algorithms. Simulation results show a high overall accuracy of our system in real-time.

1. INTRODUCTION

In this paper we address the general domain of **L**arge-scale **B**iometric **P**attern recognition (LBP). LBP problems include situations where there is a stream of biometric information acquired at a set of locations e.g., a set of cameras positioned in several airports. The goal of LBP problems is to point out individuals who act according to a predefined suspicious pattern in real-time. The combination of multiple locations and streams of input, inaccuracy of biometric tests [1] and real-time constraints make the LBP problems hard to solve, and ideal candidate for MAS implementation [2]. A representative scenario is presented below.

1.1 Problem Description

In this paper we present a framework of a multi-agent solution for the LBP problems. We then present an implementation of this framework for a specific problem we call **The airport problem**. Assume a set of L airports denoted $ap_1, ap_2, ..., ap_L$. Our goal is to identify and detain at airport L every passenger who flew from airport 1 to airport 2.... to airport L. At each airport there are cameras which take one picture of each passenger.

There are two boolean comparison algorithms, namely ca_1 and ca_2. As an input each comparison algorithm receives two pictures. The comparison algorithm returns true if the pictures match, i.e. both pictures belong to the same person. Otherwise the algorithm returns false. We assume the algorithms are independent. Each comparison algorithm has a known *false acceptance rate* (FAR) which is the probability that the algorithm will receive two pictures which do not belong to the same person and it will return true. Each comparison algorithm has a known *false reject rate* (FRR) which is the probability that the algorithm will receive two pictures which belong to the same person and it will return false. We also know that the first algorithm has a lower FAR and the second algorithm has a lower FRR: $FAR_{ca_1} < FAR_{ca_2}$ and $FRR_{ca_2} < FRR_{ca_1}$. We define a *picture-set* of size k as a set of pictures taken from k airports. A key constraint of LBP is that the suspects do not need to cooperate with the system.

1.2 Difficulties and challenges

We would like to point out some of the attributes make LBP problems difficult. The examples refer to the airport problem, although all attributes exist in the LBP domain in general. Firstly, this is a large scale problem. Assume we would like to capture every person who visited two different airports ap_1 and ap_2. Also assume there are 1000 people in each airport. The agent must create $1,000 \times 1,000 = 1,000,000$ picture-sets of size two and use a comparison algorithm to compare each pair of pictures. Note that the cameras' location can ensure that only pictures of passengers who came on a certain flight are taken, so 1000 images per airport is not an unrealistic scenario.

Moreover, biometric comparison algorithms are imperfect. For example, current state-of-the-art face recognition algorithms have an error margin that is unacceptable in large-scale situations [1]. Suppose all the pictures in the previous example are of different people. Even an algorithm with an

Algorithm 1 MLBP framework: local module

Local-module(Path p, item i, path q)
1 Let r=**Phase1**(p, i, q)
2 If r='borderline' Then return **Phase2**(q, i, q')
3 return r

Phase1(Path p, item i, path q)
1 Let q =**AddItemToPath**(p, i, ca_1)
2 Let m=$\binom{L}{2} - LT$
3 If $q^- > m$ Then return 'prune'
4 If (($|q| < L$) AND ($q^- \leq m$)) Then
4.1 Return 'continue'
5 If ($q^- < m$) Then return 'trigger alarm'
6 return 'borderline'

Phase2(Path p)
1 Let q be an empty path
2 Let m=$\binom{L}{2} - HT$
3 For each item i in $p.I$
3.1 q=**AddItemToPath**(q, i, ca_2)
3.2 If $q^- > m$ Then return 'prune'
4 return 'trigger alarm'

FAR of 1% will, on average, mistakenly positively identify 10,000 out of the 1,000,000 picture-sets. Suppose there is a person whose picture was taken at ap_2. This picture is matched 1,000 times, each time against different pictures acquired at ap_1. The probability that this picture will appear in a set that is falsely accepted is very high. Using this algorithm will make all passengers of the second airport be (probably falsely) detained.

2. MAS SOLUTION FRAMEWORK

We present a solution to the LBP problem assuming we have two biometric comparison-algorithms. The solution uses multiple agents to incrementally build candidate suspects. At each step, the algorithm tries to prune some of the candidates. Each agent consists of a local-module and an interaction-module.

The main information structure which is transferred between the agents is *path* defined as $p = \{I, R\}$. $I = \{i_1, i_2, ...i_k\}$ is a set of k items (e.g., face images of passengers). R is a set of the comparison results between any two items in I. Given a path p, we denote p^- as the number of negative comparison results in $p.R$. Similarly, we define p^+ as the number of positive comparison results in $p.R$. We also denote the number of items in $p.I$ as $|p|$. There are $p^+ + p^- = \binom{k}{2}$ comparison results in a path of length k. A path p and an item i can be joined together to create a new path of size $|p| + 1$. The method *AddItemToPath* gets a path p and an item i and returns a new path q. $q.I = \{p.i \cup i\}$ and $q.R$ holds $p.R$ along with the comparison results of items in $p.I$ and i.

Suppose we have a perfect comparison algorithm, with no FAR and FRR. The system should trigger an alarm only when it detects a path of size L which has the maximum number of positive comparison results, i.e. $p^+ = \binom{L}{2}$ and $p^- = 0$. For example, If $L = 3$, the system should trigger an alarm only if $ca(1,2) = ca(1,3) = ca(2,3) = true$. In actuality, however, comparison algorithms have FRR and we must consider cases where all items match, but some of the comparisons are falsely rejected. For the first comparison algorithm ca_1 we define a threshold LT where $0 \leq LT \leq \binom{L}{2}$. The algorithm triggers an alarm when a path of size L is created and $p^+ > LT$. In other words, the algorithm allows a path to have $p^- < \binom{L}{2} - LT$ false comparisons and still treats it as a path with matching items which might lead to a target person. Similarly we define a threshold HT for ca_2.

Each agent is responsible for one biometric information source (e.g., a camera). An agent receives new information from two sources. The first source is from his biometric information unit (e.g., a passenger picture). The agent processes the acquired item and creates a path of size one. The second source of information is forwarded paths from other agents. Each agent holds a database of paths PDB in which it stores every new path it receives.

Algorithm 1 describes the local module of the MLBP framework. The local-module is embedded in each agent. As an input the module receives a path p and a biometric item i. It returns a string that classifies the joint path q which contains all items in p and i. The local module has three possible return values:

- 'prune' - There is no point in keeping the joint path.
- 'continue' - The joint path has a potential to become a target path.
- 'trigger alarm' The joint path is a target path and the system must notify about it.

The module may return 'continue' only if the size of the joint path is smaller than L. It may return 'trigger alert' only for full paths - paths of size L. Comparing a pair of pictures is time consuming. Thus, the algorithm uses ca_1 alone to classify the new path in most cases (lines 3-5 in function **Phase1**). The only scenario in which ca_2 is used is a borderline scenario. A borderline scenario occurs when a full path ($|q| = L$), has exactly LT positive results. The algorithm then uses ca_2 (function **Phase2**). First the algorithm creates a new path which contains all items in q, but this time it uses ca_2 to compare all pairs of items. The same classification rules are applied for q', but this time the threshold is HT rather than LT.

Though ca_2 (which is used in phase 2 only) has a higher false alarm ratio, it is of less concern since at this point the number of paths has already been significantly reduced. Conversely, the low FRR of this algorithm makes it very effective in verifying the identity of the true suspect. Phase 2 is significantly more time consuming than phase 1. In phase 1 $p.R$ already contains comparison results of all items in p (using ca_1). The new item i is then compared with items in p, which totals $L - 1$ comparisons (worst case). In phase 2, the algorithm uses $\binom{L}{2}$ comparisons (worst case) to build a path from scratch using ca_2.

Also note that the pruning made by the local-module is lossless. It is lossless in the sense that a system which uses the module will have the same accuracy with and without the pruning mechanism. This fact allowed us to ignore the pruning mechanism when we analyzed the algorithm performance in terms of accuracy. However, pruning is crucial in terms of run-time.

Algorithm 2 Airport Problem - Agent A_i

ProcessImage(Image *im*)
1 For each Path p in PDB
1.1 Let q be empty path
1.2 Let r=**Local-module**(p, *im*, q)
1.3 If r==’trigger alarm’ Then trigger alarm
1.4 If r==’continue’ Then forward q to A_{i+1}

L	N	LE	HE	$\overline{FRR}$	$\overline{FAR}$
4	500	1	2	0.0700	0.0011
4	500	2	0	0.0100	0.0682

4	1000	1	1	0.0967	0.0012
5	1000	2	3	0.0588	0.0040
6	1000	2	2	0.2225	0.0000
4	1500	1	0	0.1500	0.0001
4	1500	1	2	0.0700	0.0011

Table 1: Simulation results for selected scenarios

The local-module classifies a given path. The agents create paths, process them using the local-module and send them to the relevant agents. This flow of information is made according to the problem specifications. In the following subsection, we describe implementation of the interaction-module for the airport problem.

We have a camera installed in L airports: $ap_1, ap_2, ...ap_L$. At airport L we would like to detain every person who visited all airports *in a specific order*: $ap_1 \rightarrow ap_2 \rightarrow ...ap_L$. This allows us to use a simple sequential flow of paths as follows.

Agent A_1 (located at ap_1) acquires images and sends them to A_2. The interior agent, A_k, $1 < k \leq L$ maintains a database of paths sent by A_{k-1} denoted PDB. Each path in PDB is of length $k-1$. When a passenger’s image *im* is acquired at airport k, each path in PDB is sent to the local-module along with *im* (See algorithm 2). Paths that have enough positive comparison results are sent to A_{k+1} or trigger an alarm (if the path was created by the last agent).

We are interested in individuals who traveled through the airports in a specific order. This allows the agent to restrict the paths’ flow from agent A_i to agent A_{i+1}. Moreover, the costly procedure **Phase2** of the local-module is activated only by the last agent, which is the only one to process paths of size L.

3. EXPERIMENTAL RESULTS

We would like to know how the problem size (number of people N and number of information sources L) affects the accuracy of the algorithm. We also want to know how these parameters affect the running time of the algorithm. We would like to verify that the algorithm runs in real-time.

In order to answer these questions we implemented a simulation of the airport problem. For statistical significance we averaged results from 100 trials for each parameter studied. For each trial, we created a database which contains the flight plan for each passenger. We assumed a distribution function where most of the passengers only visit one or two airports out of the possible L airports. We modeled this behavior as an exponential decay function with the fewest people visiting all L airports.

We then ran experiments on various scenarios to test the overall behavior of the system. Table 3 shows various problem instances and the global FRR and FAR achieved by the MLBP algorithm. The first two columns describe the number of airports and the number of pictures taken at each airport. Columns three and four are the thresholds chosen for the simulation. The last two columns show the actual FRR and FAR. The results are very encouraging. For example, the results in line 5 shows that out of 1000 passengers, only one passenger will need special attention and the system will point out a target suspect with a reliability of 93%. We also tried to use ca_2 in the first phase and ca_1 in the second phase of the local-module (with $L = 1000$). The result was $\overline{FAR} = 1$! The high FAR of ca_2 caused each passenger in ap_L to have at least one path with enough false positive classifications to trigger an alarm.

We also were successful in significantly reducing the time complexity factor of this problem. We focused on the last agent since its time complexity is the most significant. The last agent is the only agent who uses the costly second pruning phase. This agent has the most time intensive decision to make, deciding in real time which passenger to single out. Other agents have the luxury of having more time before a final decision has to be rendered. Even in the worse case we studied, when $N = 1000$ and $L = 5$, the final agent was able to render a judgment under 12.5 seconds using a Pentium IV 3.0 Ghz computer with 1 GB of memory.

It is important to note that increasing the length of the path (L) does not necessarily increase the time complexity. The overall time needed by the last agent to make a decision is affected by two factors: 1) LT: the first threshold determines the number of paths reaching the last agent. A low threshold means a large number of paths that reach the last agent. 2) L: Borderline paths go through the second phase. The algorithm uses $\binom{L}{2}$ tests (in the worst case) on the second phase. Therefore, the longer the path the more time needed by the last agent for each path.

4. CONCLUSIONS

In this paper we addressed the domain of large-scale biometric pattern-recognition. The combination of multiple locations and streams of input, inaccuracy of biometric tests and real-time constraints make LBP problems hard to solve, and ideal candidates for MAS implementation.

We have presented the MLBP - a multi-agent solution to handle the LBP problem. The solution uses multiple agents to incrementally build solution candidates. Each agent consists of a local-module and an interaction-module. The local-module prunes candidates which do not reach a certain threshold. Borderline cases go through a secondary process of classification. *A web version which contains additional domains and a full theoretical analysis is available at www.cs.biu.ac.il /meshulr1/MLBP.pdf*

ABSTRACT

Most existing organizational design processes focus on either the qualitative or domain-independent features of candidate designs. This paper demonstrates the significance of domain-specific features through an examination of an organizationally-driven information retrieval network. The behavior of a distributed search process and the consequences of hierarchical control are described. A model capable of predicting these characteristics is created in the ODML framework using techniques from queuing theory. This model can be used to guide the search for an appropriate design.

1. INTRODUCTION

Much of the existing work on organization design in multi-agent systems has focused on the qualitative aspects of those designs, or on a predefined set of numeric but largely domain-independent characteristics. In our recent work [2] we have developed a new representation called ODML that incorporates arbitrary quantitative information into the organizational model. Such a model can be used to make detailed predictions of how candidate designs will perform in different circumstances, which can be used as part of a larger search process through the space of design alternatives. Although such models can be more difficult to construct, we believe the benefits this more refined view can provide warrant research.

In particular, we believe that the ability to make concrete, numeric predictions about a range of domain-specific organizational characteristics can improve the design process by capturing the complexities that exist in realistic systems. In contrast to solutions that use instrumented simulations to make similarly detailed predictions, such explicit models also offer rapid but precise design evaluation, facilitating search of the design space. In this paper we demonstrate this potential by describing how an organizationally-driven information retrieval system has been modeled in the ODML framework. The end product of the modeling process is a single, succinct construct that both describes the space of alternatives and predicts the performance of individual designs.

The information retrieval model presented here is inspired by work by Zhang et al. [3], which uses a hierarchical organization to structure an information retrieval system. This allows queries to quickly propagate to data sources, and results routed back to a single agent in the network. At the top level of each hierarchy is a mediator responsible for providing a description of the data available in the information sources present in the hierarchy below it. Information sources may be an individual database, or an aggregator that manages other sources. Multiple mediators may exist, which service user queries by first using the signatures of other mediators to discover data sources, then routing the query to the appropriate mediators, and finally collecting the resulting data.

This organizational design provides several advantages. The use of hierarchies introduces parallelism into query processing and distributes the communication load. Conversely, if the data sources are widely distributed it may require an extensive search process to obtain a good result. There also exists a tension between the width and height of hierarchical structures, as narrow structures can have high latency and wide structures create bottlenecks. Determining what particular design to use can be a difficult problem, owing to the complex and interdependent nature of the organization's characteristics, interactions with the environment, and specified system requirements. We show in this paper how an ODML model facilitates this selection process by capturing these interactions, and using them to make concrete predictions about runtime behavior.

2. MODELING RESPONSE TIME

Similar to models created with other organizational languages, this model includes notions of roles, a task environment and perfor-

mance constraints. However, other relevant phenomena that must be captured in this domain are significantly different, and drive the shape of the organization in different directions. These include statistically predicting the results of the source discovery process, determining how the information contents of a hierarchy affect its expected load and approximating the effects of increased signature uncertainty caused by summarization. Although each can be modeled as a particular, distinct characteristic of the system, in reality they interact in complex ways. The tensions that arise in the resulting model embody the tradeoffs and decisions that must be made when designing the organization. This paper will focus on these expected response time of the system; the reader can refer to [2] for a description other characteristics this model possesses.

The IR system's response time is the duration of time between a query and the final response, a characteristic that is clearly important from an evaluation standpoint. Several design features affect this value. For example, each communication event incurs some message transit latency. The query processing by the databases, and the aggregation performed by both the aggregator and mediator will take some variable amount of time. Because queries are reflected to all subordinates, the latter two entities must also wait for slowest of their information sources before they can themselves respond. Finally, because multiple queries can exist simultaneously in the network, additional delays at individual agents can be incurred when a query must wait for existing processing to complete.

The rate at which an individual mediator will receive user queries it its *arrival_rate*. Responses will be returned back at this same rate, on average. More concretely, the existing model assumes that queries have a Poisson arrival distribution and mean rate *arrival_rate*. After the query makes its way down through any aggregators, the leaf databases will receive the query, also at rate *arrival_rate*. Each database has a *service_rate*, defining how quickly it can process queries. At any given time there may be previously received queries already being processed or waiting at the database. We assume FIFO processing, so the amount of time any new query must wait will depend in part on these existing queries.

Queuing theory can be used to analyze how long the wait will be, by modeling a database as a *M/M/1* queue with Poisson task arrival rate and service rate. The pdf $f_M(x,\lambda)$ and cdf $F_M(x,\lambda)$ of the *M/M/1* queue's waiting time distribution are given below, where $x \geq 0$ and $\lambda = service\_rate - arrival\_rate$.

$$\begin{aligned} f_M(x,\lambda) &= \lambda e^{-\lambda x} \\ F_M(x,\lambda) &= 1 - e^{-\lambda x}, \end{aligned}$$

The mediator waits for responses from all its information sources before progressing, so its expected service time will be dependent on the maximum service time of those below it. This value can be found by computing the maximum order statistic (the expected maximum value) of those source service times. The model makes a simplifying assumption that the source service time distributions are independent, but does not assume they are identical. The model generates the pdf $f_{(n)}$ and cdf $F_{(n)}$ distributions of this inid max order statistic using the following functions[1]:

$$f_{(n)}(x) = \Big[\prod_{i=1}^{n} F_i(x)\Big] \sum_{i=1}^{n} \Big(\frac{f_i(x)}{F_i(x)}\Big) \quad (1)$$

$$F_{(n)}(x) = \prod_{i=1}^{n} F_i(x), \quad (2)$$

where f_i and F_i represent the pdf and cdf of the ith sample, respectively (i.e., the service time distribution of the ith source).

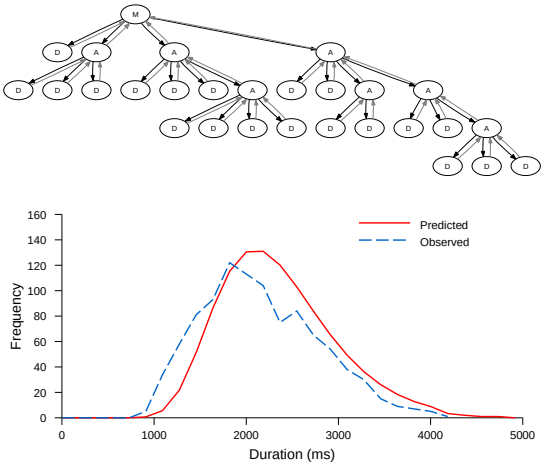

Figure 1: The predicted and observed response time distributions in organizations with twenty-eight agents. Node M is a mediator, A are aggregators, and D are databases.

The mediator itself is not simply a pass-through, but must process and aggregate the resulting data as well, introducing additional latency. Thus, the mediator can also be viewed and modeled as a *M/M/1* queue. The service rate of the mediator depends on the number of responses it receives, which depends on the number of information sources below it. The mediator's pdf and cdf can also be produced using Equations 1 and 1, with $service\_rate = response\_service\_rate/num\_sources$, and a Poisson rate of $\lambda = arrival\_rate - service\_rate$.

The model determines the total service time by combining these two activities, modeled as the sum of the times exhibited by these two random variables. The total service time pdf f_C and cdf F_C can then be determined by finding the convolution of the corresponding distribution functions, which has the general form:

$$f_C(x) = \sum_{i=0}^{d\_range/d\_step} f_s(i) f_l(x-i) d\_step \quad (3)$$

$$F_C(x) = \sum_{i=0}^{d\_range/d\_step} f_s(i) F_l(x-i) d\_step \quad (4)$$

For the mediator, f_s would be the aggregate information source pdf given in Equation 1, while f_l and F_l would be the pdf and cdf of the waiting time for the local *M/M/1* queuing process.

Note that Equations 1-4 are recursive, in that they rely upon both the pdf and cdf distributions of the sources below the mediator. The equations make no assumptions about the form of those distributions, so they can be used both when the information source is a single database or an arbitrarily complex aggregator hierarchy. This same assumption also allows Equations 1 and 2 to be used to compute the pdf and cdf distributions for the aggregator itself. The definition terminates in the exponential response distribution exhibited by the databases. By incorporating the cumulative overhead incurred by the message transit times of the query and result propagation process the model can now compute the expected *service_time* of the mediator, allowing prediction of the *response_time* distribution of the organization as a whole.

A representative prediction is shown in Figure 1. The scenario measures the response time performance of a different IR organi-

Figure 2: The utility predicted for the range of possible six-database organizations when the query rate is varied. Hollow circles are mediators and aggregators, with solid databases at the leaves. Optimal values for each rate are shown in bold.

zational design, by submitting 1000 queries to it in a Poisson fashion. The tested design is depicted above, along with the predicted and empirical response time data below. The solid line represents the distribution of response times predicted by the ODML model, while the dashed line indicates the observed frequency of response times in the simulation.

As can be seen in the performance graphs, the ODML model does a good job of predicting the response time distribution of the different organizational designs. Additional response time trials were performed for organizations with three [1M,2D], five [1M,4D], 10 [1M,2A,7D], 14 [1M,3A,10D], and 15 agents [1M,6A,8D], with similar results. The coefficient of determination R^2 was greater than 0.8 for all tested scenarios.

3. DETERMINING DESIGN UTILITY

There are many characteristics that impact design choice, including agent load, response quality and resource consumption. These are explicitly represented in the complete ODML model, and are used to derive two aggregate metrics, *response_time* and *response_recall*, which are combined to produce a single *utility* field that can then be used to compare and rank candidate designs during a search process. A complete description of how response recall is estimated in the model can be found in [2].

Figure 2 shows how utility is affected by the expected user query rate. This figure shows the full range of possible organizations that are possible in a six database environment with a maximum height of three and a minimum of two subordinates per node. The design parameters are such that response recall is identical among the alternatives, so utility is determined by the response time. When the query rate exceeds the service rate at one or more points, resulting in an infinite queue, the organization receives zero utility.

The single-level, single-mediator organization number 1 is predicted to be optimal when the query rate is 0.5 or less (i.e., less than one query every other second). This is intuitive, because the slow query rate avoids queuing delays, causing the response time to be dominated by the height of the organization. Note that other short hierarchies such as numbers 11 and 13 also have high utility.

As the query rate increases, first organization 11, then number 8 and finally number 9 become optimal, as the highly-connected mediator in organization 1 becomes a bottleneck. In contrast to most of the competing designs, organizations 11, 8 and 9 are all balanced (as is number 1). In an unbalanced organization, the segment with greater load tends to dominate the response time because the final result must wait for the slowest responder. These three designs avoid this by evenly spreading the load among participants.

The differences between the three revolve around where the final aggregation takes place, and how distributed the database search is. For example, 8 and 9 employ an additional mediator to aggregate the final results, while 11 does not. In 11 and 18, one of the mediators serves this role, which will slightly unbalance the load in the organization for any given query. Therefore, although the lack of another aggregating level saves on communication, the transient load imbalance ultimately leads to an increase in queuing delays.

These tests show one dimension of design tradeoffs that can be made in this environment. Organization 1 is fast but quite centralized. To avoid the increasing chance of bottlenecks, organizations 11, 8 and 9 trades off response time. Other organizations may trade off response quality, or other characteristics. Which design is most appropriate depends on the operational context. These needs may be incorporated into the model's definition of *utility* so that design alternatives are correctly ranked.

This range of viable alternatives, each possessing a set of interacting features, motivates the need for organizational models capable of representing the space of alternatives and predicting their quantitative character. More importantly, this work demonstrates how significant domain-specific characteristics can be affected by choices made in an organizational design. If such characteristics are not accounted for in the design process, or if they are approximated to the degree that important interactions are lost, then the ramifications of decisions that affect those characteristics may also be lost. We believe this will affect the quality of any resulting design, as those interactions are real and must be considered. This fact supports the detailed view of organizational behavior that is expressed in this paper, and the general ODML modeling framework we have designed to capture such details.

ABSTRACT

The paper demonstrates how a layered reference architecture for software agents provides a framework for a dependability model that allows to associate the sources of failures and the ensuing error handling with a specific layer, thus integrating dependability directly into the design of agents.

Multiagent System, Layered Software Architecture, Dependability

1. INTRODUCTION

Ideally, agents never fail. Practically, though, disturbances may occur that are outside the control of the agent system. We call a multiagent system dependable if it or its constituent agents include internal mechanisms that guarantee that all services are rendered according to specification even in the presence of disturbances.

The main thesis of this short paper is that if the design of agents and multiagent systems follows the principle of levels of abstraction resulting in a layered architecture, the principle will also determine the design of dependability by associating a specific failure and its remedies with an individual layer. In this way one can develop a well-structured dependability model where each kind of error handling can be isolated and localized.

2. REFERENCE ARCHITECTURE

Let us first introduce a layered reference architecture as the framework within which to integrate dependability in a systematic fashion and thus prove our thesis. The architecture as shown in Fig. 1 was developed in [2] where it is explained in detail. The layers are based on the properties of intelligent software agents as listed by Wooldridge [7]. The lower two layers provide the basis for situatedness, autonomy, reactivity and proactivity, layer L3 for utility and goal-orientation. Layer L4 realizes agent behavior encompassing utility, reactivity and goal deliberation, while layer L5 adds sociability.

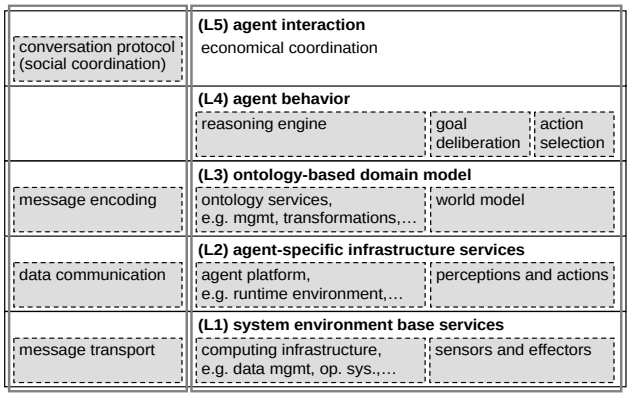

Figure 1: Reference architecture for a multi-agent system

Sociability includes agent interaction. Since a multiagent system is a distributed system where system control is distributed and agents are loosely coupled, information exchange above the physical layer must be incorporated within the individual agents. Modern message exchange software follows a layers pattern as well, referred to as a protocol stack. Fig. 1 includes the protocol stack. While interaction is primarily reflected on layer L5, layer L2 must account for the sequence of message exchanges between the agents, and layer L3 for the common understanding among the agents.

3. A DEPENDABILITY MODEL

3.1 Failures and dependability

We base our a dependability model on (some of) the definitions of Laprie [1]. Computer system **dependability** is the *quality of the delivered service* such that *reliance* can *justifiably* be placed on this service. The **service** delivered by a system is the system behavior *as it is perceived* by another special system(s) interacting with the considered system: its user(s). The service **specification** is an agreed description of the expected service. A system **failure** occurs when the delivered service deviates from the specified service.

The cause—in its phenomenological sense—of any failure is a (unintentional) **fault**. We should make sure that only very few faults occur in an agent. We speak of *fault avoidance* as the col-

lection of all measures that reduce the number of faults. Upon occurrence, a fault creates a **latent error**. A latent error becomes an **effective error** when it is activated in the course of providing a service. Effective errors can be subject to treatment. If left untreated they are observed as failures.

3.2 Dependability model for a layer

A *dependability model* describes the service, the effective errors occurring within the system, which ones are dealt with and how (*error processing*), and what the ensuing failures are. Although we only consider faults endogenous to a multiagent system, from the perspective of the individual agent some may be due to exogenous failures, henceforth called external faults. The other faults are internal. An *internal* fault may be due to a programming fault or faulty parameter settings. *External* faults are either *infrastructure failures*, i.e., failures of the hardware and software the agent depends on to function (basically layers L1 and L2), or *peer failures*, i.e., agents on the same level of service that fail to deliver on a request due to connection loss, their own total failure, or inability to reach the desired objective due to unfavorable conditions (*unfavorable outcome*).

Error processing may at best mask the fault, i.e., the state reached after servicing the request is identical to the *regular state*. Next to best, the state is still the *old state*, i.e., the fault simply causes the request to be ignored. A bit worse, servicing the request may reach a state that while no longer meeting the specification may still allow the service requestor a suitable continuation of its work (*sustainable state*). At worst, the outcome may be a state that is plainly *incorrect* if not outright disastrous.

Our goal is to relate the dependability model to the layered reference architecture. Fig. 2 shows two layers where the lower layer provides a service requested by the upper layer. The figure summarizes which faults may occur, what kind of error processing may take care of them, which ones must be passed up to the next higher layer and which of these can receive special treatment there.

4. LAYERED DEPENDABILITY MODEL

4.1 Compressed model

Fig. 2 demonstrates that error processing cannot always be confined to a single layer. Instead it must often be spread to higher layers where a wider context is available, e.g., a sequence of statements rather than a single one, or a larger database. Consequently, a layered architecture should help to organize and localize the various dependability issues. We use the layered reference architecture of Fig. 1 for organizing the dependability of agents.

The result is shown in Fig. 3. It uses an abstraction of the dependability model of Fig. 2. A layer can be in one of two operation modes. During normal activity the component receives service requests from layers higher up, eventually accomplishes them using the services of the next lower layer components and returns normal responses. It may also draw on the services of other components on the same layer or receive service requests from such components.

If the lower layer fails to service the request, this can be interpreted on the current layer as the occurrence of a fault. The mode changes to abnormal activity where the fault is analyzed and processed along the model of Fig. 2. Propagated errors are signaled as a failure to the next higher layer. Otherwise the layer returns to normal mode and tries to resume normal operation.

Abnormal activity mode may also be entered due to abnormal events on the same layer. One such event is a malfunction within the same component—an internal fault. A typical mechanism for signaling such an event is (in Java terminology) by throwing exceptions. Exceptions can also be used to model a situation where a fault was not activated further down and thus remains unrecognized while crossing a layer in normal mode and moving upwards as a normal service response. Only on a layer higher up the fault is detected as such. Another kind of abnormal event is peer failures. If they are recognized as such they are being dealt with, otherwise they propagate upwards as part of a normal service response only to induce an exception higher up.

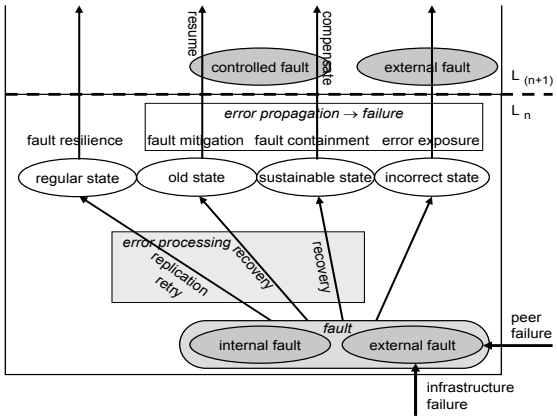

Figure 2: Dependability model: Faults, error processing and responsibilities

For the rest of this section we give a structured overview of the various faults that may occur on each layer, and short summaries of some of the approaches to cope with them (Fig. 3).

4.2 Layered model

All failures occurring on Layer L1 are infrastructure failures. The individual agent is affected by hardware, operating system, and data transmission failures. Operating systems have a built-in dependability so that only a fraction of faults such as excessive waiting or an unsuccessful disk operation are propagated upwards with a detailed description of the cause. Similarly, many of the faults typical for classical data communication are internally resolved by any of the numerous protocols so that only few failures are propagated upwards, such as network delays, connection loss, non-correctable transmission failures, unreachable destination. Some faults may cause a catastrophic failure, though. It cannot be recognized by the affected agent but will only be detected by collaborating agents ("node is down!").

Layer L2 covers specialized infrastructure services that are usually provided by agent frameworks or middleware. Typical interoperability services concern message handling and exchange, trading and naming, or agent mobility. For example, if an uncorrectable data transmission failure occurs on layer L1 resulting in a message loss, layer L2 may observe a time-out before the expected message has been received, and an exception method may invoke a retry by requesting a resend of the original message. A fault internal to layer L2 may be an invalid agent registration which is best be treated by notifying the upper layers of the failure to execute the needed agent service, where most probably the coordination layer (L5) would have to handle it by finding an alternative peer.

Layers L3 and L4 are tailored towards the domain semantics, with L3 dealing foremost with static aspects and layer L4 with the dynamics. Consequently, layer L3 mostly deals with peer failures in connection with ontologies, e.g., a mismatch in the meaning attributed to a certain term, or different coding into and decoding from the transport syntax.

Layer 4 deals with agent behavior and is in the best position to

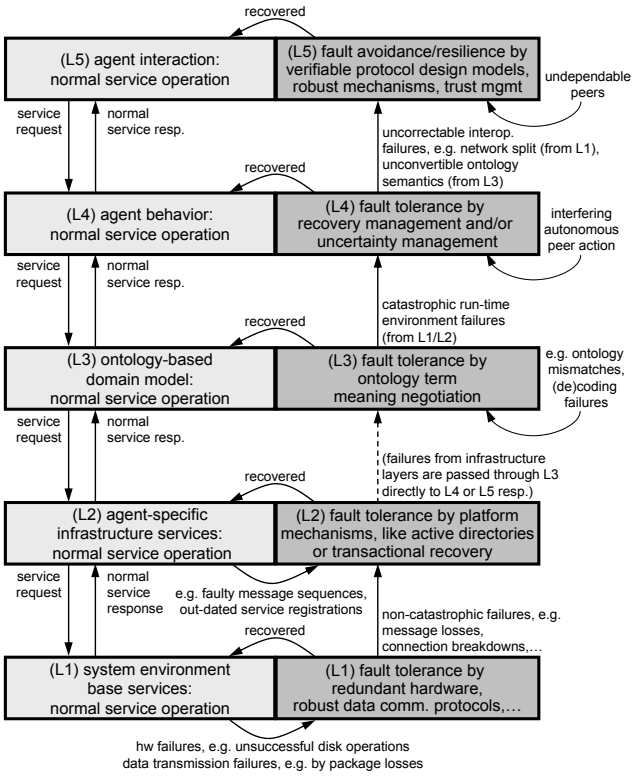

Figure 3: Dependability in the layered agent architecture

process the errors exposed from below. More precisely, L4 should be the layer of choice for all faults whose handling requires knowledge on the domain, the goals and the past interaction history. Consequently, most of the error processing will fall under the heading of fault resilience. This is true even for catastrophic infrastructure failures. Suppose the agent temporarily loses control when its platform goes down, but regains it when the platform is restarted. Recovery from catastrophic failure is usually by backward recovery on the platform layer. The resulting fault containment should now be interpreted in light of the agent's prior activities.

Layer L5 must ensure the dependable performance of the entire multiagent system. We refer to the coordinated interaction of agents as a conversation. Conversations follow a—usually predefined—conversation protocol. At runtime conversations are threatened by failures that are passed upwards from the lower layers. The infrastructure layers may pass up network splits and unreachable peers, the ontology layer semantic disagreements, the agent behavior layer unforeseen behavior of peer agents. Layer L5 may itself discover that peers respond in mutually incompatible ways. Techniques of fault resilience seem essential if the user is not to be burdened. For example, the agents may search for alternative services that are either very similar to the one originally needed, or they may attempt to agree on a new protocol with different peer roles or peers. A careful design should identify which errors should be left to the user and be passed as failures to what one could conceptually see as an additional "user" layer.

5. SPECIAL TECHNIQUES

Our group has extensively experimented with dependability issues in software agents. Below we give a few examples.

An abstraction of behavior that includes recovery is the transaction. The transactional abstraction of a conversation is the distributed transaction. Fault containment by recovery is then implemented via a 2-Phase-Commit (2PC) protocol, with a single coordinator as the initiator and any number of clients [6]. Hence, conversations spawn local transactions in the participating agents, that are coordinated by the initiating agent. (For technical details see [5]). The drawback is that 2PC robs the agents of some of their autonomy. Since 2PC ignores any transaction semantics, transactional conversations are a layer L2 technique.

Autonomy is preserved if only the individual agents are transactional but not the conversation as a whole. Hence, after recovery the agents are uncertain of the state of the conversation, they just carry beliefs. We modeled individual beliefs as fuzzy propositions over a discrete set of values and introduce a gradual consistency degree [3]. An agent can dynamically adapt its consistency degree over time. Fuzzified versions of belief revision operators allow to modify belief sets while observing a consistency prescribed degree. Fault mitigation by belief revision is a compensation technique for layers L3 and L4.

If one associates compensation with an entire conversation and, hence, an entire group of agents, the conversation must be understood to some detail. Consequently, such an approach is located on layers L4 and L5. Nested transactions for the agents fit the bill. They include diversified error processing such as local or global abort, backward recovery and retry, forward recovery and compensation. The synchronization that comes with a conversation is directly built into the nested transactions for the agents [4]. The drawback of this layer L4/L5 approach is the missing separation between agent behavior and conversation.

6. CONCLUSIONS

The paper demonstrates that a layered reference architecture for agents offers a framework for systematically allocating failure occurrences and the ensuing dependability mechanisms. Thus the architecture provides the means to include in the design of multiagent systems dependability right from the beginning. Our own work (funded by Deutsche Forschungsgemeinschaft) seems to suggest that the approach is indeed viable, but also indicates that dependability techniques for agents still raise intricate issues.

Quorum Sensing on Mobile Ad-Hoc Networks

Drexel University
Philadelphia, PA 19104

ABSTRACT

Mobile ad-hoc networks (MANETs) are an increasingly important networking paradigm that will be the backbone of important defense and first response networks. Group decision-making is key to these environments, but is made difficult when MANETs are introduced due to network disruptions, bandwidth limitations, and host mobility patterns. Results gathered using standard group decision-making algorithms can become inaccurate, time-insensitive, or computationally undecidable. This paper focuses on a group decision-making approach using agent-based quorum sensing (ABQS) on MANETs. A mobile agent collects information (e.g., votes) from each host on a network until it can make an informed decision about global preference. This agent exploits the inherent tradeoff between efficient vote collection and result accuracy in order to provide better results, when considering survivability, hosts visited, hops made, and time spent, with only a very slight drop in correctness—benefits that greatly outweigh costs. Experimental evidence from live MANETs demonstrates the effectiveness of this solution.

1. INTRODUCTION

Mobile ad-hoc networks (MANETs) are composed of mobile computers that communicate over a wireless network without the support of an existing, fixed infrastructure. Instead, hosts can join or leave the network as they come in and out of range and each host acts as a router, allowing message traffic meant for another host to pass through it on a multi-hop route to its destination. MANETs present significant difficulties due to their high degree of decentralization, unstable physical-layer connectivity and resource constraint limitations. As a result, group decision making is a challenge that must be addressed. Security decisions protect the network from intruders, routing decisions affect the ability to communicate, and bandwidth decisions ensure network efficiency [2].

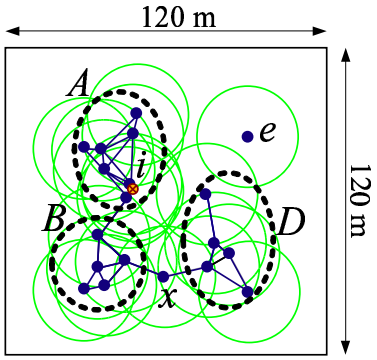

Figure 1: A simulated MANET topology.

An example group decision involving security on a MANET is highlighted in Figure 1 which depicts the *key revocation decision problem* [1]. Host *x* is believed to be compromised and no longer trustworthy so a decision must be made whether or not to revoke Host *x*'s key. This process is costly since it involves the creation and distribution of a new key plus it could possibly eliminate network connections between nodes (see cluster *D*); thus, the group should be certain that the host has really been compromised and that it can continue to operate functionally without Host *x* in the network. The obvious solution of voting is non-trivial due to the difficulties, described above, that MANETs present. Thus, elections can be incredibly inefficient or, at worst, undecidable.

In this paper, we propose an *agent-based quorum sensing* (ABQS) approach for vote collection in a MANET. In quorum sensing, vote collection is executed by a mobile agent or agents that traverses the hosts in the network. This approach promises to be more effective than conventional source/destination or broadcast message passing because the mobile agent is able to reason and adaptively choose its next destination based on certain percepts: connectivity, security, and distance to goal are examples. The agent uses a quorum sensing technique that employs a probability ratio calculation to compute a threshold. After the threshold is exceeded, the mobile agent decides that a reliable enough outcome has been determined. Furthermore, by exploiting the assumption that vote distributions are random, we can precisely calculate confidence intervals for any given threshold. This is important because it can allow principled tradeoffs between efficiency or cost of the vote collection procedure

and accuracy of the outcome decision.

2. AGENT-BASED QUORUM SENSING

There are two key components of an agent for quorum sensing:

1. An **agent migration procedure**, defining how the mobile agent navigates its environment to collect input (e.g., votes) from different hosts. In such a case, the environment is a MANET, hence agents need to sense and react to stimuli from the lower layers of the network stack (specifically the PHY, MAC and Link layers in the OSI Reference Model).
2. A **quorum evaluation procedure**, defining a statistical test to determine if the decision procedure can be terminated with high confidence of correct prediction of the outcome.

Agent Migration Procedure. Agent migration poses a unique problem on a MANETs. Most mobile agent approaches assume that communications are perfect or, at a minimum, reliable. In a MANET, migration of an agent from host *a* to host *b* may require traversal of multiple network hops that consume network resources (i.e., power, bandwidth, etc)—if it is even possible in the first place. Reliability is decreased as a consequence. Thus, this approach aims at reducing hop-count in order to increase reliability while trying to maintain a certain level of accuracy. Consider a network consisting of a set of hosts $H = \{h_1, h_2, \ldots h_{|H|}\}$. Without loss of generality, assume the quorum sensing agent starts off with a workflow that traverses these hosts in order (i.e., $h_1, h_2, \ldots h_{|H|}$). A greedy heuristic can be defined with a simple inductive argument. For the base case, assume agent a is at host h_1:

- Let $\bar{H}$ be the hosts traversed so far, hence $\bar{H} = \emptyset$ and agent a needs to visit the hosts in the set H/h_1; *succ*$(h_1) = H/h_1$.
- Let *hop-count*(h_1, h_i) be the number of network hops from host h_1 to host h_i. This measure can be sensed using sensors that can access the state information maintained by the network routing protocol in the MANET (i.e., OLSR or AODV).
- Select the next host h_i such that $\forall h_j \in H/\{h_1, h_i\}$, *hop-count*$(h_1, h_i) \leq$ *hop-count*(h_1, h_j); $\bar{H} = \bar{H} \cup \{h_i\}$.
- Migrate to h_i.

For the inductive case, assume agent a is at a host h_k:

- If the *quorum threshold* has been reached, terminate migration and return to the originating host with the result; else
  - *succ*$(h_k) = H/\bar{H}$;
  - Select the host h_i such that $\forall h_j \in H/\{h_k, h_i\}$, *hop-count*$(h_k, h_i) \leq$ *hop-count*(h_k, h_j); $\bar{H} = \bar{H} \cup \{h_i\}$.
  - Migrate to h_i.

Quorum Evaluation Procedure. In ABQS, we deploy a mobile agent to sequentially collect votes—not unlike Wald's classic sequential probability ratio test [7]. The ABQS vote collection agent contains a quorum sensor based on those found in social insects, specifically the *Leptothorax albipennis* family of ants. These ants estimate the quality of new nesting sites by observing a *quorum number*, a rough calculation of the number and suitability of nest mates [5]. Whenever this *quorum number* goes outside of an ants indecision threshold, the nesting site can be decided upon.

Our goal is to determine a threshold which results in a statistically reliable performance for the quorum sensing agent in a vote estimation task. We assume that the samples are independent. If this is not the case, we force the agent to collect votes in a random manner thereby removing the dependency. The probability density function (PDF) f is then computed for the fair binomial distribution for the corresponding number of tests as each vote is collected:

$$f(x = k) = \binom{n}{k} p^k (1-p)^{n-k}$$

Let n be the number of votes collected, k be the number of positive votes and $p = 0.5$. The value of the function f is the probability that a sample with exactly k positive votes was generated by a binomial distribution with mean of 0.5. The narrowest confidence interval C determined around the mean of 0.5 such that the combined probabilities of all its members $F(C)$ are at least 90%:

$$F(C) = \sum_{k \in C} f(x = k) \geq 0.9$$

Note that the 0.9 can be changed in order to take advantage of the tradeoff between accuracy and time mentioned earlier. Elections are too close to call and the process of collecting samples continues when the collected sample belongs to the interval C. If, however, the collected sample is outside of the interval C, then this would indicate a strong bias toward one of the two options and the election can be decided with certainty $\frac{1+F(C)}{2}$. More confidence in the predicted result can be achieved by broadening the interval C.

3. EMPIRICAL VALIDATION

We analyze the performance of ABQS briefly in simulation and focus on embodied experiments. Votes can be collected in two ways: sequential and parallel. Sequential vote collection sends out a single agent which tours the network and collects votes. ABQS has an obvious implementation in such a case because the agent determines when the election is decidable. Parallel vote collection sends one agent to each host and returns with the result. The Host collecting the votes implements ABQS as votes are received and stops collecting ballots once the threshold is surpassed.

Simulated Experiments. A MANET simulator [6] is employed to test these hypotheses for large numbers of hosts under a variety of networking scenarios. The simulator enables the creation and mobility of agents which can perform various tasks—voting, in this case. The transmission time for each agent over each link is inversely proportional to the square of the physical distance between the hosts if they are in radio range of each other. Links are random and continuously changing. Agents cannot travel between hosts that have not established direct radio contact.

The network simulator was initialized with 30 mobile hosts. Each host was given a random vote with $[60 : 40]$ bias towards the "yes" decision. Agents were given 500 iterations of the simulator to collect the votes and report their decision. The experiment was repeated 500 times during a single run of the simulator. We also performed 10 independent runs of the simulator to reduce the dependency on the random number generator used in the experiments. As a result, 5000 data points were collected for each agent. Out of these experiments, agent $\mathcal{A}$, a sequential collecting ABQS agent, was able to produce a result 83% of the times while agent $\mathcal{T}$, a sequential collecting agent which requires all votes, produced the result only in 77% of all cases. Considering only the experiments where election results were obtained or estimated, we computed measures for correctness and performance improvement. Table 1 gives the comparison of both agents based on their average performances. Agent $\mathcal{A}$ is 6% more survivable and about 19% more efficient (in terms of visited hosts, network hops and time spent) than traditional agent $\mathcal{T}$ with only 0.5% sacrifices in correctness.

Embodied Experiments. We present experiments using Drexel University's live MANET testbed[4, 3]. It consists of dozens of mobile computing hosts—PDAs and tablets—on an 802.11b wireless network with ad-hoc routing. In particular, five (5) Compaq TC-1000 tablet PCs were configured with the OLSR MANET routing protocol operating over CISCO Aironet 802.11b network cards. These hosts were placed in an actual outdoor urban environment.

Agent	No ABQS	ABQS
Correctness (%)	100.0	99.5
Survivability (%)	77.0	83.0
Hosts Visited (%)	100.0	81.1
Hops Made (hops)	131.1	107.5
Time Spent (sec)	407.6	335.3

Table 1: Performance comparison for simulated experiments.

Method	Sequential		Parallel	
	No ABQS	ABQS	No ABQS	ABQS
Correctness (%)	100.0	100.0	100.0	100.0
Survivability (%)	90.0	**100.0**	93.0	**100.0**
Hops Made (hops)	29.4	**12.6**	61.2	22.5
Hops Made *(st.dev.)*	*3.7*	*4.4*	*5.7*	*11.7*
Time Spent (sec)	14.4	7.6	5.9	**3.5**
Time Spent *(st.dev.)*	10.3	7.5	5.7	1.6

Table 2: Performance comparison for embodied experiments.

Note that this is an uncontrolled environment that includes multi-path interference, other networks as well as disruptions from foliage, automobiles and physical structures.

Hosts 1 through 3 are static, positioned linearly and approximately 40 meters apart. Hosts 4 and 5 are mobile and randomly change position. Each physical device runs five virtual hosts. A slight modification to the routing protocol makes hosts on the same physical device appear two hops away. This forces agents to treat virtual hosts just like they would physical hosts—simulating a larger network with fewer physical nodes. Host 4 begins all election procedures and we compare sequential and parallel vote collection with and without ABQS.

The votes of individual group members were pre-determined and randomly distributed prior to the vote collection in such a way that there was an exact 74% bias in each election towards a "yes" vote. Rogue hosts are uncommon in practice so a 74% bias conservatively approximates real-life situations. The threshold for ABQS was set to 95% accuracy in all of the performed experiments. All agents are compared on completion time, bandwidth utilization, whether or not it completed, and accuracy. The experiments were repeated 30 times. Average values and standard deviations of measured parameters are presented in Table 2.

In each of the experiments, all of the elections were tabulated correctly. The size of our network (25 hosts) and the number of experiments did not appear to be large enough to allow any mistakes in ABQS to manifest themselves. Both parallel and sequential vote collectors utilizing ABQS were always able to call the elections before the deadline. Vote collection without ABQS had a failure rate of 10% and 7% for sequential and parallel vote collection.

As expected, a sequential process of vote collection results in less network traffic and longer times than a parallel process. However, applying ABQS allows 57% less traffic for sequential vote collection. We recognize that the number of hops traversed prior to the making a decision for parallel ABQS does not represent accurately the savings in the bandwidth usage, since reaching a decision does not automatically remove all the vote collection agents that are still in transit. Although time costs have much higher standard deviations, we still saw a speed up of 47% for sequential and by 40% for parallel—levels that are statistically significant.

The numbers from comparison Table 2 and the histograms in Figure 2 show that both sequential and parallel methods of vote collection can gain in reliability as well as significantly increase their performance by utilizing the ABQS technique.

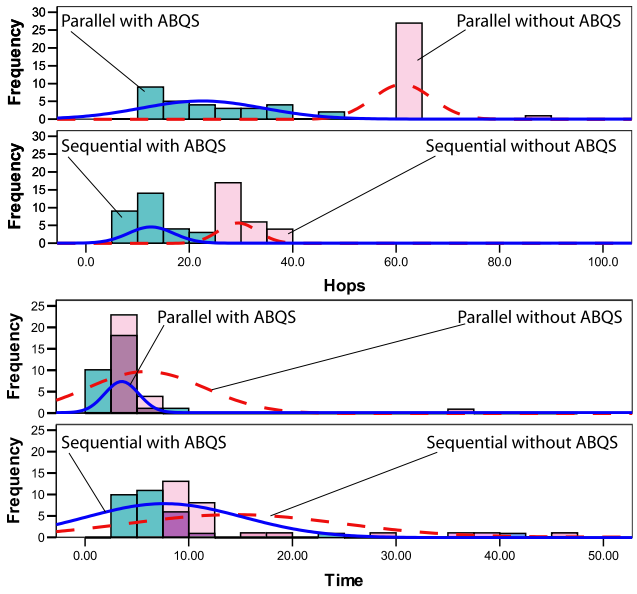

Figure 2: Histogram comparison of the number of hops and the time elapsed for all vote collection types.

4. CONCLUSIONS AND FUTURE WORK

This paper introduced a technique for *agent based quorum sensing* and provided a viable solution to distributed decision-making on a MANET. Greater efficiency was obtained in terms of significant time and bandwidth improvements at the cost of only a slight drop in decision accuracy. These results are not limited to a binary plurality vote. Preliminary results show that these techniques can be applied to other methods of vote collection: Borda count, approval vote, and plurality with multiple outcomes. The authors hope to explore that matter further, along with analyzing the exact role that vote collection order plays in efficiency.

ABSTRACT

Nowadays, most multiagent platforms are internally designed as middleware and are usually implemented in Java and run on top of an operating system. This kind of design maximizes portability and reduces the development cost; however, it may lead to low performance and scalability. In this context, our research has the long-term goal of integrating into the operating system some key services which are currently supported by middleware platforms. The first step in achieving this goal is to study some well-known, open-source platforms in order to understand to what extent the internal design of a platform influences its performance.

performance evaluation of agent systems, agent and multiagent architectures

1. INTRODUCTION

The area of Multiagent systems has produced both methodologies and actual frameworks to make the implementation of agent-based systems possible. The support software of such frameworks are often known as multiagent *platforms*. In essence, these platforms provide both a model for developing multiagent systems and an environment for running distributed agent-based applications. Among all the existent platforms, only those whose source code was available were feasible for us, since part of the study required the inspection of specific parts of the code. Three of these platforms were selected: JADE[3], MadKit[4] and AgentScape[1]. They are representative of different design principles and different programming models (from FIPA[2] compliance to multi-language support).

2. EXPERIMENT DESIGN

Services tested in this paper were either common to the three platforms or offered the same function. Moreover, these services are defined by the FIPA standard. The messaging service is the most important service due to the fact that multiagent systems are based on the communication between the agents. The service directory service is also important because an agent platform requires services offered by agents be accessible to other agents.

2.1 Messaging Service

We measured the RTT (round-trip time) of each sent message between a sender agent and a receiver agent, i.e. the time elapsed between when the message is sent to the receiver and when it comes back to the sender. The number of couples was increased in order to observe the platforms scalability. For each agent couple, we calculated an average RTT from a collection of 1000 sent messages. The result of the experiment was the average of the RTT averages from all the couples in the experiment. The experiments were also repeated changing the kernel (container in JADE terminology) and the host where the agents are placed.

The effect of message size on messaging service performance was also tested. For this purpose, we performed an experiment modifying the message size (from 1 byte up to 100000 bytes). The number of agent couples were fixed to 50 and 100.

Finally, in order to observe the platform behaviour when a massive message sending occurs, we designed a test in which many agents tried to communicate with an unique receiver. The number of sender agents was increased from 1 to 250.

2.2 Service Directory Service

We tested the service directory service response with two kinds of experiments. First, registration and deregistration time were measured by increasing the number of agent services already registered. The structures of the platforms were changed from one host to two hosts in order to determinate the influence of agent location. We also estimated the

platform response when a service search was requested. As explained above, the number of agent services already registered was increased. The agent location was also changed. We allocated the searcher and registered agents in both the same or different hosts.

3. EXPERIMENT RESULTS

In order to perform the experiments, we used two PC's Intel Pentium 4 @1.5 GHz, 256 MB of RAM memory and Sun JDK 1.5 version.

3.1 Messaging Service

Figure 1 shows the behaviours of the three platforms when the sender and receiver are placed in the same kernel located in one host. AgentScape offers the poorest RTT values. These results may be due to the fact that there is yet no mechanism to make a message blocking reception in this platform. AgentScape proposes a polling mechanism for message reception. According to this, the platform suspends the agent between each iteration. JADE and MadKit have a similar response in low load. In contrast, when load increases, JADE RTT grows with respect to MadKit. This may be due to the fact that MadKit uses a direct copy-write mechanism, while JADE uses a more complex process which is also utilized in distributed communication.

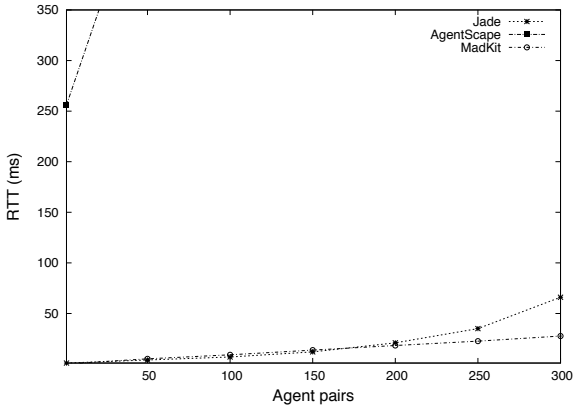

Figure 1: Message Sending, 1 host, 1 Kernel

When the agents are located in different kernels (Figure 2), JADE presents shorter RTT delays in the message sending process than the other two platforms. This is due to how containers are implemented and the fact that they communicate among them using Java-RMI. Madkit distributed messaging introduces an overload due to the set of *Communicator Agents* that are responsible for communicating different kernels through sockets. As a result, several local messages are needed to carry out a distributed communication. AgentScape uses XML-RPC technology to communicate different kernels and requires a thread for each kernel.

We can see the message size experiment in Figure 3, in this case AgentScape indicates the worst RTT values, being less adaptive to size changes than JADE and MadKit. Besides, JADE presents the best response to a multiple sending. It manages the message queues more efficiently than the others when a lot of messages are received. In contrast, AgentScape and Madkit are more influenced by this massive reception.

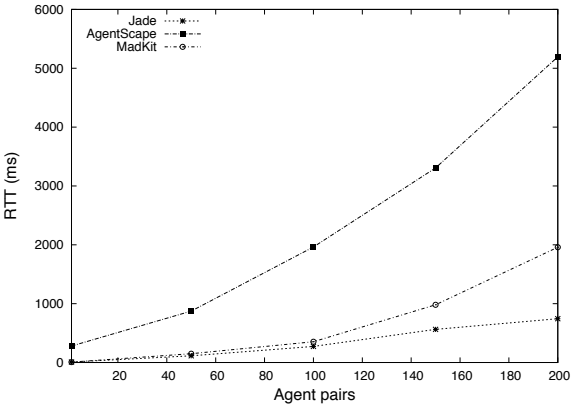

Figure 2: Message Sending, 2 hosts

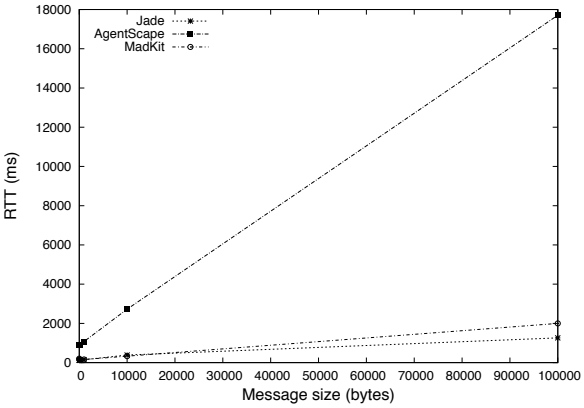

Figure 3: Message Sending 50 pairs

JADE is more scalable than the other platforms. Due to the lack of space, figures showing results for multiple sending are not included.

3.2 Service Directory Service

Figure 4 depict the registration time in 1 host. In these experiments, the differences are reduced. The number of services already registered does not have any influence on a new agent service register time. The MadKit registering service is the fastest one because it is distributed and duplicated among all the kernels. When an agent wants to register a service, it is done automatically by the local kernel. Afterwards, if there is more than one kernel, information replication is needed in the other kernels. AgentScape and JADE do not have this service distributed. In AgentScape, when an agent wants to register a new service, it must contact the *lookupService* of the platform. This platform has a better register time when the agents are in a host that is different from the lookupService. This is due to the fact that lookupService can be placed in a host without any other components of the platform. Hence, there is less overload in this host. JADE offers worse times than MadKit because agents that want to register their services must establish a communication act with the DF agent. This fact increases the time due to ACL message exchanges.

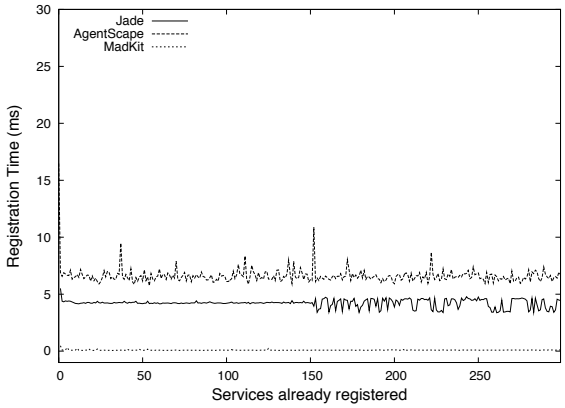

Figure 4: Registration in 1 host

As shown in Figure 5, AgentScape presents a linear increase in search time. This may be due to the fact that a method has not yet been developed in the lifecycle of the AgentScape platform to suspend the agent execution. For this reason, there are more active threads, so the platform load is higher. In contrast, MadKit and Jade offer a constant behaviour. Since JADE implements service directory service processes using communication acts with the DF agent, its result times are not as good as those in MadKit. This is a result of how MadKit implements this service. While JADE implements it as an agent (DF agent), MadKit integrates it in the platform software. In other words, this service is centralized in JADE, whereas it is distributed among the platform kernels in MadKit. Due to the lack of space, the figures of the other search experiments have been not shown, but the conclusion is similar.

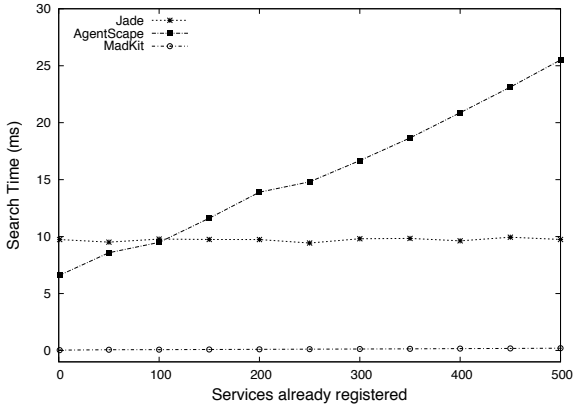

Figure 5: Search in different hosts

4. CONCLUSIONS

The main focus of the experiments was to try to link performance with internal design, that is, to identify the key design decisions that lead to better performance. In addition to the quantitative results about performance presented in the paper, two general conclusions can be drawn.

First, some platforms implement basic services (such as messaging) by means of agents, while others implement these services in their kernels. Offering services by means of agents may increase the platform modularity; however, it also degrades performance. Every time an agent needs the service, it has to communicate with the agent offering the service through an ACL act. This increases both the platform load and the service's response time. This conclusion is clearly proved in the two experiments shown in the paper. JADE implements the messaging service directly in the kernel, whereas MadKit requires an *AgentCommunicator* when agents in different hosts want to communicate. The difference in performance in this case is shown, for example, in Figure 2, in which JADE clearly outperforms MadKit. The service directory service in JADE is provided by means of an agent (the DF), while MadKit offers it directly. Again, Figure 4 shows how the platform that provides a service by means of an agent (like JADE) has a penalty in performance.

Second, centralizing services in a single host in the platform also degrades performance since this host can become a bottleneck in the case of very popular services. The experiments presented in the paper also support this conclusion. For example, Figure 5 shows that the performance for the service directory service in both JADE and AgentScape is much worse than in MadKit since, in these cases, the service is centralized. Therefore, distributing the services among the various hosts in the platform may benefit the response time of these services, however, the coordination among the hosts is an issue to be taken into account.

ABSTRACT

A multi-agent system can be analyzed and specified as an organization consisting of roles and their relations. The performance of an organization depends on many factors among which the topology of its organizational structure, i.e., the set of relations holding between its roles. This short paper provides the sketch of quantitative methods for addressing the issue of the analysis, evaluation, and comparison of organizational structures. To this aim, quantitative concepts from graph theory are applied which deliver numerical analyzes of organizational structures. Here, an illustrative number of these concepts is sketched and their connection to properties that are commonly indicated as critical for organizations (robustness, flexibility and efficiency) is shown.

1. INTRODUCTION

The notion of organization plays an important role in multi-agent systems, which is also reflected in many agent-oriented software methodologies (cf. GAIA, TROPOS). The performance of different organizations depends on organizations' characteristics such as robustness, flexibility, and efficiency. For example, hierarchies are known not to perform well in rapidly changing environments because of their poor flexibility. The paper is based on the intuition that a connection can be drawn between some of these characteristics and graph-theoretical properties of the structure of organizations. For example, flexibility depends on how strongly the roles in the organization are connected with one another. We claim that an investigation of this connection is important for the development of appropriate methods for comparing and evaluating different types of organizations and their performances.

We believe that, in order to tackle the evaluation problem, "the space of organizational options must be mapped, and their relative benefits and costs understood" [5], and to provide such a "map" a rigorous analysis of organizational structure plays a crucial role. The perspective chosen consists thus in addressing the evaluation issue from a structural perspective, that is to say, analyzing the organizational structure of MAS and providing a way to rigorously describe the pros and cons of them which lie in their structures.

More concretely, it is known for instance that *flexibility* is an advantage of network types of organizations and a disadvantage of hierarchical ones in rapidly changing environments. The notion of flexibility, though complex and multi-faceted, can be definitely given an interpretation on the basis of merely structural aspects. Intuitively, the more abundant are the connections between the roles in the organization, the more flexible is the organization. The point is to relate the notion of flexibility to precise properties of the organizational structure. Given an organization, can it be said to be flexible? And to what degree? Is it more flexible than another one as far as structure is concerned? How can a designer foster flexibility in a MAS just working on its structure? These types of questions constitute, in a nutshell, the target of the present work.

2. ORGANIZATIONAL STRUCTURE

In [3] a view on organizational structure has been proposed, inspired by foundational work on the theory of organizations (see for instance [7]), which is based on the claim that organizations do not exhibit only one structural dimension, but rather a multiplicity of interrelated dimensions, the dimensions of *power*, *coordination* and *control*.

According to this view, an organizational structure consists actually of (at least) three different structures. A natural way of modeling this notion of organizational structure is via directed graphs, which we represent here as systems of relations.

DEFINITION 1. **(Organizational structure)**
An organizational structure OS is a tuple:

$$\langle Roles, R_{Pow}, R_{Coord}, R_{Contr} \rangle$$

where $Roles$ is the finite set of roles, and $R_{Pow}, R_{Coord}, R_{Contr}$ are three irreflexive binary relations on $Roles$ characterizing the Power, respectively, the Coordination and the Control structures.

For every R_k s.t. $k \in \{Pow, Coord, Contr\}$, we denote with $Roles_k$ the subset of $Roles$ such that, if $(x, y) \in R_k$ then $x, y \in$

$Roles_k$. In other words, sets $Roles_k$ denote the set of roles involved in the structural dimension k. Each digraph $\langle Roles_k, R_k\rangle$ in OS will be also referred to as the *structural dimension* k of OS.

Besides the representation of organizational structure as systems of three different relations, the aforementioned [3] proposes also a formal analysis of the effects that each of these relations has on the activities of the agents playing roles in the organization. Briefly, the *power structure* defines the task delegation patterns possible within the organization. The *coordination structure* concerns the flow of knowledge within the organization, and the *control structure* has finally to do with the task recovery functions of the organization. In other words, the existence of a power link between role a and role b implies that every delegation of tasks from agent a (agent enacting role a) to agent b (agent enacting role b) ends up in the creation of an obligation directed to agent b. If a and b are connected via a coordination link, then every information act from a to b ends up in creating the corresponding knowledge in agent b. Finally, a control link between a and b implies that agent a has to monitor the activities of agent b, possibly taking over the tasks of agent b which have not been accomplished.

3. MEASURING STRUCTURE

This section presents three examples of equations measuring specific graph-theoretical aspects of organizational structures: connectedness, economy and univocity.

Connectedness of an OS concerns how strongly roles are linked with one another within one of the structural dimensions k, or in other words, how much is the given structure split in fragments.

$$\text{Connect}_k(OS) \;=\; 1 - \frac{|\text{DISCON}_k|}{|Roles_k| * (|Roles_k| - 1)} \qquad (1)$$

where $|R_k| > 0$ and DISCON_k is the set of ordered pairs (x, y) of $Roles_k$ s.t. there is neither a R_k-semipath[1] from x to y nor from y to x, i.e., the set of disconnected ordered pairs of the structural dimension $\langle Roles_k, R_k\rangle$. The condition $|R_k| > 0$ states that the structural dimension k does indeed exist. If the structure does not exist it cannot be measured. In practice, formula 1 measures how much that dimension is 'not disconnected'. With respect to connectedness, an important notion is that of cutpoint or, in an organizational reading, *liason role* [4], i.e., a role whose removal decreases the connectedness of the structure.

The *economy* of a given OS expresses a kind of balance between keeping the structure connected and of minimizing the number of links:

$$\text{Economy}_k(OS) = 1 - \frac{|R_k| - (|Roles_k| - 1)}{|Roles_k| * (|Roles_k| - 1) - (|Roles_k| - 1)} \qquad (2)$$

where $|R_k| > 0$. The equation is based on the intuition according to which the most 'economical' digraph of n points consists of $n-1$ links, i.e., the minimum number of links which is still sufficient to keep the digraph connected. Indeed, the nominator of the fraction, consists of the number of links in the structural dimension k which are in excess or in defect w.r.t. the optimum of $n - 1$ links. The denominator denotes instead the absolute number of links in excess in k. If $|R_k| = n - 1$ then the value of $\text{Economy}_k(OS)$ is optimal, i.e., equal to 1. The equation measures, therefore, how much k is 'not expensive' in terms of links, given that "links are not without cost in a social systems" [6]. Notice that $\text{Economy}_k(OS) = 1$ does not imply $\text{Connect}_k(OS) = 1$, it does only imply that there are enough links in R_k for it to be possibly connected. If the existence of symmetric links in R_k is assumed, then $n - 1$ links are clearly not enough any more for guaranteeing connectedness. On the other hand, notice also that $\text{Economy}_k(OS)$ can assume a value greater than 1. That indicates a sort of '*over-efficiency*' of k. In this case, it is easy to see that, if $\text{Economy}_k(OS) > 1$ then $\text{Connect}_k(OS) < 1$. In other words, if the economy measure of OS is lower than the optimal value 1, then OS has more links than the ones necessary for OS to be connected. If the economy measure is instead higher than the optimal value 1, than there are in OS too few links for it to be connected.

The property of *univocity* expresses the tendency of an OS to display the absence of redundant links ending up in the same role. In other words, how many of those connections are such that no role has more than one incident link of the same structural dimension.

$$\text{Univocity}_k(OS) \;=\; \frac{|\text{IN}_k|}{|Roles_k|} \qquad (3)$$

where $|R_k| > 0$ and IN_k denotes the set of roles x in $Roles_k$ which either have indegree equal to 1 in k or which are a source[2] of k or of some subgraphs of k. Intuitively, equation 3 measures how much a dimension k is univocal or "non ambiguous". The most univocal structures are assumed to be either the ones in which every point, except the source, has one and only one incident link (like in trees), or the ones in which exactly all points have only one incident link (like in cycles). Univocity has to do with the level of conflict and redundancies of a given structure.

4. LINKING STRUCTURAL MEASURES TO ORGANIZATIONAL PROPERTIES

In this section we show how graph-theoretical properties of organizationals structures can be used as a ground for establishing to what extent an organization exhibits key properties such as robustness, flexibility and efficiency.

Robustness. "Robustness is simply a measure of how stable the yield is in the face of anticipated risks. [...] *Adding robustness thus adds complexity*" [9].

A key "system characteristic" which should be preserved by any organization is the continuity of the task delegation chain. Failure of an agent enacting a role in this structure halts the delegation process only if the role it enacts is a *liason role*, i.e. a role the removal of which would result in a disconnected structure. So, the more alternative paths exist in the power graph the more robust is the organization: in a nutshell, low value for Univocity_{Pow}[3]. Moreover, the coordination structure determines how well information can disseminate over the organization. For robustness it is important that information about failures can spread to the roles that can take responsible action. Also this structure can serve as a back up for a failure of the power structure. So, one can easily claim that the more connected (Connect_{Coord}) and less economical (Economy_{Coord}) the coordination structure is, the more robust the organization is.

To sum up, relevant structural measures for robustness are:

Economy_{Contr}	0	Univocity_{Pow}	0	Connect_{Coord}	1

The 1 and 0 symbol indicate the value which is considered to maximize robustness with respect to that measure. For instance, the

[1] A R_k-semipath (of length n) is a sequence $\langle x_1, ..., x_{n+1}\rangle$ of distinct elements of $Roles$ s.t. $\forall x_i\ 1 \leq i \leq n$, $(x_i, x_{i+1}) \in R_k$ or $(x_{i+1}, x_i) \in R_k$.

[2] A *source* in $Roles$ is an element s s.t. $\forall d \in Roles$ with $d \neq s$ there exists a R_k-path from s to d.

[3] See also [2] for similar investigations on this issue.

maximum enhancement of robustness obtainable via modification of the connectedness measure is yielded by value 1.

Flexibility. "Flexible organizations are a looser co-operative association than classic hierarchical organizations. [...] Flexible organizations are continually in flux and are able to adapt in a flexible way to changing circumstances" [8].

As suggested by the above quote, an articulated power structure hinders flexibility constraining the distribution of tasks to predisposed patterns. In contrast, network organizations and teams, where no power structure exists, are commonly indicated as the paradigmatic example of flexible organizations. This suggests, for enhancing flexibility at the structural level, a low degrees of Connect_{Pow}. In absence of a power structure a coordination structure becomes essential because the knowledge concerning which agent might be capable to handle the new task needs to flow within the whole organization. The more roles are connected in this structure the more likely the right agent can be found to perform a new task. Connectedness together with a low level of economy (Connect_{Coord} and Economy_{Coord}) are thus directly linked also to the enhancement of the flexibility of an organization.

To recapitulate, these are the relevant measures for flexibility:

Connect_{Pow}	0	Connect_{Coord}	1	Economy_{Coord}	0

Again, 1 and 0 indicate the measures' values which are considered to maximize flexibility.

Efficiency. According to [1], efficiency mostly refers to the amount of resources used by the organization to perform its tasks. All links in the different organizational structures incur a certain cost to be maintained. So, the less links there are, the more efficient is the organization. Notice, on the other hand, that the maximum efficiency would require a power structure with one unique source from which the delegation of subtasks propagates. So, a fragmented power structure is intuitively *over-efficient* since links would miss through which the delegation activity can take place. Because of this a hierarchical, tree-like, power structure covering all the roles seems to be the most efficient. In fact, the existence of a power structure means efficient distribution of tasks, and a tree is the most efficient structure to cover all roles. Such a structure exhibits value 1 for Economy_{Pow}. As to coordination and control, the economy measure (Economy_{Coord} and Economy_{Contr}) should also be required to be optimal in order to minimize the amount of links. These are thus the measures we consider to be related to efficiency:

Economy_{Pow}	1	Economy_{Contr}	1	Economy_{Coord}	1

Again, 1 and 0 indicate the measures' values which are considered to maximize efficiency.

Needless to say, more different types of measures, which we can not expose here for space reasons, would provide a deeper analysis of the structural properties we touched upon.

5. TUNING STRUCTURAL MEASURES TO ORGANIZATIONAL PROPERTIES

At this stage the obvious question is whether organizations can be designed which maximize the adherence to all three properties at the same time. From a structural point of view and as intuition suggests, it is easy to show that this is not possible. Consider, for instance, the coordination structure. In fact, efficiency increases when Economy_{Coord} approximates 1. Maximum robustness and flexibility both require Economy_{Coord} equal to 0, while maximum efficiency requires Economy_{Coord} equal to 1:

	Robust	Flexible	Efficient
$\text{Economy}_{Coord}(OS)$	0	0	1

Intuitively, both robustness and flexibility increase the number of structural links and thus the costs of the organizational overhead, while efficiency reduces these overhead costs. Similar problems exist, for instance, for the power structure. The robustness criterion requires as many redundancies as possible, and therefore low levels of univocity, while flexibility demands the structure to be as small as possible and therefore with very low degrees of completeness. A number of similar incompatibilities can be detected and mathematically investigated.

Since it is not possible to maximize the adherence to all properties at the same time, the point becomes then to find suitable compromise solutions. An extensive analysis of the interdependencies between the various structural measures could provide useful insights on this type of issues.

6. CONCLUSIONS

The work addressed the issue of the influence of organizational structures on the performance of organizations, aiming at providing a rigorous method for analyzing, comparing and evaluating different types of structures. We proceeded as follows. First, making use of graph theory, we provided a number of meaningful measures for quantifying the adherence of organizational structures to specific structural features. Second, these measures have been used to ground a numerical analysis of the key organizational properties of robustness, efficiency and flexibility. Third, it has been shown that such an analysis pose the ground for an exact investigation of the extent to which those properties can conflict with each other, providing interesting information for a more aware design of organizational structures.

ABSTRACT

Many coordination algorithms claim to be *general*, implying that they can be used to coordinate agents in a variety of domains. However, little work has been done to quantitatively compare distinctly different approaches to coordination across a range of domains. In this paper, we present a detailed comparison of two published coordination algorithms, performed in an abstract coordination simulation environment that allows extensive, quantitative experimentation. The simulator is to used to compare two distinct approaches to coordination, token-based coordination and market based coordination. The results largely show the generality of different approaches, but performance and performance tradeoffs varies greatly across domains.

1. INTRODUCTION

Autonomous coordination is a complex process because several distributed algorithms are required to interact to produce agile, cohesive and efficient coordinated behavior. Because of the importance of autonomous coordination, many approaches have been developed, including approaches based on markets [1], tokens [5], etc. Typically, each of these approaches is designed to work in a specific domain, but the authors, usually with good reason, claim they will work in a wide range of domains. However, such claims are rarely quantitatively verified and, more importantly, competing approaches are rarely systematically compared. Thus, when a developer needs to select an approach to use in a particular domain, they are confronted with many claims but little concrete data with which to make a decision.

In this paper, we present an initial attempt at systematically and scientifically comparing distinct approaches to coordination. To make such a comparison feasible, we have developed an abstract simulation environment that is sufficient to capture a variety of real world concerns, but sufficiently abstract to be highly configurable and very fast. We used the coordination simulator to investigate the relative strengths of three distinct approaches to coordination: auction-based coordination [2]; token-based coordination [5]; and a hybrid of the two.

Based on an analysis of previous literature [1, 5], several hypotheses can be formed about the relative performance of the algorithms. Auctions are focused on maximizing overall utility taking into account the *bids* of all team members [1]. Token-algorithms are focused on scalability, hence they minimize communication, sometimes at the expense of overall utility. Thus, the clearest hypothesis is that auctions will communicate more than token algorithms, but result in better allocations of tasks and resources. More subtly, the performance advantage of an auction should be most pronounced when small changes in allocations lead to big differences in performance, i.e., typically highly constrained cases, while the token algorithms should maximize their communication advantage when the probabilistic models they rely on are most advantageous, i.e., weakly constrained cases. The empirical results support these hypotheses. Initial experiments suggested that auctions find superior allocations because they compare many options, while tokens use little communication by quickly focusing on the agents most likely able to perform tasks or having most use for resources. A hybrid algorithm that uses tokens to solicit auction bids from those agents most likely to submit winning bids then uses an auction to select from between the small number of bids should perform well. However, this hybrid algorithm should only perform well under restricted circumstances. We implemented the hybrid algorithm and compared its performance to the other algorithms.

2. COORDINATION ALGORITHMS

In this paper, we only consider the coordination tasks that can be performed by both tokens and auctions and is limited to task and resource allocation. The coordination problem in this paper is defined as: Agents, $A = \{a_1, \ldots, a_k\}$, are cooperating on a joint goal G. G is broken into discrete subtasks $\alpha_1, \ldots, \alpha_n$. Each subtask α_i when is applicable, must be performed by a single agent a to receive reward. The amount of rewards is defined as $Reward(Cap(a, \alpha), Holds(a)) \rightarrow \mathcal{R}$ where it depends on the capacity ($Cap(a, \alpha)$) that agent a can perform α and the exclusive resources that are available for a to perform α, i.e., a bucket of water is required for distinguishing a fire. The function $Assigned(a, \alpha) = 1$ if agent a is assigned to task α, otherwise it is equal to 0. Only one agent may be assigned a task at any time, i.e., $\sum_{a \in A} Assigned(a, \alpha) \leq 1$. The coordination is to maximize the reward to the team, while minimizing the *costs of coordination*. The overall reward is:

$$\sum_{i=0}^{n} \sum_{a \in A} Assigned(a, \alpha_i) Reward(cap(a, \alpha_i), Holds(a))$$

We are specifically concerned with only the volume of Messages as costs of coordination. It is the number of times agents communicated, either between themselves or with the auctioneer.

The first of the algorithms we used for comparison is market-based approach. Our implementation of this approach was based on TraderBots [2] with adaptations where are necessary to make a comparison possible. In our market-based approach, one agent acts as auctioneer and both tasks and resources are treated as merchandise. Agents bid for either single items or combinatorial sets of items in order to maximize their own utilities. The auctioneer maximizes its utility by "selling" their "merchandise". In this approach, Sandholm's winner determination algorithm [3] is used to determine the allocation for tasks and resources by the auctioneer. Because of the centralized position of the auctioneer, it develops a complete knowledge of how agents will use a task or resource if allocated. Thus, the auctioneer can perform assignments that maximize the team utility. To be fair to all the bidders, the auction should last for a fixed period of time. Where early determination is infeasible; Agents are allowed to bid for resources after tasks have been allocated. Moreover, to prevent deadlock in resource allocation, agents are only allowed to bid for resources for their *first* pending task.

In Token-based algorithms [5], tokens encapsulate both resources and tasks, allowing actors to locally decide what to do with the token. For example, a *task token* allows an actor to decide whether to perform the task or pass it off for another actor. An intelligent routing algorithm is built in the token-based approach to help agents build local decision theoretic models to determine when and where to pass tokens. By utilizing the relevance between tokens, intelligent routing algorithm is able to efficiently deploy tokens to make higher utility with less communication [5]. In this paper, tasks are allocated by the LA-DCOP token algorithm [4], agent is allow to reject previous accepted task but accept another task that it can get more reward.

The hybrid algorithm works in the following way. The auctioneer algorithm runs exactly as before, except that instead of broadcasting announcements for auctions an *auction token* is created. Each auction token is allowed to exist from the starting of the auction to the end of the auction being closed. The auctioneer has a probabilistic model of the team state, just as all agents do in the token-based approach. The auction token is then intelligently routed to the agents most likely to be able to submit the best bids. The token stops moving after the auction it presents is closing or has visited a fixed number of teammates. Note that although the intelligent routing algorithm should work to route tokens for higher bids, it should not work better than the token-based approach because of incapability of making use of the relevance between tasks and resources which have been encapsulated into auction tokens. The auctioneer determines the winner of the auction and allocates tasks and resources the same as in the basic auction case. We expect that the hybrid approach should keep high rewards as auction-based approach but reduce communication over the basic auction, by targeting only those agents likely to make good bids and reduce computation by limiting the number of bids the auctioneer must deal with.

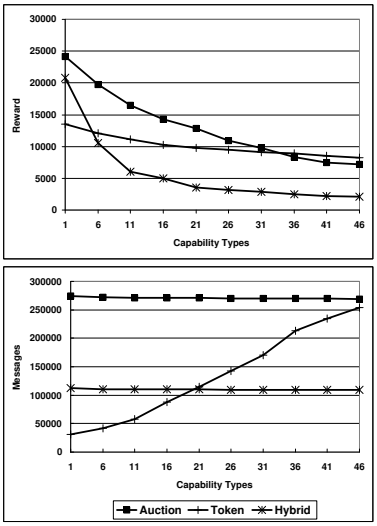

Figure 1: The reward for heterogeneous teams dramatically decrease in auction and hybrid approaches but maintains constant in token-based approach where more messages are required.

3. EXPERIMENTS

We implemented the three approaches in an abstract simulator called CoordSim. If not otherwise stated, the CoordSim are configured as follows. There are 100 agents to perform 50 tasks with 50 resources. Each task requires only one resources which could be interchangeable with four others. In the default setup, there is only one type of capability required and all agents have none-zero value for this capability, i.e., all agents are at least somewhat capable of all tasks. Auctions are held open for 40 time steps and the task tokens, resource tokens are allowed to move unless accepted. The initial threshold on a task token is 100, meaning that the task will not be accepted by an agents until it can get a reward more than 100 by performing this task. Simulation runs for 2000 steps and the results are based on 100 runs.

3.1 Heterogeneous Team

In the first experiment, we examined team performance by varying team composition and the capabilities required to perform tasks. For example, in an emergency response experiment some agents might only be able to fight fires while others could only provide medical treatment. In this experiment, we varied the number of capabilities from 1 to 46 where fewer agents in the team were available to perform particular tasks and in the most heterogeneous condition, only two agents on average are capable to performing a task.

The experimental results in Figure 1 show that for heterogeneous teams, auction and hybrid approaches earn less reward as the team becomes more heterogeneous because there are fewer agents able to compete for the more specialized tasks. The advantages of teamwide maximization of utility by the auctioneer decrease as there are progressively fewer feasible alternative bids. In contrast, reward

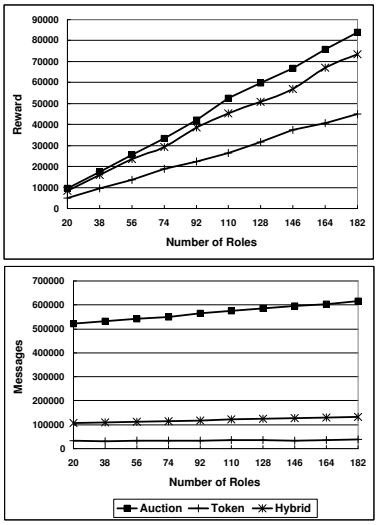

Figure 2: Reward and Messages increase dramatically with the number of tasks.

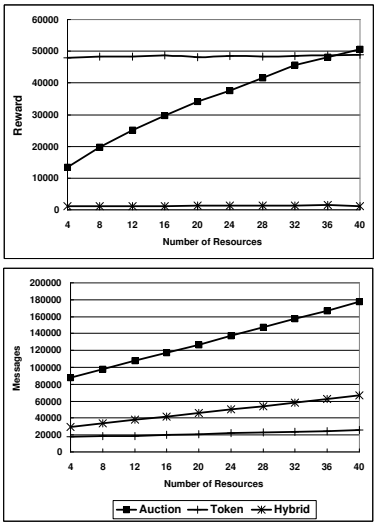

Figure 3: Reward decreases with scarcity in auction approach and is very low in hybrid approach, but with token-based approach is uniformly high

for the token-based approach remain almost flat with increasing specialization. We propose two reasons. One is that token-based approach greedily finds reasonable solution rather than searching for the optimal. As the other reason, by passing a higher number of tokens around the network and making use the relevance between them, intelligent routing algorithm gets better knowledge to route tokens. This is manifested that although the average distance to route a token increases with heterogeneity as reflected in an increase in message, token-based approach maintains the same level of reward.

3.2 Time Critical Tasks

In the second experiment, we investigated team performance when many tasks needed to be performed within a short period of time. To increase their reward, teams were required to perform tasks and allocate resources as rapidly as possible. In this study we varied the number of tasks the teams were required to finish from 20 to 182. After 2000 time steps, the accumulated reward and message count were recorded as shown in Figure 2.

All three approaches performed more tasks in order to get higher reward. As expected, the auction approach attained higher reward than the hybrid or token-based approaches. Considering both reward and messages, however, the hybrid approach performs well by almost matching the reward obtained by the auction at just a quarter of the communication cost. The reason whythe hybrid approach achieves such good performance with so little communication overhead is that the intelligent routing algorithm limits communication to a small number of agents while high bidders must always be informed in auctions.

3.3 Competitive Resources

The third experiment used 200 tasks each requiring an average of four resources with no interchange possibilities. As available resources are increased from 4 to 40, competition for them declines and they become less likely to be a bottleneck.

The experiment was stopped after 1000 time steps. Figure 3 shows that the reward for the auction based approach increased rapidly with increases in resources. Both the token-based and hybrid approaches remained flat with token-based approach earning the highest reward at all levels of scarcity while the hybrid approach yielded very limited reward. We hypothesized that because resource contention in this experiment was high the centralized control of the auction and hybrid approaches would often force agents to either bid for all four resources together or miss the task while the distributed token-based approach weakened this constraint.

ABSTRACT

This paper presents SAgent, a general-purpose mobile agent security framework that is designed to protect the computations of mobile agent applications in potentially hostile environments. SAgent works with the JADE (Java Agent DEvelopment) platform [6], a FIPA-compliant multi-agent environment. SAgent supports modular and mostly orthogonal development of agent protection techniques and secure agent applications, so protocols and applications can be developed independently of each other. To accomplish this, a clean conceptual framework is presented which encapsulates in several general class interfaces the common security functionality required by secure agent applications. Furthermore, implementations are provided for two secure multi-agent protocols, and we give experimental results showing the feasibility of these protections. While a few other research projects have examined protocols and techniques for protecting agents, these have been theoretical explorations. SAgent's goal is to bring these theoretical techniques into practice so that they can be experimented with and used, in the framework of a design generic enough to support both software-based and hardware-based protections. The abstractions are clean, giving a well-de ned way for a new security provider to implement and experiment with new techniques for protecting mobile agents.

1. INTRODUCTION

SAgent is a general-purpose agent security framework for the JADE platform that is designed to protect the computations of mobile agent applications in potentially hostile environments. The JADE (Java Agent DEvelopment) platform [6] is a popular mobile agent platform that enables the development and deployment of multi-agent applications using Java, and conforms to FIPA standards for software agents. SAgent supports the development of secure mobile agent applications, where data is protected from rogue or compromised hosts. While other researchers have developed frameworks that provide solutions for various agent security problems, such as authentication of agents, agent replication, and voting [3], SAgent is concerned speci cally with protecting the data that travels with a mobile agent. We believe that SAgent is unique in bringing into practice a software framework for protecting agents from malicious hosts with rigorous security requirements. Much of the previous work deals with securing communication or infrastructure, or providing agent authentication. Strong methods for protecting agent data have been proposed by researchers, including hardware-based techniques [9] and techniques based on clever use of cryptography and distributed protocols [2, 7], but SAgent is the rst attempt at unifying these techniques under a common framework, and as far as we're aware provides the rst experimental explorations of the proposed agent protections.

In SAgent, methods of protecting agent data are cleanly separated from applications using those protections, so both application and protection technique can be independently considered. A number of general security interfaces are de ned, which encapsulate the common security functionality required by secure agent applications. Security providers can provide implementations using these interfaces, and SAgent is distributed with two different implementations of software-based protection techniques, one by Algesheimer *et al.* [2] and one by Tate and Xu [7]. While the support for these software-based techniques is clear, the SAgent framework is general enough to support hardware-based protections just as cleanly. While the current lack of hardware to provide such protection makes this impossible to experiment with now, SAgent was designed so that if the current proposals for trusted platforms [8] become widespread and useful, then simple support in the SAgent framework would be possible.

SAgent was designed keeping in mind a basic tenet of software engineering, that de nition of proper abstractions is essential for software reusability. The key abstraction behind SAgent mirrors that of public/private key pairs in public key cryptography in which a private key is known only to the owner of the key, while the corresponding public key is available to everyone. Similarly, a mobile agent application has *public* functionality and information that it needs to perform computations at remote hosts and *private* information and functionality that is kept by the originator of the agent and not exposed to other entities. Note that while we refer to the information that travels as public, this does not mean it is under-

standable to an outside viewer encrypted data (ciphertext) can be public even if the corresponding plaintext remains unintelligible. The private information is necessary only for the nal interpretation of the results and does not need to be available in any way during the agent's travels. To that end, our design separates the public and private functionality of the agent into distinct pieces.

There are two different views of these pieces in SAgent one from the point of view of a programmer that develops protection techniques for SAgent and another from the point of view of a developer who writes applications for SAgent. The architecture of SAgent is designed so that the security provider and the application-developer can remain unaware of each other and develop protocols and applications independently of one another. Data transfer and usage in SAgent revolves around a generic, intermediate data format that is not secure but also not application-dependent. The application developer is responsible for providing translation routines that convert application-speci c data into the intermediate format, and the security provider provides routines which convert this intermediate format into a secure but protocol-speci c representation. Data can then be operated on in this secure format by going through methods in the generic public interface, which resolve to the appropriate protocol-speci c methods. The contributions of this work include

- A clean and useful abstraction of data protection in mobile agents;
- A working platform that realizes these abstractions and provides an effective framework for both security providers and agent application developers; and
- Implementation of two software-only security solutions that are usable and practical for protecting small amounts of agent data.

As this is a short paper, many details are omitted from this presentation and the full version of this paper is available as a technical report [4]. The SAgent software is freely available under the LGPL license [1].

2. SECURITY MODEL

Agent applications are decomposed into protected and unprotected computations, with only the sensitive data and computation being run in the protected environment. For instance, a shopping agent may browse through a store using unprotected computations, but could use SAgent to protect the portions of the agent which make purchasing decisions. The protected portion could include very sensitive information, such as payment authorization values, credit card numbers, or electronic cash tokens. The protected agent computation is modeled as a 3-input, 2-output function, as shown in Figure 1. The three inputs are the current agent state, the input from the host, and an input provided by any unprotected computations performed by the agent on that host. The two outputs are an updated agent state and an output that is provided to the current host. Speci c security providers guarantee slightly different security properties, but in general the agent state is protected so that it is unintelligible to an outside observer (either an attacker or a malicious host), and the host's input is protected so that it can only be used in a manner consistent with the agent functionality, which can be determined or negotiated as a contract between the originator and the host.

3. CORE INTERFACES OF SAGENT

SAgent uses sound principles of object-oriented design and achieves abstraction by speci cation of several general *interfaces*, which are extended by security providers to supply protocol-speci c implementations. The design is similar to some well-designed cryptography libraries, such as Sun's Java Cryptography Architecture, in which generic encryption and decryption interfaces are de ned, and these are bound to speci c algorithms and implementations when the cryptography objects are allocated. The core of our design, therefore, includes secure private and public interfaces, along with a secure data interface, which we describe in this section.

3.1 SecureFnPrivate Interface

The `SecureFnPrivate` interface encapsulates the private functionality in our mobile agent model, de ning the methods for interacting with the agent that are restricted to the agent originator. The originator creates an agent for a particular application using a constructor given by a particular security provider, with the result being a `SecureFnPrivate` object. Through this interface, the originator sets the initial state of the agent, and retrieves the public part (a `SecureFnPublic` object) which is then sent out in the mobile agents for this application. Each mobile agent then visits various remote hosts, utilizing its public functionality to perform computations on behalf of the originator. Note that the agent can perform both unprotected and protected computations at remote hosts, and good design would suggest that only the sensitive parts of the agent application be performed within the SAgent framework. The `SecureFnPrivate` interface also de nes the functionality that allows the originator to decode the state of the agent after the agent returns home. After successful decryption of the agent state, the state of the agent is converted from a secure data format to a generic object, understood by the application. Thus, it can be seen that the `SecureFnPrivate` interface provides exactly those methods that allow the originator to perform operations that no remote host should be allowed to do.

3.2 SecureFnPublic Interface

The `SecureFnPublic` interface encapsulates the functionality required by the agent to perform protected computations at remote hosts. The originator initializes the agent with the public functionality it requires to perform computations at a host. Upon successful contact with the host (through the host agent), the agent supplies its public part to the host and asks the host for its input. Speci - cally, this step involves reading in the host's input in a generic form and converting it into an object of type `SecureFnData`, where the speci cs of this transformation depend on the particular protocol which implements this interface. Only the encoded input is returned from the host to the agent, which is what enforces that the host data is used only as speci ed by the particular agent functionality. Similarly, if the agent has unprotected computation results that need to be included in the protected computation, then it encodes its input using the *encodeAgentInput* method. Once the agent obtains the host and agent inputs in a secure format, it calls the *evaluate* method to perform the protected computation. This method updates the agent state and returns a `SecureFnData` object representing the output to be provided to this host, which can be converted to plaintext using the *decodeHostOutput* method. This evaluation obviously depends on the speci cs of the agent application, but the evaluation is protected in a uniform way by the particular security provider. The key to all of the mobile agent computations is that computations are only performed on `SecureFnData` objects, and the privacy and/or integrity of these operations is guaranteed by the security provider and the security protocol. Any protected information stored in the agent state can be operated on through the *evaluate* method, but can not be decoded or decrypted except

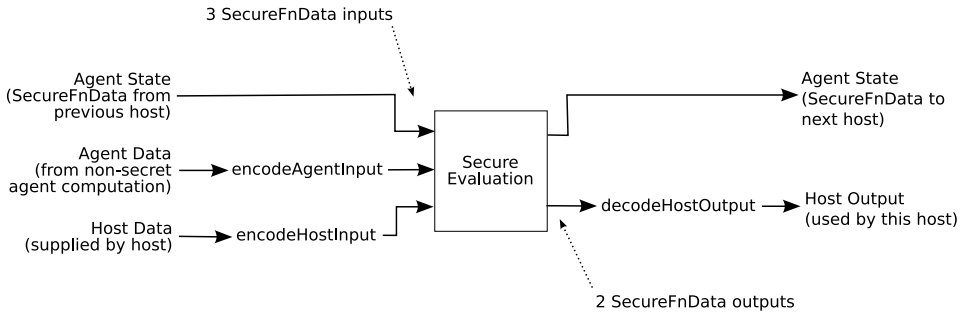

Figure 1: Agent State Update in SAgent

through the `SecureFnPrivate` object, which only the originator possesses.

3.3 SecureFnData Interface

SAgent is designed to protect the security of the mobile agent data. When data are operated upon within SAgent, the data are in a secure format. Therefore, the key idea with SAgent is that only *protected* data objects should be allowed within the protected execution. The `SecureFnData` type is simply a generic, opaque type to represent protected data, and does not provide any methods for operating on this data all operations are performed using either `SecureFnPublic` or `SecureFnPrivate` methods, including conversion to/from insecure data representations from/to `SecureFnData` objects. Different applications have different data requirements, so SAgent de nes an application-independent intermediate format that can be used within SAgent. This is just a binary representation of the data, and makes it simple for application-developers and security providers to develop their products independently of one another. The security provider just deals with bits which he encrypts, decrypts, and operates on as binary data, and is unaware of the actual form or meaning of the data in any application that may use his protocol. Once protected as a `SecureFnData` object, the actual encrypted representation of the data remains opaque to the user of the protocol. The application-developer, on the other hand, provides conversion routines between generic binary data and application-speci c data.

4. EXPERIMENTS AND EFFICIENCY

In this section we present experimental results from running the applications described earlier under both protocols provided with SAgent. Results of an extensive set of experiments on the protocols themselves, showing the how complexity grows with input size and how parameters such as cryptographic algorithms and key sizes affect ef ciency are available in [5]. The running times from our experiments are shown in the following table, where times are cumulative times given in seconds. The experiments were performed on a cluster of seven 2GHz Pentium IV machines with one host designated as the originator and the rest designated as remote hosts.

Application	Protocol		
	Insecure	ACCK	TX
Maxbid	0.11	0.53	12.24
BuyAgent	0.12	1.95	69.2

Note that in all cases except the more involved BuyAgent application running under the TX protocol, the times are just a few seconds per host visited, which is quite a low overhead for the rigorous security guarantees that these protocols provide.

5. CONCLUSIONS

We have developed a comprehensive security framework called SAgent for the JADE multiagent platform. Our framework allows the development of secure protocols and mobile agent applications, and can be used to provide both con dentiality and integrity protections for agent data. Use of generic, application-independent interfaces and data formats within SAgent allows programmers to create applications and protocols with ease and transparency. We also provide the rst software implementations of the ACCK [2] and the TX [7] mobile agent privacy protocols, with experimental results showing the feasibility of these software-only protections within our framework. We leave as future work the inclusion of support for hardware-based protections in SAgent, but believe that such an implementation would be straight-forward in a system that provides veri able Java environments through hardware-based attestation.

Coordinating Simple and Unreliable Agents

Kagan Tumer

Moffett Field, CA 94035, USA
ktumer@mail.arc.nasa.gov

ABSTRACT

Coordinating a large number of simple and unreliable agents to achieve a global objective poses a unique design challenge: How to achieve robust system level behavior in spite of the computational/reliability limitations of the agents. We investigate agent coordination in the difficult optimization problem of selecting the subset of sensing devices with distortions that provides the smallest average distortion [1]. We approach problem by assigning an agent to each device and having that agent use a simple reinforcement learning algorithm to determine whether to be part of the aggregate device. Our results show that the right agent reward structure provides significant improvements over both traditional search methods and traditional multi-agent methods. Furthermore, even in extreme cases of agent failures (i.e., half the agents fail during the simulation) this approach still outperforms a failure-free and centralized search algorithm.

1. INTRODUCTION

Coordinating simple and unreliable agents to achieve a global objective is different than traditional coordination problem in that: (i) agents have limited sensing and decision making capabilities; (ii) agents are not be able to model the other agents in the system; and (iii) agents are likely to fail (up to 50% of them) during the simulation. We propose addressing this problem by having Reinforcement-Learning (RL) agent [3] aim to maximize their own utilities and let the system reward structure overcome the limited observation and robustness problems. The design problem we face then, is to determine how best to set the utility functions of the agents in a way that will lead to good values of the global utility, without involving difficult to scale external mechanisms. Note that though the agents have simple decisions to make, this is still fundamentally a multi-agent problem: Each agent autonomously makes a decision at each time step based on its estimate of the reward it will receive; and the system is fully distributed as each agent has full autonomy over its actions.

For the joint action of agents working in such a system to provide good values of the global utility, we must both ensure that the agents do not work at cross-purposes, and that each one has a learning problem that is solvable with limited resources. Typically these two requirements are in conflict with one another. For example, providing each agent with the global utility will ensure that they will not work at cross purposes. However, each agent then faces a difficult signal to noise problem as the reward of each agent depends on the actions of all the other agents. At the other extreme, providing each agent with a simple, local utility function will provide a clear signal, but may not necessarily lead the system to high values of global utility. The challenge is is to find the best trade-off between these two requirements.

2. COMBINATION OF FAULTY DEVICES

The faulty device combination problem arises when many simple and noisy observational devices (e.g., nano or micro devices, low power sensing devices) attempt to accurately determine some value related to the phenomenon they're observing [1]. Each device provides a single number that is slightly off, similar to sampling a Gaussian centered on the value of the real number. The problem is to choose the subset of a fixed collection of the devices so that the average (over the members of the subset) distortion is as close to zero as possible. Formally, the problem is to minimize

$$\epsilon \equiv \frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} , \quad (1)$$

where $n_j \in \{0, 1\}$ is whether device j is or is not selected, and there are N devices in the collection, having associated distortions $\{a_j\}$. This is a hard optimization problem that is similar to known NP-complete problems such as subset sum or partitioning [1], but has two twists: the presence of the denominator and that $a_j \in R \, \forall j$. We denote the global utility function by $G = -\epsilon$ (so that to be consistent with the concept of "utility", the goal is to "maximize" G). The system is composed of N agents, each responsible for setting one of the n_j. The problem we face is in determining the agent utilities so that, as the agents learn to maximize their own utilities, they also maximize G.

2.1 Expected Difference Utility

The first agent utility we discuss is the **Estimated Difference Utility**, EDU, given by [5, 6]:

$$EDU_i \equiv G(z) - E_{z_i}[G(z)|z_{-i}] \quad (2)$$

where z is the full system state, z_i is the components of z that depend on agent i's actions, z_{-i} are the components of z that do not depend on the actions of agent i, and $E_{z_i}[G(z)|z_{-i}]$ is the expected value of G over the possible actions of agent i. Using Eq. 1, EDU leads to:

$$\begin{aligned} EDU_i(z) = & - \frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} \\ & + \left(p(n_i = 1) \frac{|\sum_{j \neq i}^{N} n_j a_j + a_i|}{\sum_{k \neq i}^{N} n_k + 1} \right. \\ & + \left. p(n_i = 0) \frac{|\sum_{j \neq i}^{N} n_j a_j|}{\sum_{k \neq i}^{N} n_k} \right) \end{aligned} \quad (3)$$

where $p(n_i = 1)$ and $p(n_i = 0)$ give the probabilities that agent i set its n_i to 1 or 0 respectively. In what follows, we will assume that those two actions are equally likely (i.e., for all agents i, $p(n_i = 1) = p(n_i = 0) = 0.5$).

Depending on which action agent i chose (0 or 1), EDU(z) reduces to:

$$0.5 \left(\frac{|\sum_{j=1}^{N} n_j a_j - a_i|}{\sum_{k=1}^{N} n_k - 1} - \frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} \right) \text{ if } n_i = 1 , \quad (4)$$

or:

$$0.5 \left(\frac{|\sum_{j=1}^{N} n_j a_j + a_i|}{\sum_{k=1}^{N} n_k + 1} - \frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} \right) \text{ if } n_i = 0 . \quad (5)$$

Note that in this formulation, EDU provides a very clear signal. Because EDU is aligned with G [5](i.e., actions that improve EDU also improve G) if EDU is positive, the action taken by agent i was beneficial to G, and if EDU is negative, the action was detrimental to G. Thus an agent trying to maximize EDU will efficiently maximize G, without explicitly trying to do so. Furthermore, note that the computation of EDU requires very little information. Any system capable of broadcasting G can be minimally modified to accommodate EDU. For each agent to compute its EDU, the system needs to broadcast the two numbers needed to compute G: the number of devices that were turned on (i.e., the denominator in Equation 1) and the associated subset distortion as a real number (i.e., the numerator in Equation 1 before the absolute value operation is performed. Based on those two numbers, the agent can compute its EDU.

2.2 Wonderful Life Utility

The second utility we consider is the **Wonderful Life Utility** [5, 6], given by:

$$WLU_i \equiv G(z) - G(z_{-i}). \quad (6)$$

The major difference between EDU and WLU is in how they handle z_{-i}. EDU provides an estimate of agent i's impact by sampling all possible actions of agent i whereas WLU simply removes agent i from the system. For this application, the WLU becomes:

$$WLU_i(z) = -\frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} + \frac{|\sum_{j \neq i}^{N} n_j a_j|}{\sum_{k \neq i}^{N} n_k} \quad (7)$$

Note however, that unlike with EDU, the action chosen by agent i has a large impact on the WLU. If agent i chooses action 0, the two terms in Equation 7 are identical, resulting in a WLU of zero. Depending on which action agent i chose (0 or 1), WLU reduces to 0 if $n_i = 0$ or:

$$\frac{|\sum_{j=1}^{N} n_j a_j - a_i|}{\sum_{k=1}^{N} n_k - 1} - \frac{|\sum_{j=1}^{N} n_j a_j|}{\sum_{k=1}^{N} n_k} \text{ if } n_i = 1 . \quad (8)$$

In this formulation, unlike EDU, WLU provides a clear signal only if agent i had chosen action 1. In that case, a positive WLU means that the action was beneficial to G, and a negative WLU means that the action was detrimental for G. However, if agent i had chosen action 0, it receives a reward of 0 regardless of whether that action was good or bad for G. This means that on average half the actions an agent takes will be random as far as G is concerned.

3. EXPERIMENTAL RESULTS

Each agent used a simple reinforcement learning algorithm, where each action is associated with the value of the utilities it has yielded. Agents choose actions to maximize those utility values. However, to spur exploration, rather than selecting the action with the highest expected utility, the agents used a Boltzman distribution over those utility values to select an action. In order to allow the agents to gather data, the agents took random actions for the first 20 time steps. The results are based on 20 different $\{a_i\}$ configurations, where each $\{a_i\}$ is selected from a Gaussian distribution with zero mean and unit variance. For each configuration, the experiments were run 50 times (i.e., each point on the figures is the average of $20 \times 50 = 1000$ runs).

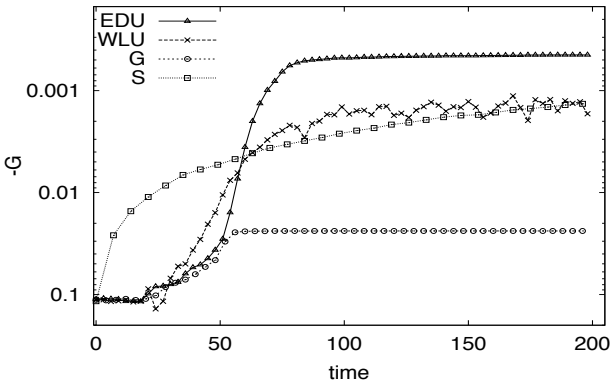

Figure 1: System Performance, N=100.

3.1 Agent Utility Performance

Figure 1 shows the simulation results. The graphs labeled G, EDU and WLU show the performance of agents using G, EDU and WLU as their reward, respectively. S shows the performance of local search where new n_i's are generated at each step by perturbing the current state and selected if the solution is better than the current best solution (in the experiments reported here, 25% of the actions were randomly changed at each time step, though somewhat surprisingly, the results are not particularly sensitive to this parameter). This local search algorithm provides the performance of an algorithm with centralized control. Because the runs are only 200 time steps long, algorithms such as simulated annealing do not outperform local search: there is simply no time for an annealing schedule. Agents use G directly have

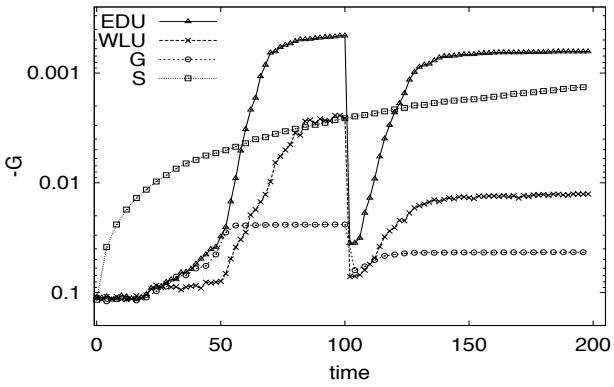

Figure 2: System performance for 100 agents, 20% of which fail at time t=100.

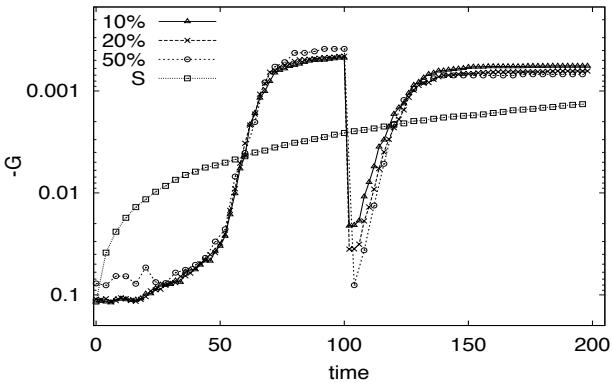

Figure 3: Effect of agent failures on EDU for 100 agents (S has no agent failures).

a difficult time learning. The noise in the system is simply too large for such agents to learn how to select their actions. WLU performs at the level of the centralized algorithm. Because agents only receive useful feedback when they take one of the two actions, the performance is between that of G and EDU. EDU outperforms both the other RL algorithms and the centralized search algorithm. This is due to EDU receiving a clear signal for each of the two actions.

3.2 Handling Agent Failures

In order to evaluate the robustness of the proposed utility functions for multiagent coordination, we tested the performance of the system when a subset of the agents failed during the simulation. At $t = 100$, a certain percentage of agents failed (e.g., were turned off) simulating hazardous condition with agents malfunctioning. The relevance of this experiment was in determining whether the proposed utility functions require all or a large portion of the agents to perform well to be effective, or whether they can handle sudden changes to their environment.

Figure 2 shows the performance of 100 agents where 20% of the agents fail at time step $t = 100$. The results of the centralized search algorithm with no failures ("S" from Section 3.1), is also included for comparison. In these experiments, the agent learning algorithms were not adjusted to account for the change in the environment. In agents that continued to function, the learning proceeded as though nothing had happened. As a consequence, not only did the agents need to overcome the sudden change in their task but they had to do so with parameters tuned to the previous environment. Despite these limitations, EDU recovers rapidly from having 20% of the agents fail. Note this is a powerful results: a distributed algorithm with only 80% functioning agents, each tuned to a different environment outperforms a 100% functioning centralized algorithm.

Figure 3 shows the performance of EDU when the percentage of agent failures increases from 10 to 50%. For comparison purposes, the search results (From Section 3.1) are also included. After the initial drop in performance when the agents stop responding, the system using EDU recovered rapidly and outperformed the fully functioning and centralized search algorithm. These results demonstrate both the adaptability of EDU and its robustness to failures of individual agents, even in extreme cases where half the agents fail during the run.

4. DISCUSSION

The combination of faulty devices is a simple abstraction of a problem that will loom large in the near future: How to coordinate a large number of agents – many of which may have limited access to information and perform unreliably – to achieve a prespecified global objective. This problem is fundamentally different from traditional multi-agent problems in at least three ways: (i) the agents have limited sensing and decision making capabilities; (ii) the agent do not model the actions of other agents; and (iii) the agents are unreliable and failure-prone.

The work summarized in this article is based on ensuring coordination among simple and unreliable agents by providing them with the proper reward structure. This approach is well-suited for addressing coordination in large scale cooperative multi-agent systems where the agents do not have preset and possibly conflicting objectives, or when the agents do not need to hide their objectives. The results shows the promise of this method by providing improvements over both a centralized algorithm and a multi-agent system using a team game approach. Furthermore, when as many as half the agents fail during simulations, the proposed method still outperforms a fully functioning centralized search algorithm.

Acknowledgments: The author would like to thank David Wolpert for invaluable discussions and for bringing the faulty devices problem to his attention, and Adrian Agogino for his many comments.

The Emergence of Global Properties from Local Interactions

Static Properties and One-Dimensional Patterns

Daniel Yamins
Division of Engineering and Applied Sciences
Harvard University Cambridge, MA 02138 USA
yamins@fas.harvard.edu

ABSTRACT

Groups of simple objects, interacting under local rules, can produce global properties of great complexity and rich functionality. In this paper, we address of whether a given global property can emerge from purely local interactions. We provide a necessary condition for the case of static properties, and provide complementary sufficient conditions for patterns on the special case of one-dimensional lattices. This work shows that two general considerations, local checkability and symmetry, are the main determinants of "emergeability," at least in these special cases. This work also shows that relatively unified constructions provide solutions to large classes of patterns.

A General Model

Groups of simple objects, interacting under local rules, can produce global properties of great complexity and rich functionality ([1, 2, 3, 4]). In this paper, we address of whether a given global property can emerge from purely local interactions. First, we describe a model of stateless, stigmergy-less agents. The three fundamental objects in the model are configurations, local dynamics, and global properties. Configurations represent agents and the spaces in which they are situated as labeled graphs.

Definition 1 ***[Configurations]*** *(Fig. 1)*
A configuration *is a graph $X = (N_X, E_X)$ of the form*

$$X = (N_X, E_X) = (N_a \cup N_g, E_a \cup E_g),$$

in which: N_a is a set of finite set of nodes labeled by the symbol a; N_g is a set of nodes labeled by the symbol g; E_g is a set of edges (directed or undirected) between nodes in N_g; and E_a is a set containing, for each $x \in N_a$, one directed edge of the form (x, y), where y is a node in N_g that is unique for each x.

Denote by $\mathcal{C}_G$ the set of configurations for which $(N_g, E_g) = G$. For a set $\mathcal{G}$ of graphs G (called underlying spatial graphs*), let $\mathcal{C}_{\mathcal{G}} = \bigcup_{G \in \mathcal{G}} \mathcal{C}_G$.*

For example, the "directed line", denoted $\overrightarrow{\mathbb{Z}}$, is the one dimensional integer lattice with global orientation given by taking $N_g = \{(g, n) | n \in \mathbb{Z}\}$ and $E_g = \{(i, i+1) \mid i \in \mathbb{Z}\}$. The graph $\overline{\mathbb{Z}}$, the "undirected line", has the same N_g, but $E_g = \{\{n, n+1\} \mid n \in \mathbb{Z}\}$. The graph G could also be higher dimensional lattices $\overrightarrow{\mathbb{Z}}^n$, $\overline{\mathbb{Z}}^n$ defined in analogy to their one-dimensional versions, in addition to rings, spheres, and graphs with less regular structure.

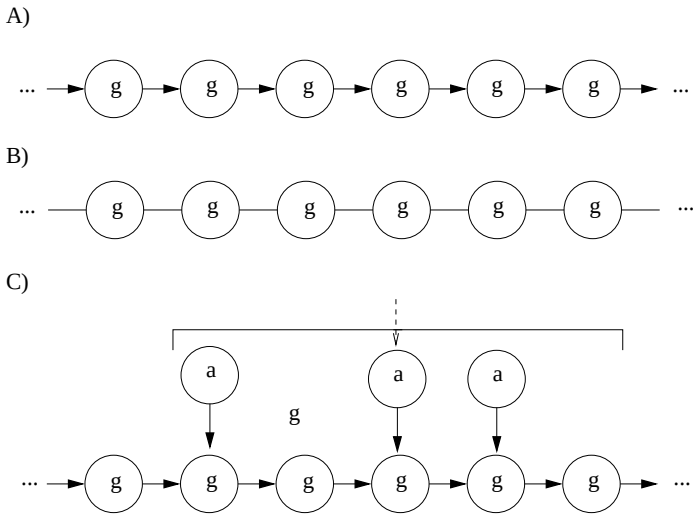

Figure 1: A) The infinite integer lattice with global orientation ("the directed line"). B) The infinite integer lattice without orientation. C) A configuration of three agents on the directed line. The bracket above the middle agent indicates the ball of radius 2 around it.

For a configuration $X = (N_g \cup N_a, E)$, let the *agents of* X be the set $Ag(X) = N_a$, and $|Ag(X)| = |N_a|$ be the number of agents in X. Given $x \in Ag(X)$, let the unique node number m for which $(x, (g, m)) \in E_a$ be denoted by $pos(x, X)$, the *position* of x in X. For $x, y \in N_g$, let $dist(x, y, X)$ be the graph distance in the underlying spatial graph G of X; this extends to a distance between $x, y \in Ag(X)$ as the graph distance between $pos(x, X)$ and $pos(y, X)$. For $x \in X$, define the *neighborhood of radius r about x in X*, denoted $B_r(x, X)$, as the subgraph $(N_B, E_B) \subset (N_X, E_X)$ where $N_B = \{y \in N_X | dist(x, y, X) \leq r\}$. Let $\mathcal{C}_{\mathcal{G}}(r)$ denote the set of all r-neighborhoods $B_r(x, X)$ for $x \in Ag(X)$ and $X \in \mathcal{C}_{\mathcal{G}}$. A configuration X is *r-connected* if $\bigcup_{x \in Ag(x)} B_r(x, X)$ is a connected subgraph of X, and r-disconnected if it is not r-connected. The set of r-connected configurations is denoted by $\mathcal{C}_{\mathcal{G}}[r]$. For two subconfigurations $A = (N_A, E_A)$ and $B = (N_B, E_B)$, define the "graph sum" $A \oplus B = (N_A \cup N_B, E_A \cup E_B)$.

The dynamics of the model are specified by local agent-based rules of motion. For each agent $x \in Ag(X)$, the rule looks at the neighborhood B of some fixed radius r around x and decides whether to move x from its initial position $pos(x, B)$ to some other point g' that is at most one position away. Formally, such a rule can be described by a map f such that for each r-neighborhood $B_r(x, X) = (N_B, E_B)$,

$$f : (N_B, E_B) \mapsto (N_B, E_B \setminus \{(x, pos(x, B))\} \cup \{(x, g')\}) \quad (1)$$

where $dist(x, g', B) \leq 1$.

Definition 2 ***[Local Rules]*** *A* local rule with information radius r *is any function* $f : \mathcal{C}_\mathcal{G}(r) \to \mathcal{C}_\mathcal{G}(r)$ *that obeys condition 1 above. Let* $\mathcal{D}_r$ *denote the set of all such* f*, and* $\mathcal{D} = \cup_r \mathcal{D}_r$*. We write* $r(f)$ *for the information radius of* f*.*

When f fixes an agent $x \in X$, we write $[f(x, X)] = S$ (S stands for "stay").

Given a sequence $s = (s_1, s_2, \dots,) \in Ag^\infty(X)$ of calls to agents and an initial configuration X_0, we could first apply f to (x_1, X_0); we could then apply f to $(x_2, X_1 = f(x_1, X_0))$, and repeat this iteratively. The resulting sequence represents trajectories generated by totally asynchronous updating, denoted by $f_s^n(X_0)$. Any such trajectory has an *ω-limit set*, denoted by $\Omega(f, s, X_0)$, which is the set of configurations that appear infinitely often in $\{f_s^n(X_0)\}$. $\Omega(f, s, X_0)$ is empty when no well-defined limit actually exists.

A choice of models for the concurrency of agent calls is given by specifying a set of sets $S = \{S_X | X \in \mathcal{C}_\mathcal{G}\}$ of valid call sequences that is invariant under the graph-equivalence $\cong$ on $\mathcal{C}_\mathcal{G}$. Totally asynchronous update (with no restriction on the relative frequence of calls to different agents) corresponds to setting $S_X^{asynch} = Ag(X)^\infty$, whereas totally synchronous update corresponds to the choice $S_X^{synch} = \{(Ag(X), Ag(X), Ag(X), \dots,)\}$.

Global properties are given by specificying a target set $P \subset \mathcal{C}_\mathcal{G}$ of 'desired' configurations. For example, *patterns*:

Definition 3 ***[Patterns]*** *Fix a graph* G*. Let* $(q)^{\oplus k}$ *denote the set of subconfigurations* Y *of graphs over* G *of the form* $Y = q_1 \oplus q_2 \oplus \dots \oplus q_k$*, where the* $q_1, \dots, q_k$ *are all disjoint and graph-equivalent to* q*. A* pattern *over* G *is a subset* $P \subset \mathcal{C}_G$ *for which there exists a finite* q *such that*

$$P = \bigcup_{k=0}^{<\infty} \{Y \oplus G \mid Y \in (q)^{\oplus k}\}.$$

In this case, we write $P = \langle q \rangle$*. We define the* length *of* P*, denoted* $|P|$*, to be the length of the underlying spatial graph of* Y *and the size of* P*, denoted* $|Ag(P)|$*, to be the number of agents in* q*.*

Given a property $P \subset \mathcal{C}_\mathcal{G}$, our motivating interest is to find (or prove the non-existence of) *solutions* to it, those dynamic rules whose trajectories satisfy the property.

Definition 4 ***[Solutions]*** *A dynamic rule* $f \in \mathcal{D}$ *is a* P-solution over $(\mathcal{G}, S)$ *if, for all* $X \in \mathcal{C}_\mathcal{G}$*, and all call-sequences* $s \in \mathcal{S}_X$*,* $\Omega(\{f_s^n(X)\}) \subset P$ *holds.*

The solution space $\mathcal{F}(\mathcal{G}, S, P)$ *is the set of all* φ*-solutions, that is*

$$\mathcal{F}(\mathcal{G}, S, P) = \{f \in \mathcal{D} | f \text{ is a } P\text{-solution over } (\mathcal{G}, S)\}.$$

Pi is locally solvable *when* $\mathcal{F}(\mathcal{G}, S, \varphi) \neq \emptyset$*. Otherwise,* P *is* locally unsolvable.

Local Checkability

Definition 5 *A* local check scheme with radius r *is a function* $\Theta : \mathcal{C}_\mathcal{G}(r) \to \{0, 1\}$*. The* check radius $\Xi(P)$ *of a property* P *is the minimal* $r > 0$ *such that there exists local check scheme* Θ *with* $r(\Theta) = r$ *such that*

$$\bigwedge_{a \in Ag(X)} (\Theta(B_r(a, X)) = 1) \ \wedge \ X \in \mathcal{C}_\mathcal{G} \ \Rightarrow \ X \in P,$$

if such exists. The connected check radius $\Xi^c(P)$ *is the minimal* $r > 0$ *such that there exists* Θ *with* $r(\Theta) = r$ *such that*

$$\bigwedge_{a \in Ag(X)} (\Theta(B_r(a, X)) = 1) \ \wedge \ X \in \mathcal{C}_\mathcal{G}[r] \ \Rightarrow \ X \in P$$

if it exists.

If $\Xi(P) < \infty$, we say P is locally checkable.

Proposition 1 *For all* $\mathcal{G}$*,* S *and* P*:* $f \in \mathcal{F}(\mathcal{G}, S, P)$ *only if* $r(f) \geq \Xi(P)$*.*

Hence, $\Xi(P) = \infty \ \Rightarrow \ \mathcal{F}(\mathcal{G}, S, P) = \emptyset$; and $\Xi^c(P) = \infty \ \Rightarrow \mathcal{F}(\mathcal{G}, S, P) = \emptyset$. Thus:

Corollary 1 *Static properties* P *is locally solvable over* $\mathcal{G}$ *only if it is are locally checkable over* $\mathcal{G}$*:*

Obviously, patterns *do* meet the local checkability condition.

Corollary 1 establishes a necessary condition that must be met for any static property to be emergeable. In the next section, we answer the converse question when restricted to the special case of connected patterns on $\mathcal{G} = \{\overrightarrow{\mathbb{Z}}\}, \{\overline{\mathbb{Z}}\}$, and $\mathcal{R}$, the locally one-dimensional lattices. We begin by defining some notation.

Patterns on the Directed Line

Given $X \in \mathcal{C}_{\overrightarrow{\mathbb{Z}}}$, and $x, y, \in X$, we say that x is *to the right* of y if there exists a directed path from $pos(x, X)$ to $pos(y, X)$ in $\overrightarrow{\mathbb{Z}}$, and if so, we write $y \leq x$. If such a path does not exist, then we say x is *to the left* of y, and write $x \leq y$. For any connected subconfiguration $Y \subset X$, let $min(Y)$ be the left-most spatial node in Y, and $max(Y)$ be that of the right-most. For $a, b \in \overrightarrow{\mathbb{Z}}$ with $a \leq b$, let $X[a, b]$ be the maximal connected subconfiguration of $Y \subset X$ with $min(Y) = a$ and $max(Y) = b$. For $x \in Ag(X) \in \mathcal{C}_{\overrightarrow{\mathbb{Z}}}$, define x^{+k} to be the kth agent to the right of x, if such exists; and x^{-k} to be the k-th agent to the left of x, if such exists. Define $re(X)$ to be the unique $x \in Ag(X)$ for which $x^+ = x^{+1}$ does not exist, and $le(X)$ to be the unique agent for which $x^- = x^{-1}$ does not exist. (These are the "right-end" and "left-end" agents of X, respectively.)

Any local rule f with radius r operating over the directed line $\overrightarrow{\mathbb{Z}}$ has three possible actions on any configuration $B_r(x, X)$. It can either move the agent x to the left, which we notate as $[f(x, X)] = L$; or it can move x to the right, which we notate as $[f(x, X)] = R$; or f can fix x, in which case $[f(x, X)] = S$ is just the same as previous defined notation.

It turns out that on $\overrightarrow{\mathbb{Z}}$, local checkability is sufficient for solutions to P to exist. To prove this, given a pattern P over $\overrightarrow{\mathbb{Z}}$, we construct a local rule that generates it. Let q be a generator in standard form of P. We first construct a rule that generates q when exactly $|Ag(q)|$ are present close enough together. In particular, let $\mathcal{Y}_q$ be the set of configurations Y with $|Ag(q)|$ agents and such that $dist(le(Y), re(Y)) \leq |q|$. Let $Y \in \mathcal{Y}_q$. Then define $T \in \mathcal{D}_{|q|}$ by

$$[T(a, Y)] = \begin{cases} L & \text{if } a = a_Y^* \\ S & \text{otherwise} \end{cases}$$

where

$$a_Y^* = re(\{a \in Ag(Y) | (pos(a) \leq pos(a'_Y)) \text{ and } (dist(a, a^-) > 1)\}).$$

in which

$$a'_Y = re(\{a \in Ag(Y) | (dist(a, a^+, Y) < dist(a, a^+, q)) \text{ or } (dist(a, a^-, Y) > dist(a, a^-, q))\}).$$

T has the three properties:

- $\Omega(T, s, Y) = \overrightarrow{\mathbb{Z}} \oplus q$, for all $Y \in \mathcal{Y}_q$ and $s \in S_Y$
- $[T(a, X)] \neq R$ for all $X \in \mathcal{C}_r$ and
- $dist(le(T_s^n(Y)), re(T_s^n(Y))) \leq |q|$ for all n, for all $Y \in \mathcal{Y}_q$ and $s \in S_Y$.

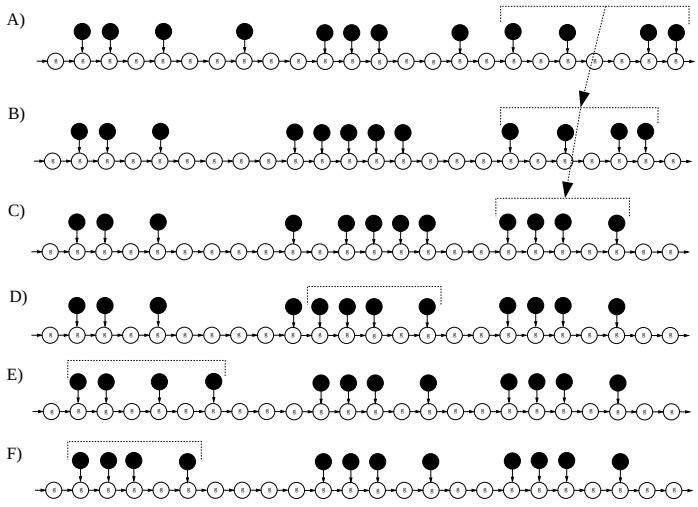

Figure 2: Illustration of the operation of the local rule constructed to solve pattern formation. A) Initial condition. B) Right-most agents comes together. C) Right-most group implements local rule T. In D) through F) this procedure repeats, propagating to the left.

In other words, T is like a solution to one unit of the pattern (Fig. 2). Our task is define a local rule which forces agents to come together closely enough to implement T, and properly draws boundaries between the units.

For $X \in \mathcal{C}$, and $a \in Ag(X)$, define $\widetilde{B}(a)$ to be the set of agents b in X with $pos(b) \leq pos(a)$ such that $X[pos(b), pos(b) + |q|]$ contains $|Ag(q)|$ or more agents but $X[pos(b^{+j}), pos(b^{+j}) + |q|]$ does not for $j = 1, \ldots, |Ag(q)| - 1$. If $\widetilde{B}(a) \neq \emptyset$, then let $a' = re(\widetilde{B}(a))$, the right-most agent in $\widetilde{B}(a)$. Then define $\gamma_X : Ag(X) \to \{0, 1, \ldots, |Ag(X)|\}$ by

$$\gamma_X(a) = \begin{cases} \text{k+1} & \text{where } a = (a')^{+k}, \text{ if } \widetilde{B}(a) \neq \emptyset \text{ and } k < |Ag(q) \\ 0 & \text{otherwise} \end{cases}.$$

Note that $\gamma_X(le(X)) \leq 1$ for all X. γ is a check which draws boundaries between units, each new unit starting again when γ_X is 1; and when not enough agents are close enough together for a unit to be declared, γ_X is zero.

We put γ and T together now. Define $f_T[P] \in \mathcal{D}_{2|q|+1}$ by: If $|Ag(X[pos(a) - 2|q| - 1, pos(a) - 1])| = 0$, then:

$$[f_T[P](a, X)] = \begin{cases} L, \text{ if } |X[pos(a), pos(a) + |q|]| \geq |Ag(q)| \\ \text{ and } \gamma_X(a) = 0 \\ [T(a, \overrightarrow{\mathbb{Z}} \oplus X[pos(a), pos(a) + |q|])], \text{ if } \gamma_X(a) = 1 \\ S, \text{ otherwise} \end{cases}$$

and if $|Ag(X[pos(a) - 2|q| - 1, pos(a) - 1])| > 0$, then

$$[f_T[P](a, X)] = \begin{cases} L, \text{ if } \gamma_X(a) = 0 \text{ and } dist(a, a^+) \neq 2|q| + 1 \text{ or} \\ X[pos(a), pos(a) + |q|] \cong q \text{ and} \\ dist(a, a^-) = 2|q| + 1 \\ [T(a, \overrightarrow{\mathbb{Z}} \oplus X[pos(a^{+l}), pos(a^{+l}) + |q| - 1])], \\ \varphi_X(a) \neq 0, \ dist(a, a^+) \neq 2|q| + 1 \\ S \text{ otherwise} \end{cases}$$

where $l = 1 - \gamma_X(a)$. The operation of $f_T[P]$ is described pictorially in figure 2. For each P, $f_T[P]$ is a local rule with information radius $2|q| + 1$. It can be shown that $f_T[P]$ is a solution to the connected P-pattern formation problem, yielding:

Theorem 1 *All connected patterns can be solved over* $\overrightarrow{\mathbb{Z}}$.

Symmetry

Any configuration X possess a *symmetry group*, $Sym(X)$; these are the permutations σ on the set $\mathbb{N}$ of node identity numbers that induce a graph automorphism on X. The underlying spatial graphs also of course have symmetry groups (think of them as trivial configurations with no agents). For example, $Sym(\overrightarrow{\mathbb{Z}}) = \mathbb{Z}$; for each $n \in \mathbb{Z}$, the symmetry σ_n corresponds to shifting all nodes in $\overrightarrow{\mathbb{Z}}$ by n steps. $Sym(\overline{\mathbb{Z}}) = \mathbb{Z} \oplus \mathbb{Z}_2$, because in addition to having all of the shift symmetries which generate the $\mathbb{Z}$ summand, the undirected line also has a flip symmetry σ^* which generates the $\mathbb{Z}_2$ summand. For any configuration X over $\overrightarrow{\mathbb{Z}}$ with $|Ag(X)| > 0$ (and finite), the symmetry group $Sym(X)$ is trivial. That is because none of the shift symmetries can take the "end-most" agent to anything other than itself. However, for all configurations Y over $\overline{\mathbb{Z}}$ that are symmetric about their middle agent(s), $Sym(Y) = \mathbb{Z}_2$.

We can put a measure on the amount of symmetry that a given geometry $\mathcal{G}$ has by measuring the size of the symmetry groups for non-trivial configurations over $\mathcal{G}$. In this sense, $\overline{\mathbb{Z}}$ has more symmetry than $\overrightarrow{\mathbb{Z}}$ (which has none). This non-zero amount of symmetry places prevent emergeability on this geometry, as reflected in the following:

Theorem 2 *No patterns can be solved over* $\overline{\mathbb{Z}}$ *in the synchronous model of concurrency.*

The proof of Theorem 2 relies heavily on the choice of the synchronous concurrency model. In fact, the small amount of symmetry-breaking which asynchrony allows is enough solve all patterns, via a construction analagous to that used in the case of $\overrightarrow{\mathbb{Z}}$ in theorem 1:

Theorem 3 *All patterns can be solved over* $\overline{\mathbb{Z}}$ *in the asynchronous concurrency model.*

Having considered $\overrightarrow{\mathbb{Z}}$ and $\overline{\mathbb{Z}}$, let us consider the set of ring graphs $\mathcal{R} = \{\mathcal{R}_m | m \in \mathbb{N}\}$, where $\mathcal{R}_m$ is the ring graph with m nodes.

Theorem 4 *Only trivial patterns over the ring lattices* $\mathcal{R}$ *can be solved.*

Theorem 4 says that the failure of existence of solutions to pattern formation is worse on $\mathcal{R}$ that it was on $\overline{\mathbb{Z}}$, since failure holds in both the synchronous and asynchronous concurrency models. The essence of this failure is, once again, symmetry. Note that $Sym(\mathcal{R}) = \bigcup_{m \in \mathbb{N}} \mathbb{Z}_m$. Unlike $\overrightarrow{\mathbb{Z}}$ which has no symmetries on non-trivial configurations, and $\overline{\mathbb{Z}}$, which has at most the finite group $\mathbb{Z}_2$, $\mathcal{R}$ has infinitely many symmetries over non-trivial configurations, and it is precisely these symmetries that are exploited in the proof of theorem 4.

In summary, proposition 1 and theorems 1, 2, 3, and 4, suggest that two rough criteria are important for whether a given global property is emergeable: A) whether it is **locally checkable** and B) whether the property **respects the symmetry** of the underlying space.

ABSTRACT

We introduce *take-it-or-leave-it auctions (TLAs)* as an allocation mechanism that allows buyers to retain much of their private valuation information, yet generates close-to-optimal expected utility for the seller. We show that if each buyer receives at most one offer, each buyer's dominant strategy is to act truthfully. In more general TLAs, the buyers' optimal strategies are more intricate, and we derive the perfect Bayesian equilibrium for the game. We develop algorithms for finding the equilibrium and also for optimizing the offers so as to maximize the seller's expected utility. In several example settings we show that the seller's expected utility already is close to optimal for a small number of offers. As the number of buyers increases, the seller's expected utility increases, and becomes increasingly (but not monotonically) more competitive with Myerson's expected utility maximizing auction.

1. INTRODUCTION

Auctions have emerged as a key mechanism for task and resource allocation in multiagent systems. We focus on the problem of allocating an indivisible good to one of a group of interested buyers, while maximizing the seller's expected utility.[1] In this setting, the *Myerson auction* yields the highest expected utility to the seller, compared to *any* other allocation mechanism [13]. Despite being the optimal allocation mechanism, the Myerson auction has several undesirable features. First, buyers must fully reveal their true valuations for the good.[2] Buyers may be unwilling to reveal private information because such information is proprietary or its revelation would have a negative strategic long-term impact. For example, after such an auction the buyers will be at a disadvantage in future negotiations with the seller (who may be able to extract more surplus in the future using information about the buyers' valuations). Similar long-term adverse effects have been observed in other truthful full-revelation auction mechanisms [17]. Second, buyers may not understand the complex, unintuitive rules of the Myerson auction, and therefore choose to not participate. Third, for a layman, it is unintuitive to submit true valuations because bid shading is rational in many commonly used auction mechanisms. Buyers are thus likely to shade bids even in Myerson auctions, with unpredictable and suboptimal results. For these reasons and potentially others, to our knowledge, the theoretically elegant Myerson auction is not being used anywhere.

In the most commonly used auction mechanisms—the *English auction* (a.k.a. ascending open-cry auction) and the *Dutch auction* (a.k.a. descending auction)—bidders do not reveal their valuations completely [9]. Unfortunately, in these auctions, the seller's expected utility is not optimal and in fact can be arbitrarily far from optimal. The *Vickrey auction* [20] (a.k.a. second-price sealed-bid auction) suffers from both full valuation revelation and seller's expected utility being arbitrarily far from optimal.

In this paper we present a mechanism that achieves close-to-optimal expected utility for the seller while allowing each buyer to retain much of her private valuation information. Our *take-it-or-leave-it auction (TLA)* mechanism consists of a sequence of take-it-or-leave-it offers made by the seller to the buyers, each buyer in turn. Before the auction is held, the seller announces the order in which the buyers receive offers and the amount of each offer. During a fixed time after receiving an offer, the buyer has to accept ("take") the offer, at which point the auction ends, or reject ("leave") the offer, in which case the seller may proceed to make other offers. After rejecting an offer, the buyer never has the option of

[2]Recently, cryptographic techniques have also been proposed to address this drawback [14].

accepting that offer.[3] We show how rational buyers should act in such an auction and how the seller can optimize the sequence of offers given her knowledge about the buyers. In this sense, our approach is *automated mechanism design* [7].

Sequences of take-it-or-leave-it offers have been studied in the context of optimal auctions previously [3]. However, in that paper there is an assumption that the seller can decide the accuracy to which the buyers learn their own valuations. One way they can achieve this is by withholding information. In our model, the seller has no control of the buyers' information.

In many applications the seller may be aware of some statistical information about the buyers. By taking this information into account, the seller can design mechanisms so as to maximize her expected utility. In our setting, this is done by making the assumption that every buyer's valuation is drawn from some known probability distribution. This assumption violates the *Wilson doctrine* which states that mechanisms should be designed without the use of any priors. Some examples of auctions that follow the Wilson doctrine include Vickrey, English, Dutch, and first-price sealed bid auctions. These types of auctions are not optimal, and in fact can be arbitrarily far from optimal. Further, it is generally not possible to design utility maximizing auctions (or even approximately optimal auctions) without using priors. The Myerson auction, on the other hand, does not adhere to the Wilson doctrine, and as a result is able to extract more surplus from the buyers. Just as is done in the Myerson auction, we use priors in our mechanism.

2. THE SETTING AND BACKGROUND

We study the usual auction setting in which a seller has an indivisible good that she can allocate to any one (or none) of a set of buyers $B = \{1, \ldots, n\}$. Each buyer i has a valuation v_i for the good that is drawn from a distribution f_i with cumulative density F_i. The buyers' valuations are drawn independently.[4] The distributions f_i are common knowledge, but the valuation v_i is only known by the buyer i herself. The setting is *symmetric* if each buyer draws her valuation from the same distribution. Otherwise the setting is *asymmetric*. Finally, we make the standard auction theory assumption that there is no aftermarket.

By designing the rules of the auction, the seller tries to maximize her expected utility. The seller has a valuation v_0 (potentially zero) for the good. By the standard quasilinearity assumption about the seller, the seller's utility is v_0 if she keeps the item, and if she allocates the item to a buyer, her utility is the revenue that she receives from the buyers.

To motivate the buyers to participate in the auction, the rules of the auction have to guarantee that each buyer receives no less utility by participating than by not participating. Such *ex post* participation constraints imply that 1) a buyer who does not get the good cannot be charged, and 2) the buyer who receives the good cannot be charged more than her valuation.

[3]At first glance, it appears that the Dutch auction and TLAs are equivalent. This is not true. The Dutch auction is more powerful in the sense that the seller can make an infinite number of offers, and less powerful in the sense that the seller has to make the offers symmetrically to the buyers.

[4]If the valuations can have arbitrary correlations, then even designing an approximately optimal auction is hard computationally [16].

The optimal mechanism for our setting is the Myerson auction [13]. It is the benchmark against which we will compare our TLA mechanism.[5]

DEFINITION 1. (Myerson auction [13])

- *Every buyer i reveals a valuation $\hat{v}_i$.*
- *For each buyer i, compute that buyer's* virtual valuation*: $\psi_i = \hat{v}_i - \frac{1-F_i(\hat{v}_i)}{f_i(\hat{v}_i)}$.*
- *Select the buyer i^* with the highest virtual valuation ψ_{i^*}.*
- *If $\psi_{i^*} > v_0$, buyer i^* receives the item and pays the smallest valuation, $\underline{\hat{v}}_i$, that would still have made her win.*
- *If $\psi_{i^*} \leq v_0$, the seller keeps the good and no payments are made.*

In the symmetric setting, the Myerson auction is a second-price auction with an appropriately tailored reserve price. However, this is not the case in the asymmetric setting.

3. TAKE-IT-OR-LEAVE-IT AUCTION

In this section we define our idea of using a sequence of take-it-or-leave-it offers as an auction mechanism.

DEFINITION 2. (Take-it-or-leave-it auction (TLA)) *Let $\mathcal{A} = \langle b_1, a_1\rangle, \langle b_2, a_2\rangle, \ldots, \langle b_k, a_k\rangle$ be a sequence of k offers. Let an offer $\mathcal{A}_j$ be a tuple $\langle b_j, a_j\rangle$, where a_j is the amount of the offer and $b_j \in B$ is the buyer to whom the offer is made. The entire sequence of offers $\mathcal{A}$ is revealed by the seller to the buyers before the auction. The auction proceeds as follows:*

- *For j from 1 to k*
  - *Let $\langle b, a\rangle = \mathcal{A}_j$. The seller offers the good to buyer b for amount a.*
  - *If buyer b accepts, she gets the good and pays a to the seller. The auction ends.*
  - *If buyer b rejects offer a, the auction continues.*
- *If the auction has reached this point, the seller keeps the good and collects no payments.*

It is worth mentioning that every instance of a TLA is *ex ante* individually rational (the strongest such form) since a buyer can always reject any offer. The notion of incentive compatibility (*i.e.* truthtelling) does not apply here since it's not a direct revelation mechanism.

The following auction mechanism turns out to be an interesting special case:

DEFINITION 3. (Single-offer TLA) *A TLA is a* single-offer TLA *if each buyer gets at most one offer, i.e., $b_q \neq b_r$ for all $q, r \in \{1, 2, \ldots, k\}$, $q \neq r$.*

When we need to differentiate between a single-offer TLA and a TLA in which a buyer may receive multiple offers, we will refer to the latter as a *multiple-offer TLA*.

Note that in a TLA it is entirely possible for the seller to allocate the good to a buyer who does not have the highest valuation, thus making the mechanism *inefficient*. This is also the case in the Myerson auction. It is well-known that in the asymmetric setting there is no mechanism that maximizes both seller's expected utility and efficiency.

[5]The proof of optimality of the Myerson auction assumes that the setting is *regular*, i.e., the hazard rate $f_i/(1-F_i)$ is increasing for each buyer i [13]. This assumption is satisfied in all cases where we benchmark against the Myerson auction (in Section 7), so we are benchmarking against the real optimum.

3.1 Strategies and utility

A formal notation for strategies in a TLA is useful. Strategies for TLAs are slightly different than for other auctions since a single buyer may need to make many decisions during the course of an auction.

DEFINITION 4. (Strategy for a TLA) *A buyer's* strategy *for a TLA is a function from the buyer's valuation and the number of the offer (made to that buyer), to one of two possible actions:* accept *or* reject*:*

$$s_i : \mathbb{R} \times \{j \mid b_j = i, j \in \{1, 2, \ldots, k\}\} \rightarrow \{accept, reject\}.$$

A strategy profile *is* $s = (s_1, \ldots, s_n)$*. A* strategy profile excluding s_i *is* $s_{-i} = \{s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_n\}$*, and a* strategy profile s with s_i replaced with s_i' *is* (s_{-i}, s_i')*.*

We make the standard assumption of quasilinearity, that is, a buyer's utility u_i is zero if she does not get the good (and does not pay anything), and $v_i - a$ if she gets the good and pays amount a. Given a strategy profile s and the valuation v_i, the expected utility $u_i(v_i, s)$ of buyer i in a TLA $\mathcal{A}$ is

$$u_i(v_i, s) = \sum_{\{j|b_j=i\}} \left(\prod_{l=1}^{j-1} R_l \right) u_i^j(v_i, s_i)$$

where $u_i^j(v_i, s_i) = \begin{cases} v_i - a_j & if \quad s_i(v_i, j) = accept \\ 0 & if \quad s_i(v_i, j) = reject. \end{cases}$

Here, R_l is the probability that offer l is rejected by buyer b_l if that offer is made. These probabilities depend on the buyers' strategy profile s, as discussed next.[6]

4. EQUILIBRIUM ANALYSIS

We use definitions from game theory to help us understand how rational buyers will behave in a TLA. We use two of the most prevalent solution concepts for sequential games: dominant strategies and perfect Bayesian equilibrium.

4.1 Single-offer TLAs

A strategy s_i^* for a buyer with valuation v_i is called a *dominant strategy* if for all other strategies s_i' and all strategies s_{-i}, we have $u_i(v_i, (s_i^*, s_{-i})) \geq u_i(v_i, (s_i', s_{-i}))$. As the following proposition illustrates, the strategies employed by rational buyers in a single-offer TLA are straightforward and truthful. They are dominant strategies, so a buyer is best off playing that way regardless of what the other buyers' preferences are and even if others play irrationally. Also, a buyer does not have to know much about her own valuation (the determination of which can be a complex optimization problem itself, see e.g. [18, 19, 15, 10]), merely whether it is greater or less than the offer, making a single-offer TLA easy to play.

PROPOSITION 1. *In a single-offer TLA, a buyer's dominant strategy is*

$$s_i^*(v_i, j) = \begin{cases} accept & if \quad v_i > a_j \\ reject & if \quad v_i \leq a_j. \end{cases}$$

The strategy profile $s^* = (s_1^*, s_2^*, \ldots, s_n^*)$ *is thus a dominant strategy equilibrium.*

[6]When buyer i computes the utility, $R_l \in \{0, 1\}$ when $b_l = i$, because the buyer knows her own strategy.

4.2 Multiple-offer TLAs

If the sequence of take-it-or-leave-it offers includes potentially multiple offers per buyer, the buyers' equilibrium strategies become significantly more intricate. The reason is that *a rational buyer will be reluctant to accept an offer at—or somewhat below—her valuation, because there is a chance that the auction will make her a significantly lower offer later on.* The analysis is further complicated by the fact that a buyer's passing on an offer gives a signal to the other buyers and the seller about the buyer's valuation.

In the equilibrium analysis that follows, we study *threshold strategies*. In any finite-action game where types are drawn from independent atomless distributions and each player's utility function does not directly depend on other's types, a pure strategy equilibrium always exists [12]. (This existence result can be extended to the setting with interdependent valuations in several auction-like settings [2].) Clearly, a TLA is such a game. Furthermore, since each buyer receives strictly decreasing offers in an optimal TLA (see Proposition 4), we can restrict our attention to a strategy in which a player can simply decide at the beginning of the game the first offer she will accept. This reasoning partitions the type space into regions, one for each offer. We say these regions are separated by *thresholds*. If the player's type falls within a region, then the first offer the player will accept is the offer corresponding to the region. Thus, without loss of generality we can focus on threshold-based pure strategies in our analysis of an equilibrium of a multiple-offer TLA.

Perfect Bayesian equilibrium (PBE) [8] is the most common solution concept for sequential games with observed actions and private valuations (types). In such a game, with independently drawn valuations, each buyer i has a strategy s_i and beliefs (for each step j of the game, the buyer has, for each other buyer k, a cumulative probability density function F_k^j about the type of k). A strategy profile s^* is a PBE if the following conditions hold: 1) Each buyer updates her beliefs using Bayes rule whenever possible; 2) Whenever it is buyer i's turn to move, s_i prescribes an action that maximizes i's expected utility from then on, given i's beliefs; and the three technical conditions: 3a) At every step of the game, buyer i's beliefs about other buyers are independent of buyer i's valuation, 3b) the beliefs about buyer i can only be changed when i acts, and 3c) at every step of the game, for every triple of buyers i, k, and l ($i \neq l$, $k \neq l$), i and k have the same beliefs about l.

We illustrate the PBE analysis through a 5-offer 2-buyer auction and present the general method after that. For readability, we refer to buyer 1 in the feminine and buyer 2 in the masculine. Suppose that the seller's chosen TLA prescribes that the first offer goes to buyer 1 and the remaining four offers alternate between the buyers.

Buyer 1, when facing the first offer, must decide whether or not she should accept it. If her valuation, v_1, is less than the first offer, a_1, then clearly she must reject. However, the converse is not as simple. *Even though she might stand to gain positive utility by accepting the first offer, she might expect to gain even more utility by rejecting the first offer and accepting a later offer.* For each offer made to a buyer, we would like to compute a *threshold* value above which the buyer will accept and below which she will reject. (If the buyer's valuation is equal to the threshold, she is indifferent between rejecting and accepting.) We will refer to buyer i's

threshold at offer j as t_i^j.

At the last offer made to each buyer, both buyers have dominant strategies. They simply accept if the offer is below their valuation and reject otherwise. This is analogous to the strategies employed by buyers in a single-offer TLA.

Now, consider the third offer (the second offer made to buyer 1). Buyer 1 knows what her utility is if she accepts this offer. She wishes to determine what her *expected* utility is if she rejects the third offer (in a gamble to face the fifth offer). To compute this she needs to compute the probability that buyer 2 rejects the fourth offer. At this point in the game, buyer 1 knows that buyer 2 has rejected the second offer. Assuming buyer 2 is playing in equilibrium, his valuation must be less than t_2^2, his threshold when facing the second offer. Buyer 1 must take this into account when computing the probability that buyer 2 will reject the fourth offer. *That is, buyer 1 updates her belief about the distribution from which buyer 2's valuation is drawn.* Buyer 1 is able to perform these computations using her knowledge about buyer 2's prior distribution, which is common knowledge. After buyer 2 has rejected the second offer, by Bayes rule, the right tail of his valuation distribution (probability density function) above t_2^2 can be cut, and the remaining distribution needs to be rescaled to make its integral one. Thus the new cumulative distribution is $F_2^4(x) = F_2(x)/F_2\left(t_2^2\right)$. (In general, we will write F_i^j to denote the world's belief about buyer i's distribution when facing offer j. If a buyer i is facing her first offer j, then $F_i^j = F_i$.) With this new notation, we can write equations describing the thresholds for buyers 2 and 1 when facing offers 2 and 3, respectively:

$$\begin{aligned} t_2^2 - a_2 &= F_1^3\left(t_1^3\right)\left(t_2^2 - a_4\right) \\ t_1^3 - a_3 &= F_2^4(a_4)\left(t_1^3 - a_5\right). \end{aligned}$$

We evaluate F_1^3 at t_1^3 since we know that buyer 1 will only reject if her valuation is below t_1^3.

Determining the strategy that buyer 1 should use at the first offer is slightly more complicated since buyer 1 could reject the first offer in a hope to accept the third offer or the fifth offer. The following equation describes buyer 1's threshold at the first offer:

$$t_1^1 - a_1 = F_2^2\left(t_2^2\right) \cdot \max\left\{t_1^1 - a_3, F_2^4(a_4)\left(t_1^1 - a_5\right)\right\}.$$

4.2.1 A simplifying observation

At this point we have completely *characterized* the strategies that the buyers will use, but we have said nothing about how to compute these strategies. Computing the strategies is complicated by the max operation in the above equation. The determination of the strategies could be split into cases, with each case corresponding to a particular term within the max operation being greatest. However, as we move beyond 5 offers, this becomes complex. As the number of offers increases by one, the number of max operations in the system increases by one, thus doubling the number of cases to analyze. Therefore, the number of cases is exponential in the number of offers.[7]

This computation would be easier if we could assume that the thresholds only depend on the next offer. In the above equation, this would mean that $t_1^1 - a_3 \geq F_2^4(a_4)\left(t_1^1 - a_5\right)$. We observe that if this inequality does not hold, the third offer would in effect be wasted because it certainly would be rejected. Since this paper is concerned with optimal TLAs, we can assume that such offers will never be made.[8]

4.2.2 Equilibrium for multiple buyers and offers

Algorithm 1 below is a general procedure for generating the system of equations that determines buyers' thresholds. Before describing the algorithm we need to introduce some additional notations. First, we need an expression for evaluating updated distributions:

$$F_i^j(x) = \begin{cases} F_i(x) & \text{if} \quad i \notin \{1, \ldots, b_{j-1}\} \\ \frac{F_i(x)}{F_i\left(t_i^{j'}\right)} & \text{if} \quad i \in \{1, \ldots, b_{j-1}\} \end{cases}$$

where j' is the most recent offer made to buyer i. Second, we need an expression for the probability that a buyer will reject a given offer j:

$$R_j = \begin{cases} F_{b_j}^j(a_j) & \text{if} \quad b_j \notin \{b_{j+1}, \ldots, b_k\} \\ F_{b_j}^j\left(t_{b_j}^j\right) & \text{if} \quad b_j \in \{b_{j+1}, \ldots, b_k\}. \end{cases}$$

The above value R_j depends on whether or not the buyer faces another offer or not. If the buyer does face another offer, then the expression involves a threshold value. Otherwise, the expression only involves the offer. The algorithm below makes a pass through the offers. If an offer is not the last one offered to a buyer, then an equation is output containing an expression for the threshold.

ALGORITHM 1.
// *Output system of threshold equations*

- *For j from 1 to k, If buyer b_j faces another offer j' after offer j*
  - *Then output the equation*

$$t_{b_j}^j - a_j = R_{j+1}R_{j+2}\cdots R_{j'-1}\left(t_{b_j}^j - a_{j'}\right)$$

The product of R_j's that is output for each equation is the expression describing the probability that the auction will go from offer $j+1$ to offer j' without a buyer accepting an offer.

With the above discussion in mind, we can now present our main equilibrium result.

THEOREM 2. *Suppose we have a multiple-offer TLA $\mathcal{A} = \langle b_1, a_1\rangle, \langle b_2, a_2\rangle, \ldots, \langle b_k, a_k\rangle$ that is optimal in the sense of maximizing the seller's utility, subject to the constraint that only k offers are made. Consider the following strategy for buyer i with valuation v_i facing offer a_j:*

$$s_i^*(v_i, a_j) = \begin{cases} accept & \text{if} \quad v_i > a_j, i \notin \{b_{j+1}, \ldots, b_k\} \\ reject & \text{if} \quad v_i \leq a_j, i \notin \{b_{j+1}, \ldots, b_k\} \\ accept & \text{if} \quad v_i > t_i^j, i \in \{b_{j+1}, \ldots, b_k\} \\ reject & \text{if} \quad v_i \leq t_i^j, i \in \{b_{j+1}, \ldots, b_k\} \end{cases}$$

where the t_i^j values solve the system of equations generated by Algorithm 1. The strategy profile $s^* = (s_1^*, s_2^*, \ldots, s_n^*)$ is a perfect Bayesian equilibrium.

[7]Actually, the number of cases is further increased by the fact that as an offer is added, the number of terms in the existing max operations of that buyer's threshold equations increases by one (a max operations with 2 terms is added in the equation where there was no max operation before).

[8]This assumes that the order in which buyers receive offers is not fixed. If this order is fixed (for example, due to external constraints), then making a surely rejected offer can be beneficial in order to *in effect* change the order without actually changing it.

PROOF. It is easy to see that the technical Conditions 3a-3c of PBE are satisfied. As described above, the buyers update their beliefs using Bayes rule whenever possible, so Condition 1 is satisfied. What remains to be shown is that Condition 2 is satisfied, i.e., that it is never profitable to deviate from the above strategy (in any of the four scenarios). For the first two scenarios, the proof is analogous to the proof of Proposition 1. For the other two scenarios, in which the buyers face another offer later in the auction, we need to make use of the thresholds. Consider buyer i with valuation v_i, facing offer a_j. Let $a_{j'}$ be the next offer that buyer i faces. Suppose $v_i > t_i^j$, but buyer i rejects. The highest expected utility she can expect to get later in the auction is $R_{j+1} \cdots R_{j'-1}(v_i - a_{j'})$. But, by the construction of the thresholds (and the fact that the thresholds only depend on the next offer), this is less than $v_i - a_j$. So buyer i is better off accepting the offer. The scenario where $v_i \leq t_i^j$ is proven similarly. □

5. OPTIMIZING THE OFFERS

So far we have described how we would expect buyers to behave in a TLA. Now we turn to the problem faced by the seller: how to maximize expected utility? The seller can choose the order in which the offers are made as well as the offer values. Before describing the optimization problem, we formalize the seller's objective.

DEFINITION 5. (Seller's expected utility) *Given an instance $\mathcal{A}$ of a TLA, the seller's expected utility from step j onward is defined recursively as*

$$\pi_j = \begin{cases} (1 - R_j)\, a_j + R_j v_0 & \text{if } j = k \\ (1 - R_j)\, a_j + R_j \pi_{j+1} & \text{if } j < k. \end{cases}$$

The seller's expected utility *is given by π_1, and we denote it by $\pi(\mathcal{A})$.*

We can now formally define the design problem faced by the seller.

DEFINITION 6. (TLA design problem) *Given a limit k_{max} on the number of offers made, the seller's TLA* design problem *is to compute $\mathcal{A}^* = \text{argmax}_{\{\mathcal{A} \mid |\mathcal{A}| \leq k_{max}\}} \pi(\mathcal{A})$.*

Note that in Definition 6 the k_{max} parameter is exogenous. It is a constraint imposed on the optimization problem that comes from some external source, for example a limit on the amount of time or resources the seller is able to commit to the auction.

We now discuss some characteristic properties of optimal TLAs.

PROPOSITION 3. *For any given TLA design problem, an optimal TLA exists in which no buyer receives consecutive offers.*

PROOF. If a buyer receives consecutive offers, she will never accept any of them except possibly the lowest. Thus, the other ones of those offers can be removed from $\mathcal{A}$. □

Offers might not decrease over time in optimal TLAs:

EXAMPLE 1. *Consider the 2-buyer, 3-offer setting where buyer 1's valuation is uniformly distributed on the interval $[0, 1]$ and buyer 2's valuation is uniformly distributed on the interval $[1, 4]$. The only optimal sequence of offers is $\mathcal{A} = \langle 2, 2.125\rangle, \langle 1, 0.5275\rangle, \langle 2, 2.0\rangle$.*

However, decreasing offers can be made to each buyer:

PROPOSITION 4. *For any given TLA design problem, an optimal TLA exists in which each buyer individually receives strictly decreasing offers.*

PROOF. If, in equilibrium, all the rejection probabilities R_j of the other buyers that get offers in between two offers of buyer i are zero, that is equivalent to buyer i receiving consecutive offers, which is unnecessary by Proposition 3. We can therefore restrict attention, without loss in the seller's expected utility, to TLAs where this never occurs.

We now show that a buyer will never accept an offer that is equal to or higher than her previous offer. The main idea is that since the buyer knows the sequence of offers at the start of the auction, she knows she can get more utility by accepting an earlier, lower offer, rather than accepting the later, higher offer. Suppose that in an optimal TLA, buyer i is offered a_j at some point in the auction, and the next offer to buyer i is $a_{j'}$, where $a_j \leq a_{j'}$. Without loss of generality, say buyer i's valuation v_i is at least $a_{j'}$. (If it is less than, then buyer i will clearly never accept the offer.) Then the expected utility from accepting offer a_j is $v_i - a_j$, while the expected utility from rejecting offer a_j and later accepting offer $a_{j'}$ is strictly less than $v_i - a_{j'}$ since the utility must be multiplied by the probability that the auction will continue to offer $a_{j'}$ without another buyer accepting an offer and thus ending the auction. Let r denote the probability that no other buyer accepts in between. Since $a_j \leq a_{j'}$ and $r < 1$ (by the argument in the paragraph above), we have $v_i - a_j > r(v_i - a_{j'})$, so buyer i will never accept offer $a_{j'}$. Thus, the wasted offer a'_j can be removed from the auction and the auction remains optimal. □

6. COMPUTATIONAL RESULTS

In this section we develop the computational methodology for solving for an optimal TLA (which involves as a subproblem solving for how the buyers will behave). Designing a TLA involves finding an order (the b_j values) in which the buyers receive the offers, and determining the value of each offer (the a_j values).

6.1 Multiple-offer TLAs

In computing the optimal multiple-offer TLA, we assume that the order of the offers is fixed (e.g., one can include an outer loop to try all orders) and then optimize the TLA for that order as follows.

We run Algorithm 1 to generate the equations for the thresholds t_i^j. Because the shorthand values R_j are expanded in each of those equations, each equation has on the right hand side the offer levels $a_1, a_2, \ldots, a_k$, the specific functional forms of the prior distributions on the types $F_1, F_2, \ldots, F_n$, and the thresholds t_i^j. To compute the optimal offers, we run a non-linear optimizer with these equations as constraints and the expanded recursion for $\pi(\mathcal{A})$ from Definition 6 as the objective, which is now just a function of the offer levels $a_1, a_2, \ldots, a_k$. The output of the optimizer is the values of the optimal offer levels $a_1^*, a_2^*, \ldots, a_k^*$.

The computational complexity of the above procedure is difficult to analyze. Indeed, non-linear optimization problems as a class have resisted rigorous analysis. However, algorithms for finding local optima behave well in practice.

6.1.1 A tractable case

Although the question of complexity remains open for the general case, we have developed a linear-time algorithm for the special case of two buyers with uniform distributions on the interval $[0, 1]$. This algorithm relies heavily on results obtained recently [5, 6]. The authors examine auctions in which the amount of information a buyer can transmit to the seller is severely limited. One of the main results is that when a buyer is limited to choosing from among k possible messages, the buyer's valuation range is partitioned into k continuous intervals (the intervals are, in general, asymmetric among the bidders). The buyer signals which interval her valuation happens to fall in. It turns out that the thresholds that separate the intervals are the same as the equilibrium thresholds in an optimal TLA. (Note that these are the equilibrium thresholds, not the offer levels.) This is easily seen by considering a TLA where each buyer receives k offers, and thus has k threshold values. The TLA could be converted to a direct mechanism where the buyer simply states the first offer that she is willing to accept. Then the problem of computing the thresholds in a TLA becomes the same as computing the thresholds in a communication-bounded auction. The following theorem from [5] (stated using our threshold notation) motivates Algorithm 2.

THEOREM 5. *([5]) When there are two buyers with valuations drawn uniformly from the interval* $[0, 1]$ *the thresholds in an optimal* $2k$*-offer TLA,* $k \geq 2$*, are:*

$$t_i^j = \begin{cases} t + \frac{(2k-j-1)\cdot(1-t)}{2k-3} & \text{if} \quad j \in \{1, 2, \ldots, 2k-1\} \\ \frac{1}{2} & \text{if} \quad j = 2k \end{cases}$$

where $t = \frac{-2\alpha+\sqrt{1+3\alpha}}{2(1-\alpha)}$ *and* $\alpha = \frac{1}{(2k-3)^2}$*. The first offer in the TLA goes to buyer 1, and the offers alternate after that.*

Algorithm 2 computes the offer levels for a multiple-offer TLA with two buyers having uniform distributions on the interval $[0, 1]$.

ALGORITHM 2.
// Let $k_{max} \geq 4$ *be an even number denoting the total number of offers made.*

1. *(Initialize.)* $k \leftarrow \frac{k_{max}}{2}+1$, $\alpha \leftarrow \frac{1}{(2k-3)^2}$, $t \leftarrow \frac{-2\alpha+\sqrt{1+3\alpha}}{2(1-\alpha)}$, $t_2^{k_{max}} \leftarrow \frac{1}{2}$
2. *(Compute thresholds.) For* j *from* 1 *to* $k_{max} - 1$
   (a) *If* j *is odd, then* $i \leftarrow 1$*, else* $i \leftarrow 2$
   (b) $t_i^j \leftarrow t + \frac{(k_{max}-j-1)(1-t)}{2k-3}$
3. *(Compute last offers.)* $a_{k_{max}} \leftarrow t_2^{k_{max}}$, $R_{k_{max}} \leftarrow \frac{a_{k_{max}}}{t_2^{k_{max}-2}}$, $a_{k_{max}-1} \leftarrow t_1^{k_{max}-1}$, $R_{k_{max}-1} \leftarrow \frac{a_{k_{max}-1}}{t_1^{k_{max}-3}}$
4. *(Compute offers.) For* j *from* $k_{max} - 2$ *down to 1*
   (a) *If* j *is odd, then* $i \leftarrow 1$*, else* $i \leftarrow 2$
   (b) $a_j \leftarrow t_i^j - R_{j+1}\left(t_i^j - a_{j+2}\right)$
   (c) *If* $j > 2$*, then* $R_j \leftarrow \frac{t_i^j}{t_i^{j-2}}$*, else* $R_j \leftarrow t_i^j$

THEOREM 6. *Algorithm 2 computes an optimal TLA for the setting with two buyers having uniform distributions on the interval* $[0, 1]$*.*

PROOF. Immediate from Theorems 2 and 5. □

6.2 Single-offer TLAs

Now we are considering single-offer TLAs, so we have $k_{max} \leq n$ by definition. Since making at least some offer to every buyer cannot hurt the seller's expected utility, we always have an optimal single-offer TLA with $k = k_{max}$. So, we set $k = k_{max}$.

For convenience, we will think of the optimization problem as two separate problems. The first problem is to determine the order in which the buyers receive the offers. The second problem is to compute the actual offer values.

First, consider symmetric settings, i.e., $F_i = F_j$ for all buyers i, j. In this case the order does not matter, so we set them arbitrarily. The offer values can be determined by first making an offer to the last bidder equal to the inverse virtual valuation of the reserve price and computing the expected profit from this offer as the new reserve price. Formally:

ALGORITHM 3.
// Compute offers for single-offer TLA

1. *(Initialize.)* $\pi \leftarrow v_0$
2. *(Compute offers.) For* i *from* k_{max} *down to 1*
   (a) $a_i \leftarrow argmax_a \left(1 - F_i(a)\right) a + F_i(a)\pi$
   (b) $\pi \leftarrow (1 - F_i(a_i))a_i + F_i(a_i)\pi$

PROPOSITION 7. *Algorithm 3 computes an optimal single-offer TLA in the symmetric settings.*

PROOF. Consider the last offer made in a TLA. The result of the last offer does not affect the result of any of the other offers. Thus, the seller should make an optimal offer, which is computed in step 2(a) during the first iteration. Now consider the next to last offer. Again, the result of this offer does not affect any of the previous offers. Also, the expected utility the seller earns if this offer is rejected has already been computed and is stored in π. Thus, the offer computed in step 2(a) is the optimal offer. Continuing with this backward induction, it is easy to see that Algorithm 3 correctly computes the optimal offer levels. □

If we assume that F_i can be evaluated in constant time and that the "argmax" computation can also be done in constant time, then Algorithm 3 runs in time linear in the number of offers k_{max}. For a wide range of common distributions, including uniform and exponential distributions, these assumptions hold.

Now, consider asymmetric settings. Clearly the order of offers now can make a difference to the seller's expected utility. For general asymmetric preferences, we do not know of an efficient algorithm for ordering the offers. (For example, always greedily making an offer to the remaining buyer from whom the seller can myopically expect the greatest utility is not generally optimal.) One could try all possible orderings, running Algorithm 3 to evaluate each ordering. However, for a large number of buyers this would be infeasible since the number of orderings is $k_{max}!$. Fortunately, we have been able to show that in some commonly used special cases one can order the buyers in polynomial time. Theorem 8 illustrates just one of many results. We denote a uniform distribution over the interval $[a, b]$ as $\mathrm{U}[a, b]$.

THEOREM 8. *With* $v_i \sim \mathrm{U}[0, w_i]$*, an optimal single-offer TLA can be determined in* $O(n \log n)$ *time by sorting the buyers in decreasing order of* w_i *and passing the sequence to Algorithm 3.*

PROOF. Omitted due to space. □

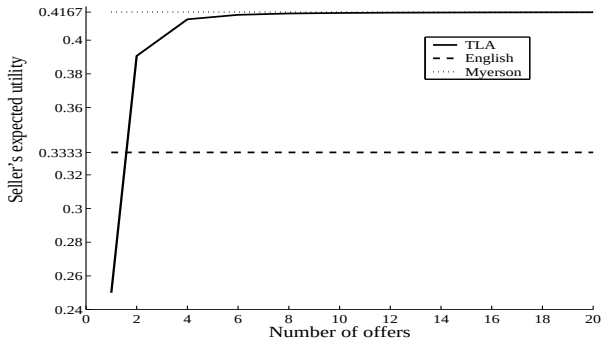

Figure 1: Seller's expected utility as the number of offers increases. The two buyers' valuations have uniform distributions on the interval $[0, 1]$.

7. ECONOMIC PERFORMANCE OF TLAS

In this section we present experiments and theoretical results to give an indication of how one can expect our TLAs, optimized as explained above, to perform in practice. (Throughout these experiments, we set the seller's valuation v_0 to zero.)

First we studied the performance of our optimal single-offer TLA as the number of buyers increases. Naturally, as the number of buyers increases, the expected utility of the single-offer TLA increases. Table 1 shows how well an optimal single-offer TLA fares relative to Myerson's utility-maximizing auction as the number of buyers increases (and each buyer is made exactly one offer).[9] The single-offer TLA is close to optimal. Interestingly, the relative performance does not improve monotonically, but does improve when the number of buyers is large.[10] The advantage of our single-offer TLA over the English auction is greatest when the number of buyers is not very large. Also, it tends to be greatest in the asymmetric settings. (Naturally, our multiple-offer TLAs would yield even greater expected utility for the seller.) In the case of 1 buyer, a TLA performs exactly as the Myerson auction, and the English auction does not generate any expected utility for the seller.

Figure 1 shows how the seller's expected utility in an optimal multiple-offer TLA increases as the number of offers increases. As can be seen, the TLA performs extremely well after a small number of offers. We also studied how well the seller's expected utility in an optimal multiple-offer TLA increases as the number of offers increases. The following result, which follows immediately from a result in [5] and the correspondence between communication-bounded auctions and TLAs, shows that we can expect a TLA to perform well for a wide variety of distributions.

THEOREM 9. *([6]) The revenue loss in an optimal k-offer TLA with symmetric buyers having regular distributions*[11] *is* $O\left(\frac{1}{k^2}\right)$.

For some distributions, including the uniform distribution, the above bound is tight. This result is asymptotic, but in practice TLAs yield close to optimal expected utility for the seller, as exemplified in Table 2 where we considered several 2-buyer settings, showing how close a TLA gets to the expected utility generated by Myerson's utility-maximizing auction as the number of offers increases. Even with a small number of offers, the expected utility of a TLA is close to optimal, and increases monotonically with the number of offers.

Total number of offers:	1	2	3	English
$v_1 \sim$ U$[0,1]$, $v_2 \sim$ U$[0,1]$	.600	.938	.979	.800
$v_1 \sim$ U$[0.5,2]$, $v_2 \sim$ U$[0,1]$	.857	.977	.992	.625
$v_1 \sim$ U$[1,4]$, $v_2 \sim$ U$[0,1]$	.932	.994	.997	.350
$v_1 \sim$ Exp$[2]$, $v_2 \sim$ Exp$[2]$	.551	.932	.977	.749
$v_1 \sim$ Exp$[2]$, $v_2 \sim$ Exp$[4]$	.726	.968	.986	.658

Table 2: Seller's expected utility of an optimal 2-buyer TLA and English auction divided by the expected utility of the Myerson auction. The number of offers for the TLA is varied from 1 to 3. In each case, it is optimal to give the first offer to buyer 1

In principle, it is possible to achieve optimal expected revenue using an ascending auction, albeit one with asymmetric prices. We call such an auction an *asymmetric ascending auction*. (An asymmetric descending auction can be constructed similarly.) In an ascending auction, there is a single price, visible by all bidders, that rises. Bidders drop out when they no longer would like to buy the item at the current price. As discussed previously, this auction does not generate optimal expected revenue for the seller and in fact can be arbitrarily far from optimal. Alternatively, in an asymmetric ascending auction, there is a single price (the *virtual price*) that rises. But instead of the auctioneer communicating this price to the bidders, she insteads communicates asymmetric prices to each bidder, using the inverse of the virtual valuation function evaluated at the current virtual price to compute prices for each bidder. It is straightforward to demonstrate that this method generates optimal expected revenue for the seller.[12]

One advantange of TLAs over asymmetric ascending auctions is that much less communication is required. This is especially important in auctions in which there is some cost to communication, for example when the bidders and the auctioneer communicate via a network. (In general, there is no upper bound on the amount of communication required for an ascending auction.) In fact, a TLA is, in some sense, an approximation of an asymmetric descending auction when there is some limit on the communication resources available to the bidders.

Finally, we mention that a single-offer TLA implements the Myerson auction in the case of a single buyer.

8. MECHANISMS SIMILAR TO TLAS

We are aware of one fielded mechanism that is similar to a TLA. Amazon.com has recently introduced the "Gold Box" on their web site [1]. Each day, registered users are given up to ten take-it-or-leave-it offers for ten different goods. The offers expire after one hour, and after an offer is rejected, it is no longer available to the user. The offer levels appear to

[9] We denote the exponential distribution having mean $1/\mu$ as Exp$[\mu]$ (its cumulative density is $F(x) = 1 - e^{-\mu x}$).

[10] In the third row, the optimal single-offer TLA deterministically allocates the good to the highest buyer, thus making the allocation *efficient* in this case, where the Myerson auction is inefficient.

[11] Recall that a distribution F_i is said to be regular if $f_i/(1 - F_i)$ is increasing.

[12] As in the proof of the optimality of the Myerson auction, the bidders' distributions must be regular for the result to hold.

Num buyers:	1	2	4	6	8	10	20	100
$v_i \sim \mathrm{U}[0,1]$	1 / 0	.938 / .800	.981 / .978	.894 / .997	.900 / 1	.907 / 1	.937 / 1	.992 / 1
$v_i \sim \mathrm{U}[0,i]$	1 / 0	.980 / .646	.959 / .844	.953 / .898	.952 / .922	.952 / .936	.958 / .963	.979 / .987
$v_i \sim \mathrm{U}[i,i+1]$	1 / 0	.979 / .735	.990 / .866	.993 / .910	.995 / .933	.996 / .946	.998 / .973	1 / .995
$v_i \sim \mathrm{Exp}[2]$	1 / 0	.932 / .749	.994 / .961	.847 / .991	.837 / .997	.833 / .999	.836 / 1	.872 / 1
$v_i \sim \mathrm{Exp}[i]$	1 / 0	.509 / .657	.917 / .813	.900 / .824	.918 / .822	.927 / .819	.942 / .813	.948 / .810

Table 1: The left (right) number in each cell is the ratio of the expected utility of an optimal single-offer TLA (English auction) to the expected utility of the Myerson auction.

be below the normal retail price, but we do not know what pricing strategy is in use. The techniques developed in this paper could be used to compute optimal values for these prices so as to maximize Amazon's expected utility (under certain reasonable assumptions).

A piece of closely related research concerns online auctions [11] and online exchanges [4]. In those papers the authors examine how bids should be treated in an online setting where the auctioneer (or exchange administrator) has to make accept/reject decisions about expiring bids before all potential future bids are received. The authors have developed online algorithms and analyzed how well their algorithms do compared to an omniscient algorithm that knows all future bids in advance. Many of those algorithms end up choosing bid acceptance thresholds, so in that sense they use (implicit) take-it-or-leave-it offers.

This setting differs from ours in that there is not only uncertainty about future decisions that will be made, but there is uncertainty about the types of decisions that will be faced. In our setting, the sequence of offers is known in advance by all parties. In addition, in the online model there are multiple units of the item available for exchange, while we have focused only on the single unit case.

Finally, most retail is of the form of making take-it-or-leave-it offers. In the typical retail setting the seller posts price for each item she wishes to sell. The seller generally does not have specific information about a given buyer, and so all buyers face the same prices (i.e. the prices are *non-discriminatory*). This distinguishes the typical retail setting from single-offer TLAs where the prices are *discriminatory*.

9. CONCLUSIONS AND FUTURE WORK

We introduced TLAs as a selling (or buying) mechanism that has low valuation revelation as do the most commonly used auction mechanisms (English and Dutch auctions), yet, unlike them, generates close-to-optimal expected utility for the seller. We showed that in single-offer TLAs, each buyer's dominant strategy is to act truthfully. In multiple-offer TLAs, the buyers' optimal strategies are more intricate, and we derived the perfect Bayesian equilibrium for the game. We developed algorithms for finding the equilibrium and for optimizing the offers in single-offer and multiple-offer TLAs so as to maximize the seller's expected utility (subject to an exogenous constraint on the number of offers), and proved that optimal TLAs have many desirable features. We applied a result due to Blumrosen and Nisan to TLAs to show that the seller's expected utility is close to optimal already for a small number of offers. We also showed in several examples that as the number of buyers increases, the seller's expected utility increases and becomes increasingly (but not monotonically) more competitive with Myerson's expected utility maximizing auction. Myerson's uses full valuation revelation and is arguably impractical because the rules are unintuitive, unlike ours in which the mechanism is simply a sequence of take-it-or-leave-it offers. Even our single-offer TLA tends to yield significantly greater utility to the seller than the English auction when the setting is asymmetric or the number of buyers is not very large.

Future research includes developing fast offer-ordering algorithms for asymmetric single-offer TLAs for arbitrary valuation distributions, as well as fast special-purpose algorithms for PBE finding, offer ordering, and offer value optimization in multiple-offer TLAs. We also plan to extend this work to auctions of multiple identical units and to auctions of multiple distinguishable items.

ABSTRACT

This paper develops a new combinatorial auction protocol called the Groves Mechanism with SubModular Approximation (GM-SMA). This protocol satisfies the following characteristics: (1) it is false-name-proof, (2) each winner is included in a Pareto efficient allocation, and (3) as long as a Pareto efficient allocation is achieved, the protocol is robust against the collusion of losers and the outcome is in the core. As far as the authors are aware, the GM-SMA is the first protocol that satisfies all three of these characteristics.

The basic ideas of the GM-SMA are as follows: (i) It is based on the VCG protocol, i.e., the payment of a winner in this protocol is identical to the payment in one instance of the Groves mechanism, which is a class of protocols that includes the VCG. (ii) When calculating the payment of a bidder, we approximate the valuations of other bidders by using a submodular valuation function (submodular approximation). Simulation results show that the GM-SMA achieves a better social surplus and seller's revenue than existing false-name-proof protocols, as long as the submodular approximation is close enough to the original valuations.

1. INTRODUCTION

Internet auctions have become an integral part of Electronic Commerce and a promising field for applying AI and agent technologies. Among various studies related to Internet auctions, those on combinatorial auctions have lately attracted considerable attention (an extensive survey is presented in [3]). Although conventional auctions sell a single item at a time, combinatorial auctions sell multiple items with interdependent values simultaneously and allow the bidders to bid on any combination of items. In a combinatorial auction, a bidder can express complementary or substitutable preferences over multiple bids. By taking into account complementary/substitutable preferences, we can increase the participants' utilities and seller's revenue.

One desirable characteristic of an auction protocol is that it is *strategy-proof*. A protocol is strategy-proof if, for each bidder, declaring his/her true valuation is a *dominant strategy*, i.e., an optimal strategy regardless of the actions of other bidders. In theory, the revelation principle states that in the design of an auction protocol, we can restrict our attention to strategy-proof protocols without loss of generality [8]. In other words, if a certain property (e.g., Pareto efficiency) can be achieved using some auction protocol in a dominant-strategy equilibrium, i.e., a combination of dominant strategies of bidders, then the property can also be achieved using a strategy-proof auction protocol.

Furthermore, a strategy-proof protocol is also practical for Internet auctions. For example, if we use the first-price sealed-bid auction, which is not strategy-proof, the bidding prices must be securely concealed until the auction is closed. On the other hand, if we use a strategy-proof protocol, knowing the bidding prices of other bidders is useless; consequently, such security issues become less critical.

The Vickrey-Clarke-Groves (VCG) protocol [2, 4, 9] is a strategy-proof protocol that can be applied to combinatorial auctions. The VCG protocol satisfies Pareto efficiency. Under several natural assumptions, the VCG protocol is the only strategy-proof, Pareto efficient protocol [6].

However, the VCG protocol has several limitations, including the problems described below.

Vulnerability to false-name bids: The authors have pointed out the possibility of a new type of fraud called false-name bids, which utilizes the anonymity available on the Internet [11, 12]. False-name bids are bids submitted under fictitious names, e.g., multiple e-mail addresses. Such a dishonest action is very difficult to detect, since identifying each participant on the Internet is virtually impossible.

We say a protocol is *false-name-proof* if, for each bidder,

declaring his/her true valuations using a single identifier (although the bidder can use multiple identifiers) is a dominant strategy. The VCG is not false-name-proof [11, 12].

Vulnerability to loser collusion: As shown in [1], in the VCG protocol, there is a chance that some bidders, who would be losers if they bid their true valuations, become winners and increase their utility if they collude and adjust their bids.

The outcome is not in the core: As shown in [1], in the VCG protocol, there is a chance that the result of the auction is not in the core. This means that a seller has an incentive to deviate from the protocol and to sell goods to the bidders who are not winners in the VCG protocol.

In this paper, we introduce a new combinatorial auction protocol called the *Groves Mechanism with SubModular Approximation* (GM-SMA). The basic ideas of this protocol are as follows.

- This protocol is based on the VCG protocol. More precisely, the payment of a winner in this protocol is identical to the payment in one instance of the Groves mechanism [4], which is a class of protocols that includes the VCG[1].
- In this protocol, when calculating the payment of bidder i, we approximate the valuations of bidders except for i, by using a *submodular* valuation function (submodular approximation).

The GM-SMA satisfies the following characteristics.

(1) The GM-SMA is false-name-proof.

(2) In the GM-SMA, each winner is a bidder who is included in a Pareto efficient allocation[2].

(3) In the GM-SMA, as long as the allocation is Pareto efficient, the protocol is robust against the collusion of the losers and the outcome is in the core.

As far as the authors are aware, the GM-SMA is the first protocol that satisfies all three of these characteristics.

The VCG protocol can always achieve a Pareto efficient allocation as long as there exists no false-name bid. However, it is not false-name-proof and cannot guarantee to achieve a Pareto efficient allocation when false-name bids are possible. In addition, even without false-name bids, the VCG protocol does not satisfy characteristic (3).

Furthermore, in existing false-name-proof protocols [10, 11], characteristic (2) is not satisfied, i.e., a bidder who is not included in any Pareto efficient allocation becomes a winner quite often. In such a case, the outcome is not in the core. Also, losers who are in a Pareto efficient allocation will have a strong incentive to collude and act as a single bidder.

In [1], an ascending protocol that utilizes a proxy is presented. In this protocol, a bidder cannot increase his/her utility by using multiple identifiers. Also, as long as each bidder bids straightforwardly, a Pareto efficient allocation is achieved and characteristic (3) is satisfied. However, unless the valuations of bidders are submodular, bidding straightforwardly is not a dominant strategy, i.e., a bidder may have an incentive to misreport his/her valuation.

The rest of this paper is organized as follows. First, we describe the model of combinatorial auctions (Section 2). Next, we describe a general framework for describing strategy-proof and false-name-proof protocols called the Price-Oriented, Rationing-Free (PORF) protocol [10] (Section 3). By describing a protocol as a PORF protocol, proving the protocol is strategy/false-name proof becomes much easier. Then, we describe the VCG protocol and its limitations (Section 4) as well as existing false-name-proof protocols and their limitations (Section 5). Furthermore, we describe the details of the GM-SMA (Section 6) and show its characteristics (Section 7). Finally, we evaluate the social surplus and the revenue of the seller in the GM-SMA through a simulation (Section 8).

2. MODEL

Assume there are a set of bidders $N = \{1, 2, \ldots, n\}$ and a set of goods $M = \{1, 2, \ldots, m\}$. Each bidder i has his/her preferences over $B \subseteq M$. Formally, we model this by supposing that bidder i privately observes a parameter, or signal, θ_i, which determines his/her preferences. We refer to θ_i as the *type* of bidder i. We assume θ_i is drawn from a set Θ. We also assume a *quasi-linear, private value* model with *no allocative externality*, defined as follows.

DEFINITION 1. *utility of a bidder*
The utility of bidder i, when i obtains a bundle, i.e., a subset of goods $B \subseteq M$ and pays $p_{B,i}$, is represented as $v(B, \theta_i) - p_{B,i}$.

We assume the valuation v is normalized by $v(\emptyset, \theta_i) = 0$. Furthermore, we assume *free disposal*, i.e., $v(B', \theta_i) \geq v(B, \theta_i)$ for all $B' \supseteq B$.

In a traditional definition [7], an auction protocol is (dominant strategy) *incentive compatible* (or *strategy-proof*) if declaring the true type/valuation is a dominant strategy for each bidder, i.e., an optimal strategy regardless of the actions of other bidders.

In this paper, we extend the traditional definition of incentive compatibility so that it can address false-name bid manipulations, i.e., we define that an auction protocol is (dominant strategy) incentive compatible if declaring the true type *by using a single identifier* is a dominant strategy for each bidder. To distinguish between the traditional and extended definitions of incentive compatibility, we refer to the traditional definition as strategy-proof and to the extended definition as *false-name-proof*.

As in the case of strategy-proof protocols, the revelation principle holds for false-name-proof protocols [12]. Thus, we can restrict our attention to false-name-proof protocols without loss of generality.

We say an auction protocol is *Pareto efficient* when the sum of all participants' utilities (including that of the auctioneer), i.e., the social surplus, is maximized in a dominant-strategy equilibrium. We have proved that there exists no false-name-proof protocol that satisfies Pareto efficiency [12]. Therefore, we need to sacrifice efficiency to some extent when false-name bids are possible.

[1]Strictly speaking, the GM-SMA is not an instance of the Groves mechanism, since it is not guaranteed to achieve a Pareto efficient allocation.

[2]Note that the converse is not true, i.e., a bidder who is included in a Pareto efficient allocation is not necessarily a winner. Thus, there is a chance that the GM-SMA could fail to achieve a Pareto efficient allocation. This is inevitable since the GM-SMA is false-name-proof [12].

3. PRICE-ORIENTED, RATIONING-FREE (PORF) PROTOCOL

In this section, we describe a general framework for describing strategy-proof protocols called Price-Oriented, Rationing-Free (PORF) protocol [10]. By describing a protocol as a PORF protocol, proving that the protocol is strategy-proof or false-name-proof becomes much easier.

A PORF Protocol is defined as follows.

DEFINITION 2. *PORF Protocol*

- *Each bidder i declares his/her type $\tilde{\theta}_i$, which is not necessarily the true type θ_i.*
- *For each bidder i and for each bundle $B \subseteq M$, the price $p_{B,i}$ is defined. This price must be determined independently of i's declared type $\tilde{\theta}_i$, while it can be dependent on declared types of other bidders.*
- *We assume $p_{\emptyset,i} = 0$ holds. Also, if $B \subseteq B'$, $p_{B,i} \leq p_{B',i}$ holds.*
- *For bidder i, a bundle B^* is allocated, where $B^* = \arg\max_{B \subseteq M} v(B, \tilde{\theta}_i) - p_{B,i}$. Bidder i pays $p_{B^*,i}$. If there exist multiple bundles that maximize i's utility, one of these bundles is allocated.*
- *The result of the allocation satisfies* allocation feasibility*, i.e., for two bidders i, j and bundles allocated to these bidders B_i^* and B_j^*, $B_i^* \cap B_j^* = \emptyset$ holds.*

It is straightforward to show that a PORF protocol is strategy-proof. The price of bidder i is determined independently of i's declared type, and he/she can obtain the bundle that maximizes his/her utility independently of the allocations of other bidders, i.e., the protocol is rationing-free.

On the other hand, in a PORF protocol, the prices must be determined appropriately to satisfy allocation feasibility. The definition of a PORF protocol requires that if there exist multiple bundles that maximize i's utility, then one of these bundles must be allocated, but it does not specify exactly which bundle should be allocated. Therefore, if there exist multiple choices, the auctioneer can adjust the allocation of multiple bidders in order to satisfy allocation feasibility.

In [10], it is shown that any strategy-proof protocol can be described as a PORF protocol, i.e., the following theorem holds.

THEOREM 1. *If a protocol is strategy-proof, then the protocol can be described as a PORF protocol.*

In this paper, we assume that a protocol satisfies the following condition.

DEFINITION 3. *weakly-anonymous pricing rule (WAP) For bidder i, the price of bundle B is given as a function of the types of other bidders, i.e., the price can be described as $p(B, \Theta_{N'})$, where N' is the set of bidders other than i, and $\Theta_{N'}$ is the set of types of bidders in N'.*

The above condition requires that if two bidders face the same types of opponents, their prices must be identical for all bundles. The WAP condition is intuitively natural and virtually all well-known protocols, including the VCG, satisfy this condition.

For a PORF protocol that satisfies the WAP condition, we define the following additional condition.

DEFINITION 4. *no super-additive price increase (NSA) For any subset of bidders $S \subseteq N$ and $N' = N \setminus S$, and for $i \in S$, let us denote B_i as a bundle that maximizes i's utility, then $\sum_{i \in S} p(B_i, \bigcup_{j \in S \setminus \{i\}} \{\theta_j\} \cup \Theta_{N'}) \geq p(\bigcup_{i \in S} B_i, \Theta_{N'})$.*

An intuitive description of this condition is that the price of buying a combination of bundles (the right side of the inequality) must be smaller than or equal to the sum of the prices for buying these bundles separately (the left side).

In [10], it is shown that for a PORF protocol with the WAP, the NSA is a sufficient condition for a protocol to be false-name-proof, i.e., the following theorem holds.

THEOREM 2. *If a PORF protocol with the WAP satisfies the NSA condition, then the protocol is false-name-proof.*

4. VCG PROTOCOL

Next, we show how the VCG protocol can be described as a PORF protocol. Since a PORF protocol is strategy-proof, in the rest of this paper, we assume each bidder i declares his/her true type θ_i.

To simplify the protocol description, we introduce the following notation. For a set of goods B and a set of bidders S, where Θ_S is a set of types of bidders in S, we define $V^*(B, \Theta_S)$ as the sum of the valuations of S when B is allocated optimally among S.

To be precise, for a feasible allocation $g = (B_1, B_2, \ldots)$, where $\bigcup_{i \in S} B_i \subseteq B$ and for all $i \neq i', B_i \cap B_{i'} = \emptyset$, $V^*(B, \Theta_S)$ is defined as $\max_g \sum_{i \in S} v(B_i, \theta_i)$, where θ_i is the type of bidder i.

The price of bundle B for bidder i (VCG price) is defined as follows:

$$p_{B,i} = V^*(M, \Theta_{N \setminus \{i\}}) - V^*(M \setminus B, \Theta_{N \setminus \{i\}}).$$

This protocol is identical to the Vickrey-Clarke-Groves (VCG) mechanism [2, 4, 9], i.e., if B is allocated to i in a Pareto efficient allocation, then $p_{B,i}$ is equal to the payment in the VCG protocol and B maximizes i's utility.

This protocol satisfies allocation feasibility since the following theorem holds.

THEOREM 3. *If B is allocated to i in a Pareto efficient allocation, then B maximizes i's utility at the VCG price.*

Proof: If we assume this theorem does not hold, then there exists another bundle $B' \neq B$ that maximizes i's utility. Thus, the following formula holds.

$$v(B', \theta_i) - p_{B',i} > v(B, \theta_i) - p_{B,i}$$

From this formula and the definition of $p_{B',i}, p_{B,i}$, we obtain:

$$v(B', \theta_i) + V^*(M \setminus B', \Theta_{N \setminus \{i\}}) > v(B, \theta_i) + V^*(M \setminus B, \Theta_{N \setminus \{i\}}).$$

This contradicts the assumption that allocating B to i is Pareto efficient. □

Note that this theorem also holds when B is an empty set. From this theorem, if there exist multiple Pareto efficient allocations, the auctioneer can choose one of them arbitrarily, since every bidder has the highest preference for the bundle that is allocated in that allocation (which can be an empty bundle). Thus, allocation feasibility is satisfied.

Let us describe how this protocol works.

EXAMPLE 1. *Assume there are two goods* 1 *and* 2*, and three bidders, bidder* 1*,* 2*, and* 3*, whose types are θ_1, θ_2, and θ_3, respectively. The valuation for a bundle $v(B, \theta_i)$ is determined as follows.*

	{1}	{2}	{1, 2}
θ_1	6	0	6
θ_2	0	0	8
θ_3	0	5	5

Accordingly, the prices of these bundles for each bidder are given as follows.

	{1}	{2}	{1, 2}
bidder 1	3	8	8
bidder 2	6	5	11
bidder 3	8	2	8

As a result, bidder 1 *obtains good* 1 *at price* 3*, and bidder* 3 *obtains good* 2 *at price* 2*.*

Now, we can see that this result is not in the core. Let us assume another allocation where both goods are sold to bidder 2 at price 7. Then, both the seller and bidder 2 prefer this allocation to the outcome of the VCG protocol. Such a coalition, in this case, the coalition of the seller and bidder 2, is called a *blocking* coalition.

Let us consider another situation.

EXAMPLE 2. *Assume there are two goods* 1 *and* 2*, and three bidders, bidder* 1*,* 2*, and* 3*, whose types are* θ_1, θ_2*, and* θ_3*, respectively. The valuation for a bundle* $v(B, \theta_i)$ *is determined as follows.*

	{1}	{2}	{1, 2}
θ_1	4	0	4
θ_2	0	0	8
θ_3	0	3	3

Accordingly, the prices of these bundles for each bidder are given as follows.

	{1}	{2}	{1, 2}
bidder 1	5	8	8
bidder 2	4	3	7
bidder 3	8	4	8

As a result, bidder 2 *obtains both goods at price* 7*.*

Now, we can see that the VCG protocol is vulnerable to the collusion of losers. If bidder 1 and bidder 3 collude and increase their valuations, they can create a situation identical to Example 1. Then, bidder 1 obtains good 1 at price 3, and bidder 3 obtains good 2 at price 2. For each bidder, this price is less than his/her valuation, thus bidders can increase their utilities by engaging in collusion.

5. EXISTING FALSE-NAME-PROOF PROTOCOLS

In this section, we describe a false-name-proof protocol called the Max Minimal-Bundle (M-MB) protocol [10] as a representative false-name-proof protocol.

To simplify the protocol description, we introduce a concept called a *minimal bundle*.

DEFINITION 5. *minimal bundle*
Bundle B *is called minimal for bidder* i *if for all* $B' \subset B$ *and* $B' \neq B$*,* $v(B', \theta_i) < v(B, \theta_i)$ *holds.*

In the M-MB protocol, the price of bundle B for bidder i is defined as follows:

- $p_{B,i} = \max_{B_j \subseteq M, j \neq i} v(B_j, \theta_j)$, where $B \cap B_j \neq \emptyset$ and B_j is minimal for bidder j.

In short, the price of bundle B is equal to the highest valuation of a bundle, which is minimal and conflicting with bundle B.

It is clear that this protocol satisfies allocation feasibility [10]. Also, as shown in [10], this protocol is false-name-proof since it satisfies the NSA condition.

Let us describe how this protocol works. Let us consider a situation identical to Example 1. The prices of these bundles are given as follows.

	{1}	{2}	{1, 2}
bidder 1	8	8	8
bidder 2	6	5	6
bidder 3	8	8	8

As a result, bidder 2 obtains both goods at price 6.

As shown in this example, in the M-MB protocol, some goods can be allocated to a bidder who is not included in any Pareto efficient allocation. This is true for other existing false-name-proof protocols such as the LDS protocol [11]. In such a case, losers who are in a Pareto efficient allocation will have a strong incentive to collude. For example, if bidder 1 and bidder 3 collude and act as a single bidder whose valuation for the set is 11, then they can obtain both goods at price 8, which is smaller than the sum of their valuations.

6. GROVES MECHANISM WITH SUBMODULAR APPROXIMATION (GM-SMA)

In this section, we describe the details of the Groves Mechanism with SubModular Approximation (GM-SMA).

6.1 Protocol Description

To define the prices used in the GM-SMA, we introduce a concept called submodular approximation.

DEFINITION 6. *submodular approximation* U^*
The function $U^*(B, \Theta_S)$ *defined below is called a submodular approximation of* V^**.*

For a feasible allocation $g = (B_1, B_2, \ldots)$*, where* $\bigcup_{i \in S} B_i \subseteq B$ *and for all* $i \neq i', B_i \cap B_{i'} = \emptyset$*,* $U^*(B, \Theta_S)$ *is defined as* $\max_g \sum_{i \in S} v'(B_i, \theta_i)$*.* v' *is a function that satisfies* $v'(B, \theta_i) \geq v(B, \theta_i)$ *for all* i, B*.*

Furthermore, we assume v' *is chosen so that* U^* *becomes submodular, i.e., for all* $S \subseteq N, B', B'' \in M$*, the following condition holds:*

$$U^*(B', \Theta_S) + U^*(B'', \Theta_S) \geq U^*(B' \cup B'', \Theta_S) + U^*(B' \cap B'', \Theta_S).$$

From this definition, U^* satisfies the following conditions:

- For all $S \subset N, B \subset M$, $U^*(B, \Theta_S) \geq V^*(B, \Theta_S)$ holds.
- For all $S \subset N, B \subset M$, $U^*(M, \Theta_N) \geq U^*(B, \Theta_S) + U^*(M \setminus B, \Theta_{N \setminus S})$ holds.

The Groves Mechanism with SubModular Approximation (GM-SMA) is described as a PORF protocol in which prices are defined as follows.

- When $B = \emptyset$, $p_{B,i} = 0$.
- Otherwise, $p_{B,i} = U^*(M, \Theta_{N\setminus\{i\}}) - V^*(M\setminus B, \Theta_{N\setminus\{i\}})$.

Note that we use U^* only for the first term.

The PORF description of a protocol is very convenient for proving the theoretical properties of the protocol, but implementing it can be rather costly. Alternatively, the GM-SMA can be implemented as follows.

1. The auctioneer finds a Pareto efficient allocation. The auctioneer can choose an arbitrary one if there exist multiple Pareto efficient allocations.
2. When B is allocated to bidder i in that allocation, the auctioneer calculates the GM-SMA price $p_{B,i}$. If $v(B, \theta_i) \geq p_{B,i}$, then B is allocated to bidder i at price $p_{B,i}$. If $v(B, \theta_i) < p_{B,i}$, B is not allocated to any bidder.

This protocol is quite similar to the Groves mechanism [4], since the payment of a winner in this protocol is identical to the payment in one instance of the Groves mechanism. However, it is not an instance of the Groves mechanism because it does not guarantee to achieve a Pareto efficient allocation. This protocol can be considered as a modification of the Groves mechanism, in which a winner has an option not to obtain the goods if the payment becomes too high.

6.2 Examples

Here, we describe how the GM-SMA works in the situation of Example 1. In this example, we use $v'(\{1\}, \theta_2) = v'(\{2\}, \theta_2) = 8/2 = 4$, and we use $v'(\cdot, \cdot) = v(\cdot, \cdot)$ for other bundles and bidders. By choosing v' in this way, U^* satisfies the submodular condition.

The GM-SMA prices are given as follows.

	$\{1\}$	$\{2\}$	$\{1,2\}$
bidder 1	4	9	9
bidder 2	6	5	11
bidder 3	10	4	10

As a result, bidder 1 obtains good 1 at price 4, and bidder 3 obtains good 2 at price 4.

This outcome is in the core. Since the revenue of the seller is 8, the seller does not have an incentive to deviate from the protocol with bidder 2 (who is willing to pay at most 8).

Next, we describe how the protocol works in the situation of Example 2. Here, v' is defined in a similar way to the previous example. The GM-SMA prices are given as follows.

	$\{1\}$	$\{2\}$	$\{1,2\}$
bidder 1	5	8	8
bidder 2	4	3	7
bidder 3	8	4	8

As a result, bidder 2 obtains both goods at price 7. In this case, even if bidder 1 and bidder 3 collude and create a situation identical to Example 1, their utilities cannot be positive since each must pay 4 in that situation. In this case, the GM-SMA gives the same result as the VCG.

6.3 Submodular Approximation

In this subsection, we discuss how to choose v' so that U^* becomes submodular. It is known that if each bidder's valuation satisfies a condition called the *gross substitutes* condition[3], then U^* becomes submodular [5].

DEFINITION 7. *gross substitutes*
Given a price vector $p = (p_1, \ldots, p_m)$, we denote

$$D_i(p) = \{B \subset M : \forall C \subset M, v(B, \theta_i) - \sum_{j \in B} p_j \geq v(C, \theta_i) - \sum_{j \in C} p_j\}.$$

$D_i(p)$ represents the collection of bundles that maximizes the net utility of bidder i under price vector p. We say that the gross substitutes condition is satisfied, if for any two price vectors p and p' such that $p' \geq p$, $p'_j = p_j$, and $j \in B \in D_i(p)$, then there exists $B' \in D_i(p')$ such that $j \in B'$.

In short, the gross substitutes condition states that if good j is demanded with price vector p, it is still demanded if the price of j remains the same, while the prices of some other goods increase.

We describe two representative valuations that satisfy the gross substitutes condition.

DEFINITION 8. *unit-demand valuation*
Bidder i's valuation is called unit-demand valuation if, for each good $j \in M$, a valuation v_{ij} is given and, for any bundle B, $v(B, \theta_i)$ is calculated as $\max_{j \in B} v_{ij}$.

In short, a bidder with a unit-demand valuation requires only one of M.

DEFINITION 9. *additive valuation*
Bidder i's valuation is an additive valuation if, for each good $j \in M$, a valuation v_{ij} is given and, for any bundle B, $v(B, \theta_i)$ is calculated as $\sum_{j \in B} v_{ij}$.

In short, the valuation for a bundle of an additive valuation bidder is the sum of the valuations of each good.

We can obtain v' by approximating v by unit-demand valuation or additive valuation. For example, if we approximate the function v by additive valuation, we first calculate a valuation vector $\vec{v}_i = (v_{i1}, v_{i2}, \ldots, v_{im})$ that satisfies the following conditions. Then, we define $v'(B, \theta_i)$ as $\sum_{j \in B} v_{ij}$.

- For each bundle B, $v(B, \theta_i) \leq \sum_{j \in B} v_{ij}$.
- $\vec{v}_i$ is minimal, i.e., the above condition is not satisfied if we decrease any v_{ij}.

So far, we have considered a method for constructing U^* by using a gross substitutes valuation. However, the gross substitutes condition is not a necessary condition for U^* to be submodular [5]. This means that there is a chance that we can construct U^* based on a weaker condition than the gross substitutes condition. In that case, we can expect to obtain a better approximation of v. We intend to examine such a method in our future works.

7. CHARACTERISTICS OF GM-SMA

In this section, we examine the characteristics of the GM-SMA.

[3]The fact that each v' is submodular is not suffcient to guarantee that U^* is submodular [5].

7.1 Allocation Feasibility

The following characteristic holds.

PROPOSITION 1. *The GM-SMA price of a bundle is larger than (or equal to) the VCG price. Also, for bidder i, the difference between the GM-SMA price and the VCG price is the same for every bundle except for an empty bundle, i.e., the difference is equal to* $U^*(M, \Theta_{N\setminus\{i\}}) - V^*(M, \Theta_{N\setminus\{i\}})$.

The proof is straightforward, since U^* is greater than or equal to V^*.

THEOREM 4. *The GM-SMA satisfies allocation feasibility.*

Proof: This is derived from the fact that the VCG protocol satisfies allocation feasibility. From Proposition 1, the GM-SMA prices are larger than the VCG prices by the same amount (except for an empty bundle). Thus, if a bidder is included in a Pareto efficient allocation, the bundle in the allocation maximizes the bidder's utility with the GM-SMA price, or the bidder prefers to obtain an empty bundle. Therefore, if there exist multiple Pareto efficient allocations, the auctioneer can choose one Pareto efficient allocation arbitrarily. Then, every bidder has the highest preference for the bundle that is allocated in that allocation, or an empty bundle. Thus, allocation feasibility is satisfied. □

On the other hand, since a bidder who obtains some goods in the VCG might prefer obtaining an empty bundle, the GM-SMA cannot guarantee Pareto efficiency. This is inevitable since there exists no false-name-proof protocol that satisfies Pareto efficiency.

7.2 False-name-Proofness

In this subsection, we show that the GM-SMA is false-name-proof.

THEOREM 5. *The GM-SMA is false-name-proof.*

Proof: This can be proven by showing that the GM-SMA prices satisfy the NSA condition. We show when bidder i' obtains B' and bidder i'' obtains B'', then $p_{B,i}$, i.e., the price for obtaining $B = B' \cup B''$ with a single identifier i, is less than (or equal to) $p_{B',i'} + p_{B'',i''}$. We can prove the case of more than two identifiers in a similar way.

From our definition of the GM-SMA prices, the following conditions hold. N' is a set of bidders except i, i', i''.

$$p_{B',i'} = U^*(M, \Theta_{N'\cup\{i''\}}) - V^*(M \setminus B', \Theta_{N'\cup\{i''\}})$$

$$p_{B'',i''} = U^*(M, \Theta_{N'\cup\{i'\}})) - V^*(M \setminus B'', \Theta_{N'\cup\{i'\}})$$

$$p_{B,i} = U^*(M, \Theta_{N'}) - V^*(M \setminus B, \Theta_{N'})$$

From the fact that i' obtains B' and i'' obtains B'', the following conditions hold.

$$V^*(M \setminus B', \Theta_{N'\cup\{i''\}}) = v(B'', \theta_{i''}) + V^*(M \setminus B, \Theta_{N'})$$

$$V^*(M \setminus B'', \Theta_{N'\cup\{i'\}}) = v(B', \theta_{i'}) + V^*(M \setminus B, \Theta_{N'})$$

Also, from the definition of U^*, the following conditions hold.

$$\begin{aligned} U^*(M, \Theta_{N'\cup\{i'\}}) &\geq U^*(B', \Theta_{\{i'\}}) + U^*(M \setminus B', \Theta_{N'}) \\ &\geq v(B', \theta_{i'}) + U^*(M \setminus B', \Theta_N) \end{aligned}$$

$$\begin{aligned} U^*(M, \Theta_{N'\cup\{i''\}}) &\geq U^*(B'', \Theta\{i''\}) + U^*(M \setminus B', \Theta_{N'}) \\ &\geq v(B'', \theta_{i''}) + U^*(M \setminus B'', \Theta_{N'}) \end{aligned}$$

From above conditions, we obtain:

$$\begin{aligned} & p_{B',i'} + p_{B'',i''} - p_{B,i} \\ &= U^*(M, \Theta_{N'\cup\{i''\}}) - V^*(M \setminus B', \Theta_{N'\cup\{i''\}}) \\ &\quad + U^*(M, \Theta_{N'\cup\{i'\}}) - V^*(M \setminus B'', \Theta_{N'\cup\{i'\}}) \\ &\quad - [U^*(M, \Theta_{N'}) - V^*(M \setminus B, \Theta_{N'})] \\ &\geq v(B'', \theta_{i''}) + U^*(M \setminus B'', \Theta_{N'}) \\ &\quad - v(B'', \theta_{i''}) - V^*(M \setminus B, \Theta_{N'}) \\ &\quad + v(B', \theta_{i'}) + U^*(M \setminus B', \Theta_{N'}) \\ &\quad - v(B', \theta_{i'}) - V^*(M \setminus B, \Theta_{N'}) \\ &\quad - U^*(M, \Theta_{N'}) + V^*(M \setminus B, \Theta_{N'}) \\ &\geq U^*(M \setminus B', \Theta_{N'}) + U^*(M \setminus B'', \Theta_{N'}) \\ &\quad - U^*(M, \Theta_{N'}) - V^*(M \setminus B, \Theta_{N'}) \\ &\geq U^*(M \setminus B', \Theta_{N'}) + U^*(M \setminus B'', \Theta_{N'}) \\ &\quad - U^*(M, \Theta_{N'}) - U^*(M \setminus B, \Theta_{N'}) \end{aligned}$$

Since U^* is submodular, the following condition holds:

$$\begin{aligned} & U^*(M \setminus B', \Theta_{N'}) + U^*(M \setminus B'', \Theta_{N'}) \\ &\geq U^*(M, \Theta_{N'}) + U^*(M \setminus B, \Theta_{N'}). \end{aligned}$$

Therefore, the above formula is non-negative. Thus, $p_{B',i'} + p_{B'',i''} \geq p_{B,i}$ holds. □

7.3 Robustness against Collusion of Losers

Next, we examine the effect of the collusion of losers.

DEFINITION 10. *strict loser*
We call a bidder who is not included in any Pareto efficient allocation a strict loser.

In the GM-SMA, a loser can be a strict loser or a non-strict loser. A non-strict loser is included in some Pareto efficient allocation but fails to obtain any good.

THEOREM 6. *In the GM-SMA, if strict losers collude and obtain some goods, the sum of their utilities becomes negative.*

Proof: Let us assume a set of strict losers S colludes and obtains B using a single identifier i.

From the fact that each bidder in S is a strict loser, the following formula holds. N' is a set of bidders other than S.

$$V^*(B, \Theta_S) + V^*(M \setminus B, \Theta_{N'}) < V^*(M, \Theta_{N'})$$

Also, the following condition holds for $p_{B,i}$.

$$\begin{aligned} p_{B,i} &= U^*(M, \Theta_{N'}) - V^*(M \setminus B, \Theta_{N'}) \\ &\geq V^*(M, \Theta_{N'}) - V^*(M \setminus B, \Theta_{N'}) \\ &> V^*(B, \Theta_S) \end{aligned}$$

Thus, the sum of the utilities of S becomes negative. Also, since the GM-SMA prices satisfy the NSA condition from Theorem 5, even if S uses multiple identifiers, the sum of the prices does not decrease. Therefore, the sum of the utilities of S remains negative even if S uses multiple identifiers. □

On the other hand, the VCG prices do not satisfy the NSA condition. Therefore, as shown in Example 2, the sum of the losers' utilities can be positive if they collude and use multiple identifiers.

If a Pareto efficient allocation is achieved in the GM-SMA, all losers are strict losers. Thus, the following theorem holds.

THEOREM 7. *When a Pareto efficient allocation is achieved in the GM-SMA, if losers collude and obtain some goods, the sum of their utilities becomes negative.*

7.4 Core Outcome

Next, we examine whether the outcome of the GM-SMA is in the core. First, we show that the following lemma holds.

LEMMA 1. *If U^* is submodular for goods, then U^* is bidder-submodular, i.e., for any set of goods B and for any set of bidders Z, W, the following formula holds: $U^*(B, \Theta_Z) + U^*(B, \Theta_W) \geq U^*(B, \Theta_{Z\cup W}) + U^*(B, \Theta_{Z\cap W})$.*

The details of the proof are described in [12].

The following theorem holds.

THEOREM 8. *When the GM-SMA achieves a Pareto efficient allocation, then the outcome is in the core, i.e., there exists no blocking coalition.*

Proof: Let us assume that goods are allocated to a set of bidders $S_{ww}\cup S_{wl}$ in a Pareto efficient allocation, and bundle B_i is allocated to bidder i in $S_{ww}\cup S_{wl}$. Now, let us assume there exists a blocking coalition that consists of the seller and $S_{ww}\cup S_{lw}$, where $S_{wl}\cap S_{lw} = \emptyset$. In other words, in the blocking coalition, the auctioneer takes away the goods from S_{wl} and re-allocates goods among $S_{ww}\cup S_{lw}$. We assume B'_i is re-allocated to bidder i in $S_{ww}\cup S_{lw}$.

In the blocking coalition, the utility of the seller must be larger than the utility in the GM-SMA, i.e., $\sum_{i\in S_{ww}\cup S_{wl}} p_{B_i,i}$. To maximize the revenue of the seller, while each bidder in $S_{ww}\cup S_{lw}$ obtains the same utility as the GM-SMA, each bidder i in S_{lw} should pay $v(B'_i,\theta_i)$, and each bidder i in S_{ww} should pay $v(B'_i,\theta_i) - (v(B_i,\theta_i) - p_{B_i,i})$. This is because if a bidder pays more than this, the bidder will lose the incentive to join the coalition.

The revenue of the seller in the blocking coalition is given as follows. We represent $B_{S_{ww}} = \bigcup_{i\in S_{ww}} B_i$, i.e., a set of goods allocated to S_{ww} in the Pareto efficient allocation.

$$\begin{aligned}&\sum_{i\in S_{lw}} v(B'_i,\theta_i) + \sum_{i\in S_{ww}} [v(B'_i,\theta_i) - (v(B_i,\theta_i) - p_{B_i,i})]\\ &= V^*(M,\Theta_{S_{ww}\cup S_{lw}}) - V^*(B_{S_{ww}},\Theta_{S_{ww}}) + \sum_{i\in S_{ww}} p_{i,B_i}\end{aligned}$$

By subtracting the revenue of the seller in the blocking coalition from the revenue of the seller in the GM-SMA, the remainder is given as follows:

$$\sum_{i\in S_{wl}} p_{B_i,i} + V^*(B_{S_{ww}},\Theta_{S_{ww}}) - V^*(M,\Theta_{S_{ww}\cup S_{lw}}).$$

The following condition holds. We represent $B_{S_{wl}} = \bigcup_{i\in S_{wl}} B_i$, i.e., a set of goods allocated to S_{wl} in the Pareto efficient allocation.

$$\begin{aligned}&\sum_{i\in S_{wl}} p_{B_i,i}\\ &= \sum_{i\in S_{wl}} [U^*(M,\Theta_{N\setminus\{i\}}) - V^*(M\setminus B_i,\Theta_{N\setminus\{i\}})]\\ &= \sum_{i\in S_{wl}} [U^*(M,\Theta_{N\setminus\{i\}}) - V^*(B_{S_{ww}},\Theta_{S_{ww}})\\ &\qquad - V^*(B_{S_{wl}}\setminus B_i,\Theta_{S_{wl}\setminus\{i\}})] \qquad (1)\end{aligned}$$

From the fact that U^* is bidder-submodular, the following conditions hold.

For $i,j\in S_{wl}, i\neq j$,

$$\begin{aligned}&U^*(M,\Theta_{N\setminus\{i\}}) + U^*(M,\Theta_{N\setminus\{j\}})\\ &\geq U^*(M,\Theta_N) + U^*(M,\Theta_{N\setminus\{i,j\}}).\end{aligned}$$

For $i,j,k\in S_{wl}, i\neq j, j\neq k, k\neq i$,

$$\begin{aligned}&U^*(M,\Theta_{N\setminus\{i\}}) + U^*(M,\Theta_{N\setminus\{j\}}) + U^*(M,\Theta_{N\setminus\{k\}})\\ &\geq 2\cdot U^*(M,\Theta_N) + U^*(M,\Theta_{N\setminus\{i,j,k\}}).\end{aligned}$$

By repeating this, we obtain:

$$\begin{aligned}&\sum_{i\in S_{wl}} U^*(M,\Theta_{N\setminus\{i\}})\\ &\geq (|S_{wl}|-1)U^*(M,\Theta_N) + U^*(M,\Theta_{N\setminus S_{wl}}). \qquad (2)\end{aligned}$$

Also, the following formula holds:

$$\begin{aligned}&\sum_{i\in S_{wl}} V^*(B_{S_{wl}}\setminus B_i,\Theta_{S_{wl}\setminus\{i\}})\\ &= (|S_{wl}|-1)V^*(B_{S_{wl}},\Theta_{S_{wl}}). \qquad (3)\end{aligned}$$

In short, for each $i\in S_{wl}$, $v(B_i,\theta_i)$ is counted $|S_{wl}|-1$ times in the above formula.

From formulae 1,2, and 3, we obtain:

$$\begin{aligned}&\sum_{i\in S_{wl}} p_{B_i,i} + V^*(B_{S_{ww}},\Theta_{S_{ww}}) - V^*(M,\Theta_{S_{ww}\cup S_{lw}})\\ &\geq (|S_{wl}|-1)U^*(M,\Theta_N) + U^*(M,\Theta_{S_N\setminus S_{wl}})\\ &\quad -|S_{wl}|V^*(B_{S_{ww}},\Theta_{S_{ww}}) - (|S_{wl}|-1)V^*(B_{S_{wl}},\Theta_{S_{wl}})\\ &\quad +V^*(B_{S_{ww}},\Theta_{S_{ww}}) - V^*(M,\Theta_{S_{ww}\cup S_{lw}})\\ &\geq (|S_{wl}|-1)U^*(M,\Theta_N)\\ &\quad -(|S_{wl}|-1)(V^*(B_{S_{ww}},\Theta_{S_{ww}}) + V^*(B_{S_{wl}},\Theta_{S_{wl}}))\\ &\quad +U^*(M,\Theta_{S_N\setminus S_{wl}}) - V^*(M,\Theta_{S_{ww}\cup S_{lw}})\\ &\geq 0.\end{aligned}$$

As a result, the revenue of the seller in this coalition does not exceed the revenue of the GM-SMA. Therefore, this coalition cannot be a blocking coalition. □.

8. EVALUATION

In this section, we evaluate the social surplus and the revenue of the seller in the GM-SMA through a simulation. As a representative of existing false-name-proof protocols, we use the M-MB protocol [10]. This is because using another false-name-proof protocol, i.e., the LDS protocol, would require us to tune various parameters to obtain a good social surplus [11].

We decide the valuation of bidder i by the following method.

- With probability r, where $0\leq r\leq 1$, bidder i is a *single-minded* bidder, and with probability $1-r$, bidder i is a unit-demand valuation bidder.
- If bidder i is a single-minded bidder, i wants to have bundle B, where $|B| = k$. B is chosen randomly, and the valuation for B is randomly chosen from $[0, 1000k]$. The gross utility of i is 0 if i fails to obtain any single good in B.
- If bidder i is a unit-demand valuation bidder, i wants to have any one of k goods. These goods are chosen randomly, and the valuation for the good is randomly chosen from $[0, 1000]$.

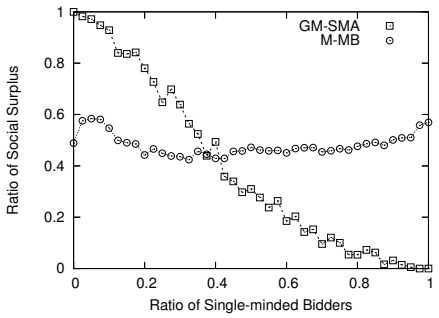

Figure 1: Ratio of Social Surplus

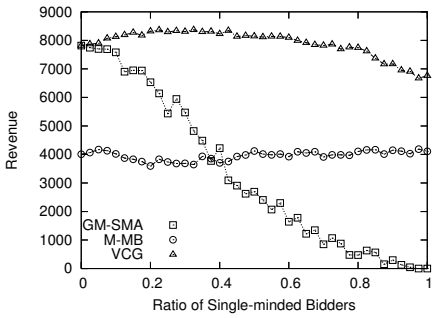

Figure 2: Revenue

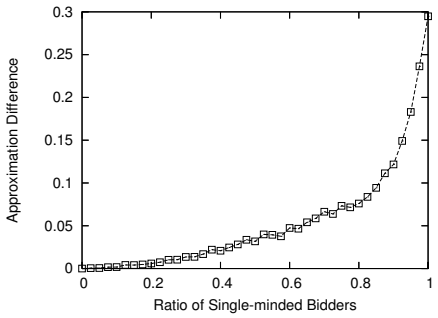

Figure 3: Approximation Difference

If bidder i is a unit-demand valuation bidder, we use $v'(\cdot,\cdot) = v(\cdot,\cdot)$. If bidder i is a single-minded bidder, we approximate v using an additive valuation, where $v_{ij} = v(B,\theta_i)/|B|$ for $j \in B$.

We set $N = 50$, $M = 10$, and $k = 4$, and generated 100 instances. Figure 1 shows the average social surplus of the GM-SMA and the M-MB Protocol by varying the ratio of single-minded bidders. If the ratio is zero, all bidders have unit-demand valuation and their valuations are submodular. Thus, the outcome of the GM-SMA is equivalent to that of the VCG. The social surplus is normalized by the social surplus of a Pareto efficient allocation. Figure 2 shows the revenue of the GM-SMA, M-MB, and VCG protocols. In the VCG protocol, we assume each bidder declares his/her true valuation without using false-name bids. We can see that when the ratio of single-minded bidders is less than 0.4, the GM-SMA outperforms the M-MB protocol both in terms of the efficiency and the revenue.

Also, to evaluate the accuracy of the submodular approximation, for each bidder, we calculate *approximation difference* defined as follows:

$$\frac{U^*(M,\Theta_{N\setminus\{i\}}) - V^*(M,\Theta_{N\setminus\{i\}})}{V^*(M,\Theta_{N\setminus\{i\}})}.$$

If this approximation difference were smaller, the submodular approximation would be more accurate. Figure 3 shows the average approximation difference. We can see that the efficiency and the revenue of the GM-SMA critically depend on the accuracy of the submodular approximation.

9. CONCLUSIONS

In this paper, we developed a new combinatorial auction protocol called the Groves Mechanism with SubModular Approximation (GM-SMA). The basic ideas of this protocol are as follows: (i) it is based on the VCG protocol, (ii) it utilizes submodular approximation, i.e., when calculating the payment of bidder i, we approximate the valuations of bidders other than i by using a submodular valuation function.

The GM-SMA satisfies the following characteristics: (1) it is false-name-proof, (2) each winner is a bidder who is included in a Pareto efficient allocation, (3) as long as the allocation is Pareto efficient, the protocol is robust against the collusion of losers and the outcome is in the core. The GM-SMA is the first protocol that satisfies all three of these characteristics.

Simulation results showed that the GM-SMA achieves a better social surplus and seller's revenue than an existing false-name-proof protocol, as long as the submodular approximation is close enough to the original valuations.

The efficiency and the revenue of the GM-SMA critically depend on the accuracy of the submodular approximation. Our future works include investigating better approximation methods.

ABSTRACT

Auction mechanism design is a subfield of game theory dedicated to manipulating the rules of an auction so as to achieve specific goals. The complexity of the dynamics of auctions, especially continuous double auctions, makes it difficult to apply the usual analytic game-theoretic methods to do this. This paper takes an experimental approach, searching a parameterized space of possible auction types, and presents a new pricing policy for continuous double auctions. The paper further demonstrates how this policy, together with a shout improvement rule, helps to reduce the fluctuation of transaction prices in auctions involving agents with minimum intelligence while keeping the overall efficiency high.

1. INTRODUCTION

Auctions, as a subclass of *markets*, have been widely used in solving real-world resource allocation problems, and in structuring stock or futures exchanges. This is due to the fact that auctions, when well designed [9], achieve desired economic outcomes like high *allocative efficiency*. Auctions are also an excellent scenario in which to study the dynamics and characteristics of micro-economics and they play an important role in computer-based control systems [2].

Research on auctions originally interested economists and mathematicians. They view auctions as games and have successfully applied traditional analytic methods from game theory to some kinds of auctions [11], for example the second-price sealed-bid auctions or Vickrey auctions [23]. The high complexity of the dynamics of some other auction types, especially *double-sided auctions* [5] or DAs[1], however makes it difficult to go further in this direction [10, 20, 25].

As a result, researchers turned to experimental approaches. Starting in 1955, Smith pioneered the experimental approach [21] conducting auctions involving human traders that revealed many of the properties of double auctions. For example, his work showed that in *continuous double auctions* or CDAs[2], even a handful of traders can lead to high overall efficiency, and transaction prices can quickly converge to the theoretical equilibrium. Smith's focus was mainly on the convergence of transaction prices in different scenarios rather than examining why high efficiency is obtained—this is the same topic that interests us. In a computerized world, a question that arises naturally is whether these results can be replicated in electronic auctions. In Smith's experiments, as in real markets traditionally, the traders are human beings, but computer programs are supposed to be automatic and work without human involvement. Obviously humans are intelligent creatures, but programs are not, at least for the foreseeable future. Is it intelligence that contributes to the high efficiency, or something else?

Gode and Sunder [7, 8] were among the first to address this question, claiming that no intelligence is necessary for the goal of achieving high efficiency; so the outcome is due to the auction mechanism itself. They introduced two trading strategies: *zero intelligence without constraint* (ZI-U) and *zero intelligence with constraint* (ZI-C), and showed that ZI-U, the more naïve version, which shouts an offer at a random price without considering whether it is losing money or not, performs poorly. In contrast, ZI-C — which lacks the motivation of maximizing profit just like ZI-U, but guarantees no

[1] In DAs, both competing sellers and buyers can make offers, in contrast to the most common auction mechanisms, such as the English auction, where only buyers bid.

[2] A CDA is a continuous DA in which any trader can accept an offer and make a deal any time during the auction period.

loss — generates high efficiency solutions [7] and provides a lower bound on the efficiency of markets [8]. These results were however questioned by Cliff and Bruten [2], who thought Gode and Sunder's conclusion was not convincing because the scenarios considered were not as comprehensive as in Smith's experiments, and showed [2] that in different scenarios the ZI-C agents performed poorly, especially in terms of convergence to the theoretical equilibrium.

Cliff and Bruten further designed an adaptive trading strategy called *zero intelligence plus* or ZIP, and showed ZIP worked better than ZI-C, generating high efficiency outcomes and converging to the equilibrium price. This led Cliff and Bruten to suggest that ZIP embodied the minimum intelligence required by traders. Subsequent work has led to the development of further trading strategies, including that proposed by Roth and Erev [18], which we call RE, and that suggested by Gjerstad and Dickhaut [6], commonly referred to as GD.

This work on trading strategies is only one facet of the research on auctions. Gode and Sunder's results suggest that auction mechanisms play an important role in determining the outcome of an auction, and this is further bourne out by the work of Walsh *et al.* [25] (which also points out that results hinge on both auction design and the mix of trading strategies used). For example, if an auction is *strategy-proof*, traders need not bother to conceal their private values and in such auctions complex trading agents are not required. While typical double auctions are not strategy-proof, McAfee [12] has derived a form of double auction that is strategy-proof (though this strategy-proofness comes at the cost of lower efficiency).

The work described here differs from the bulk of the literature. It differs because that bulk of work considers the design of trading strategies, looking for approaches that can achieve high efficiency [6, 17] or high profit [19, 22]. In contrast, we follow the work of Phelps *et al.* in looking to optimize several metrics — price fluctuation and efficiency — by manipulating the design of the auction itself, and we aim to do this, as Walia *et al.* [24] do, for populations of ZI-C agents. In particular, this paper presents some preliminary experimental results in designing auction mechanisms, showing how a new *pricing policy* and a new *shout improvement rule* can augment a traditional continuous double auction involving zero intelligence agents to reduce the fluctuation of transaction prices, while keeping overall efficiency high.

This paper is organized as follows. Section 2 discusses recent related work in auction mechanism design. Section 3 introduces our new pricing policy and shout improvement rule, and describes the experimentation work and results. We follow that with a discussion of our results in Section 4 and conclude with a brief summary in Section 5.

2. AUCTION DESIGN

Mechanism design applied to auctions explores how to design the rules that govern auctions to obtain specific goals.

2.1 Auction types

Generally an auction involves buyers and sellers who aim to exchange commodities at agreed prices. The most common auction form is English auction, in which there is a single seller, and multiple buyers compete by making increasing bids for the commodity — the one who offers the highest price wins the right to purchase the good being auctioned. Since only one type of trader makes offers in an English auction, it belongs to the class of *single-sided auctions*. Accordingly, there are *double-sided auctions* or DAs, in which both sellers and buyers make *shouts*[3]. Two most common forms of DAs are *clearing house* or CH and *continuous double auction* or CDA. In a CH, an auctioneer collects *bids* — shouts made by buyers — and *asks* — shouts made by sellers; the market-clearing (or equilibrium) price is then determined by maximizing the number of transactions and guaranteeing that if a trader is involved in a transaction, those with more competitive offers are also involved; and the market finally clears at that price. In a CDA, a trader can make a shout and accept an offer from someone at any time, which makes a CDA able to process many transactions in a short time. Both kinds of double auction are of practical importance as well, with, for example, CDA variants being widely used in real-world stock or trading markets including the New York Stock Exchange (NYSE) and Chicago Mercantile Exchange.

One can think of different forms of auctions as varying according to certain aspects of the auction rules, forming a parameterized auction space. For example, Wurman *et. al.* [27] parameterized auction rules using the following classification:

- Bidding rules: How many sellers and buyers are there? Are both groups allowed to make shouts? How is a shout expressed? Does a shout have to beat the corresponding market quote if one exists?
- Information revelation: When and what market quotes are generated and announced? Are shouts visible to all traders?
- Clearing policy: When does clearing a market take place? When does a market close? How are crossing shouts matched? How is a transaction price determined?

2.2 Performance metrics

Auctions with different values for the parameters described above may vary greatly in performance. Popular performance measurements include, but are not limited to, *allocative efficiency* and Smith's *coefficient of convergence* α.

The allocative efficiency, E_a, of an auction is used to measure how much social welfare is obtained through an auction. The *actual overall profit*, P_a, of an auction is:

$$P_a = \sum_i |v_i - p_i| \tag{1}$$

where p_i is the price of a trade made by agent i and v_i is the private value of agent i for all agents who trade. The *theoretical* or *equilibrium profit*, P_e, is:

$$P_e = \sum_i |v_i - p_0| \tag{2}$$

for all agents whose private value is no less competitive than the equilibrium price, where p_0 is the equilibrium price, the price at which, if all agents bid their private value, supply would equal demand. Given these:

$$E_a = \frac{100 P_a}{P_e} \tag{3}$$

[3]Another term for offers made by traders.

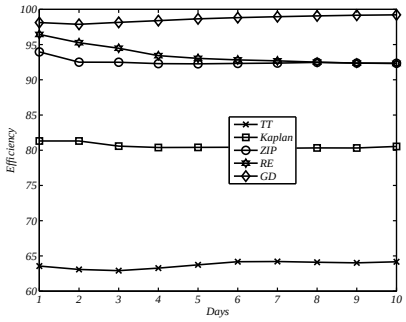

Figure 1: Typical values of E_a for CDA markets populated with common trading strategies

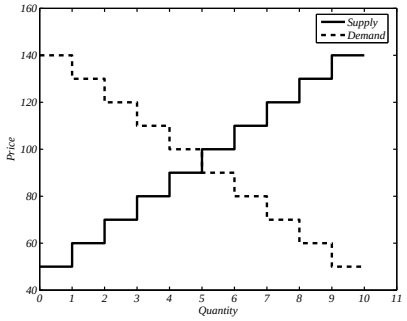

Figure 2: The supply and demand schedules

By way of indicating typical efficiencies achieved in a CDA, Figure 1 shows the trend of the overall efficiencies of homogeneous CDAs lasting 10 days with 50 rounds per day[4] in which 10 buyers and 10 sellers all use the same strategy, one of: TT[5], Kaplan[6], ZIP, RE, and GD. The results are averaged over 400 iterations and obtained in JASA—an extensible Java-based auction simulation environment [13].

The convergence coefficient, α, was introduced by Smith [21] to measure how far an active auction is away from the equilibrium point. It actually measures the deviation of transaction prices from the equilibrium price:

$$\alpha = \frac{100}{p_0}\sqrt{\frac{1}{n}\sum_{i=1}^{n}(p_i - p_0)^2} \qquad (4)$$

2.3 Auction design and performance

It is not yet clear how auction design, and thus the choice of parameter values, contributes to observed performance. Thus it is not possible to determine how to create an auction with a particular specification. It *is* possible to design simple mechanisms in a provably correct manner from a specification, as shown by Conitzer and Sandholm [3, 4]. However it is not obvious that this kind of approach can be extended to mechanisms as complex as double auctions. As a result, it seems that we will have to design double auction mechanisms experimentally, at least for the foreseeable future.

Of course, doing things experimentally does not solve the general problem. A typical experimental approach is to fix all but one parameter, creating a one-dimensional space, and then measure performance across a number of discrete sample points in the space, obtaining a fitness landscape that is expected to show how the factor in question correlates to a certain type of performance and how the auction can be optimized by tweaking the value of that factor [16]. In other words, the experimental approach examines one small part of a mechanism and tries to optimize that part[7]. The situation is complicated when more than one factor needs to be taken into consideration — the search space then becomes complex and multiple dimensional, and the computation required to map and search it quickly becomes prohibitive. Instead of manual search, some researchers have used evolutionary computation to automate mechanism design in these situations.

For example, Cliff [1] explored a continuous space of auction mechanisms by varying the probability of the next shout (at any point in time) being made by a seller, denoted by Q_s. The continuum includes the CDA ($Q_s = 0.5$) and also two purely single-sided mechanisms that are similar to the English auction ($Q_s = 0.0$) and the Dutch flower auction ($Q_s = 1.0$). Cliff's experiments used genetic algorithms and found that a Q_s that corresponds to a completely new kind of auction led to a better α value than that obtained for other auctions when all traders used the ZIP strategy. Walia, Byde and Cliff [24] continued with this work, showing that the new "irregular" mechanism can lead to high efficiency in ZI-C markets as well. Taking another tack, Phelps *et al.* [14, 16] demonstrated how genetic programming can be used to find an optimal point in a space of pricing policies, where the notion of optimality is based on efficiency and trader market power, and transaction prices are determined from matching bids and asks and market quotes.

In this paper we make some preliminary steps towards an evolutionary computation analysis that extends the work of [24]. In particular, we demonstrate that a new policy for setting transaction prices and a new shout improvement rule are capable of lowering the fluctuations in transaction price while keeping efficiency high. Both these new mechanisms are parameterized, and so the space of all such mechanisms can be searched using evolutionary techniques.

3. EXPERIMENTAL SETUP

We start by looking at the impact of a new pricing policy and then go on to look at a shout improvement rule.

3.1 A new pricing policy

A pricing policy defines how transaction prices are determined from the offers made by traders. In traditional CDAs, a typical pricing policy sets the price in the middle of the

[4] In an experimental environment, an auction typically includes a specific number of *days* (called *periods* in some of the literature), and each day in turn consists of a number of consecutive *rounds*. At the beginning of each day, traders are initialized and the auction begins/resumes running until the day ends. Days in an auction are totally isolated from each other except that knowledge obtained by traders over the previous days may remain. The division of days helps to identify the change of performance caused by the adaptive behavior of traders with the accumulation of knowledge over time.

[5] TT denotes the Truth-telling strategy, in which agents truthfully report their private values.

[6] "Kaplan" refers to Todd Kaplan's sniping strategy, in which agents wait until the last minute before attempting to steal the deal [19].

[7] And of course there are rarely any guarantees as to the optimality of the results.

matching ask-bid pair using the following expression with $k = 0.5$

$$p = k \cdot p_a + (1 - k) \cdot p_b \quad (5)$$

where p_a and p_b are prices offered respectively by the seller and the buyer. This is the usual *k-double auction* pricing rule [20], which is clearly a discriminatory policy[8], and which we denote as the KP*ricing*P*olicy* hereafter. In contrast to this, CHs usually adopt a non-discriminatory or *uniform* pricing policy. Phelps *et al.* [16] have shown that $k = 0.5$ is the best value to use when optimizing a combination of allocative efficiency and trader market power[9].

Determining the transaction price merely by the corresponding bid and ask, however, may be problematic. In a CDA with ZI-C traders using the KPricingPolicy (denoted as kCDA-ZIC hereafter), the transaction prices fluctuate wildly as shown in Figure 3(a). This result, which is due to the randomness with which ZI-C makes offers, is seen in Gode and Sunder's results [7]. In contrast, in markets involving more complex trading strategies like GD, the phenomenon is less obvious. Figure 3(d) shows the same measurements as Figure 3(a) but for all-GD traders (a setup called kCDA-GD hereafter).

The above results are obtained by running kCDA-ZIC and kCDA-GD in JASA with similar settings to the auctions that gave rise to Figure 1. Figure 3(a) and Figure 3(d) show the first 10 iterations, each with a different random seed, detailing the dynamic characteristics of the transaction prices set in these auctions. It is important to note that this is 10 separate runs over 10 days, with each run starting from scratch. If we did not start over from scratch at the end of each 10 days of trading, the prices for GD would fluctuate even less because there would be no "start of run" variation. The supply and demand schedules are fixed for all the iterations and those in Figure 2.

There are several reasons why we consider it worth studying the fluctuation in transaction prices in markets populated by ZI-C traders. First, as Walia *et al.* [24] argue, auction mechanisms that do well with ZI-C are likely to be "robust to trader-irrationality", in other words they are markets that will work reliably well. Second, markets in which one can trade with minimal intelligence and still have good performance are nearly as good as markets that are strategy-proof — traders are free from some of the burden of having to make good offers. Finally, reducing fluctuation is good for participants in the market — participants in a low fluctuation market are guaranteed not to be given a transaction price too far from the equilibrium, and this may mean traders are more likely to use this kind of market than another with higher fluctuations.

To reduce the fluctuation, we used a new pricing policy that we call the NP*ricing*P*olicy*. This keeps a sliding window of matching ask-bid pairs and uses the average price of those shouts to set the transaction price. If n is the window length and t the number of matching ask-bid pairs at a given point in time, then the transaction price for the tth transaction is given by:

$$p_t = \frac{1}{2n} \sum_{i=(t-n+1)}^{t} (p_{a_i} + p_{b_i}) \quad (6)$$

where p_{a_i} and p_{b_i} are the ask and bid prices corresponding to the ith transaction respectively. The NPricingPolicy generalizes the usual k-double auction pricing policy (KPricingPolicy) since when $n = 1$, it becomes the KPricingPolicy with $k = 0.5$, and when n is the number of matching ask-bid pairs in the entire auction, the NPricingPolicy is the rule commonly used to set prices in a CH[10].

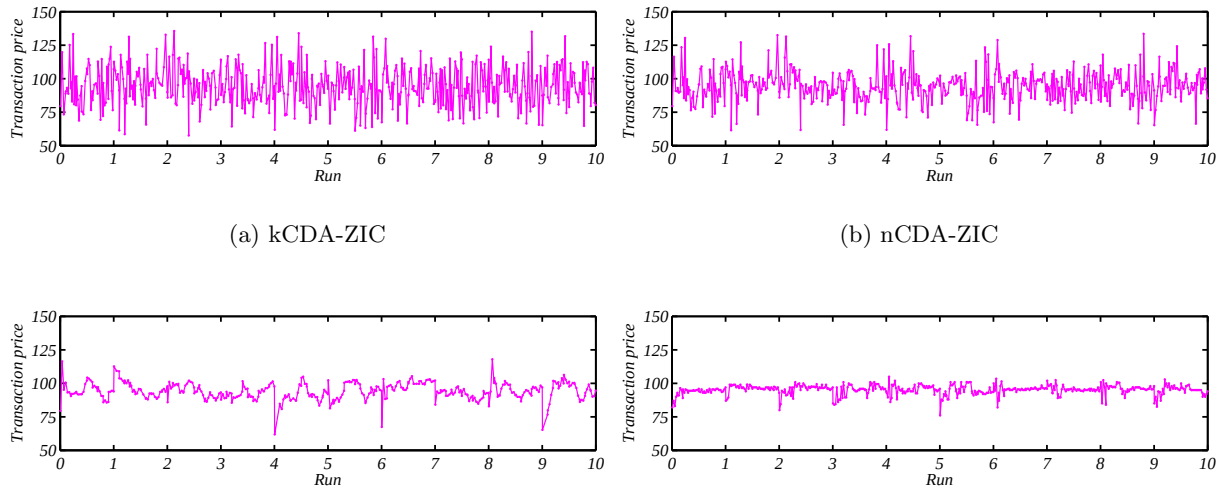
We replaced the KPricingPolicy with the NPricingPolicy, $n = 4$, in the same auctions as before, giving nCDA-ZIC and nCDA-GD respectively. Figures 3(b) shows that the price fluctuation is reduced for ZI-C markets, but is still higher than that of kCDA-GD[11]. This qualitative conclusion is supported by the quantitative data provided by measuring α for the different markets. The means and standard deviations of α and E_a in CDA-ZICs are plotted in Figures 4(a)–4(b), and Table 1 gives the numeric values of α and E_a over the full 10 day run of these markets. Averages and standard deviations are those obtained from 400 iterations of each 10 day run.

The values from Table 1 tell us $\alpha = 12.2$ for the nCDA-ZIC. This value plus twice its standard deviation (1.5) is less than $\alpha = 15.6$ for the kCDA-ZIC. Since the 95% confidence interval is two standard deviations around the mean, we can conclude that the NPricingPolicy significantly reduces α in ZI-C markets. By the same calculation, the improvement of α in the nCDA-GD is not significant (it is less than one standard deviation).

We note that the NPricingPolicy merely sets transaction prices differently, which affects the distribution of profit across the traders but not the overall efficiency. This is confirmed by the fact that the E_as of the nCDA-ZIC and nCDA-GD are identical to their kCDA counterparts as shown in Figure 4(b), where the values are superimposed on each other, and Table 1.

Overall, then, we can conclude for now that the nCDA is significantly better than the traditional CDA in terms of α when populated by ZI-C agents and no worse in terms of efficiency. The results for GD agents suggest that nCDA is robust against different types of trading strategies. To confirm this we need to assess its performance with other trading strategies.

3.2 Shout improvement rule



Though the NPricingPolicy does well in reducing fluctuation of transaction prices in the kCDA-ZICs, the difference between $\alpha = 12.2$ for the nCDA-ZIC vs. $\alpha = 4.0$ for the nCDA-GD in Table 1 tells us that there may still be space to improve the performance of markets with ZI-C traders. Why do we still get the obvious fluctuation of transaction prices in Figure 3(b) even when we use the NPricingPolicy? The answer is that the random selection of offers by ZI-C causes some variation even though the NPricingPolicy does its best to smooth out prices. This variation is less than that

[8] Meaning it varies from trade to trade.

[9] [16] does not just search through possible values of k. Instead it searches through all possible arithmetic combinations of shout prices and market quotes, evolving a horribly complex expression which is virtually indistinguishable from the $k = 0.5$ version of (5).

[10] Thus n makes a continuum of auction spaces with CDA and CH at either end, and exploring other points in this space is a subject of our current work.

[11] The result for nCDA-GD is similar to that for kCDA-GD in Figure 3(d), so omitted here.

when we do not smooth prices, but more than that typically generated by GD.

To see how this happens, consider $(p_{a_{(t-1)}}, p_{b_{(t-1)}})$ and (p_{a_t}, p_{b_t}) to be two consecutive matching ask-bid pairs. If the agents are GD, the two spreads — $[p_{a_{(t-1)}}, p_{b_{(t-1)}}]$ and $[p_{a_t}, p_{b_t}]$ — will likely be close if not overlapping since GD makes shouts that are close to previous shouts. This is not true for ZI-C agents for which p_{a_t} and p_{b_t} are selected randomly and independently. Thus for ZI-C agents, $[p_{a_t}, p_{b_t}]$ may easily be well away from the previous spread $[p_{a_{(t-1)}}, p_{b_{(t-1)}}]$. If this is the case, the transaction price, p_t, determined by (6) may fall outside of the spread and the transaction price is selected to be the closest boundary of $[p_{a_t}, p_{b_t}]$ to p_t to make sure neither agents will make a loss.

Whichever of p_{a_t} and p_{b_t} is used in this case, it will be some distance from $[p_{a_{(t-1)}}, p_{b_{(t-1)}}]$. Since $p_{(t-1)}$ has to fall into $[p_{a_{(t-1)}}, p_{b_{(t-1)}}]$ for the same reason, we will get two transaction prices p_t and p_{t-1} that are not near to each other. If the auction mechanism forces ZI-C agents to "adapt" their shouts, then the fluctuation might be avoided.

Our approach is to use a *shout improvement rule* that forces buyers to bid above a running estimate of the equilibrium price, and sellers to ask below it. Thus any matching ask-bid pair must reside on the respective side of the estimate. When we use the NPricingPolicy, the price that is set will not vary far from the previous transaction price. If the estimate changes smoothly and converges to the equilibrium price, the transaction price curve is expected to be smooth as well[12].

More specifically, the shout improvement rule works in a way that is similar to the NPricingPolicy, maintaining a sliding window over a series of m transaction prices and using the average of the prices within the window as the estimate, p_e:

$$p_e = \frac{1}{m} \sum_{i=t-m+1}^{t} p_i \tag{7}$$

where p_i is the transaction price obtained at the time i (de-

[12]Interestingly, we designed the shout improvement rule originally to improve the overall efficiency, since if the estimate is totally accurate (though this is impossible with incomplete knowledge), the efficiency can be guaranteed to be 100.

termined by (6) for the NPricingPolicy). Now, at the beginning of auctions, the transaction prices may deviate greatly from the equilibrium price, and so the rule may cut off those shouts that are actually on the right side of the equilibrium price. As a result, we introduce an additional parameter, δ, to relax the restriction. All bids above $p_e - \delta$ and all asks below $p_e + \delta$ are permitted.

Note that this shout improvement rule is very different from the common "NYSE rule" that forces subsequent offers to be improvements on one another. That rule applies to offers for the same good, and so the value is "reset" by a match between bid and ask. Our rule, in contrast, maintains continuity between the offers made for successive goods (and so, as discussed later, we eventually need to consider its response to price shocks).

We call the auction mechanism obtained by adding the shout improvement rule CDA *with Estimated Equilibrium* or CDAEE. We replace CDA with CDAEE with $n = 4$ and $\delta = 0$ in the 4 experiments described in the previous section and get markets we call *k*CDAEE-ZIC, *n*CDAEE-ZIC, *k*CDAEE-GD, and *n*CDAEE-GD. The results of the 2 ZI-C markets are plotted in Figures 4(c)-4(d) and all numeric values are presented in Table 1. Figure 3(c) demonstrates the dynamic transaction price curve in nCDAEE-ZIC.

Clearly our results show average α is lower for nCDAEE-ZIC (6.0) than for nCDA-ZIC (12.2) and the difference is even more significant than between nCDA-ZIC and kCDA-ZIC (the 95% confidence intervals do not overlap), but average E_a for nCDAEE-ZIC is slightly lower than for nCDA-ZIC. Worse results are observed in nCDAEE-GD, where average α increases and average E_a is down.

One reason for this may be that GD agents adapt their shouts gradually even if their previous shouts were on the wrong side of the estimated equilibrium price and got rejected. Within the limited amount of time as the auctions last, GD agents may not be able to adapt themselves enough to make transactions, which leads to low efficiency.

This indicates that it may be beneficial to relax the shout improvement rule a little and we do this using different positive values of δ—5, 10, 15, 20—in nCDAEE markets, getting 4 new auction mechanisms denoted as *n*CDAEE*d5*, *n*CDAEE*d10*, *n*CDAEE*d15*, and *n*CDAEE*d20*. We ran these mechanisms using ZI-C and GD agents respectively and the results are shown in Figures 4(e)-4(f)[13], and Table 1.

The nCDAEE markets with $\delta \geq 5$ seem to avoid the low efficiency in the nCDAEEs with $\delta = 0$ and the kCDAEEs. Table 1 shows that the nCDAEEd5, 10, 15, 20-ZIC markets perform better than the nCDA-ZIC, and the nCDAEEd20-GD performs no worse than the nCDA-GD in terms of both α and E_a. Though only the improvement on α in markets using ZI-C traders is close to being statistically significant — obtaining low α in the ZI-C markets is our major goal in this paper — we believe that these results show that the shout improvement rule has the potential to augment the improvements demonstrated by the NPricingPolicy.

3.3 Evolving DAs using genetic algorithms

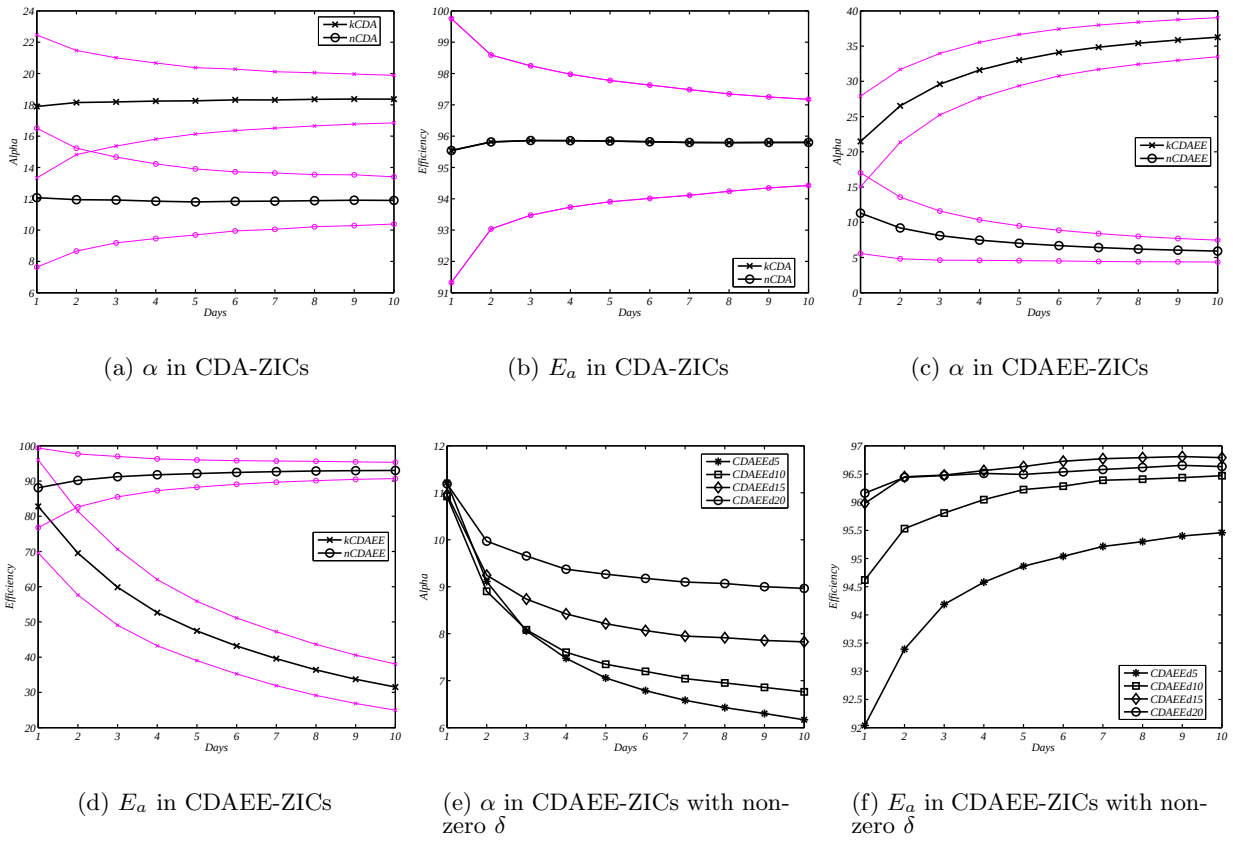
The above manual parameter tweaking is obviously not an ideal method for auction design. Our ultimate goal is to automate the process. As the first step in this direction, we conducted a series of experiments by encoding various auction parameters into a binary vector of 24 bits and evolving a population of 100 DA individuals, each associated with a randomly generated vector at the very beginning.

Each vector specifies (1) what policy is used to determine transaction prices, KPricingPolicy or NPricingPolicy, (2) what rule is used to regulate shout improvement, the NYSE rule, the CDAEE rule using sliding window mechanism as in Section 3.2, or the CDAEE rule using the Widrow-Hoff learning algorithm[14] [26] to adapt the equilibrium price estimate, and (3) when to clear the market, or, in particular, a probability $\tau \in [0, 1]$ with which the market clears whenever a new shout arrives. The search space is thus multi-dimensional, and includes points corresponding to the usual CDA ($\tau = 1$), CH ($\tau = 0$), and all the other auction mechanisms discussed above. This enables us to optimize auction mechanisms automatically by searching the space.

We first experimented up to 100 generations with minimizing α as the goal[15] and all DA individuals were evaluated in the same setting as before using homogeneous ZI-C traders. The results showed that the CDAEE shout improvement rule with the sliding window mechanism not only dominated the other choices across the whole population over generations but also appeared in the fittest mechanism individual found during evolution. This fittest individual takes 0 for δ, which is consistent with the trend exhibited by the nCDAEEd*-ZIC markets in Table 1, where nCDAEE-ZIC, or nCDAEEd0-ZIC, has the lowest average α (4.0). We also tested with maximizing E_a as the goal and found that a similar shout improvement rule prevailed with $\delta = 12$. This result is also confirmative since Table 1 shows that nCDAEEd10-ZIC has the highest average E_a among nCDAEEd*-ZIC markets.

Besides δ, the evolutionary experiments identified the values of other parameters for the fittest auction mechanisms as well. For example in the case of E_a defined as fitness, $\tau = 0.69$ was found to be optimal. This is unexpected since a CH is more efficient than a CDA with the same setup and intuitively clearing a market less frequently helps avoid less competitive shouts being involved in transactions. We leave this issue and others as our future work.

4. DISCUSSION



The main result of this paper, then, is that we have identified a new variation on the double auction, a continuous double auction with a new pricing policy and a new shout improvement rule, in which zero intelligence agents can perform well. As Walia *et al.* argue, that we get high efficiency and low α even for ZI-C agents, agents that are on the borderline between rational and irrational trading behavior, suggests that the new auction is pretty robust.

However, there is more we can do to test the robustness of this auction. For a start, we need to run further iterations of the existing experiments to identify the significance or otherwise of the improvements due to the shout improvement rule on top of the new pricing policy. We also need to examine how the new auction performs on other performance metrics and when using trading strategies other than ZI-C and GD, and we are currently running experiments with the other trading strategies in JASA, namely ZIP, Kaplan, RE,

[13] Only ZI-C markets are shown, again to save space, and standard deviations were omitted from these figures to make them cleaner.

[14] the Widrow-Hoff learning algorithm is used in the ZIP and PVT strategies to calculate the target price towards which the shout price should move.

[15] The fitness function is $F = 100 - \alpha$.

and PVT, the strategy introduced by Preist and van Tol [17]. If these tests show the mechanism to be worthwhile, we will continue with a heuristic strategy analysis of the kind introduced by Walsh *et al.* [25], using it as in [15] to evaluate the expected profit generated by the auction when traders are free to choose trading strategy.

Finally, we need to examine whether there are negative aspects of the new auction other than those already identified for some parameter settings. We note that the windows used to determine transaction price and to enforce shout improvement are similar to the history used by GD to set its offers. Experiments with GD [6] show that, as one would expect, increasing the window length slows convergence. This can be problematic when the market suffers *price shocks* — external events that alter agents' private values. This is not a scenario much considered in the literature, where traders are usually optimized for long term profit and efficiency rather than transient behavior (GD being an exception), but it seems important that the market itself be able to respond swiftly to external pressures, and response to price shocks is something we need to investigate in detail.

5. SUMMARY

This paper has described some experiments in mechanism design for auctions. As a first step towards new work on automated mechanism design, we have explored by hand some aspects of the continuous double auction. In particular, we looked at setting the transaction price by averaging over n different matched bids and asks, and incorporating a shout improvement rule that forces offers to beat the last m offers plus or minus some value δ, and showed that these modifications created an auction that can achieve high efficiency and low variation in transaction price even for agents with zero intelligence.

This new auction type is interesting on its own, as a counterpart to the mechanisms discovered by [1] and [24], but more interesting, we believe, is that n, m, and δ, along with Q_s from [1] provide a parameter space that can be searched automatically for additional new kinds of auction that optimize performance on metrics other than E_a and α, and for agents employing other kinds of trading strategies. The final contribution of this paper is to demonstrate that such an automated search can discover interesting new types of auction.

ABSTRACT

We consider the problem of auction design with agents that have interdependent values, i.e. values that depend on each others' private signals. We adopt the *contingent bids* model of Dasgupta and Maskin [3], and allow agents to submit bids of the form "if player 1 bids \$x for good A then I will bid \$y." Our main contribution is to identify a specific *linear* valuation model for which there exists an efficient auction for a single item, and then extend this to provide an approximately efficient combinatorial auction with single-minded bidders. In both auction, winners and payments are computed from the fixed point of the valuation mapping defined by contingent bids. We also adopt search in order to construct a variation on the single-item auction with improved revenue. In closing, we discuss the (many) challenges in moving to more general models of interdependent valuations.

1. INTRODUCTION

We consider the problem of auction design with agents that have interdependent values. In this setting, the value of an allocation can depend on the private signals of the other agents.

Allocation problems with interdependent values often arise in auction settings. Consider, for example, the sale of a case of vintage wine to a group of buyers with distributed information about the actual quality (and thus value) of the wine. Some of the bidders may have tasted similar wines, some may have read reviews, while still others may be complete novices. Interdependent values can also arise when a bidder's value for an allocation depends on the details of the allocation of goods to *other* bidders, and thus its value depends (indirectly) on the values of other bidders. Consider an auction for wireless spectrum. A wireless company might assign more value to some bundle of licenses if non-competing companies (e.g. with different business models) win the remaining licenses.

In addition to settings of electronic commerce, we believe that interdependent value models will be useful for many coordination problems in multiagent systems. Consider, for example decision making about resource allocation on *computational grids*, for instance in allowing a team of scientists to evaluate their value for receiving the right to be the first to work with a new data set. Accurately determining this value may require aggregating the private information of a number of different teams.

The design of efficient (and optimal) auctions with interdependent values has received some attention in the economic theory literature. In particular, under the assumption that the private information (signal) of a bidder can be captured by a single number (in combination with monotonicity requirements that prevent arbitrary information from being encoded in this number), then there exist *ex post* efficient auctions [10]. For more general models with multi-dimensional signals there are strong negative results about the ability to implement efficient outcomes (or even much at all!) in an equilibrium [3, 8].

We too will work within the one-dimensional signal model. Specifically, we follow Dasgupta and Maskin [3], but depart from the other literature on interdependent value models, by working with *contingent bids*. As we discuss in the next section, the alternative is to work in a direct revelation framework, but this appears much more cumbersome for bidders. With contingent bids, a bidder can state information such as "my bid value is \$x when bidder 2's value is \$y." Bidders do not need to describe either their own signal to the mechanism, nor the domain of signals for the other bidders. We agree with Dasgupta and Maskin that this seems very difficult. In our wine example, all bidders would have to agree with the auctioneer on a language to talk about the quality of wine. In our grid computing example, all research groups would have to agree on a common language to discuss the potential value of some new data. In this aspect, our focus on contingent bids differentiates this work from the earlier work in distributed AI of Dash et al. [4] and Ito et al. [5, 7], who consider direct revelation mechanisms.

We adopt contingent bids as first-order representations of agents' private valuation models. Our main contribution is to provide a specific instantiation of Dasgupta and Maskin's [3] contingent bid model. In particular, we define a linear contingent-bid language and establish necessary and sufficient conditions for bids to satisfy the technical conditions required for the existence of an efficient auction. We first introduce this for the single item allocation problem and later extend the language to allow for combinatorial auctions with *single minded* bidders. A single minded bidder is interested in just one particular bundle of goods.

In pursuit of an auction with improved revenue properties, for instance of importance to a seller of vintage wine, we then generalize the auction to include a "dummy" agent that represents the interest of the seller and submits a bid to increase competition and also to have the effect of setting a reservation price. Following the ideas introduced in Likhodedov and Sandholm [12, 13] we then use search to identify an auction with better revenue properties within this class of generalized auctions. Unlike the existing theory on optimal auctions with interdependent values [2], in which *interim* individual rationality (IR) is provided,[1] our auctions have the more reasonable property of *ex post* IR. This means that an agent will never pay more than its value for an allocation.

In closing, we discuss the many challenges in moving towards more general models of interdependent valuations. Even within the setting of one-dimensional signals we identify a significant practical problem in extending multi-unit auctions to allow for more than single-minded bidders. The problem relates to the amount of information that bidders are required to report to an auction about the possible valuations of other bidders.

1.1 Related Work

Dash et al. [4] define a multi-item variant on the efficient, direct-revelation mechanism for multiple identical items in Krishna [10]. Unlike the model of Dasgupta and Maskin [3] (DM), which we adopt in this paper, the model of Dash et al. requires that the mechanism knows the valuation function and signal domains of each bidder. Bidders report their signal and the mechanism determines the outcome and payments. Ito and colleagues [5, 6, 7] also study a model with one-dimensional signals in the context of a multi-item allocation problem. Unlike Dash et al. [4], their mechanisms do not need to know the valuation functions of agents. However, they remain direct revelation schemes, in that agents bid both valuation functions and signals. Again, the language for describing an agent's signal must be common knowledge to all agents and the mechanism. Ito and colleagues assumed special structure to the problem, namely that the interdependency is acyclic: there are "experts" whose signal affect the values of the other agents ("amateurs"). The experts' values are unaffected by the signal of any amateur and no amateur's signal affects the value of any other amateur. This allows for positive results in their model, which is otherwise quite general.

Jehiel et al. [9] and earlier Jehiel and Moldovanu [8], provide strong limits on *ex post* Nash implementation with interdependent valuations. When signals are multi-dimensional then efficiency is generally impossible, and it can be the case that *no* interesting social choice function can be implemented. Although, see Bikhchandani [1] for a discussion of when this negative result breaks down (and implementation is again possible.) In grid computing, an example of a multi-dimensional signal is when an agent has two signals, one relates to the *novelty* of the data set and one relates to the *noise* in the data set. One cannot combine these into one dimension while retaining properties such as increasing value with signal, also required for *ex post* implementation. Multidimensional signals present a new challenge, unseen in private value settings, because there are typically multiple signal values that correspond to the same value on some bundle of goods and no good way to provide incentives for an agent to report the correct *pair* of signals. Reports of the correct pair of signals are important to allow other agents to learn their correct value.

Finally, work on two-stage mechanisms [16] and other ascending price designs (see Krishna [10]) also shares the concern of DM for limiting the knowledge required of the mechanism and agents. We are not aware of previous attempts to instantiate the contingent bid model of DM, as we do in this paper.

[1]Cremer and McLean [2] show that if there is even a small amount of correlation between agent signals then the seller can extract *all* of the surplus from the participants. However, this requires interim IR. We are not aware of any revenue optimality results for the more reasonable requirement of *ex post* IR.

2. PRELIMINARIES

Consider a single item problem. Each agent $i \in \{1, \ldots, N\}$ has a signal $s_i \in S_i$ from some signal space S_i. The value $z_i(s) \geq 0$ of agent i for the item depends on the joint signals $s = (s_1, \ldots, s_N)$.[2] The efficient allocation is to allocate the item to the agent with maximal value. Assume quasilinear utilities, with utility $z_i(s) - p$ for the item at price p. Throughout the paper, vector notation s_{-i} denotes $(s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_N)$.

First suppose that the auctioneer has knowledge of valuation functions $(z_1, \ldots, z_N)$, but not signals. One can construct a truthful and efficient "second-price" auction for some technical restrictions as follows. Each agent reports its signal $\hat{s}_i$, perhaps untruthfully. The auctioneer computes $z_i(\hat{s})$ for every i, allocates the item to the agent with $\max_i\{z_i(\hat{s})\}$ and then charges the agent $p_i =$

$$\min_{s_i'} \quad z_i(s_i', \hat{s}_{-i}) \tag{1}$$
$$\text{s.t.} \quad z_i(s_i', \hat{s}_{-i}) \geq \max_{j \neq i}\{z_j(s_i', \hat{s}_{-i})\}$$

The auction is efficient if valuations satisfy *monotonicity*,

$$\frac{\partial z_i(s)}{\partial s_i} \geq 0, \quad \forall s, \forall i, \tag{2}$$

and the *single-crossing condition* (SCC),

$$\frac{\partial z_i(s)}{\partial s_i} > \frac{\partial z_j(s)}{\partial s_i}, \tag{3}$$

for all s such that $z_i(s) = \max_{j \neq i}\{z_j(s)\}$.

THEOREM 1. *[10] The second-price auction is efficient when the monotonicity and single-crossing property holds.*

PROOF. (sketch) Each agent i faces a price p_i that solves Eq. (1) and is independent of its own report. Suppose the other agents bid truthfully, with $\hat{s}_{-i} = s_{-i}$. Then, by SCC and monotonicity, if agent i bids truthfully ($\hat{s}_i = s_i$) then it is allocated the good whenever its value is greater than p_i, and not allocated the good otherwise. (Fix s_{-i}. Then SCC implies that for all signals less than that which defines p_i agent i is not a winner, and for all signals greater agent i is the winner.) By reporting its true signal, the agent maximizes its utility with respect to a price that is independent of its own report. This is an *ex post* Nash equilibrium (but not dominant strategy equilibrium). Truthful reporting is only best-response when the other agents are also truthful (but whatever their true signals), because the reports of the other agents are required for agent i's true value to be correctly determined. □

This auction reduces to the Vickrey auction for private value models. Yet, there is a practical problem with this protocol. As argued by DM, the auctioneer must know the signal space of agents (in order to define an expressive language for signals), and also the

[2]Notation $z_i : S_1 \times \ldots S_N \rightarrow \mathbb{R}_{\geq 0}$ denotes an agent's value as a function of the signals of all agents. Below, $b_i : \mathbb{R}_{\geq 0}^{N-1} \rightarrow \mathbb{R}_{\geq 0}$ denotes a contingent bid function, and $v_i \in \mathbb{R}_{\geq 0}$ is reserved to denote the *value* of agent i: as determined either via $z_i(s)$ or as the fixed point defined by agents' contingent bids.

valuation function z_i of each agent. This seems to be a heavy burden. Moreover, each agent must report its signal. In general, a signal (for instance information about a case of wine, or the data set in grid computing) can be difficult for a participant to describe.

Instead, DM work in the framework of *contingent bids*. Let $v_i = z_i(s) \geq 0$ denote agent i's value for the good. Agents submit *contingent bids*, $b_i : \mathbb{R}_{\geq 0}^{N-1}$, where $b_i(v_{-i})$ is the (reported) value given values $v_{-i} = (v_1, \ldots, v_{i-1}, v_{i+1}, v_N)$ of other agents. Given contingent bids, the auctioneer determines reported values as the *fixed point* of the mapping:

$$(v_1, \ldots, v_N) \longmapsto (b_1(v_{-1}), \ldots, b_N(v_{-N})) \tag{4}$$

We refer to this fixed point as a *valuation equilibrium*, and denote the fixed point as v°. Agent i is said to bid truthfully when v° corresponds to interdependent valuations $z(s)$ given signals, i.e.

$$b_i(z_{-i}(s_i, s'_{-i})) = z_i(s_i, s'_{-i}), \quad \forall s'_{-i}, \forall s_i \tag{5}$$

Each agent submits a contingent bid, so that its value in the valuation equilibrium is equal to its true value given the signal information s_{-i} that is implicit in the fixed-point values of the other agents. *When all agents bid truthfully the fixed point* $(v_1^\circ, \ldots, v_N^\circ) = (z_1(s), \ldots, z_N(s))$.

DM propose the following contingent bid auction, which is well defined when there exists a *unique* valuation equilibrium:

1. Given bids, compute the valuation equilibrium $(v_1^\circ, \ldots, v_N^\circ)$.
2. Allocate the item to the agent with the maximal fixed-point value, breaking ties at random.
3. For the winner, agent i, compute payment p_i as $\min v_i'$ s.t. $v_i' \geq \max_{j \neq i}\{v_j^*\}$, where $v_j^* = b_j(v_i', v_{-ij}^*)$ for all $j \neq i$, denoting the fixed-point valuations to other agents when agent i's bid is adjusted to some value v_i'.

The payment to the winner is computed as the minimal (non-contingent) value that the winner could have submitted and still remained the winner.

THEOREM 2. *[3] The contingent-bid auction is efficient (in an ex post Nash equilibrium) when valuations satisfy monotonicity and SCC, and when the fixed point of the mapping defined by contingent bids is unique.*

The proof follows (modulo technicalities about the uniqueness of fixed points) from the structure of the proof of Theorem 1. Agents will bid truthfully in equilibrium.

Contingent bids make interdependent value auctions practical. The mechanism does not need to know the signal spaces or valuation functions of agents. On the other hand, DM note that the bidders must now have knowledge of each others' valuation functions to be able to deduce implicit signal information in the valuation equilibrium.[3] We adopt a different view on this issue. Let us simply consider the contingent-value model as *the* underlying model of value interdependency. With this view point, the contingent bid model requires an agent to know enough about other agents (and that this is known by other agents and so on *ad infinitum*) to define its value contingent on their values.

[3]In fact, DM remark that all that is necessary is that the agents are able to make correct inferences at the inflection point that defines the price, i.e. where the winner changes from one agent to another agent.

3. A LINEAR VALUATION MODEL

An actual instantiation of the contingent-bid auction requires a concrete bidding language, designed so that bids submitted in the language define a mapping (Eq. 4) with a unique fixed point, and so that valuations at this fixed point satisfy monotonicity and SCC. In this paper we adopt a linear bidding language,

$$b_i(v_{-i}) = v_{i0} + \sum_{j \neq i} \alpha_{ij} v_j, \tag{6}$$

where $v_{i0} \geq 0$ denotes agent i's stand-alone value when other agents have zero value, and $\alpha_{ij} \in [0, 1)$ is a weight assigned by agent i to the value of other bidders. Conceptually, the stand-alone value v_{i0} plays the role of the *signal* and the α-weights indicate implicit structure about the relationships between valuation functions $z = (z_1, \ldots, z_N)$ in the economy.

3.1 Example

Suppose there are three companies, $\{1, 2, 3\}$, bidding in an auction. Their values are interdependent. For example, company 1 is paying attention to the values of company 2 and company 3:

$$b_1(v_2, v_3) = 50 + 0.3v_2 + 0.5v_3 \tag{7}$$

In Eq. (7), company 1 places the weight 0.3 on the value of company 2 and weight 0.5 on the value of company 3. Similarly, we assume 2 and 3 have the following (truthful) contingent bids:

$$b_2(v_1, v_3) = 60 + 0.4v_1 + 0.4v_3$$
$$b_3(v_1, v_2) = 70$$

Namely, 1 and 2 are paying attention to the values of the other companies, while 3 ignores the others' values. The sum of weights are less than 1.0, which ensures uniqueness of the valuation equilibrium (the details of this result are shown in Section 3.2.) The valuations implied by these bids are computed as the fixed point $(v_1^\circ, v_2^\circ, v_3^\circ)$ of mapping Eq. (4). In this case, the fixed point can be found by solving:

$$v_1^\circ = 50 + 0.3v_2^\circ + 0.5v_3^\circ \tag{8}$$
$$v_2^\circ = 60 + 0.4v_1^\circ + 0.4v_3^\circ \tag{9}$$
$$v_3^\circ = 70, \tag{10}$$

for $(v_1^\circ, v_2^\circ, v_3^\circ) = (126.6, 138.6, 70.0)$. Because at the fixed point, company 2 has the maximum value it is the winner. Its payment is computed as v_2' that solves $v_2' = \max\{v_1^*, v_3^*\}$, where $v_1^* = b_1(v_2', v_3^*)$ and $v_3^* = b_3(v_2', v_1^*)$ (i.e. the updated fixed point values for the other companies when 2's bid is $b_2(v_1, v_3) = v_2'$). We have $v_1^* > v_3^*$, since $v_1^* = b_1(v_2', v_3^*) = 50 + 0.3v_2' + 0.5v_3^*$ and $v_3^* = b_3(v_2', v_1^*) = 70$, and so $v_1^* = 85 + 0.3\max\{v_1^*, v_3^*\}$. Solving, $v_2' = v_1^*$ and $v_1^* = 850/7 \approx 121.4$ solves $v_1^* = 85 + 0.3v_1^*$. Thus, company 2 wins for a price of 121.4. Notice that this is less than v_1°, since the contingent value of company 1 is also reduced in determining the threshold bid at which 2 would have just won.

3.2 Establishing Technical Conditions

Given the linear bidding language we must show the uniqueness of a fixed point, and then also monotonicity and SCC. First, we prove conditions on weights α_{ij} for which the fixed point of the mapping $(v_1, \ldots, v_N) \mapsto (b_1(v_{-1}), \ldots, b_N(v_{-N}))$ is unique. For this we adopt Banach's Fixed Point Theorem (see Vohra [17]).

THEOREM 3 (BANACH'S FIXED POINT THEOREM). *(BFPT) Let (Y, d) be a complete metric space*[4] *and let $f : Y \to Y$*

[4]A distance d is a *metric* for set Y if it satisfies: $d(x, y) + d(y, z) \geq$

be a contraction mapping on Y, i.e. such that there is some real number $q < 1$ for which

$$d(f(x), f(y)) \leq q \cdot d(x, y)$$

for all $x, y \in Y$. Then, the function f admits a unique fixed point x^*, which can be computed as the limit of applying f from any arbitrary point x_0 in Y.

Note that BFPT requires a complete metric space but allows a metric space that is not compact. So, for Y adopt the space of non-negative valuations, i.e. $\mathbf{R}^N_{\geq 0}$ for N bidders. Instantiate mapping f as $b(v) = (b_1(v_{-1}), \ldots, b_N(v_{-N}))$, where b_i is the contingent bid function, Eq. (6). This is a function into $\mathbb{R}^N_{\geq 0}$. Define the distance metric, d, as:

$$d(v, w) = \max_{i \in \{1,\ldots,N\}} |v_i - w_i|, \tag{11}$$

for $v, w \in \mathbb{R}^N_{\geq 0}$. For example, consider two agents with $\alpha_{12} = \alpha_{21} = 0.5$, and consider values $v = (v_1, v_2) \in \mathbf{R}^2_{\geq 0}$ and $w = (w_1, w_2) \in \mathbf{R}^2_{\geq 0}$. Then, we have $d(v, w) = \max(|v_1 - w_1|, |v_2 - w_2|)$ and $d(b(v), b(w)) = \max(|s_1 + v_2/2 - (s_1 + w_2/2)|, |s_2 + v_1/2 - (s_2 + w_1/2)|) = \max(|v_1/2 - w_1/2|, |v_2/2 - w_2/2|)$. Clearly, $\max(|v_1/2 - w_1/2|, |v_2/2 - w_2/2|) < \max(|v_1 - w_1|, |v_2 - w_2|)$. This analysis extends to the general case.

LEMMA 1. *There is a unique valuation equilibrium when $\sum_{j \neq i} \alpha_{ij} < 1$ for all bidders i, and this equilibrium can be computed as the limit to a sequence of the contingent-bid mapping $b : \mathbb{R}^N_{\geq 0} \to \mathbb{R}^N_{\geq 0}$, starting from an arbitrary $v^0 \in \mathbf{R}^N_{\geq 0}$.*

PROOF. Fix some $v, w \in \mathbb{R}^N_{\geq 0}$. To show is $\max_i\{|b_i(v) - b_i(w)|\} < \max_i\{|v_i - w_i|\}$. Consider any agent i. We will establish $|b_i(v) - b_i(w)| < \max_{j \neq i}\{|v_j - w_j|\}$, which implies the required result. Expanding, we require $|s_i + \sum_{j \neq i} \alpha_{ij} v_j - (s_i + \sum_{j \neq i} \alpha_{ij} w_j)| < \max_{j \neq i}\{|v_j - w_j|\}$. Simplifying, we require $|\sum_{j \neq i}(v_j - w_j)| < \max_{j \neq i}\{|v_j - w_j|\}$. For this, it is sufficient to show that $\sum_{j \neq i} \alpha_{ij} |v_j - w_j| < \max_{j \neq i}\{|v_j - w_j|\}$, which is true since $\sum_{j \neq i} \alpha_{ij} < 1$ and $\alpha_{ij} \in [0, 1)$. □

Thus, for uniqueness it is sufficient that the language restricts the total weight that each bidder i assigns to the values of other bidders so that $\sum_{j \neq i} \alpha_{ij} < 1$. For truthful bidding to form an *ex post* Nash equilibrium we also need the analogs to monotonicity and SCC to hold in the contingent-bid model.

LEMMA 2. *For all contingent bids with $\sum_{j \neq i} \alpha_{ij} < 1$ for all bidders i, then $\partial v_j^\circ / \partial v_{i0} < \partial v_i^\circ / \partial v_{i0}$ for all bidders i, j (i.e. the analog to the single-crossing condition).*

PROOF. Consider some finite number of agents, N. Adopt w_i to denote v_{i0} in agent bids. Towards a contradiction, assume

$$\frac{\partial v_1^\circ}{\partial w_1} \leq \frac{\partial v_2^\circ}{\partial w_1} = \alpha_{21} \frac{\partial v_1^\circ}{\partial w_1} + \sum_{j \neq \{1,2\}} \alpha_{2j} \frac{\partial v_j^\circ}{\partial w_1} \tag{12}$$

Since $\sum_{j \neq 1} \alpha_{1j} < 1$ and $\alpha_{1j} \geq 0$ this implies $N > 2$ and $\partial v_j^\circ / \partial w_1 > \partial v_2^\circ / \partial w_1$ for some $j \neq \{1, 2\}$. W.l.o.g., suppose that $\partial v_3^\circ / \partial w_1 > \partial v_2^\circ / \partial w_1 \geq \partial v_1^\circ / \partial w_1$. Considering agent 3, this requires

$$\alpha_{31} \frac{\partial v_1^\circ}{\partial w_1} + \alpha_{32} \frac{\partial v_2^\circ}{\partial w_1} + \sum_{j \neq \{1,2,3\}} \alpha_{3j} \frac{\partial v_j^\circ}{\partial w_1} > \frac{\partial v_2^\circ}{\partial w_1} \tag{13}$$

Thus, we must have $N > 3$ agents. W.l.o.g., suppose that $\partial v_4^\circ / \partial w_1 > \partial v_3^\circ / \partial w_1$. This induction continues indefinitely, leading to a contradiction for any finite number of agents. □

Informally, the system of equations cannot sustain a fixed point at which the dependency of some v_j°, for $j \neq i$, on v_{i0} is greater than that of v_i° itself because the effect is "dampened" in all bids by some multiplier less than one. Monotonicity, which requires $v_i^\circ / \partial v_{i0} \geq 0$ is immediate since all coefficients in the mapping $v \mapsto b(v)$ are non-negative.

THEOREM 4. *The contingent-bid auction defined with the linear contingent-bid language is efficient (in an ex post Nash equilibrium) when the language is expressive.*

By "expressive", we mean that a bidder should be able to use the language to define a bid value that is equal to its true value, whatever the values of the other bidders. The proof follows from Lemmas 1 and 2, together with Theorem 2. Informally, once uniqueness is ensured so that the auction is well defined, fix the bids b_{-i} from agents $j \neq i$. Agent i faces an agent-independent price, defined in terms of the smallest uncontingent bid $b'_i(v_{-i}) = v'_{i0}$ at which it would win in the valuation equilibrium, given bids b_{-i}. Then, by SCC and monotonicity, and assuming the other agents are bidding truthfully, the agent will win (and make this payment) when it bids truthfully whenever its true value is greater than this price and not otherwise. Realize that an agent cannot gain by misstating either its stand-alone value v_{i0} or its α-weights.

4. TOWARDS REVENUE OPTIMALITY

We can consider a family of modified interdependent value auctions to find an auction with improved revenue. Following the direction set by Likhodedov and Sandholm [12] (in private value combinatorial auctions), we introduce a "dummy agent" (indexed zero) to represent the seller and then modify the winner-determination problem by defining static *weights* $\beta_i \in [0, 1]$ on each agent. An allocation $x = (x_0, x_1, \ldots, x_N)$, with $x_i \in \{0, 1\}$, $x_0 \in \{0, 1\}$ to indicate whether the dummy agent receives the item and the item goes unsold, and $\sum_{i=0}^N x_i = 1$, is selected to solve:

$$\max_x \left\{ \beta_0 v_0(x) + \sum_{i=1}^N \beta_i v_i^\circ(x) \right\}, \tag{14}$$

where $v_i^\circ(x) = v_i^\circ$ if $x_i = 1$ and 0 otherwise, $v_0(x) = v_0$ if $x_0 = 1$ and 0 otherwise denotes the value of the dummy agent (v_0 can be thought of as the reservation price), and v_i° are agent's fixed point values.

Value v_0 and weights β are fixed before bids are received and heuristically optimized by the auction designer using prior information about agent values. The weighted contingent-bid auction is defined as:

1. Define v_0 and weights $\beta \in [0, 1]^{N+1}$.
2. Receive bids and compute the fixed point $(v_1^\circ, \ldots, v_N^\circ)$. (Note that agents cannot make their bids contingent on the dummy agent's value, and that the dummy agent's value is uncontingent and fixed at v_0.)

$d(x, z)$, $d(x, y) = d(y, x)$, $d(x, x) = 0$, and $d(x, y) = 0 \Rightarrow x = y$ for all $x, y, z \in Y$. A metric space is *complete* if it contains all limit points of *Cauchy sequences*, where a Cauchy sequence is a sequence in which $\lim_{m \to \infty} d(x_m, x_{m+1}) = 0$. E.g., (0,1) is not complete because $1/2, 1/3, \ldots$ is Cauchy but does not have a limit in the space. On the other hand, $[0, 1]$ is complete, as are $\mathbf{R}^d$ and $\mathbf{R}^d_{\geq 0}$. A complete metric space need not be closed (or compact).

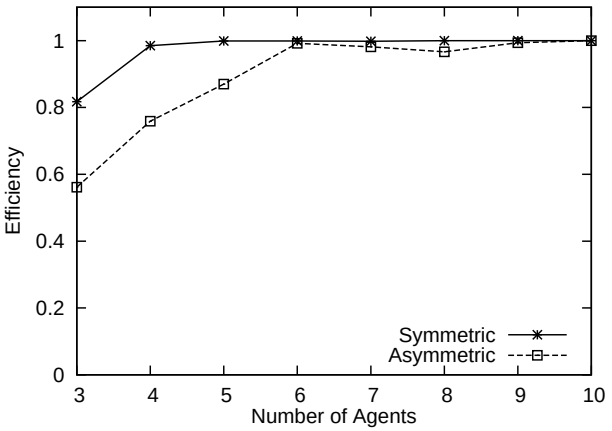

Figure 1: Average Efficiency in the Optimal Auction for the Symmetric and Asymmetric Environments.

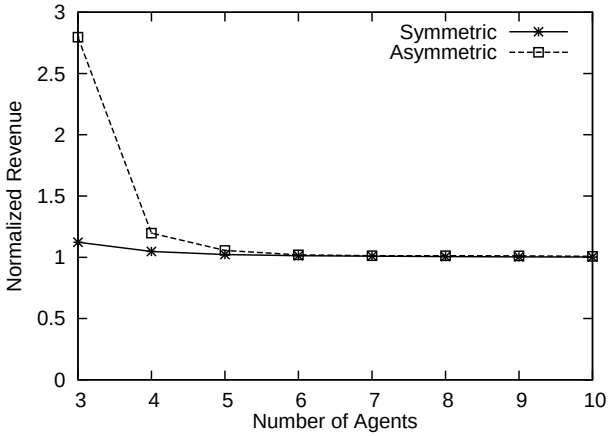

Figure 2: Average Normalized Revenue in the Optimal Auction for the Symmetric and Asymmetric Environments.

3. Compute the winner as the agent with the maximal weighted value. If the dummy agent wins then the good is not sold and no revenue is received.

4. If the item is sold to agent $i \neq 0$, then compute the payment: Decrease v_i' until $\beta_i v_i' = \max_{j \neq i, j=0}\{\beta_j v_j^*\}$, where v_j^* is the new fixed point for agent j given value v_i' to agent i (i.e., $v_j^* = b_j(v_i', v_{-ij}^*)$ for all j). This value, at which i would be just about to stop winning, is the payment.

Clearly, this auction reduces to the standard auction when the weights are symmetric and $v_0 = 0$. From Myerson's [15] work on optimal auctions, we should expect weights that bias in favor of agents that are *a priori* less competitive. It should also be fairly clear that the auction remains truthful. One needs to show that the price to the winner is still independent of its bid, and that the winner wins when its fixed point valuation is above the price, and only then. (The proof is omitted in the interest of space.)

In our experiments, we consider a symmetric environment with the signal s_i for each agent $i \neq 0$ is sampled $s_i \sim Uniform(0, 100)$, and an asymmetric environment with the signal for agent i is sampled from distribution $Uniform(0, L_i)$, where $L_i = 10 + i\delta$ and $\delta = \frac{300-10}{N}$. This has the effect of making the expected signal value of agents increase with the index of the agent in the asymmetric environment. Then, for each agent i we determine the α-weights that define the contingent valuations as follows:

(1) Each $j \neq i$ has $\alpha_{ij} = 0$ with prob. 0.5, otherwise sample α_{ij} from $Uniform(0, 1)$.
(2) Determine a total alpha-weight, m_i, as follows:
(3.1) For the *symmetric* environment, by sampling from a Gaussian distribution with mean 0.5 and standard deviation 0.25, truncated to $[0, 1)$.
(3.2) For the *asymmetric* environment, by sampling from a Gaussian distribution with mean $\mu_i = 0.3 + i\delta'$ and standard deviation 0.25, truncated to $[0, 1)$, with $\delta' = \frac{1.0-0.3}{N}$. The effect is to cause the expected total weight assigned to the values of other agents to increase with the index of the agent.
(4) Normalize weights α_i to have total weight m_i, by multiplying each α_{ij} by $\frac{m_i}{\sum_{j \neq i} \alpha_{ij}}$.

We use search over auction parameters $(v_0, \beta_0, \beta_1, \ldots, \beta_N)$, to maximize the expected revenue. In all cases, we normalize weights so that $w_0 = 1/N$ and $\sum_{i=1}^{n} w_i = 1$, so that $\sum_{i=0}^{n} = (1 + N)/N$. Normalization is achieved by setting weights on $i > 1$ and making w_1 a dependent variable. The search space is discretized, with $v_0 \in \{0, 10, \ldots, 100\}$, and weights $w_i \in \{0, 0.1, \ldots, 1\} \cup \{1/N\}$. Because our problem was quite small and because our goal was to get an initial understanding of whether revenue can be improved in interdependent value auctions we simply enumerate all grid points and select the optimal auction parameters. Future work will explore local search and other approximation methods, as in Likhodedov and Sandholm [13].

To evaluate a parameterization, we average over 4000 instances for the symmetric environment and 5000 instances for the asymmetric environment. We compare the average revenue and efficiency in the optimized auctions with the revenue and efficiency of the standard contingent bid auctions.

Figure 1 illustrates the average efficiency of the optimal auction, i.e. the average ratio of total value in the optimal auction to the maximal value (achieved in the standard auction), for different numbers of agents. Figure 2 illustrates the average normalized revenue of the optimal auction, i.e. the average ratio of total revenue in the optimal auction to the total revenue in the efficient auction, for different numbers of agents. As expected, we see that the auctions can be optimized for revenue, although at some loss in efficiency and with the benefit quickly dropping off as the number of agents increases to 5 or more. In addition, for our distributions, the possible benefit is greater in the asymmetric setting than in the symmetric setting.

Looking at the optimal parameters, the optimal revenue was achieved in the symmetric environment with symmetric weights. For the asymmetric environment, the optimal weights were sometimes asymmetric, for instance when there are 3 agents the optimal weight assignment was 0.5 for agent 1, 0.3 for agent 2, and 0.2 for agent 3. Moreover, optimal weights were always decreasing with agents as we expected from Myerson's [15] study of asymmetric private value auctions. This suggests that for local search it would be useful to restrict the search space to only allow states with weights that are (weakly) decreasing with agent index. The optimal choice for v_0 in the asymmetric environment varied from 50 to 110, and averaged around 80.

5. SINGLE-MINDED CAS

Many interesting auction scenarios have *multiple items* and inter-

dependent values. For instance, consider selling a mix of different bottles and allowing bidders to put together there own "cases" of wine. By adopting *single-minded* bidders, interested in a particular bundle of goods, we consider the simplest possible model of interdependent value CAs. Agents have *two*-dimensional, consisting of the description of the bundle in which it is interested and its signal, conveying information about the value of its bundle (and perhaps about the value of other agents for other bundles.) We construct an approximately efficient auction, which satisfies a generalization of the single-crossing condition.

5.1 Extending the Contingent-Bid Language

Let G denote the set of goods. A single-minded bidder has an *interesting bundle* $W_i \subseteq G$ and an interdependent valuation function $z_i(X, s) \geq 0$ on bundles $X \subseteq G$, defined in terms of signals $s = (s_1, \ldots, s_N)$ as:

$$z_i(X, s) = \begin{cases} z_i(s) & \text{if } X \supseteq W_i \\ 0 & \text{otherwise} \end{cases} \quad (15)$$

Here, we assume *free-disposal*, so that an agent's value is (weakly) increasing with additional goods. Function, $z_i(s) \geq 0$, defines the agent's value for an interesting bundle given signals s.

The contingent-bid language is extended to allow a bid by agent i to report an interesting bundle, $\hat{W}_i$ (perhaps untruthfully), a stand-alone value $v_{i0} \geq 0$, and *weight-bundle pairs* $\{(\alpha_{i1}, X_{i1}), \ldots, (\alpha_{iN}, X_{iN})\}$ for agents $j \neq i$. Taken together, this defines the following contingent bid function:

$$b_i(X, v_{-i}) = \begin{cases} v_{i0} + \sum_{j \neq i} \alpha_{ij} v_j(X_{ij}), & \text{for } X \supseteq \hat{W}_i \\ 0, & \text{otherwise} \end{cases} \quad (16)$$

We follow the earlier notation: b_i is a contingent-bid, now for each bundle X, and $v_i(X)$ denotes an agent's value for a bundle (determined either in a fixed point, or via its valuation function z_i and signals of others). We also require $\alpha_{ij} \in [0, 1)$ and $\sum_{j \neq i} \alpha_{ij} < 1$ for all i, as before. The valuation equilibrium is defined as a fixed point of the mapping $(v_1, \ldots, v_N) \mapsto (b_1(v_{-1}), \ldots, b_N(v_{-N}))$, where $v_i : 2^G \to \mathbb{R}_{\geq 0}$ and $b_i(v_{-i}) : 2^G \to \mathbb{R}_{\geq 0}$ (i.e. the restriction of the agent's contingent bid function, given values of other agents for each bundle.)

An agent's value for some bundle X is defined in terms of the value of other agents $j \neq i$ for other bundles X_{ij}, and also depends on whether $X \supseteq \hat{W}_i$. Realize that X_{ij}, the bundle that bidder i picks out for bidder j, in defining its dependency on the valuation function of bidder j, need not be the same as either $\hat{W}_i$ or $\hat{W}_j$. This provides useful expressiveness as well as ensuring that the knowledge requirements are reasonable. (See the example in Section 5.3.)

THEOREM 5. *The single-minded contingent bid model has a unique fixed point when $\sum_{j \neq i} \alpha_{ij} < 1$ for all i.*

PROOF. By reduction to the single-item contingent bid model. Given a set of contingent bids b, simplify the bids as follows: for each agent i, replace X_{ij} with $\hat{W}_j$ if $X_{ij} \supseteq \hat{W}_j$ and replace X_{ij} with $\emptyset$ otherwise. Since $v_i(\emptyset) = 0$ for all agents, this has the effect of removing any dependence on bundles of this kind. Given this simplification, the fixed point can be characterized as the fixed point to the system of equations

$$b_1(\hat{W}_i, v_{-1}) = v_{10} + \sum_{j \neq 1} \alpha_{1j} v_j(\hat{W}_j) \quad (17)$$

$$\cdots \qquad \cdots$$

$$b_N(\hat{W}_N, v_{-N}) = v_{N0} + \sum_{j \neq N} \alpha_{Nj} v_j(\hat{W}_j), \quad (18)$$

which have exactly the same form as for the single-item contingent bid model because the same bundle $\hat{W}_i$ appears for agent i in all equations. Thus, there is a unique solution. □

5.2 Failure of Generalized SCC

It is tempting to generalize the efficient auction described for the single item case as follows: (1) compute the fixed point valuation functions v° defined by the mapping induced by Eq. (16); (2) compute the efficient allocation $X^* = (X_1^*, \ldots, X_N^*) = \arg\max_{X \in \Gamma} \sum_i v_i^\circ(X_i)$ to maximize total value (breaking ties at random), where Γ denotes the feasible allocations (restricted to allocations in which agent i either receives $\emptyset$ or $\hat{W}_i$); and (3) compute payment to each winner i, as:

$$\begin{aligned} &\min \quad v_i' \\ &\text{s.t.} \quad v_i' + \sum_{j \neq i} v_j^*(X_j^*) \geq \max_{X \in \Gamma} \sum_{j \neq i} v_j^*(X_j), \end{aligned} \quad (19)$$

where $v_j^*(X) = b_j(X, (\vec{v}_i', v^*_{-ij}))$, and $\vec{v}_i'(X) = v_i'$ for $X \supseteq \hat{w}_i$ and zero otherwise. This has the same structure as the previous auction: v^*_{-i} denotes the revised fixed point when agent i bids value v_i' on its interesting bundle $\hat{W}_i$; thus, agent i pays the smallest amount it could have bid and still won, also accounting for the effect of its new report on the values of other agents.

For truthful bidding to be an *ex post* Nash equilibrium in this auction, it would be sufficient for the valuations to satisfy a generalized form of the monotonicity and single-crossing conditions,[5] which combine as:

DEFINITION 1 (GENERALIZED SCC). *If, for signals $(s_1, \ldots, s_N)$ there is a pair of allocations X and X', tied for value, i.e.:*

$$\sum_{j=1}^{N} z_j(X_j, s) = \sum_{j=1}^{N} z_j(X_j', s) = \max_{X'' \in \Gamma} \sum_j z_j(X_j'', s) \quad (20)$$

then for every agent i such that $X_i \neq X_i'$, we require:

$$\left[\frac{\partial}{\partial s_i} z_i(X_i, s) > \frac{\partial}{\partial s_i} z_i(X_i', s) \right]$$
$$\iff \left[\frac{\partial}{\partial s_i} \sum_{j=1}^{N} z_j(X_j, s) > \frac{\partial}{\partial s_i} \sum_{j=1}^{N} z_j(X_j', s) \right] \quad (21)$$

In words, generalized SCC requires that the value of agent i for X is improving more quickly than for X' with respect to its signal whenever this is true for the economy of agents in aggregate, and vice versa. Conceptually, this will be true when the marginal effect of an agent's signal on its own value dominates the marginal effect of its signal on the aggregate economy.

THEOREM 6. *[14] The second-price interdependent value single-minded CA auction is efficient in an ex post Nash equilibrium when the generalized SCC property holds.*

For private value single-minded CAs, this auction is equivalent to the VCG mechanism and truthful bidding is a dominant strategy equilibrium. But, we will show that generalized SCC, and thus incentive compatibility, fails in our interdependent value model. Consider Eq. (21) for single-minded CAs. The LHS of the bidirectional condition is only true when $X_i = W_i$ and $X_i' = \emptyset$. We see that generalized SCC requires that whenever an allocation in

[5]Personal communication [14]. Earlier conditions, as described in Dasgupta and Maskin [3], appear too strong to be useful.

which agent i wins and an allocation in which agent i loses are tied for total value, then if a change in agent i's signal changes the allocation it must be that an *increase* in its signal causes the allocation in which the agent is the winner to be selected. Thus, generalized SCC reduces to the following requirement: *for any signals s_{-i} of other agents, if an agent i is a winner for some signal s_i then the agent must remain a winner for all higher signals.* Notice that the allocation of items to other agents can change for higher signals, as long as agent i always retains bundle W_i.

5.3 Example

Consider goods $G = \{A, B, C\}$ and 5 agents, with (truthful) contingent bids:

$$b_1(AB, v_{-1}) = 10 + 0.5v_2(C) \quad (22)$$

$$b_2(C, v_{-2}) = 10 + 0.4v_1(A) \quad (23)$$

$$b_3(ABC, v_{-3}) = 5 + 0.2v_1(AB) + 0.6v_2(ABC) \quad (24)$$

$$b_4(A, v_{-4}) = 1 + 2/3v_1(ABC) \quad (25)$$

$$b_5(BC, v_{-5}) = 1 + 2/3v_1(ABC) \quad (26)$$

This can be simplified, replacing X_{ij} with W_j if $X_{ij} \supseteq W_j$ and $\emptyset$ otherwise (and removing this term.) We are left with $b_2(C, v_{-2}) = 10 + 0.4v_1(\emptyset) = 10$, $b_1(AB, v_{-1}) = 10 + 0.5v_2(C) = 15$, $b_3(ABC) = 14$, and $b_4(A) = b_5(BC) = 11$.

Suppose agents bid truthfully with $b_i = v_i$ for all agents. The final allocation is $(AB, C, \emptyset, \emptyset, \emptyset)$. To compute the payment by agent 1, we solve (by Eq. 19) $\min v_1'$ s.t. $v_1' + 10 \geq 5 + 0.2v_1' + 6$ (for allocation $(\emptyset, \emptyset, ABC, \emptyset, \emptyset)$), $v_1' + 10 \geq 10 + 1 + 2/3v_1'$ (for allocation $(\emptyset, C, \emptyset, A, \emptyset)$, and $v_1' + 10 \geq 1 + 2/3v_1' + 1 + 2/3v_1'$ (for allocation $(\emptyset, \emptyset, \emptyset, A, BC)$. The first two constraints require $v_1' \geq 1.25, v_1' \geq 3$, while the third constraint not binding. Thus, agent 1's payment is $p_1 = 3$. At a bid equal to this price, the auctioneer would be indifferent between allocation $(AB, C, \emptyset, \emptyset, \emptyset)$ and $(\emptyset, C, \emptyset, A, \emptyset)$. For agent 2, we solve $\min v_2'$ s.t. $10 + 0.5v_2' + v_2' \geq 5 + 0.2(10 + 0.5v_2') + 0.6v_2'$ (allocation $(\emptyset, \emptyset, ABC, \emptyset, \emptyset)$) and $10 + 0.5v_2' + v_2' \geq 2 + 4/3(10 + v_2'/2)$ (allocation $(\emptyset, \emptyset, \emptyset, A, BC)$. Only the second constraint is binding, and requires $v_2' \geq 32/5$. Thus, agent 2's payment is 32/5=6.4.

To see the failure of generalized SCC, let w_1 denote agent 1's stand-alone value and consider what happens as w_1 is increased from 10. When $w_1 = 19$ we have $v_1(AB, v_{-1}) = 19 + 0.5v_2(C)$, and solving for the valuation equilibrium we find $v_1(AB) = 24, v_2(C) = 10, v_3(ABC) = 79/5 = 15.8, v_4(A) = 17$ and $v_5(BC) = 17$. At this point, allocations $X = (AB, C, \emptyset, \emptyset, \emptyset)$ and $X' = (\emptyset, \emptyset, \emptyset, A, BC)$ are tied for value. In addition, $\partial v_1^\circ(X_1)/\partial w_1 > \partial v_1^\circ(X_1')/\partial w_1 = 0$. For the analog to generalized SCC in the contingent-bid model, we need:

$$\frac{\partial}{\partial w_1}\left[v_1^\circ(X_1) + v_2^\circ(X_2)\right] > \frac{\partial}{\partial w_1}\left[v_4^\circ(X_4') + v_5^\circ(X_5')\right], \quad (27)$$

but this does not hold because $\partial(v_1^\circ(X_1) + v_2^\circ(X_2))/\partial w_1 = 1 < \partial(v_4^\circ(X_4') + v_5^\circ(X_5'))/\partial w_1 = 4/3$.

The implication of this failure of generalized SCC is that if agent 1 has true value greater than 34, and the other contingent valuations of agents were unchanged its equilibrium strategy is not to bid truthfully. For example, if its stand-alone value was 20 but its α-weights were unchanged from the example, and if the bids b_{-1} were unchanged, then the agent would *lose* if bidding truthfully. The selected allocation would give A to agent 4 and BC to agent 5. The agent could do better by reporting an uncontingent bid of $b_1(AB, v_{-1}) = 15$; it would win and make a payment of 3.

Failure of generalized SCC occurs in this example because agent 1's value does not affect the value of the other agent (agent 2) with which it must form a winning coalition. On the other hand, its value affects the value of both agents 4 and 5 in the competing coalition.

5.4 A Truthful Single-Minded CA

We can instead define an approximately efficient auction using a *greedy* allocation rule, which is parameterized with some constant $c > 0$. The auction generalizes the auction proposed in Lehmann et al. [11] for single-minded bidders and private values to the setting of interdependent values.[6] It also reduces to our single-item auction when all agents bid on bundles with overlapping goods, so that only one agent can win. The auction is defined as follows:

1. Compute fixed point values $(v_1^\circ, \ldots, v_N^\circ)$ on reported bundles bundles $(\hat{W}_1, \ldots, \hat{W}_N)$.
2. Sort bids in *decreasing* order of $v_i^\circ/|\hat{W}_i|^c$, breaking ties at random. Constant $c > 0$ determines the dependence of bid rank on the number of items in the interesting bundle. Walk down the list, accepting bids if the goods demanded are still unallocated. This is the greedy allocation rule.
3. Let $g_i^c(v^\circ) \in \{0, 1\}$ denote whether agent i is allocated its interesting bundle in the greedy allocation, given fixed point values v°. For a winner, with $g_i^c(v^\circ) = 1$, define the payment as the $\min v_i'$ s.t. $g_i^c((v_i', v_{-i}^*)) = 1$ where v_{-i}^* denotes the new fixed point given (uncontingent) bid $b_i(X, v_{-i}) = v_i'$ on $X \supseteq \hat{W}_i$ and 0 otherwise.

LEMMA 3. *For all contingent bids with $\sum_{j \neq i} \alpha_{ij} < 1$ for all bidders i, the greedy allocation rule satisfies the generalized single-crossing condition (with stand-along value v_{i0} in the role of signal s_i.).*

PROOF. (sketch) From Lemma 2 we have $\frac{\partial}{\partial v_{i0}} v_j^\circ(\hat{W}_j) < \frac{\partial}{\partial v_{i0}} v_i^\circ(\hat{W}_i)$, for all $j \neq i$. So, if agent i is winning for some stand-alone value, v_{i0}, then it will continue to win for a higher signal because its value will increase by more than the value of any other agent and therefore its rank in the ordered list of bids to accept can only improve. □

The greedy rule recovers the generalized SCC requirement because agent i must only compete unilaterally with each other agent that demands one or more of the same goods. By comparison, the efficient allocation rule considered competition between coalitions of agents in deciding whether agent i was a winner.

THEOREM 7. *The greedy contingent-bid auction for single-minded bidders and multiple items supports truthful bidding in an ex post Nash equilibrium when the bidding language is expressive. Moreover, when parameter $c = 1/2$ the greedy auction is $\sqrt{m}-$competitive w.r.t. efficiency, for m goods.*

We omit the proof of equilibrium in the interest of space, and because it is in all essential aspects the same as that of the single-item contingent bid auction. Truthfulness follows from the property of generalized SCC (Lemma 3). The worst-case approximation of $\sqrt{m}$ for the greedy rule with ordering metric $v_i^\circ/|W_i|^{1/2}$ follows immediately from Lehmann et al. [11]. The average case efficiency may be much better.

[6] Lehmann et al. [11] adopted the greedy allocation rule because the efficient winner-determination problem is NP-hard. Here, we adopt the greedy allocation rule because the efficient allocation rule is not implementable in an ex post Nash equilibrium when agents have interdependent values. Of course, computational complexity also provides another reason to prefer this rule in interdependent value problems with many bids.

5.5 Example: Truthful Greedy Auction

For this example, adopt $c = 1$ so that the rank of bids is determined by computing the per-item bid value. Consider the greedy auction on the earlier example, where we have $v_1^\circ(AB) = 15, v_2^\circ(C) = 10, v_3^\circ(ABC) = 14, v_4^\circ(A) = 11$ and $v_5^\circ(BC) = 11$. The auction assigns adjusted values $15/2, 10, 14/3, 11$ and $11/2$ to each bid (i.e. the per-item bid values), and places the bids in decreasing order as bids $4, 2, 1, 5$ and 3. Agent 4 is allocated A, agent 2 is allocated C, and then no other agents receive any goods because one or more items in their interesting bundles are already allocated. The allocation is $(\emptyset, C, \emptyset, A, \emptyset)$. (Note that this is not the efficient allocation.) Agent 2's payment is determined by considering the values of bids that it displaces, namely the bids from agents 3 and 5. (It must simply remain ranked above agents 3 and 5 to remain a winner.) Considering agent 3, the constraint is $v_2' \geq 1/3(5 + 0.2(10 + 0.5v_2') + 0.6v_2')$ (where the factor $1/3$ is included because agent 3 bids on 3 items, and thus this reduces its rank), which gives $v_2' \geq 70/23$. Considering agent 5, the constraint is $v_2' \geq 1/2(1+2/3(10+0.5v_2'))$ (factor $1/2$ because agent 5 bids on 2 items), which reduces to $v_2' \geq 23/5$. The latter constraint is binding, and agent 2's payment is $p_2 = 23/5 = 4.6$. Agent 4 displaces bids from agents 1 and 3, and its payment is computed as $\min v_4'$ s.t. $v_4' \geq \max\{15/2, 14/3\} = 15/2 = 7.5$.[7]

6. CONCLUSIONS AND FUTURE WORK

We have instantiated the contingent bid model of Dasgupta and Maskin [3] to provide a concrete protocol for interdependent value auctions. A simple linear bidding language is demonstrated to satisfy the technical conditions required for the efficiency of a contingent-bid second-price auction. Seeking good revenue properties, we also illustrated protocols with better expected revenue.

In addition, we described a protocol for interdependent-value combinatorial auctions (CAs) with single-minded bidders. Thus, we find a positive counterpoint to the negative general conclusions in the literature on interdependent value auctions with multi-dimensional private information [8, 9].[8] An important future direction is to study other models that provide structure to value interdependencies and allow for similarly positive results.

In principle, a more general pricing method described in Dasgupta and Maskin [3] can be used to design truthful auctions in combinatorial auctions without the restriction to single-minded bidders. (As long as the generalized SCC condition continues to hold, and with single-dimensional private information.) However, we wish to draw attention to what we believe to be a severe practical limitation of the generalized method:

*in addition to reporting contingent bids, agents are required to report the residual domain of valuations that it believes to be possible for **other** agents, given its own signal and given its knowledge about the functional form of the valuations of other agents.*

This requirement, which is also discussed in Perry and Reny [16], is used to ensure that agent-independent payments can be computed that are consistent (in a utility-maximizing sense) with the efficient allocation. Requiring that every bidder reports exact and complete information on the residual valuation domains of other bidders seems untenable in practical systems. It seems likely to place a large burden on participants. We think future work should seek mechanisms for interdependent values that are (necessarily) inefficient when agents do not reveal adequate information, but fully efficient in the complete-revelation limit.

[7] It is instructive to consider the effect of agent 1 increasing its value in the greedy auction. Recall that this is where we observed the failure of generalized SCC in the proposed efficient auction. In order to win in the greedy auction, agent 1 must rank above agents 3 and 4, of which agent 4 dominates. To rank above agent 4, we need $v_1'/2 \geq 1 + 2/3v_1'$, which is impossible for $v_i' \geq 0$. So, agent 1 can never win in this auction given the contingent bids of the other agents.

ABSTRACT

This paper describes the design and evaluation of SouthamptonSCM, the runner-up in the 2005 International Trading Agent Supply Chain Management Competition (TAC SCM). In particular, we focus on the way in which our agent purchases components using a mixed procurement strategy (combining long and short term planning) and how it sets its prices according to the prevailing market situation and its own inventory level (because this adaptivity and flexibility are key to its success). We analyse our buying and selling strategies in the actual competition and in controlled experiments. Through this evaluation, we show that SouthamptonSCM performs well across a broad range of environments.

1. INTRODUCTION

Effective supply chain management is vital to today's economy and increasingly organisations are looking to the agility and automation afforded by agent-based approaches [4]. To this end, the International Trading Agents Competition for Supply Chain Management (`http://www.sics.se/tac`) (TAC SCM) provides a benchmarking environment for testing and evaluating agents in a challenging and realistic setting. Specifically, in the TAC SCM scenario, the aim is to design an agent representing a computer manufacturer, that competes with other agents for computer components (from the supplier side) and computer orders (from the customer side). These agents are also responsible for managing their limited production capacities, in order to deliver the products to customers before the due date they agreed in the order.

In more detail, a game includes six agents (competition entrants) that compete with one another to procure raw components and fulfil customer orders for assembled PCs. Each agent can produce 16 distinct computer types from four components: CPU, motherboard, memory and hard disk (*e.g.* a PC with a 2GHz IMD processor with 1GB memory and a 300GB hard drive). Consequently, on each of the 220 simulation days of the game, agents receive new request for quotes (RFQs) and actual orders (if offers they have previously sent win) from the customers. From the supplier side, an agent receives offers to deliver particular quantities and types of components at particular prices in response to the RFQs that it sent on the previous day. Thus, in each day of the game (lasting 15 seconds), the agent must decide on the following: (i) which new supplier RFQs to send and which supplier's offers to accept; (ii) which customer RFQs to respond to, and at what price; and (iii) how to schedule the production of PCs given the availability of components, the limited capacity of the factory and the delivery deadlines of pending orders. Now, an agent spends money on buying the components, paying for the storage of both components and PCs, paying penalties if it defaults on a promised delivery date and paying overdraft penalties if it is in debt to the bank. The agent earns money by selling PCs and receives interest from the bank if its balance is positive. The success of an agent is measured in terms of its profit (*i.e.*, its bank balance at the end of the game).

Against this background, we present the design and evaluation of our agent (SouthamptonSCM) that was the runner-up in the 2005 competition (out of 32 initial participants). The main contributions of this work are as follows. First, we develop techniques to enable the agent to adapt its price setting to the prevailing market situation, its own internal state (inventory level) and the time that has elapsed. At their core, these techniques employ fuzzy reasoning in order to allow the agent to adapt its prices daily so that it can fully exploit its production capacity, while still maximising its revenue by selling at appropriate prices. Second, we develop a mixed procurement strategy that enables the agent to buy components according to what is needed in the near future (by predicting customer demand) and also to order a small quantity of components far in advance (at a lower price) to meet the minimum daily usage. This strategy balances flexibility in dealing with the dynamically changing market, with the need to procure components at low cost whilst also minimising inventory stock. This is especially useful when the demand is increasing and the agents are thus competing for the components, since it is this case that causes component prices to increase. To evaluate the effectiveness of these developments, we analyse the performance of our agent in the actual competition and also in more systematic controlled experiments.

The remainder of the paper is organized as follows. Section 2 presents our agent. In section 3 we evaluate it. Finally, in section 4 we conclude and discuss future work.

2. SouthamptonSCM

SouthamptonSCM is composed of three sub-agents (see figure 1).[1] The *customer agent* receives RFQs from the customers and decides what offers to respond with. It also communicates with the factory agent to obtain the updated inventory levels and to send the

[1]Here we use the notion of sub-agents (instead of modules) because each of them can autonomously communicate with the suppliers and customers to get the RFQs, can send offers and obtain orders, and can decide how to respond to this information.

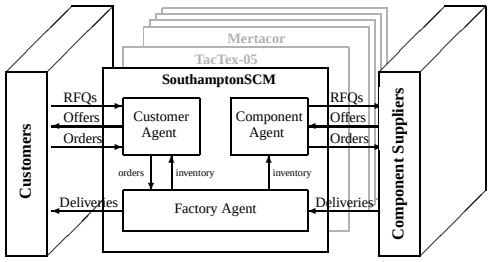

Figure 1: SouthamptonSCM agent architecture.

relevant customer PC orders. The *component agent* decides which RFQs and which orders to send to which suppliers. The *factory agent* receives the supplies delivered from the suppliers, decides based on the available resources (computer components and factory cycles) in what order the customer orders should be produced, and determines the schedules for delivering the finished PCs to the customers. We now deal, in turn, with each sub-agent.

2.1 The Customer Agent

The customer agent is the key component in our architecture (because we believe that offering the appropriate price at the right time is vital for success). If the price is too low, the agent will receive a low profit and if it is too high it will fail to win any orders (because customers always choose the lowest offer price among those they receive). Given this, the key challenges are to determine which customer RFQs to bid for and at what price. To achieve this, we use fuzzy reasoning to determine how to set prices according to the agent's inventory level, the market demand and the time into the game. Moreover, the parameters involved in the fuzzy rules can be adapted according to the quantity of the received and expected customer orders so as to maximise the factory utilisation.

The customer agent we used in last year's competition has previously been described in [3] and in several respects this year's design is similar. However, due in part to the changes in the rules of this year's competition and also because SouthamptonSCM 2005 is built upon last year's experiences, there are also a number of important differences. Most importantly:

- When prioritising customer RFQs, SouthamptonSCM 2005 considers the potential profit that each RFQ will generate (SouthamptonSCM 2004 did not consider the cost of the components). Moreover, when checking on the availability of the components required to assemble the requested finished product, unlike SouthamptonSCM 2004 that just considered the quantity of components held as inventory, the 2005 agent also considers pending component orders that are due to be delivered before the due date of the RFQ (see Section 2.1.1).

- SouthamptonSCM 2005 also calculates the offer prices of finished products differently. Although it uses the same basic technique as the 2004 agent, the 2005 agent has two rule bases for calculating prices: one for when it is close to the end of the game and one for other days in the game (see Section 2.1.2). The 2004 agent, also used two rule bases but these were: one for the end stage of the game and one for when it was expecting a large component delivery.[2]

[2]This rule was motivated by the use of a day 0 procurement strategy that ordered the majority of the components needed for the entire game on day 0. Since changes in the TAC SCM game specification for the 2005 competition removed the benefit of this procurement strategy, the customer agent had to be updated.

We now deal, in turn, with each of the these differences.

2.1.1 Choosing Customer RFQs.

The customer agent receives customer RFQs requesting a quantity of a particular PC for delivery on a specified day. When selecting which RFQs to respond to, SouthamptonSCM rates them according to the potential profit that they may bring and according to the inventory it holds. The latter inventory driven strategy offers customers PCs according to what is currently available and also what can be produced given the delivery date of pending components orders. This consideration of promised component deliveries is new and is included this year since changes to the supplier model mean that there are no longer significant delivery delays in these component orders[3] [1].

In more detail, suppose a customer RFQ is represented as a tuple $(i,\ q,\ p_{res},\ c_{penalty},\ d_{due})$, where $i \in \{1,\cdots,16\}$ is the type of PC the customer wants, $q > 0$ is the quantity, $p_{res} > 0$ is the reservation price (maximum it will pay), $c_{penalty} > 0$ is the fine paid if the computers are not delivered on time, and d_{due} is the desired delivery date. On each day, the customer agent receives a bundle of such RFQs and sorts them in the decreasing order of the profit margin of the type of PC requested:

$$p_{res} - p_{base} - \frac{c_{penalty}}{q},$$

where p_{base} is the cost of buying components (sum of the buying price for each component). The intuition is that the agent will first serve customers with high profit margins and low penalties. This is because the higher the p_{res}, the more profit will be made (compared to selling the same product to a customer with a low p_{res}). At the same time, the agent also wants to avoid getting high penalty orders because of the inherent uncertainties that exist in the game.

For each RFQ in the list, the agent first checks whether it can be supplied from its stock of finished PCs (see Section 2.3). If it can, the corresponding PC inventory is decreased. Otherwise, the agent checks whether it holds sufficient components within both its current inventory and its expected delivery queue (*i.e.* components that have been ordered, but have not yet arrived), and also whether it has a sufficient remaining production capacity to manufacture the required PCs. If it does, the agent decreases its available component inventory.

2.1.2 Fuzzy Rules for Calculating Offer Prices

For each type of PC, the agent uses a fuzzy reasoning inference mechanism which is based on the standard Sugeno controller [6] to calculate the offer price of components. Full details of this process are described in [3], however, here we present the rule bases as used in the 2005 agent. Now, due to the constraint that the TAC SCM game is played over a fixed number of days, we use two rule bases: one for the majority of the game days where the aim is to sell finished products at maximum profit, and one for the last stages of the game where the aim is to 'off-load' any remaining finished product and component inventory. Splitting the rule bases enables us to reduce their complexity and thus maintain their interpretability.

In more detail, in the first rule base, for each PC type the agent considers the current customer demand state and the inventory level of the components that make up that particular PC type. There are twelve such rules within this base and the following three are representative examples:

$\mathcal{R}_1$: if D is *high* and I is *low* then r_1 is *very-big*

[3]These changes were introduced to remove the incentive to adopt a day 0 procurement strategy.

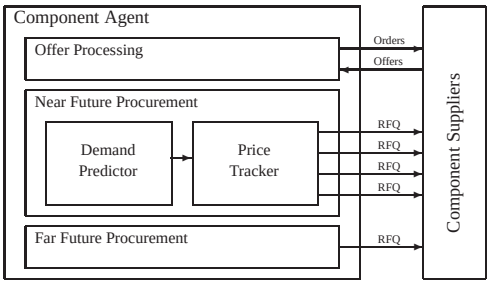

Figure 2: Overview of the component agent.

$\mathcal{R}_2$**:** if D is *medium* and I is *high* then r_2 is *very-medium*

$\mathcal{R}_3$**:** if D is *low* and I is *high* then r_3 is *small*

In these rules, the customer demand (D) is expressed in the fuzzy linguistic terms *high*, *medium*, and *low*, and the inventory level (I) in the terms *high*, *medium*, and *low*. The output of each rule is a fuzzy variable (r_1 to r_3 in these examples), and thus, the outputs of all the rules are combined by the Sugeno controller to give a single scalar result, r, that represents the *price adjustment factor* used to generate a reference price [2] for each type of PC. When r is high, the reference price approaches (or is even higher than) the highest transaction price recorded on the previous day (this information is made available to the agents through the daily market report), whilst when r is low, the reference price approaches the lowest transaction price. Given the reference price of each type of PC, an offer price is calculated by modifying the reference price by a factor related to the requested due date. The intuition here is that the sooner the due date, the higher the offered price. Thus, rule $\mathcal{R}_1$ captures the fact that if the customer demand for this kind of PC is high and the agent has a low inventory in stock, then the offer price should be very high since here there is an opportunity to maximise the agent's profit.

The second rule base is employed for the days near the end of the game (last 20 in this case) and it considers the current inventory level, the customer demand and also how close it is to the end of the game. There are 22 such rules that capture different combinations of situations of these three variables, and, three such rules in this rule base, are:

$\mathcal{R}_1'$**:** if D is *high* and I is *high* and E is far then r_1' is *big*

$\mathcal{R}_2'$**:** if D is *high* and I is *high* and E is *medium* then r_2' is *medium*

$\mathcal{R}_3'$**:** if D is *low* and I is *high* and E is *close* then r_3' is *very-small*

Here, the days to the end of the game (E) are expressed in the fuzzy linguistic terms: *far*, *medium*, and *close*. Thus, for example, rule $\mathcal{R}_3'$ captures the fact that if there is little demand for a particular type of PC, the agent has a high inventory, and there is a little time until the end of the game, then the price adjustment factor should be very small (thus ensuring a low offer price and hence reducing the risk of being left with inventory at the end of the game).

2.2 The Component Agent

The component agent is responsible for dealing with the component suppliers and aims to ensure that there are always sufficient components in stock to address the customers' changing demand for finished products. In doing so, it addresses a challenge that is common to all supply chains facing dynamically changing customer demand. That is, it must procure components at a low cost, whilst simultaneously maintaining a minimal component inventory in order to reduce the daily storage cost and also the possibility of being left with redundant stock if customer demand changes.

Now, the 2005 component agent uses a completely different strategy to that of last year. In 2004, it procured most of its components by placing a large order on day 0 (due to the fact that the suppliers have their full capacity available on day 0 and thus offer the lowest possible price [3]). However, in 2005, the game rules were changed in order to reduce the lottery effect in the supplier interactions, to discourage the use of a day 0 procurement strategy [7], and to deter agents from requesting large quantities of components without intending to order them [1]. This means that the component agent used in 2004 is no longer effective, and thus, we present our updated component agent here.

In addressing the procurement challenge this year, the agent faces a common dilemma concerning the lead time of component orders. More specifically, ordering components with a long lead time (*i.e.* for delivery a long time into the future) generally leads to low procurement costs (since the suppliers have adequate spare capacity over this long period). However, the agent is then exposed to the risk that the customer demand may change, leaving it with excessive component stock. Conversely, ordering components with a short lead time allows the agent to effectively track the changing customer demand and maintain minimum stock inventory. However, due to the short lead time, the suppliers generally have less flexibility in scheduling the production of these orders (since the order is competing with those from other agents for the limited production capacity available), and thus, procurement costs are high.

Now, to tackle this dilemma, SouthamptonSCM employs a mixed procurement strategy; dividing the remaining days of the game into two classes: near future and far future (see figure 2). For the days in the far future, the agent periodically orders a small fixed quantity of components, so as to ensure that a minimum quantity of stock is available in order to keep the factory running (see section 2.2.1 for details). For the days in the near future (which is 35 days in this case[4]), the agent makes a short term prediction of the future customer demand, and orders sufficient components to address this demand (see section 2.2.2 for details). In addition, within this near future, the agent also *tests* the market in order to track current prices. This price information is used to choose the appropriate lead time and reserve price of the RFQ sent to the suppliers. In more detail, since each agent can send a maximum of five RFQs for a particular component to each supplier each day, the agent uses four RFQs for the near future procurement (*i.e.* to actually order components with short lead time and also to track the component prices). The remaining RFQ is used to buy components for the far future.

2.2.1 Far Future Procurement

Of the two strategies, the far future procurement one is the simpler. For this, the agent assumes that in the far future, there will be a daily minimum need for 30 CPU and 60 other components (this ratio is required since there are four different types of CPU, but other components are only available in two different types), and thus checks whether there is sufficient current and pending component inventory to meet this need. If not, it submits an RFQ for a fixed amount to the relevant supplier, requesting delivery on the date at which the predicted inventory falls below the daily minimum need (up to a maximum of 120 days into the future).

2.2.2 Near Future Procurement

The near future procurement strategy is more complex. It con-

[4]In our experimental evaluation, we found that a larger number than 35 led to significantly more redundant components in stock due to the difficulty of predicting the fluctuating customer demand, whilst a smaller amount was not able to keep the stock above a minimum usable threshold.

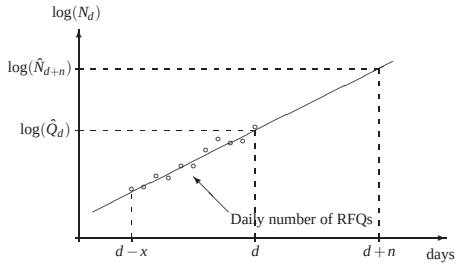

Figure 3: Linear regression process by which Southmapton-SCM predicts the future customer demand.

sists of two elements, a daily demand predictor that predicts the future demand of components, and a market tracker that generates the RFQs to be sent to the suppliers, both to order actual components required and to test the market to discern the most profitable order lead time and set appropriate reserve price.

Demand Predictor

As described above, the agent buys components for the near future based on a prediction of customer demand. Now, according to the game specification, the number of RFQs that each agent receives from the customers is described by three independent random walks; one for each market segment (finished product PCs are classified into three such segments: high, mid and low range). In more detail, the number of RFQs that an agent receives, within a single market segment, on day d is denoted by N_d, and is drawn from a Poisson distribution whose expected value is given by the parameter, Q_d. Thus, for each market segment:

$$N_d = \text{Poisson}\left(Q_d\right) \tag{1}$$

Again, according the game specification, the value of Q_d is updated each each day between minimum and maximum limits according to a multiplicative trend parameter, τ_d, and thus:

$$Q_{d+1} = \min\left(Q_{\max}, \max\left(Q_{\min}, \tau_d Q_d\right)\right) \tag{2}$$

where the trend, τ_d, is itself updated each day, again between minimum and maximum limits, according to a random walk:

$$\tau_{d+1} = \max\left(\tau_{\min}, \min\left(\tau_{\max}, \tau_d + \text{random}\left(-0.01, 0.01\right)\right)\right) \tag{3}$$

Now, since τ_d varies relatively slowly (and can thus be assumed to be constant over short periods of time), the agent can estimate the values of Q_d and τ_d (these estimated values are denoted by $\hat{Q}_d$ and $\hat{\tau}_d$) by recording, for the previous x days, the number of RFQs received within each market segment (*i.e.* $N_{d-x} \ldots N_d$), and then performing a linear regression of the logarithm of these values against d (we take the logarithm since the trend is multiplicative). Having found these values, the agent can then extrapolate, and predict the number of RFQs that will be received on day $d+n$, and thus:

$$\hat{N}_{d+n} = \min\left(Q_{\max}, \max\left(Q_{\min}, \left(\hat{\tau}_d\right)^n \hat{Q}_d\right)\right) \tag{4}$$

This process is shown diagrammatically in figure 3. In trials, we found that by using data from the previous 10 days, and predicting a value for 10 days into the future (*i.e.* $x = 10$ and $n = 10$), we obtained a good estimate for the average demand within the near future. This process gave significantly better results than the simple alternative of using the number of RFQs received on the current day, as an estimate for future days.

Having predicted the number of RFQs that will be received, within each market segment, on each day within the near future, the agent then calculates the expected daily usage of each component type (D_{id}). This is calculated by weighting the maximum number of PCs that can be manufactured on any day, D_{total},[5] by a factor that incorporates both the expected number of RFQs that will be received within each market segment (*i.e.* $\hat{N}^{low}_{d+n}$, $\hat{N}^{medium}_{d+n}$ and $\hat{N}^{high}_{d+n}$ as described above) and a weighting that describes how many of the PC types within any market segment actually contain the specific component being considered (for any component this weighting is described by r^{low}_{id}, r^{medium}_{id} and r^{high}_{id} and, for example, for component id of 200 these values are 0.4, 0.5 and 0.6 respectively). Thus:

$$D_{id} = \frac{D_{total}\left[r^{low}_{id}\hat{N}^{low}_{d+n} + r^{medium}_{id}\hat{N}^{medium}_{d+n} + r^{high}_{id}\hat{N}^{high}_{d+n}\right]}{\hat{N}^{low}_{d+n} + \hat{N}^{medium}_{d+n} + \hat{N}^{high}_{d+n}} \tag{5}$$

Given D_{id}, the current available stock of each component, and the expected deliveries from the suppliers from previous orders, the agent checks whether stock levels in the near future will fall below a minimum threshold. This threshold represents a buffer stock level, and guided by the principle that towards the end of the game the inventory level should decrease, it starts from 0 on day 0, increases gradually to a fixed number of 300 CPU and 600 other components over the first 30 days, and subsequently decreases to zero again over the last 10 days. If stock levels are predicted to fall below the buffer level within the near future, the agent identifies the quantity required (with a maximum order size of 80 components) and the latest date that this quantity should arrive by. This information is passed to the price tracker, which actually generates the RFQs that are sent to the suppliers.

Price Tracker

The price tracker acts to maintain an estimate of the current market price of the components. Due to the behaviour of the competing agents, this market price depends on the due date with which components are requested. For example, if the competing agents are ordering components with very short lead times, then the supplier will have little spare capacity, and thus, the corresponding offer prices that the agent receives will be greater than those of orders with long lead times. Every day the the price tracker generates four RFQs which are sent to each supplier. The due dates of these RFQs are distributed over three regions within the near future (*i.e.* less than 10, 10 to 20, and more than 20 days into the future) and the offer price that the agent receives in response to these RFQs enables it to track the changing market price of the component and also to identify the order lead times that will result in the minimum procurement costs.

Now, in more detail, the four RFQs generated by the price tracker fall into two different classes: those that actually order the components requested by the demand predictor, and those that have zero quantity (and are simply used to track the market price). On any day, up to four of these RFQs will be used to actually order components (depending on the requirements of the demand predictor), and within the constraints of the delivery date requested by the demand predictor, the lead time of these RFQs will be determined by the results of the market testing. This market testing is also used to set an appropriate reserve price for the RFQ.[6]

[5] In this case, $D_{total} = 364$, since, given the factory production capacity of 2000 cycles per day and an average production cost for a PC of 5.5 cycles, approximately $2000/5.5 = 364$ PCs can be manufactured per day.

[6] Note, the setting of this reserve price is particularly important in the case of our agent. This is because the suppliers maintain a record of the reputation of each agent that is dependent on the ratio of offers that are sent compared to the actual number of orders that

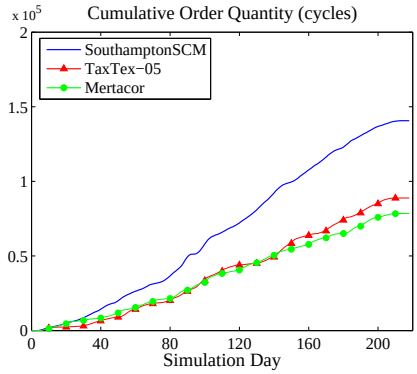

Figure 4: Cumulative order quantities in game tac4-4253.

2.3 The Factory Agent

One of the main challenges for the factory agent is scheduling what to produce and when to produce it (*i.e.*, how to allocate supply resources and factory time). The strategy we use for SouthamptonSCM 2005 agent is broadly similar with that of last year's agent. This strategy involves manufacturing PCs according to customer orders and satisfying orders with an earlier delivery date (see [3] for more detail). Now, since the computers stored in the factory will be charged storage cost, each order will be delivered as soon as it is filled. The agent builds the PCs according to the customers' orders it has obtained (which has the advantage of ensuring that the factory always produces the needed computers on time). However, if on any day, there are still free factory assembling cycles available, and the numbers of finished PCs in stock are below a certain threshold, then the agent produces additional PCs of each kind uniformly (subject to the availability of components) in order to maximise the factory utilisation. It is critical that this threshold is set appropriately; a high threshold will lead to excessive finished PC inventory, which may be hard to sell if demand is low. In 2005, this threshold is set to 80, and this is shown to work well in both low and high demand markets.

3. EVALUATION

Our evaluation is composed of three components: (i) the results from the 2005 competition; (ii) our post-hoc analysis of some typical games in the actual competition; and (iii) a systematic range of controlled experiments.

3.1 Competition Results

TAC SCM consists of a preliminary round (predominantly used for practice and fine tuning) followed by a seeding round that determines the groupings for the final rounds. The top 24 agents from the seeding round are organised into 4 groups that represent each of the four quarter-finals. The top three teams of quarter-finals 1 and 3 are entered into semi-final 1, and similarly, the first 3 teams from quarter-finals 2 and 4 are entered into semi-final 2. Finally, the first 3 teams in both semi-finals are entered into the final round.

In the 2005 competition, there were 32 entries and SouthamptonSCM was placed seventh among all the participants in the seeding round and entered group B for the quarter-final. Here, it had the second highest score, in its semi-final it had the highest score, and in the final, it was the runner-up (to TacTex-05 [5]).[7]

3.2 Competition Game Analysis

In this section, we analyse the performance of SouthamptonSCM in terms of the efficiency of both its buying and selling strategies. That is, we consider the effectiveness of the customer pricing model and the mixed component procurement strategy. Thus we select a particular game from the final (game tac4-4253) and analyse it in more detail.[8]

3.2.1 Analysing the Selling Strategy

To complement and better understand the competition result and to evaluate the effectiveness of our pricing model (since we attribute our success in selling PCs to the pricing technique we employ), we conducted a post hoc analysis of a game from the final. In order to reduce the complexity of this analysis, we consider just the top three performing agents within this game (*i.e.* in this case SouthamptonSCM, TacTex-05 and Mertacor (who also happen to be the top 3 agents in the overall competition)). Now, an essential factor in the performance of the trading agent is the ability to respond to customer RFQs with competitive offer prices. Thus, we analyse the game data and we consider just those RFQs for which all three of the above agents responded with offers. We then consider which of the three agents actually won these orders (noting that the order is always assigned to the agent that offers the lowest price). In figure 4 we show the resulting order quantities (expressed as factory production cycles averaged over all products), that were won by each of the three agents. Significantly, the SouthamptonSCM agent wins a far larger proportion of the orders than the other two agents. This is consistent with the overall game analysis, where the orders these three agents delivered in the game are: 7331 for SouthamptonSCM, 6742 for TacTex-05, and 5588 for Mertacor.

Now, there is little advantage to win these orders, if the offer price was excessively low. Thus, in figure 5, we compare the average offer prices for those orders that were won by each of the three agents. Specifically, in figure 5a we show the average offer prices of the orders that were actually won by SouthamptonSCM, in figure 5b those won by TacTex-05, and in figure 5c those won by Mertacor. In each case, as expected, we see that the agent that won the orders actually submitted offers with the lowest average price. However, despite winning the majority of the orders, the prices offered by SouthamptonSCM were not significantly lower than those of the other agents. Indeed, the opposite is true. The margin by which SouthamptonSCM undercut the other agents is actually smaller than the margin with which the other agents undercut SouthamptonSCM. For example, in this game, on average SouthamptonSCM undercut Mertacor's prices by 3.0% and TaxTex-05's prices by 4.1%. Conversely, on average, TacTex-05 undercut SouthamptonSCM's prices by 6.5% and Mertacor undercut the prices of SouthamptonSCM by 5.6%.

Thus, the selling strategy of our agent is able to accurately predict the market price of the finished products, and is able to undercut the competing agents by a small margin. In so doing, our agent wins a greater proportion of the orders than the other agents, but

are placed. Agents with higher reputation are given priority treatment and receive lower offer prices. Thus SouthamptonSCM maintains a perfect reputation record by adopting the policy of accepting all offers that it receives (this is dealt with by the *Offer Processing* in figure 2). Thus, it is essential that the agent sets the reserve price of RFQs to an appropriate value, to avoid being obliged to accept an excessively expensive offer.

[7]TacTex-05 is believed to have won by learning between games, and improving its buying strategy over the course of the final.

[8]In order to analyse a representative game, we select randomly from those games in the final that did not experience particurly low customer demand where all players ended the game year in debt. As such, we choose the first game of the final on server tac4 (*i.e.* game tac4-4253).

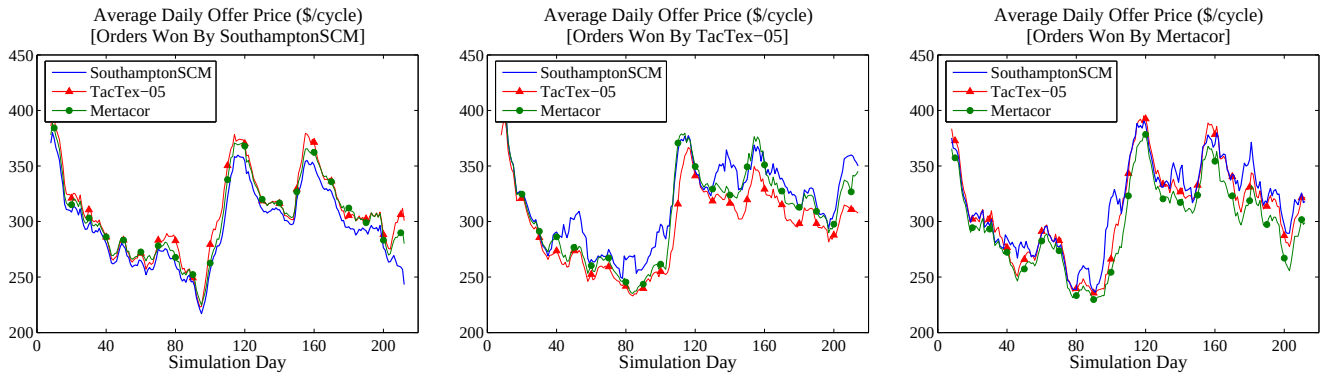

Figure 5: Daily offer prices for orders won by (a) SouthamptonSCM, (b) TaxTex-05 and (c) Mertacor in game tac4-4253.

does not unnecessarily reduce the price of its offers. Since the ultimate profitability of the agent depends on both the price and the quantity, SouthamptonSCM thus has the highest revenue.

3.2.2 Analysing the Buying Strategy

To investigate the effectiveness of its mixed procurement strategy, we compare, on a daily basis, the component ordering policies adopted by the three top performing agents (*i.e.* SouthamptonSCM, TacTex-05 and Mertacor). Now, in order to make this comparison, we can not average over all components as we did in the previous section. The large range in the base price of the components makes such averages meaningless. Thus, we select one component for this comparison, and here we use the IMD 2GHz CPU, since this is not the most expensive component (the higher performing 5GHz CPU has a higher base price), and yet, it largely determines the cost of the finished product PC. Whilst space does not allow us to present all the results, we note that the qualitative results that we present are representative for all the other components.

Now, in figure 6a, we show the daily average unit cost of the CPUs that were procured by each of the agents. As can be seen, SouthamptonSCM paid a similar price to TacTex-05 in the first half of the game. However, after that, SouthamptonSCM procures components at a much cheaper price. In figure 6b, we show the cumulative quantity of CPUs that were procured by each of the agents. Now, in this game, the demand for the IMD 2GHz CPU increased in the second half of the game, and thus we observe that all three agents purchase CPUs at a greater rate in the second half of the game (*i.e.* the gradient of the cumulative plot increases). Indeed, SouthamptonSCM and TacTex-05 end up having obtained an identical quantity of CPU, with Mertacor buying significantly less. However, since, on average, SouthamptonSCM is able to procure these CPUs at a lower price, when we compare the cumulative cost of this procurement, as shown in figure 6c, we see that SouthamptonSCM has paid less for these CPUs in total than TecTex-05 although they both have obtained identical quantity of CPU.[9]

We can see the reason for this difference in procurement costs by considering the lead time of these component orders. Thus, figures 6d, 6e and 6f, show a histogram of the lead time of component orders that arrive during each simulation day (in this figure larger orders are shown with darker shading). In figure 6d, we can see the result of the mixed procurement strategy that SouthamptonSCM adopts. Here, it is clear that each case sees a combination of orders that were placed with a long lead time (up to to 120 days during the second half of the game) and a short lead time of 5-20 days (corresponding to the near and far future procurement strategies). Note that TacTex-05 uses a predominantly short lead time strategy, whilst Mertacor uses a long lead time strategy.

Thus, during the first half of the game, orders with a short lead time result in procurement at a low cost. Here we see that TaxTec-05 procures components at less cost than Mertacor. However, in the second half of the game, the opposite is true and orders with a short lead time are more expensive. Here in this half of the game, SouthamptonSCM procures components at less cost than Mertacor. However, overall, the mixed procurement strategy of SouthamptonSCM allows it to achieve the best result in both halves of the game; in the first half it achieves similar low prices to TacTex-05, whilst in the second half it achieves prices significantly lower than both the other agents. Thus, we believe that the mixed procurement strategy incorporating both long and short lead times with market price tracking, enables SouthamptonSCM to adapt to the behaviour of the competing agents and buy components at a cheap price.

3.3 Controlled Experiments

To evaluate the performance of our agent in a more systematic fashion than is possible within the actual competition, we ran a series of controlled experiments. In previous work we have already analysed our pricing model through controlled experiments and showed that the way SouthamptonSCM sets its offering prices is significantly better than the benchmark strategies we considered [3]. Thus, here we focus on evaluating the buying strategy.

As mentioned earlier, we attribute the success of our agent to the mixed procurement strategy that it uses to purchase components at minimum cost. Thus, here we analyse how the buying behaviour works when compared to two other common alternatives. These two strategies are identical to SouthamptonSCM, except for the method they use to procure components (*i.e.* the way in which they schedule factory production and offer finished products to the customers is unchanged). The three types of agents we use are:

- **Mixed agent (MIX-agent)**. This agent uses our mixed procurement strategy (described in Section 2.2). In this case, the daily minimum need for CPU in the far future is set to 30 and the corresponding value for other components, is set to 60.
- **Long-term planning agent (LTP-agent)**. Compared with the mixed strategy, the LTP-agent still uses one RFQ each

[9]The difference in costs in figure 6 is small, but reflects the competition's competitive nature (note that 6b and 6c are cumulative plots). The difference represents a $6-7\%$ saving in material costs, whilst the difference in overall margin between SouthamptonSCM and TacTex-05 was only 1%.

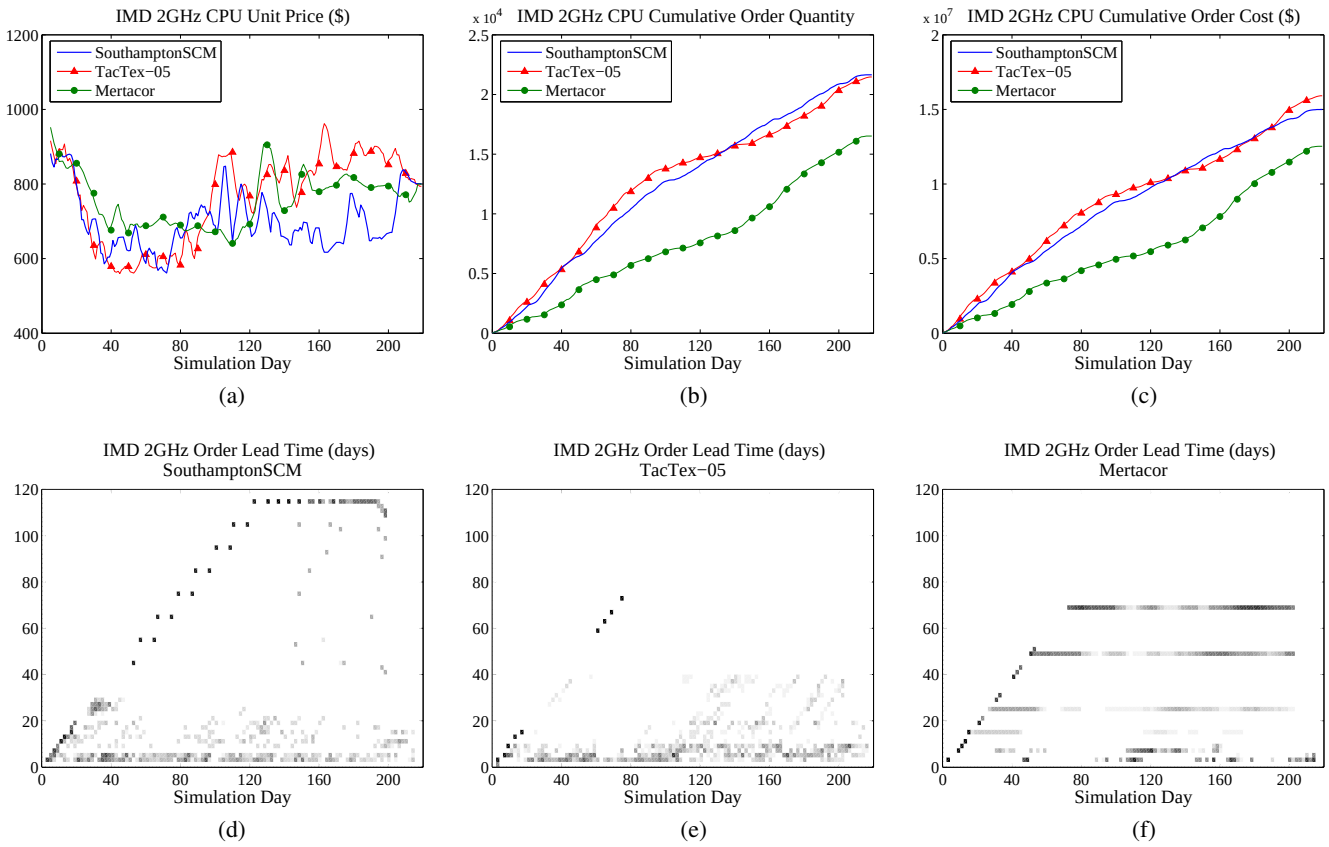

Figure 6: Comparison of component order prices, quantity and daily lead times for IMD 2GHz CPU orders in game tac4-4253.

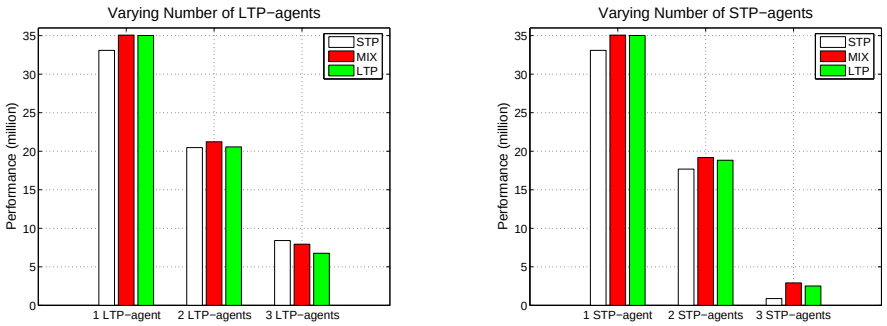
day for far future procurement, but the quantity that is requested is greater. Thus this agent attempts to guarantee that it can obtain the components cheaply (by ordering with long lead times), but runs the risk that some components may ultimately turn out to be unusable (due to a downturn in customer demand). Specifically, the minimum need for CPU in the far future is set to 60 and the corresponding value for other components, is set to 120.

- **Short-term planning agent (STP-agent)**. This agent does not buy any components for the far future, and thus, only uses the near future procurement strategy. This strategy is able to predict and adapt to changes in customer demand. However, it runs the risk of paying a high price for some components when the supplier has little spare capacity.

Besides these three kinds of agents, the other competing participants within the game are the dummy agents provided by the organisers. These use a naïve build-to-order strategy that procures components with a short lead time (typically several days). Thus this agent risks paying high component prices, particularly so since it also sets the reserve price of RFQs that it submits to 0, and thus, to maintain its reputation, it may have to accept high offer prices.



Given this background, five groups of experiments were conducted to examine the performance of each kind of agent in various situations. The number of MIX-agent, LTP-agent and STP-agent were: in setting A (1, 1, 1), in setting B (1, 2, 1), in setting C (1, 1, 2), in setting D (1, 1, 3), and in setting E (1, 3, 1). In each case, the remaining agents are the dummy agent provided by the organiser. The average revenue of each kind of agent in each experiment is then plotted (see figure 7).

Now, in figure 7a, the results for setting A, B and E are presented.[10] Here from A to B to E, we increase the number of LTP-agents and decrease the number of dummy agents. In setting A, MIX- and LTP-agents perform significantly better than the STP-agent,[11] but we cannot differentiate statistically which is better between MIX- and LTP-agents. In setting B, we cannot differentiate statistically which agent is better among these three type of agents. In setting E, the STP-agent is significantly better than the LTP-agent and MIX-agent is slightly better than the LTP-agent. But we cannot differentiate statistically which agent is better between STP- and MIX-agents. From these three experiments, we can conclude that with an increasing number of LTP-agents, the performance of the STP- and MIX-agents are getting better, while that of the LTP-agent is relatively worse. This is because more agents are requesting components for the far future, leaving more spare production capacities for the suppliers in the near future. Thus the component price for the near future will drop which means the agents that purchase many more components in the near future will benefit from this price and thus have a low cost.

Similarly, in figure 7b, the result for settings A, C and D are presented. Here from A to C to D, we increase the number of STP-agents and decrease the number of dummy agents. In settings A

[10]The performance for the dummy agents are not shown in the figure since they are much worse than these three type of agents and incorporating them would make it difficult to see the difference among the three.

[11]In this case and in the statistics below, significance is computed by a Student's t-test ($p < 0.15$).

(a) Experimental results for settings A, B and E. (b) Experimental results for settings A, C and D.

Figure 7: Comparison of performance in various settings.

and C, MIX- and LTP-agents are significantly better than the STP-agent. But we cannot differentiate statistically which agent is better between MIX- and LTP-agent. This is because there are only two agents that purchase components for far away which is not likely to cause the price increase of the components in the far future. But for the STP-agent, there are some dummy agents which order components for a due date in the next several days, thus more competition in the near future leads to an the increase in the component price and higher overall procurement costs. In setting D, we obtain the same result as in setting C, but with a much smaller p value of the Student's t-test. This means the performance of STP-agents are actually getting worse when there are more agents like itself. However, in all the cases we investigated, the MIX-agent is the most stable one as it performs consistently in the presence of various numbers of STP- and LTP-agents. Overall, it obtains the highest average performance (17.82) and the lowest variance (11.68).

Moreover, as more agents use the same broad strategy of sensing the market and ordering intelligently for the near and far future, the performance of all the agents are negatively affected, (*i.e.*, the performance of all the agents is getting worse from experiment A through B to E, and from A through C to D). This happens because as the agents within the game become increasingly homogeneous, there is greater competition for components at a given time (because there are several agents ordering components for broadly the same due date for the far future), and thus the suppliers have less spare capacity, and component costs increase.

4. CONCLUSIONS

This paper provides a number of insights into building agents for supply chain management applications. Specifically, it details the design, implementation and evaluation of SouthamptonSCM; an agent that successfully participated in the 2005 TAC SCM. This agent employs fuzzy reasoning to determine how to set prices and uses a mixed component procurement strategy that balances long and short term orders. Through analysing an actual competition game from the 2005 final we found that this strategy enables SouthamptonSCM to buy more components at lower prices than the other most successful agents in the game. In a series of controlled experiment, where we varied the number of short-term and long-term-planning agents in the game, we found that the mixed procurement strategy was the most stable in all the cases that we considered.

Now, as well as being successful with the TAC SCM competition, several aspects of our agent design and strategy are applicable in a wider context. Firstly, the general structure of the component agent is to employ a mixed strategy where orders in the far future cover the minimum baseline quantities needed in low demand markets, whilst orders in the near future handle current changing demand. This mixture of baseline and opportunistic purchasing behaviour is a common strategy in this domain and the technology we develop for achieving this can be readily transferred. Second, we believe our pricing model technology will also be useful in real SCM applications where just undercutting competitors' prices can significantly improve profitability. Specifically, to apply our model in other domains, the designers of the rule base would need to adapt the fuzzy rules to reflect the factors that are most relevant. Now we believe that customer demand and inventory level are highly likely to be critical factors for almost all cases and thus these rules can remain unaltered. By using different rule bases, different factors can easily be incorporated (as we did here, in order to handle the additional need to reduce inventory towards the end of the game).

Our future work in this area focuses on the component agent. We would like to improve it so that it can adapt the quantity for far future and near future procurement automatically between the rounds of the games according to the procurement behaviours employed by the opponents. This can be achieved based on our controlled experiment results, where if there are more LTP-agents in the game, the agent will adapt its behaviour to the direction of STP-agent. Similarly, if there are more STP-agents, the best response is to change the buying behaviour to the direction of the LTP-agent. This knowledge of opponnets' behaviour can be obtained from the game history and thus this adaptation can be used in repeated games within the same participants.

Reducing Costly Information Acquisition in Auctions

ABSTRACT

Most research on auctions assumes that potential bidders have private information about their willingness to pay for the item being auctioned, and that they use this information strategically when formulating their bids. In reality, bidders often have to go through a costly information-gathering process in order to learn their valuation for the item being auctioned. Recent attempts at modelling this phenomena has brought to light complex strategic behavior arising from information-gathering, and has shown that traditional approaches to auction and mechanism design are not able to overcome it. In this paper, we show that if the auction designer has some information about the agents' information-gathering processes, then it is possible to create an auction where, in equilibrium, agents have incentive to only gather information on their own valuation problems and to reveal the results truthfully to the auctioneer. Additionally, simulation results show that, from a system-level perspective, the overall cost of information acquisition is substantially lower in this new auction when it is compared to a classic auction mechanism.

1. INTRODUCTION

Most research on auctions assumes that the problem facing bidders is how to bid given their private preferences for the item(s) being auctioned. In reality, however, bidders often have to go through a costly information-gathering process in order to determine what their actual preferences are. This process may involve such things as asking questions about a product in order to learn whether it is of high or low quality, solving optimization problems in order to ensure that the bidder bids on the minimum amount of materials needed to complete some job, or conducting research on a firm in order to learn whether its assets complement the assets currently held by the potential bidder.

Recently, researchers have started studying how computational and informational constraints influence both the auctioneer and the bidders. One direction of research has focused on what happens if the auctioneer does not have infinite computational powers. In many interesting auction domains, such as combinatorial auctions, the auctioneer is required to solve (possibly multiple) $\mathcal{NP}$-hard problems. Determining how to replace it with approximation algorithms, while still maintaining the desirable game-theoretic properties, as well as characterizing the domains of truthful social choice functions, has been a vibrant research area [5, 11, 13, 10, 14].

Researchers have also started studying computational and informational constraints faced by bidders. Most of the auction literature has assumed that the bidders know how they value the items being auctioned. However, in many settings bidders do not have adequate information in order to formulate their valuations and instead must learn them by computing or acquiring information (at some cost). One model that has been studied allows a bidder the choice between participating in the auction without knowing its true valuations or paying a fee to learn them. Questions asked using this model include what sort of incentives are required for bidders to acquire information about their valuations [1], and how does information acquisition depend on the rules of the auction [3, 15, 16].

It has also been noted that a bidder's decision as to whether to compute or gather information about it's valuations can depend on the preferences of others [18]. We have proposed explicitly modeling the information-gathering actions of bidders along with the decisions they make when deciding how to use their information-gathering resources. We placed this *deliberative-agent* model into a game theoretic framework, and have analyzed classic auctions in order to gain an understanding of the impact that computational and information-gathering constraints have on agents' strategic behavior [7]. This brought to light new forms of strategizing on the part of the bidders where they actively gathered information on their competitors, and provided a possible explanation for behavior seen in practice [17].

In recent work we studied the problem of designing auctions specifically for bidders who must gather information [9] in order to determine their actual valuations and formulate their bids. We proposed three intuitive properties for auctions. We argued that the auction should not have to know

the details of the bidders information-gathering processes (*preference-formation independence*), bidders should not have incentive to gather information about other bidders (*deliberation-proof*), and that the auction should support some level of honesty among the bidders (*non-misleading*). However, we showed that it is impossible to design an (interesting) auction that has these three properties.[1] The contribution of this paper is that we show by that relaxing one of the properties, preference-formation independence, and allowing the auction to use some minimal amount of information about the bidders, it is possible to avoid strategic-deliberation and misleading behavior.

The rest of the paper is organized as follows. In the next section we describe our deliberative-bidder model, and discuss the problems faced in designing auctions for such bidders. In Section 3 we describe an optimal-search procedure and discuss how it can be incorporated into an auction. We then show that this auction provides the appropriate incentives for deliberative bidders. In particular it reduces the strategic burden placed on these bidders as they decide how to use their (limited) deliberation resources. Finally, Section 5 reports on experimental results which illustrate the feasibility of running such a procedure, as well as the effects it has on reducing the total cost of information gathering.

2. DELIBERATIVE BIDDING AGENTS

In this section we provide the background and motivation for the rest of the paper. We start by presenting our model of a deliberative agent. We discuss the implications of having deliberative agents participate in auctions and, in particular, we highlight the complex strategic behavior that may arise when bidders are deliberative. We then discuss some of the challenges in designing auctions for such agents.

In the rest of this paper we assume that the reader has a basic understanding of elementary game theory and auction theory. While we do explain key concepts as they are needed, a more thorough treatment on this topic can be found in microeconomic texts or books specializing on auctions [12, 6]. We pause now to comment on the terminology used in this paper. We use the terms "bidder" and "agent" interchangeably. That is, every agent is a bidding agent. We also use the terms "deliberative" and "information-gathering" interchangeably.

2.1 Deliberative agents

In this paper we assume that bidders are *deliberative*. A deliberative bidder is one who must compute or gather information in order to determine how much it values the item(s) being auctioned, has restrictions on its computing or information-gathering capabilities, and who carefully considers how to use its available resources given its restrictions.

We assume that a deliberative agent has a set of deliberation resources, which we will simply refer to as the agent's resources. We denote the resources of agent i by R_i. An agent is able to apply its resources to any preference-determination problem it wishes. If there are m possible problems, then we let $(r_1, \ldots, r_m) \in R_i^m$ denote the situation where the agent has devoted r_j resources to problem j. In particular, the agent is allowed to deliberate on its own preference-formation problems, as well as the problems of any other agent.

We model deliberation-resource limitations through cost functions. The cost function of agent i is $\text{cost}_i : R_i^m \rightarrow \mathbb{R}^+$. The only restriction placed on the cost functions are that they must be additive and non-decreasing.

A deliberative agent i is endowed with a multi-set of algorithms $\mathcal{A}_i = \{A_i^j\}$ where A_i^j is the algorithm agent i can use on problem j. We use the term *algorithm* in its broadest sense; algorithms are step-by-step procedures for solving some problem. In particular, we include information gathering processes in our set of algorithms. The algorithms of a deliberative agent have the anytime property; they can be stopped at any point and are guaranteed to return a solution, but if additional resources are allocated to the problem then a better solution (or at least no worse a solution) will be returned.

A deliberative agent carefully decides how to allocate its resources on algorithms given its cost function. To help with this process, deliberative agents are equipped with a set of *performance profiles*, $\mathcal{PP}_i = \{P_i^j\}$, one performance profile for each algorithm. A performance profile has two components. First, it describes how allocating resources to a problem changes the output of the algorithm. In particular, it describes, for any resource allocation to a problem, what possible solutions the algorithm may return, conditional on any and all features of the algorithm and problem instance which are deemed to be of importance to the agent. This is coupled with a procedural component, which, given the descriptive part of the performance profile, returns a deliberation policy that describes how the agent should optimally allocate deliberation resources. A performance profile can be as simple as a probability distribution over possible valuations coupled with a rule that states whether the agent should deliberate or not, or it may use a more sophisticated procedure that allows agents to condition their deliberation policies on current results [8].

To summarize, a deliberative agent is defined by

$$\langle R_i, \text{cost}_i(\cdot), \mathcal{A}_i, \mathcal{PP}_i \rangle$$

where R_i is the set of deliberation resources of agent i, $\text{cost}_i : R_i^m \rightarrow \mathbb{R}$ is a cost function which limits the amount of resources the agent can use, $\mathcal{A}_i$ is the multi-set of algorithms available to the agent, and $\mathcal{PP}_i$ is the associated set of performance profiles.

2.2 Auctions and Deliberative Bidders

A deliberative bidder needs to decide how and whether to gather information on valuations and then how to use the information it has in order to bid. Figure 1 illustrates this process. Motivating the bidders is the desire to maximize their utility. In particular, the utility of a deliberative bidding agent depends on its valuation, whether or not it has won the item that was up for auction, and the price that it pays if it was the winner. That is, if an agent i had used resources $r = (r_1, \ldots, r_m)$, had determined valuation $v_i(r_i)$ had won the item, and had to pay price p, then its (expected) utility would be

$$u_i = v_i(r_i) - p - \text{cost}_i(r).$$

If the agent had not won the auction then its utility is

$$u_i = -\text{cost}_i(r).$$

[1] Auctions where the outcome is completely independent of the bidding strategies of the agents trivially satisfy the three properties.

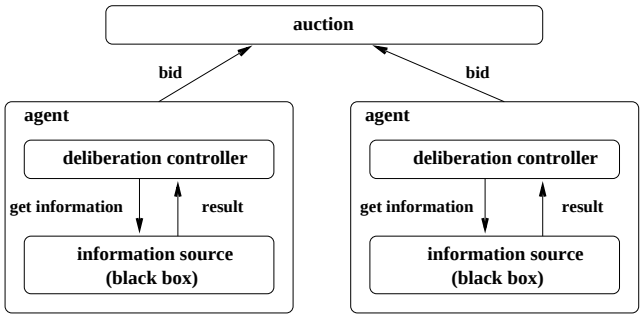

Figure 1: An auction with two deliberative bidders. Each bidder must gather information in order to determine how much it values the item that is being auctioned. A bidder may also have incentive to gather information on other participants in the auction.

Note that the bidder may use its deliberation resources on problems which do not directly affect its own valuation. However, this will still influence its utility since it incurs a cost for the total amount of resource usage.

A strategy for a deliberative bidder is a policy which specifies what actions (deliberative and bidding) to execute at every stage in the auction. We define a *history* at stage t, $H(t) \in \mathcal{H}(t)$, as the set which includes all actions (both deliberative and bidding) that the bidder itself has taken up to stage t, the results of the deliberation actions, as well as all actions other bidders may have taken (these may not have been observed by the agent). A (deliberation) *strategy* is a mapping from the set of histories to the set of actions (deliberative or bidding) for each stage in the game. That is, $S_i = (\sigma_i^t)_{t=0}^{\infty}$ and

$$\sigma_i^t : \mathcal{H}(t) \mapsto A_i$$

where A_i is the set of actions available to bidder i.

To clarify this definition we present a simple example. In a direct auction, bidders submit their bid directly to the auctioneer at some deadline T. The strategies of a deliberative bidder have the following form; $S_i = (\sigma_i^t)_{t=0}^{\infty}$ where

$$\sigma_i^t(H_i(t)) = \begin{cases} d_i^j & \text{if } t < T \text{ or } t > T \\ \hat{v} & \text{if } t = T \text{ and } \hat{v} \in \mathbb{R} \end{cases}$$

where $\hat{v}$ is the bid submitted to the auctioneer, and d_i^j is a deliberative action.

In this new, enlarged, strategy space we look for equilibria, which we call *deliberation equilibria*. When we studied the deliberation equilibria in standard auctions, we noted that the equilibrium strategies of the bidders could be very complex. In particular, deliberative bidders have incentive to deliberate on the valuation problems of other bidders, and to base their own deliberation actions on the results [7]. We call this behavior *strategic deliberation*.

We believe that strategic deliberation is a undesirable phenomenon. When bidders strategically deliberate they use their own costly information-gathering resources on valuation problems that do not directly relate to their own preferences, thus wasting these resources. Additionally, the strategic burden placed on the bidders is potentially overwhelming. They must take into consideration the bidding actions of competitors, the deliberation actions of competitors, as well as the results of their competitors deliberation actions, in order to determine how to best deliberate and bid for themselves.

Recently, we studied the problem of designing auctions explicitly for deliberative bidders [9]. To this end we proposed three desirable properties for such auctions. First, we argued that a well-designed auction should reduce the strategic burden of the bidders. In particular, a well-designed auction should not provide any incentive for bidders to strategically deliberate. That is, auctions should be *deliberation-proof*. Second, we proposed that an auction should encourage bidders to take actions which are consistent with their actual valuations. That is, bidders should not try to willfully mislead others concerning their valuations. We called this property *non-misleading*. Finally, we argued that an auction should not be involved in the information-gathering or deliberative process of the bidders. In particular, the auction should not depend on the actual form of the cost functions, anytime algorithms or performance profiles of the bidders. We called this property *preference-formation independence*.

While each of these properties is desirable in isolation, unfortunately it is impossible to design an (interesting) auction with all three [9]. In the rest of this paper we relax the preference-formation independent property and allow the auction to use some information about the information-gathering processes of the bidders. We show that by relaxing this one property it is possible to have an auction where the other two properties are achieved.

3. AN OPTIMAL-SEARCH AUCTION

The preference-formation independence property is very strong since it means that the auction is not able to use any information about the information-gathering processes of the bidders. In this section we slightly relax this property and allow the auction designer to use some information about the cost functions and performance profiles of the bidders. In Section 4 we show that this is enough to get a deliberation-proof and non-misleading auction.

The key insight is that if the auction designer has information about the bidders' cost functions and performance profiles, then it can use this information to sort the bidders. The auction can then process the bidders in order, getting each one in turn to gather information and bid until some criterion has been met. By using an optimal search procedure from the operations research literature [19], coupled with carefully designed reservation prices, it is possible to create an auction where the most promising bidders (i.e. the ones most likely to have a high valuation and thus win the auction) are asked to participate early in the process, and, secondly, where bidders are provided with enough information that they no longer have incentive to gather information about others.

This is not the first time that someone has proposed using a search procedure in an auction. In particular, Burguet [2] and Cremer, Spiegel and Zheng [4] have studied this idea and have proposed both auctions and revelation mechanisms. While the auction in this paper is based on the Cremer-Spiegel-Zheng auction, our bidder model, motivation, and the properties we prove differ substantially. Both Burguet and Cremer *et al.* assume that the bidders can only gather information on their own valuations, as opposed to our assumption that bidders are free to gather information

on any problem they wish. Second, their goal is to design an auction which maximizes the revenue of the seller and so are interested in extracting the expected surplus from the bidders by imposing appropriate admission fees. Instead, we focus on the strategic behavior of the bidders and show that the auction has desirable properties from their perspective.

We now describe the assumptions that have been made in this paper. First, we assume that there are n deliberative bidders, and that the performance profiles and the cost functions of the bidders are known to the auction designer and to each other. Second, we assume that the cost functions and the performance profiles of the bidders are independent. Both these assumptions are required for the results.

To simplify the explanation of the auction, as well as the notation, we will make certain assumptions about the performance profiles of the agents. In particular, we assume that while a bidder i does not know its valuation *a priori*, it does know that it comes from some interval $[0, \overline{v}_i]$ with probability distribution P_i which is equivalent to the descriptive component of the bidder's performance profile. We argue that this assumption is not unduly restrictive. First, deliberative agents with performance profiles like this still have incentive to strategically deliberate in standard auctions. Second, the proposed auction will still work in settings where bidders have more sophisticated performance profiles. The only repercussion is that sorting the bidders, as will be described next, becomes more complex.

In the rest of this section we describe the optimal-search auction. We first give an overview of the optimal search procedure used by the auctioneer, and then describe how the auctioneer uses it when setting up an auction. In the next section (Section 4) we prove that this has the properties we desire.

3.1 Optimal Search

In the operations research literature a search problem is often formulated in the following way. Assume that there are n boxes (bidders) to open (ask to deliberate), and each box (bidder) i has some random value v_i which is drawn from distribution (performance profile) $P_i(v)$ with density f_i. If the searcher opens a box (queries a bidder) i then it incurs a cost of cost_i. The payoff to the searcher is the maximum value found up to the point when it stops. The question is, then, in what order should the boxes (bidders) be searched (asked to deliberate) and when should the process stop?

Weitzman proved that this problem can be solved optimally using a very simple procedure [19]. First, each box (or bidder) is assigned a *cutoff value* K_i where

$$K_i = \int_0^{K_i} K_i f_i(v)dv + \int_{K_i}^{\overline{v}_i} v f_i(v)dv - \text{cost}_i.$$

If the searcher had already opened a box with reward K_i then it would be ambivalent between opening box i or keeping reward K_i. If the best reward found so far is less than K_i then the searcher is best off opening box i.

Once the cutoff values have been computed, the optimal search procedure is completely characterized by the following rules:

1. (**Selection Rule**) If a box is to be opened, it should be that closed box with highest reservation price.
2. (**Stopping Rule**) Terminate search whenever the maximum sampled reward exceeds the reservation price of every closed box.

The cutoff values and the search procedure have some interesting properties which make them particularly useful for our application. The cutoff values are not the expected valuations of the bidders and, in fact, the optimal search procedure may well search a bidder with a low expected value before a bidder with a higher expected value. As Weitzman noted "Other things being equal, it is optimal to sample first from distributions that are more spread out or riskier in hopes of striking it rich early and ending the costly search" [19]. Interestingly, one of the main incentives driving bidders to strategically deliberate is very similar. Bidders are better off paying some small amount to learn whether or not a competitor has a high valuation for an item (and thus would be likely to win the auction) and only then deciding whether it is worth while to gather information on its own valuation problem [7]. Some other appealing properties of the cutoff values and the search procedure are that as the cost of learning a valuation increases, the cutoff value decreases, and as the search progresses the valuations needed to stop the search decrease.

We note that the cutoff value calculation is equivalent to finding a fixed-point, and may be a computational challenge for the searcher. However, in many settings, finding the fixed point is relatively straightforward. For example, if v_i is drawn from the uniform distribution over $[0, 1]$, and the cost of learning v_i is 0.25, then the cutoff value is

$$\begin{aligned} K_i &= \int_0^{K_i} K_i dv + \int_{K_i}^{1} v dv - 0.25 \\ &= K_1^2/2 + 0.25. \end{aligned}$$

Solving for K_i, we get $K_i \approx 0.293$.

3.2 The Auction

The optimal-search auction progresses through a series of stages. First, using its knowledge of the performance profiles and cost functions of each bidder, it computes the cutoff values. It labels the bidders in decreasing order of cutoff values so that $K_1 > K_2 > \ldots K_n$. It then asks each bidder in turn to gather information on its valuation problem and reveal the result. If, after asking the first t bidders to deliberate and reveal their results, the highest valuation is greater than K_{t+1} then the auction is halted, the highest bidder wins the item, and the auction has followed the optimal search procedure. However, it is not possible to simply get each bidder to truthfully reveal their valuations when asked. Instead, the auctioneer uses reserve prices and a sequence of second-price auctions to get the bidders to truthfully reveal whether or not their deliberations have resulted in valuations which are larger than a specific cutoff value.

In stage 1, the auctioneer tells bidder 1 that it should gather information on its valuation problem. The auctioneer then makes a take-it-or-leave offer of price p_1^1 to the agent. If the offer is accepted then the auction stops, bidder 1 gets the item and pays p_1^1. If the offer is rejected then the auction continues to the next stage. If the auction reaches stage t then bidder t is asked to deliberate on its valuation problem. Once it has done so then bidders 1 to t participate in a second-price auction with bidder and stage specific reserve prices. If bidder i submits a bid which is greater than its reserve price p_i^t then the auction stops. If only one bidder submitted a bid which was greater than its reserve price then

it is given the item and it pays its reserve price. If there are multiple bidders who submitted bids that were higher than their reserve prices then the highest bidder i wins the item and pays $p = \max[p_i^t, b_{-i}]$ where $b_{-i} = \max\{b_j | b_j > p_j^t$ and $j \neq i\}$. If the auction reaches the final state, n, then all bidders have been asked to gather information on their valuations. All bidders then participate in a second-price auction with no reserve prices.

The auctioneer must be careful when it comes to setting the reserve prices. If it is not done properly then bidders may have incentive to lie about their valuation after they have learned them. If the reserve prices are too low then a bidder may want to submit a bid which is higher than its true valuation in order to stop the auction early so as to avoid competition from others. If the reserve prices are set too high then a bidder may submit a bid which is lower than its true valuation in the hopes that as the auction progresses the reserve prices will drop. Cremer *et al* showed that it is possible to set the reserve prices so that in (Bayes-Nash) equilibrium the bidders bid truthfully [4]. This is done by working backwards through the stages of the auction.

If the auction reaches the last stage, then all bidders know their valuation. Since they participate in a second-price auction, each bidder is best off bidding truthfully. In the second last stage the first $n-1$ bidders know their valuations. Assume all of these bidders but i bid truthfully. Our goal is to set the reserve price of bidder i, p_i^{n-1} so that bidder i will only submit a bid greater than p_i^{n-1} if its valuation is greater than or equal to K_n. If $v_i = K_n$ then the only way the bidder can win the auction is if all bidders who know their valuations submitted a bid less than K_n. That is $v_{-i} < K_n$. If bidder i bid truthfully, the auction would stop, it would win, and it would pay its reserve price. Its expected payoff is

$$(K_n - p_i^{n-1})\Pi_j P_j(K_n) \quad (1)$$

where $1 \leq j < n$, $j \neq i$. If bidder i lied about its valuation at stage $n-1$ then the auction would continue to the final stage where all bidders are informed and all participate in a second-price auction. Bidder i will only win if all bidders, including bidder n, have valuations which are less than $v_i = K_n$. Since, by assumption, all other bidders are telling the truth about their valuations, agent i knows that the first $n-1$ bidders (minus itself) must have valuations which are less than K_n. Thus, its payoff if it waits for the last round is

$$\Pi_{1\leq j\leq n-1} P_j(K_n) \int_0^{K_n} (K_n - v_{-i}^n) d\frac{\Pi_{1\leq j\leq n} P_j(v_{-i}^n)}{\Pi_{1\leq j<n-1} P_j(K_N)} \quad (2)$$

where $j \neq i$ and v_{-i}^n is the highest valuation of the bidders from 1 to n, not including bidder i. Bidder i is ambivalent between declaring its true valuation in round $n-1$ and waiting for the second-price auction in the next round whenever (1)=(2). If the reserve price p_i^{n-1} is set such that (1)=(2) then bidder i will truthfully reveal its valuation, given that all other bidders are also doing the same.

The appropriate reserve prices for earlier rounds are determined in a similar fashion. If in stage t bidder i has valuation $v_i = K_{t+1}$, and assuming that all bidders j, $1 \leq j \leq t$, $j \neq i$ reveal their valuations truthfully, then, if bidder j bids truthfully, the auction will stop and its payoff will be

$$(K_{t+1} - p_i^t)\Pi_j P_j(K_{t+1}) \quad (3)$$

where $1 \leq j < t$, $j \neq i$. If the bidder waits until the next stage and then reveals its true valuation, its expected payoff is

$$(K_{t+1} - p_i^{t+1})\Pi_j P_i(K_{t+2}) + \quad (4)$$
$$\Pi_j P_j(K_{t+1}) \int_{K_{t+2}}^{K_{t+1}} (K_{t+1} - v_{-i}^{t+1}) d\frac{\Pi_j P_j(v_{-i}^{t+1})}{\Pi_j P_j(K_{t+1})}$$

where $1 \leq j < t+1$ and $j \neq i$, and where bidder i will pay p_i^{t+1} if $v_{-i}^{t+1} < K_{t+2}$ and v_{-i}^{t+1} if $v_{-i}^{t+1} > K_{t+2}$. If p_i^t is set such that (3)=(4) then bidder i is best off bidding truthfully in stage t, assuming that all other possible bidders also bid truthfully.

4. PROPERTIES

The optimal-search auction described in the previous section has some properties which make it appealing. First, there exists a Bayes-Nash equilibrium where the bidders truthfully reveal their valuations at the right time. Secondly, and of particular interest, it is structured so that bidders have no incentive to strategically deliberate. That is, the optimal-search auction is deliberation-proof and non-misleading.

Proposition 1 *The optimal-search auction is non-misleading. There exists a Bayes-Nash equilibrium where bidders truthfully reveal their valuations when asked by the auctioneer.*

Proof: (Sketch) The full proof is quite technical and follows the proof described in Cremer *et al* [4]. Thus, we only provide an overview of the proof. The main idea is that the reserve prices used by the auctioneer have been carefully chosen so that a Bayes-Nash equilibrium, where the bidders truthfully reveal the results of their deliberation, exists. If the auction does not stop before all bidders have been asked to deliberate on their own valuation problems, then a second-price auction is run. At this point, all the bidders know their valuations and so are best off bidding truthfully. At stage $t < n$, using the equilibrium hypothesis that all other bidders who have learned their valuations truthfully reveal them, the reserve prices for bidder i were carefully designed so that it is in it's best interest to truthfully reveal the valuation it obtained via deliberation. This is because in stage t bidder i is participating in a second-price auction with $t-1$ other bidders and so it's bid does not change the price it will pay if it wins in stage t. Additionally, the reserve prices are such that if $v_i \geq K_{t+1}$ then bidder i is best off revealing this and stopping the auction in stage t, while if $v_i < K_{t+1}$ then the bidder is best off letting the auction continue. In either situation, truth-telling is bidder i's best response, given its beliefs about the potential valuations of all other bidders, conditional on the fact that the auction has reached stage t and the hypothesis that all other bidders truthfully reveal their valuation once they have learned it.

□

Proposition 2 *The optimal-search auction is deliberation-proof. Deliberative bidders have no incentive to use their deliberation resources on the valuation problems of others.*

Before we present the proof of this proposition, we provide some insight into why bidders strategically deliberate in auctions. Strategic deliberation is caused when there is some

form of asymmetry between the bidders in terms of the cost functions or the performance profiles. Strategic deliberation often occurs when one bidder gathers information on a competitor in order to check whether the competitor has a high valuation or not. Based on this information, the deliberating bidder will then decide whether or not it is worthwhile to deliberate on its own valuation problem. Interestingly, the optimal search procedure uses a similar motivation for sorting agents. In particular, it queries agents in such an order so that agents that other bidders may want to gather information on (i.e those with potentially high valuations and low cost) are asked to deliberate and reveal their results early in the process, thus removing the need for other agents to gather information on them.

Proof: (Sketch) If the auction stops before a bidder is asked to deliberate, then the bidder has no incentive to deliberate on any problem and thus will not strategically deliberate. If a bidder already knows its valuation then it has no incentive to learn the valuations of other bidders in the optimal-search auction, since it will participate in second-price auctions. Therefore, the only situation of interest is when the auction asks a bidder to gather information and it has not yet done so on its own valuation problem.

Another useful observation is that if $\text{cost}_i < \text{cost}_j$ then bidder i has no incentive to deliberate on the valuation problem of bidder j. That is, if it is more expensive to deliberate on another bidder's valuation problem compared to ones own, then one will not deliberate on the other's problem.

Case 1: Assume that $K_i > K_j$, and assume that the auction has reached stage i. Since the performance profiles of all bidders are common knowledge, bidder i can determine $E[v_i]$ and $E[v_j]$. If $E[v_i] \leq E[v_j]$ then it must be the case that $K_i < K_j$ since $\text{cost}_i > \text{cost}_j$. This is a contradiction, and so it must be the case that $E[v_j] < E[v_i]$.

If $E[v_i] > K_j$, then in expectation the auction will stop before it reaches bidder j and thus the valuation of bidder j is irrelevant. Therefore, bidder i has no incentive to incur a cost from learning it. Assume that $E[v_i] < K_j$. Let $t = \max\{t | K_t < E[v_i]\}$. That is, in expectation, stage t is the earliest stage in which bidder i could influence the outcome of the auction. If $K_t > E[v_j]$ then we are in a similar situation as before and so for the same reason bidder i has no incentive to deliberate on the valuation problem of bidder j. If $K_t < E[v_j] < E[v_i]$ then it is possible that v_j will effect what price bidder i may pay, but in expectation it will not effect the allocation decision of the auction. Since strategic-deliberation is driven by allocation uncertainty as opposed to price uncertainty, bidder i has no incentive to deliberate on player j.

Case 2: Now assume that $K_j > K_i$. If the auction never reaches stage i then bidder i has no incentive to deliberate on any valuation, and thus certainly not on the problem of bidder j. Assume that the auction does reach stage i. This can only occur if $v_j < K_i$. Since, the auction is implementing an optimal search process, we know that it must be the case that

$$v_j - \sum_{1<l<i} \text{cost}_l < E[v_i] - \text{cost}_i - \sum_{1<l<i} \text{cost}_l.$$

Therefore, by simple algebra,

$$v_j < E[v_i] - \text{cost}_i$$

Clearly bidder i now has no incentive to deliberate on bidder j's problem. In expectation bidder i has a higher valuation than bidder j and thus will be allocated the item before bidder j would. Secondly, even if bidder j influenced the price that bidder i had to pay, learning the actual valuation of bidder j will not change the deliberation strategy of bidder i.

□

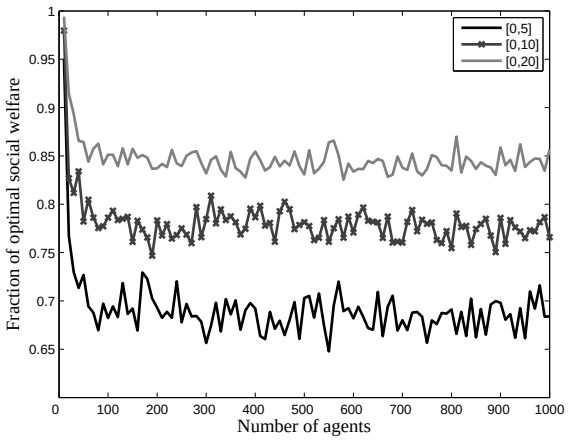

Figure 2: Fraction of the optimal allocation the search auction achieves. In this example all agents have their cost functions fixed to 1.0.

5. EXPERIMENTAL RESULTS

We investigated how the optimal-search auction worked in practice. In particular, we were interested in the economic efficiency of this approach, and whether it significantly reduced the amount of deliberation among the agents. To this end, we conducted two sets of simulations. The first set of simulations compared the allocation made by the search auction to the optimal allocation (made by a second-price auction). The second set of simulations compared the total cost of deliberation of all agents in the search auction with that of a second-price auction.

We set the parameters of the two sets of experiments the same way. We divided the bidders into six different classes, and then ran second-price auctions and optimal-search auctions in each class as we varied the number of bidders.

Each bidder had some valuation v_i which was drawn independently from the uniform distribution over $[0, V]$, where V was either 5, 10 or 20. For each of these valuation intervals, we set the cost functions in one of two ways. We first set the cost function of all agents in each class to be cost = 1.0. This meant that the cutoff values used in the optimal-search auction were the same for all bidders who's value had been drawn from the same interval. This put the optimal-search auction at a disadvantage since it had to run with minimal information available to it. We varied the cost functions for the bidders in other experiments. In particular, for any bidder who had a valuation drawn from the interval $[0, V]$, we randomly drew a cost constant cost_i from the uniform distribution over $[0, V/2]$. This meant that with high probability each bidder had a different cutoff value allowing the optimal-search auction to order the bidders to its advantage.

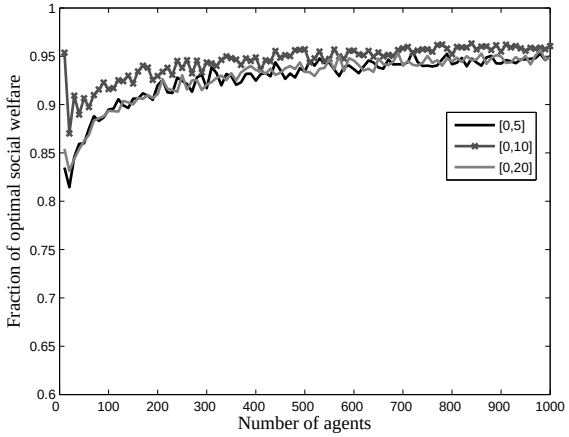

Figure 3: Fraction of the optimal allocation the search auction achieves. In this example, cost functions are drawn uniformly and independently from an interval related to their valuations.

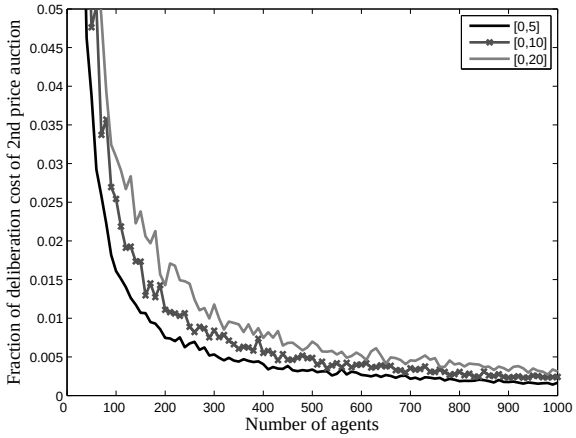

Figure 4: Cost incurred by all agents in the search auction compared to cost incurred in a second price auction. As the number of agents increase, the fraction becomes vanishingly small. Cost functions were fixed so that they were all equal to 1.0. This means that all agents (in each experiment) had the same cutoff value.

For each of the six parameter configurations we ran a series of second-price auctions and optimal-search auctions. We compared the efficiency of the optimal-search auction with that of the efficient second-price auction in order to determine what the efficiency loss was. We also compared the total cost of deliberation done by all bidders in the second-price auction with that done in the optimal-search auction in order to determine whether there was a substantial overall savings with the optimal-search auction. In each experiment we varied the number of bidders from 2 to 1000, and repeated each experiment 100 times. We present the average of our results.

In our first set of experiments we measured the efficiency of the search auction with that of the second-price auction. The second-price auction is guaranteed to allocate the item to the agent who has the highest valuation, while the search-auction allocates the item to the agent who has the highest valuation amongst the agents who have been asked to deliberate before the auction is stopped. It is possible that the search-auction is stopped before the agent with the actual highest valuation is asked to deliberate. Figures 2 and 3 show our findings.

In Figure 2, the search auction is at a disadvantage since all the cutoff values for the agents in each experiment are the same. However, we still observe that the search auction is within at least 65% of optimal (the allocation of the second-price auction) for all parameter settings. The allocation does depend on the interval from which the valuations are being drawn, with values from $[0, 5]$ leading to a lower allocation than the others. If the auction had more than 100 bidders, then the allocation did not seem to be affected by the number of bidders (this was expected). In Figure 3 the search auction was able to make better allocations when it was able to distinguish between the agents based on their cutoff values. Once we had at least 200 bidders, the allocation made by the search auction was always within 90% of optimal.

In our second set of experiments we studied whether or not the search auction reduced the total amount of deliberation done by all agents significantly, compared to what would happen in a second-price auction. In a second-price auction, given our setup, each agent would have incentive to gather information on their own valuation problem, while in the search auction only a subset of the agents will likely be asked to gather information (and thus incur a cost). Figures 4 and 5 show our results. Even if the search auction has little information by which to sort the agents (Figure 4) the overall savings in deliberation cost from a system-wide perspective is substantial. This is even more marked in the experiments where agents had different cutoff values, allowing the search auction to query the most promising agents first (Figure 5).

To conclude, our experiments show that the search auction does quite well when it comes to allocating the item. It also greatly reduces the amount of deliberation done by all agents in the auction.

6. CONCLUSION

A common assumption in auction research is that bidders have private information about their willingness to pay for the item being auctioned and that they use this information strategically when formulating their bids. In reality, bidders often have to undergo a costly information-gathering process in order to determine their valuations for the item being auctioned. Recent attempts at modelling this phenomenon has brought to light complex strategic behavior that had previously been overlooked. In particular, bidders may either have incentive to actively gather information on others or may have incentive to "fool" other bidders about their results. Earlier work proved that if the auction designer had no information about the bidders' information-gathering processes then this strategic behavior on the part of the agents was impossible to avoid.

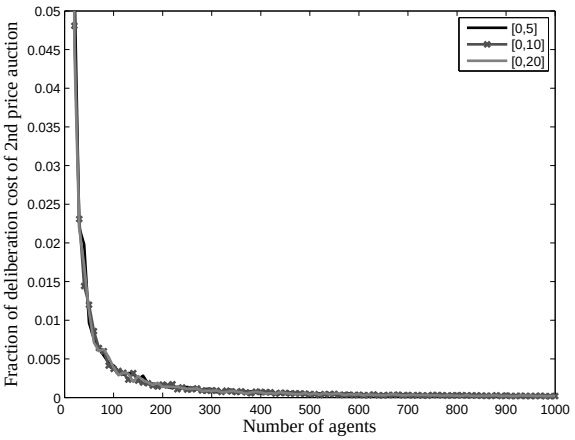

Figure 5: Cost incurred by all agents in the search auction compared to cost incurred in a second price auction. As the number of agents increase, the fraction becomes vanishingly small. Cost functions were drawn uniformly and independently from intervals related to their valuations.

In this paper we showed that by providing the auction designer with some minimal amount of information about the information-gathering processes of the bidders, it is possible to design an auction such that the bidders only gather information on their own valuation problems, and, when asked, report the results truthfully to the auctioneer. The insight is that by carefully ordering the agents using an optimal search procedure, and then asking them sequentially to gather information and reveal their results, it is possible to remove the uncertainty that drives the complex strategic behavior of deliberative agents in standard auctions. We additionally showed, via simulation results, that the savings in terms of overall information-gathering costs is significant.

There are several directions in which this work can be taken. This paper focussed solely on single-item auctions, and so generalizing the approach to multi-item auctions is an obvious next step. Second, the search auction relied on the assumption that the performance profiles and cost functions of the agents are known to everyone. While it seems likely that the auction also provides the correct incentives so that bidders will truthfully reveal their performance profiles and cost functions, this still needs further analysis. Finally, it is our belief that optimal search procedures from the operations research literature may find use in other settings, for example in situations where the total amount of communication has to be minimized.

ABSTRACT

An expanding auction—a special type of an ascending-price open-cry auction—allows the auctioneer to dynamically add (identical) items to the single item offered initially. Expanding auctions are becoming an increasingly popular business-to-consumer auction mechanism. The auctioneer's revenue from an expanding auction depends, in large part, on its schedule for increasing the number of units offered. As we show, the naïve strategies commonly used for increasing the number of items offered in contemporary e-commerce implementations of expanding auctions are sub-optimal. In this study we provide a strategy that, given some assumptions about buyers' behaviors, maximizes the expected revenues of the auctioneer in an expanding auction. We model the auction process as a state graph in which nodes are auction states and edges are transitions. With this model, finding the optimal strategy is equivalent to solving a search problem on the state graph. We prove that the search problem to be solved, although seemingly exponentially complex, is actually linearly bounded. Based on this result, we introduce an informed decision strategy that optimizes the auctioneer's revenue.

Keywords

Expanding auction, auctioneer's revenue.

1. INTRODUCTION

Auctions are a popular electronic commerce tool [7]. Multi-unit auctions are also in use, however they are not as widely deployed as single-unit auctions are. This is despite the availability of an array of theoretical multi-unit auction solutions [5, 8]. We believe that the reasons for the limited use of multi-unit auctions are practical limitations of existing solutions such as high computational costs, difficulty of optimizing auctioneer's revenues [9], attack vulnerability, etc. The expanding multi-unit auction (initially studied in [11], though in limited detail), which is in use in several business-to-consumer (B2C) sites, is not an exception in this respect. Agents might be able to resolve some of these problems [10, 12], either on behalf of auctioneers or on behalf of buyers, however they should be provided with appropriate strategies for such decisions. The auctioneer's strategies for placing additional items up for sale in the expanding auction that are currently implemented in e-commerce sites do not optimize its revenues. In this study we overcome this limitation. We provide a novel strategy for the auctioneer to decide whether it should increase the number of items sold, or keep the number unchanged. The strategy is computationally feasible in real-world auctions, and it optimizes the auctioneers' expected revenues. This work is the first to provide such a strategy for an expanding auction.

Various mechanisms were developed to support the sale of multiple items [5, 7]. Some of these are sealed-bid auctions, e.g., Generalized Vickrey Auction (GVA) [3, 13]. GVA ensures that bidders expose their true valuation functions, which are defined over the possible allocations of the goods. GVA calculates the allocation that maximizes the sum of the bidders' utilities hence maximizing the auctioneer's revenue. The main disadvantage of this mechanism is that it is too complicated for practitioners, and in particular for consumers, to understand [2].

Ascending multi-unit auctions [2, 4] provide a reliable process of price discovery. This is important in auctions where a common value component is present, as is the case for commodities sold to consumers. An ascending bid multi-unit auction may be realized by enhancing the demand schedules approach. This method may be considered as a multi-round version of the multi-unit sealed bid mechanism [4]. Associated activity rules ensure that every bidder will contribute to price discovery as long as the auction process proceeds.

A better open format mechanism for allocating multiple units is the ascending clock mechanism [2]. Compared to the ascending bid multi-unit format this design has many advantages. Bidders have to submit only a single quantity in each round instead of a demand schedule, which makes the auction easier to implement and more comprehensible. Collusions are avoided by this mechanism, yet a uniform price is set in a similar manner to the uniform price auctions discussed earlier. This protocol yields revenues similar to the expected outcome with GVA. The main disadvantage here is that the number of units sold must be smaller than the number of units requested (as demand is greater than supply). Therefore this mechanism is more suitable to limited supply

goods like communication spectrum or treasury bills, but not for commodities.

The expanding auction format is not well studied in terms of its theoretical properties. It is an open ascending price auction, and thus it has similarities to other such protocols. However, it has a simple, comprehensible user interface. Further, it is simple to implement. And as we show in this study, optimizing the auctioneer's expected revenues can be performed in linear time.

2. EXPANDING AUCTIONS

One of the reasons for multi-unit auctions' lack of popularity as B2C Internet auctions may be the likelihood of premature termination of the auction execution process. Premature termination may occur when the number of participants in the auction does not exceed the number of units offered (assuming each bidder desires one unit of the good). In single unit auctions such premature termination has a minor chance of occurring because the participation of a single bidder is usually unlikely. In multi-unit auctions the auctioneer may set a reservation price to prevent the loss expected from premature termination. However, this approach may deter bidders from the auction.

An emerging new auction type used in B2C e-commerce sites, which addresses the problem of premature auction termination, is the expanding multi-unit auction[1] (in short: the expanding auction). In an expanding auction, initially one item of a good is offered to the bidders. The bidders are free to raise their bids whereas the auctioneer is free to raise the number of units offered by one each time a new bid is received, with no upper limit on the number of units to be offered. The auction terminates when no more bids are placed. The winner list consists of the n highest bids offered where n is the number of units offered upon auction termination. The first bidder to enter the winner list is the first one to leave it. Similarly, with the Japanese auction [6] the auctioneer sets a bid rate used to gradually raise the price. Bidders are not allowed to raise their bids at a rate other than the one set by the auctioneer. It is assumed that each bidder desires one unit of the good and is risk neutral, therefore his/her utility function is given by $U_i=V_i-p$, where p is the price paid and V_i is bidder i's valuation of the good.

The expanding auction increases the auctioneer's control over the execution process. In a typical multi-unit auction the auctioneer has no control over how the execution will proceed once the initial parameters have been set. In contrast, in the expanding auction, the number of units offered may be changed dynamically. This allows the auctioneer to terminate the execution by gradually raising the number of units offered, or to continue the process to a certain extent by preserving the number of units offered. The control granted enables the auctioneer to set the number of units offered according to the number of bidders participating in the auction, making it easier to avoid the premature termination phenomenon observed in typical multi-unit auction mechanisms.

[1] We found no reference in the literature for the mechanism described here as the 'Expanding multi-unit auction' mechanism.

The most important aspect in the implementation of an expanding auction is the decision under which conditions to raise the number of units offered and under which to preserve it unchanged. This decision has a significant effect on auction execution, and more importantly on the auctioneer's revenues.

A simple but naive strategy for addressing this issue, used by B2C sites, is the step function strategy. For example, a step function strategy is used by an auction site named OlSale. (details are in the OlSale statute [1]). The strategy is based on a step function set by the auctioneer, composed of <price level, number of units> pairs that determine the number of units to be offered when the current bid reaches a certain level. Figure 1 depicts the step function strategy. When the current bid reaches p_1 the auctioneer offers one more unit, raising the number of units offered to 2. When the price reaches p_2 the auctioneer offers an additional unit raising the number of units to 3, and so on.

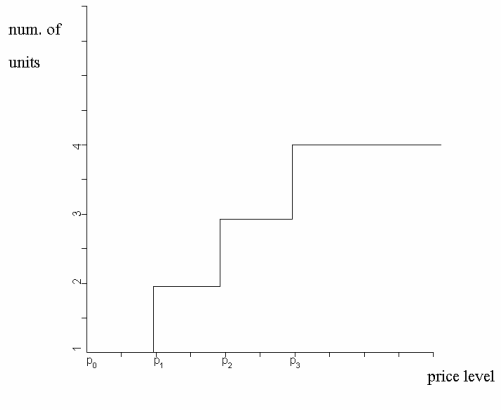

Figure 1. A step function policy

The step function strategy is simple to implement, however it is not trivial to configure its parameters in order to maximize the auctioneer's revenue. The same step function may yield higher revenues under certain conditions and lower revenues in others. This is illustrated in Example 1.

Example 1. Let (b_1,b_2,b_3) be 3 bidders with maximal bidding values (100,1000,2000), correspondingly. The bidders participate in an expanding auction in which the minimum bid rate is 10 and the step function is as given in Figure 1. Suppose that p_1=100; b_2 and b_3 may win the auction with bids equal to (100,110) respectively. If p_1=1000, b_2 and b_3 may win the auction with bids equal to (1000,1010), resulting in higher revenues obtained by the auctioneer compared to p_1=100. In contrast, when the bidding values are (100,110,120), p_1=100 results in higher revenues obtained by the auctioneer. With p_1=100, b_2 and b_3 will win the auction with bids equal to (100,110), respectively, whereas with p_1=1000 only b_3 will win the good at a price of 120.

The goal of this study is to overcome the weakness of the naïve step function policy presented above. We devise a strategy that, by taking into account the expected maximal bidding values, outperforms the step function strategy. It is important to note that this study assumes the new strategy it offers will maintain its optimality as long as the behavior of the bidder population does not undergo a fundamental change. Clearly, in a population of rational bidders, this assumption

might not hold. Yet, typical human participants in B2C sites are not rational bidders. Therefore, the suggested new strategy should be valuable for contemporary expanding auction sites. Optimal bidder strategies and their effect on the suggested auctioneer's strategy are left for future research and are out of the scope of this paper.

3. THE INFORMED DECISION STRATEGY

We model the expanding auction by a state graph. The nodes of the graph represent the states of the auction at a given point in time, and the edges represent transitions between states. Each state denoted by S has the following properties:

- The price a bidder must pay to join the winner list, denoted by l_d, where d denotes the bid sequence. For instance, l_2 denotes the price a bidder must pay to join the winner list after 2 bids have already been submitted and accepted by the auctioneer. Note that all states that may be formed after the auctioneer has received exactly d bids share the same price level l_d.
- The number of units the auctioneer is willing to sell at price l_d, denoted by n_S.
- A list B_S of maximal bidding values[2] (MBV) of the bidders currently participating in the auction. B_S contains MBVs of bidders which are either in the winner list, or willing to pay more than l_d and may therefore join the winner list at a later stage.
- A list of MBVs of the bidders in the winner list, denoted by B_{sw}. Clearly, $B_{sw} \subseteq B_S$.

Two operators will define the transition between states. The operators are defining the auctioneer's decision on *how to proceed with the auction process* given a particular state. The *raise*() operator corresponds to the auctioneer's decision to raise the number of units by one whereas the *preserve*() operator corresponds to his/her decision to keep the number of units offered unchanged. The operators are activated on states and produce new states.

The winner list is a queue that consists of bids placed by bidders. The size of this queue is equal to the number of units offered by the auctioneer. Once a bidder enters the winner list he/she is positioned at the end of the list. The first bidder to leave the list is the first bidder that entered the list (FIFO). The transition between states may affect the size of the queue, that is, the size is increased by one once the auctioneer decides to raise the number of units offered, otherwise the size remains unchanged.

Example 2. This example illustrates the state tree representing possible executions of an expanding auction process (cf. Figure 2). It has the following properties:

- The initial number of units offered by the auctioneer denoted by n_0 is 1.
- The reservation price denoted by l_0 is 90.
- The minimum bid increment denoted by Δ is 10.
- The initial list of the MBVs of the participating bidders denoted by B_0 is (100,120,130).

To simplify the illustration, in this example (and only in this example) it is assumed that the auctioneer first receives bids originating from bidders that have lower MBVs than other participating bidders have. This means that if multiple bidders submit equal bids at the same price level l_d the auctioneer will accept the bid originating from the bidder with the lowest MBV among the MBVs of the submitting bidders. The assumption ensures a single representation of the state graph illustrated in Figure 2. It will not be assumed further that this assumption holds.

In Figure 2, a state S_i is represented as follows: S_i=(b_1,b_2,b_3|n_i). In this representation, b_i refers to the MBV of bidder i, and n_i is the number of items offered by the auctioneer. Within the list of MBVs, some may be emphasized in bold-face font. The emphasized MBVs correspond to the bidders which are in the current winner list. Note that since not all bidders participate in the auction at all states, in some states the MBV list includes only a subset of bidders.

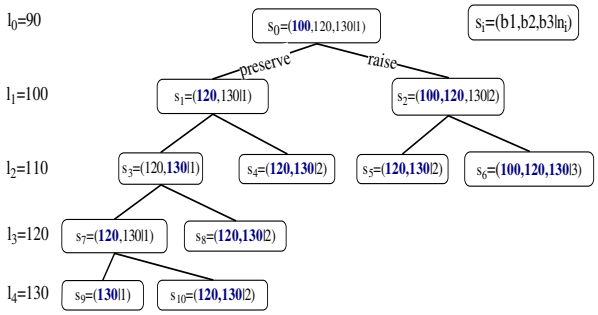

Figure 2. A state graph representing the dynamics of an auction process

The auction in Figure 2 starts with bidder b_1 obtaining the unit offered at 90$. In case that the auctioneer decides to raise the number of units offered, bidder b_2 joins the winner list by offering 100$ for the second unit. A transition from S_2 to its *raise* descendent S_6 results in b_3 joining the winner list with a bid of 110$. More interesting is the transition from S_2 to its *preserve* descendent, which results in the removal of b_1 from the winner list to be replaced by bidder b_3. Bidder b_1 also leaves the auction since he/she is not willing to pay more than 100$ for the good. The auction halts when all bidders in a given state are also in the winner list and therefore do not have the incentive to bid. These states are the terminating states (S_4 ,S_5 ,S_6 ,S_8 ,S_9 ,S_{10}).

It is important to observe that given the MBVs of bidders entering the auction we can infer the most beneficial strategy by forming and inspecting the state tree. In this example, raising the number of units offered repeatedly leads the process to state S_6 in which the auctioneer gains 100+100+90=300, thus outperforming all other terminating states.

In developing a decision strategy that is based on the state tree described, we face two fundamental problems. Firstly, the MBVs of bidders entering the auction are unknown. Secondly,

[2] The maximal bidding value of a bidder is the maximal bid he/she is willing to offer during the auction. This value may differ from the private value, depending on his/her strategy.

the search for the most beneficial strategy may be expensive in terms of complexity of the search problem to be solved.

To address the first problem, we assume that for each bidder b_i participating in the auction, a probability distribution function f_i of his/her maximal bidding value is given or can be learned from historical biddings. The probability distribution function f_i depicts the price bidder i is willing to pay for the good compared to its catalog price. The comparison to the catalog price is expressed in percentage points thus normalizing the data collected across different types of goods.

Using the statistical data gathered, a strategy that takes into account the bidding profile of the bidders participating in the auction can be devised. The informed decision strategy (in short, IDS) we propose is such a strategy. It is a simulation-based strategy that, given the current state of the auction, attempts to determine the auctioneer's action that would yield the best results. It does this by generating MBVs vectors of bidders participating in an auction and the current state of the auction. To find what the auctioneer's best choice for proceeding the auction is, a search problem that takes into account all possible scenarios has to be solved for each MBV vector generated. A solution should determine whether the auctioneer should increase the number of units sold by one, or preserve it unchanged. The knowledge applied to the simulation quantifies the value of each choice, thus improving the chance of making a good decision.

Given the auctioneer's reservation price l_0 and the maximal bidding value of the bidders participating l_{max}, we can establish a bound on the number of bid levels. The worst case is arrived at when only one unit is offered during the lifetime of the auction. Hence, the number of bid levels is bounded by $(l_{max} - l_0)/\Delta$. Since the branching factor of the tree is 2, the number of states in the state tree is bounded by $O(2^{(l_{\max}-l_0)/\Delta})$. Therefore, computing the complete state tree is too expensive in terms of the time it takes for the auctioneer to respond to bid offers submitted by the participating bidders. The responsiveness of the auction process will be downgraded significantly, causing bidders to leave the auction. In Section 4 we show that the complexity of the search problem can be reduced to linear time.

Provided that bidders' MBVs can be estimated and the complexity of the search problem can be reduced to linear time, the IDS may be implemented in real-world Internet auctions. We presume that an auctioneer implementing the IDS would like to control the amount of time allocated to computing the action needed to maximize his/her revenues. This will enable the auctioneer to guarantee an acceptable responsiveness level for new bids received.

The algorithm presented below describes the implementation of the IDS within the auction execution process. The time frame allocated by the auctioneer for computing the optimal strategy is denoted by t_p, and the time in which a new bid that raises the price of the good sold is received is denoted by t_0:

1. $t_0 \leftarrow now$, $nRaise \leftarrow 0$, $nPreserve \leftarrow 0$
2. Generate an MBV vector v_{sample} based on the probability distribution functions of participating bidders.
3. Using the IDS compute the optimal action to be taken based on vector v_{sample}. If raising the number of units sold by one is the best course of action then $nRaise \leftarrow nRaise+1$, else $nPreserve \leftarrow nPreserve+1$.
4. If $now < t_0 + t_p$ go to step 2.
5. If $nRaise > nPreserve$ raise the number of units sold by one, if $nRaise < nPreserve$ preserve the number of units sold. Otherwise choose one of the operators randomly.

Detailed explanations of step 3 above are in the proceeding sections.

4. CALCULATING THE STRATEGY IN LINEAR TIME

Given a state S and the required statistical data for deriving the MBVs of the bidders currently participating in an auction, it is possible to compute the optimal set of actions the auctioneer has to perform to maximize his/her revenue. As shown above, the complexity of this analysis is bounded by $O(2^{(l_{\max}-l_0)/\Delta})$. This complexity is infeasible for real-world applications of auction sites. In this section we show that the complexity of the search problem is actually linear in the maximal number of bid levels of the auction. We do this by utilizing the knowledge we have with regards to the properties of the problem domain we address. This knowledge enables us to prune a substantial part of the states in the graph. We show that the search problem can be bounded by $(l_{max} - l_0)/\Delta$, thus proving that the analysis can be completed in a linearly bounded computation time. This result enables the implementation of the IDS in real-world Internet auctions.

The proof starts by introducing a set of invariants that capture some basic properties of the state tree. Using these invariants, we initially prove that the number of states to be analyzed can be reduced to $O(((l_{max} - l_0)/\Delta)^2)$, thus providing a polynomial time bounded analysis procedure. Based on the first proof, we later prove that the number of states that have to be analyzed is linearly bounded by $O((l_{max} - l_0)/\Delta)$.

Invariant 1. Given a state S, a descendent state will be produced if there exists a bidder $b^* \in B_S$ which is not in the current winner list, and his/her MBV satisfies $p_{b^*} \geq l_d + \Delta$. When this condition holds, state S will have 2 descendent states; otherwise it will have no descendent states. Formally: $b^* = \exists b \in B_S \mid b \notin B_{sw}, p_b \geq l_d + \Delta$

Invariant 2. Given a state S, we denote the bidders' list that would result from the auctioneer's decision to raise the number of units offered by $B_{raise(s)}$. The list $B_{raise(s)}$ consists of the bidders belonging to S's winner list and an additional bidder b^* that joins S's winner list (see Invariant 1). Bidders that do not participate in S's winner list, but their MBVs satisfy $p_b > l_d + \Delta$, are included in the descendent state bidder list although they do not participate in its winner list. Formally:

$$B_{raise(s)} = \{(b \in B_S \mid (b \in B_{sw}) \vee (p_b > l_d + \Delta) \vee (b = b^*)\}$$

Invariant 3. Given a state S, we denote the bidders' list that would result from the auctioneer's decision to preserve the number of units offered by $B_{preserve(s)}$. When traversing from S to its preserve descendent state, a bidder $b' \in B_{sw}$ will be removed from S's winner list, substituted by another bidder b^*

that satisfies $b^* \in B_S$, $b^* \notin B_{sw}$. Bidder b' will remain in the descendent bidder list only if his/her MBV satisfies $p_{b'} > l_d + \Delta$. Provided that bidder b' satisfies this condition the bidder list of the descendent state is given by $B_{preserve(s)} = B_{raise(s)}$.
Otherwise the bidder list is given by:

$$B_{preserve(s)} = \{(b \in B_S \mid (b \in B_{sw}, b \neq b') \vee (p_b > l_d + \Delta) \vee b^*\}$$

Invariant 4. When traversing from state S to state *raise*(S), no bidder is dropped from the winner list. This results from the additional unit offered by the auctioneer. Hence, $B_{sw} \subset B_{raise(s),w}$.

Figure 3 illustrates a formal description of the state graph formed as a result of computing an auction execution. Each node S_i in the graph consists of its bidder list denoted by B_i. The initial number of units offered by the auctioneer is denoted by n_0 and the reservation price set initially by the auctioneer is denoted by l_0. The auctioneer's decision to raise the number of units is reflected in the graph by traversing to the right. The descendent state created is characterized by an additional unit offered to the participating bidders and a price level that is higher by Δ. In case that the auctioneer preserves the number of units the graph branches to the left forming a state that is characterized by the same number of units offered and a price level that is higher by Δ. Note that the state tree formed is not necessarily a complete tree but is shown as such to cover cases in which a complete tree is formed.

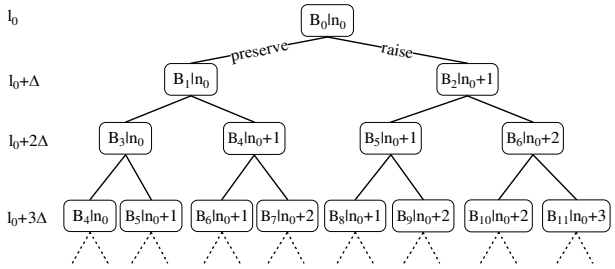

Figure 3. An auction execution state graph

For a given state S_i we define its preserve branch denoted by *preserve_branch*(S_i) as the set of states formed by iteratively traversing left starting at state S_i until we reach a terminating state. The following algorithm defines (and constructs) *preserve_branch*(S_i):

1. $S \leftarrow S_i$, *preserve_branch*(S_i) $\leftarrow S_i$
2. If deg(S) = 0 stop.
3. *preserve_branch*(S_i)$\leftarrow$*preserve_branch*(S_i)$\cup$ {*preserve*(S)}
4. $S \leftarrow$ {*preserve*(S)}
5. go to step 2

In a similar manner we define *raise_branch*(S_i). *raise_branch*(S_i) is formed by iteratively traversing right, starting at state S_i to its raise descendents. *raise_branch*(S_i) is constructed by the algorithm:

1. $S \leftarrow S_i$, *raise_branch*(S_i) $\leftarrow S_i$
2. If deg(S) = 0 stop
3. *raise_branch*(S_i)$\leftarrow$*raise_branch*(S_i)$\cup$ {*raise*(S)}
4. $S \leftarrow$ {*raise*(S)}
5. go to step 2

Following, we introduce three theorems. These show that the complexity of searching the auction's state tree can be reduced to polynomial and linear.

Theorem 1. Let T_0 be a state tree of an expanding auction whose root is S_0. Let S_{T_0} be the set of terminating states of T_0. Let $S_{T_0}^*$ be the subset of terminating states reached by traversing on *raise_branch*(S_i) for each state S_i in *preserve_branch*(S_0). We define $S_{T_0}^*$ formally as follows. Let P_{T_0} = *preserve_branch*(S_0) and $R_{T_0} = \cup$ *raise_branch*(s) $\mid s \in P_{T_0}$ then $S_{T_0}^* = \{ s \in R_{T_0} \cup P_{T_0} \mid \deg(s)=0\}$. This theorem presents two claims: (1) $S_{T_0} = S_{T_0}^*$. That is, $S_{T_0}^*$ covers all the terminating states in the state tree produced by the auction execution. (2) The number of states to be visited for computing $S_{T_0}^*$ is bounded by $O(((l_{max} - l_0)/\Delta)^2)$.

Proof (of claim 2)**.** Each traversal from state S_i to its terminating state in *raise_branch*(S_i) is bounded by $O((l_{max} - l_0)/\Delta)$ states (the depth of the tree). In the worst case the size of *preserve_branch*(S_0) is $(l_{max} - l_0)/\Delta$. It hence follows that number of states to be visited in *preserve_branch*(S_0) is bounded by $O(((l_{max} - l_0)/\Delta)^2)$ ■

From Theorem 1 it follows that one needs to search only $O(((l_{max} - l_0)/\Delta)^2)$ nodes to find the best auctioneer's action. For space reasons, the proof of Claim 1 is omitted. The definitions introduced in Theorem 1 and the approach to proving it are illustrated in Figure 4.

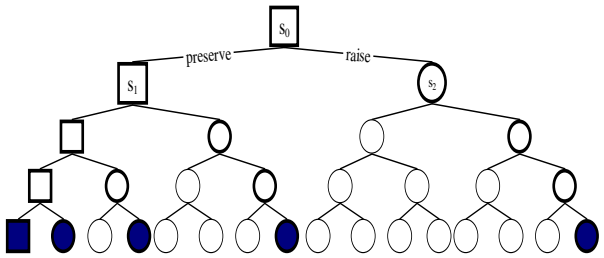

Figure 4. $S_{T_0}^*$,R_{T_0},P_{T_0} definitions: P_{T_0} states are rectangle shaped, R_{T_0} states are marked with a thick border style, $S_{T_0}^*$ are filled shapes.

Theorem 2. Let S_1, S_2 be two states such that S_2=*preserve*(S_1). Let S_{1r}, S_{2r} be the terminating states reached by traversing *raise_branch*(S_1) and *raise_branch*(S_2), respectively. Let Rev(S_{1r}) and Rev(S_{2r}) be the revenues collected by the auctioneer at states S_{1r} and S_{2r}, respectively. Given Rev(S_{1r}), Rev(S_{2r}) can be computed as following:

If $P_b \geq (depth(S_{1r})+1)\cdot\Delta + l_{s1}$ then $\text{Rev}(S_{2r}) = \text{Rev}(S_{1r}) + (depth(S_{1r}) + |B_{s_1 w}|)\cdot\Delta$. Otherwise, $\text{Rev}(S_{2r}) = \text{Rev}(S_{1r}) - (l_{s1} - \Delta\cdot(|B_{s_1 w}| - 1))$. Here, P_b denotes the MBV of the bidder b that leaves S_1 winner list when traversing from S_1 to S_2; l_{s1} denotes the price level of state S_1 and $depth(S_{1r})$ denotes the number of states produced while traversing from S_1 to S_{1r}. Figure 5 illustrates the states produced in case that $P_b < (depth(S_{1r})+1)\cdot\Delta + l_{s1}$. Figure 6 illustrates the state produced in case that $P_b \geq (depth(S_{1r})+1)\cdot\Delta + l_{s1}$.

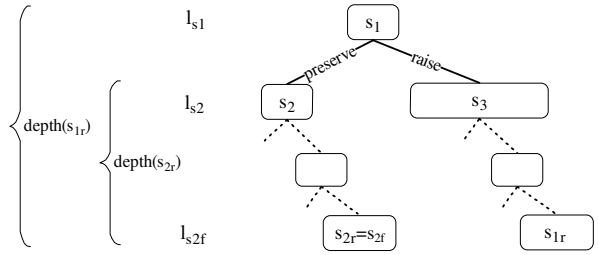

Figure 5. The auctioneer's revenue in case that $P_b < (depth(S_{1r})+1)\cdot\Delta+l_{s1}$

This theorem presents three claims. Claim (1) states that, in the case of $P_b < (depth(S_{1r})+1)\cdot\Delta+l_{s1}$, when traversing from S_1 to S_2 the auctioneer loses the revenue received from bidder b's participation in the winner list at state S_1. Therefore the auctioneer's revenue at state S_{2r} is smaller by P_b than its potential revenue at state S_{1r}.

Claim (2) states that, in the case of $P_b \geq (depth(S_{1r})+1)\cdot\Delta+l_{s1}$, bidder b submits an additional bid at state S_{2f} and thus increases the potential revenue at state S_{2r} by $(depth(S_{1r})+1)\cdot\Delta$ compared to the revenue obtained at state S_{1r}.

Claim (3) states that the number of states produced while traversing from S_2 to S_{2r} equals $depth(S_{1r})$ in case $P_b \geq (depth(S_{1r})+1)\cdot\Delta+l_{s1}$ or equals $depth(S_{1r})$-1 otherwise.

Proof: Traversing $raise\_branch(S_1)$ to a terminating state we discover $depth(S_{1r})$ new states. These states were produced as a result of $depth(S_{1r})$ bids received by the auctioneer. The same bids are received by the auctioneer while traversing from S_1 to S_2 and then along $raise\_branch(S_1)$. Observing state S_2 and $raise(S_1)$ it is evident that $B_{s2} \cup \{b\} = B_{raise(s1)}$ since while traversing from S_1 to S_2 bidder b, which leaves the winner list, might leave the bidder list as well. Assuming that $B_{s2} = B_{raise(s1)}$ we can conclude that since these states share the same price level l_{s2}, all $depth(S_{1r})$ bids received by the auctioneer while traversing $raise\_branch(S_1)$ will produce new states while traversing from S_1 to S_2 and then along $raise\_branch(S_2)$. Moreover, knowing that none of these bids belong to bidder b, which participates in S_1 winner list and therefore does not have the incentive to send bids to the auctioneer, we conclude that even if $B_{s2} = B_{raise(s1)} \setminus b$, all $depth(S_{1r})$ bids will produce new states while traversing from S_1 to S_2 and then along $raise\_branch(S_2)$ until we reach state S_{2f}. Observing states S_{1r}, S_{2f} shown Figures 5 and 6 we conclude that they both share the same price level since they are both at a distance of $depth(S_{1r})$ from S_1, and that $B_{s_{2f}w} \cup \{b\} = B_{s_{1r}w}$, since b has left the winner list while traversing from S_1 to S_2, and all bids that were accepted by the auctioneer while traversing from S_1 to S_{1r} were also accepted while traversing from S_1 to S_{2f}. It is important to observe that in case that $b \chi B_{s_{2f}w}$, b is the only bidder in state S_{2f} that is willing to raise the price level. Otherwise, there exists another bidder b' that is willing to do so; that is, $P_{b'} \geq l_{s2f} + \Delta$, and therefore the same bidder b' should participate in S_{1r} leading us to the conclusion that S_{1r} is not a terminating state.

In order for bidder b to participate in S_{2f}, the condition $P_b \geq depth(S_{1r})\cdot\Delta+l_{s1}$ must hold true. Further, bidder b will be willing to raise the price level if $P_b \geq (depth(S_{1r})+1)\cdot\Delta+l_{s1}$; this results in a new state in which all bidders participate in the winner list, and therefore it is a terminating state. That is, we reached S_{2r} (see Figure 6). The revenue obtained in this case equals $Rev(S_{1r})+(depth(S_{1r})+|B_{s_jw}|)\cdot\Delta$, since bidder b pays $l_{s1}+(depth(S_{1r})+1)\cdot\Delta$ instead of $l_{s1}-\Delta\cdot(|B_{s_jw}|-1)$ in state S_{1r}. The number of states produced while traversing from S_2 to S_{2r} consists of $depth(S_{1r})$-1 states produced while traversing from S_2 to S_{2f} and an additional state produced in this case, therefore $depth(S_{1r}) = depth(S_{2r})$.

If the condition above does not hold, bidder b will not participate in S_{2f} while other bidders participate in the winner list. Therefore, we reached the terminating state S_{2r}. Since bidder b does not participate in the winner list the auctioneer's revenue decreases by $l_{s1}-\Delta\cdot(|B_{s_jw}|-1)$ compared to S_{1r} revenue. The number of states produced while traversing from S_2 to S_{2r} consists of $depth(S_{1r})$-1 states produced while traversing from S_2 to S_{2f}, therefore $depth(S_{1r})$-1= $depth(S_{2r})$ ■

For space limitations, the proof of the theorem is presented only in part. Theorem 2 provides a better understanding of the auction execution process. Based on this understanding, we can refine, and precisely define, step 3 of the algorithm presented in Section 3. That step computes the optimal action to be taken based on the current state of the auction denoted by S_1 and the MBVs of the participating bidders given by vector v_{sample}.

Theorem 3. The number of states to be visited for computing *IDS* is bounded by $O((l_{max} - l_0)/\Delta)$. The proof is expressed by the algorithm presented below. ■

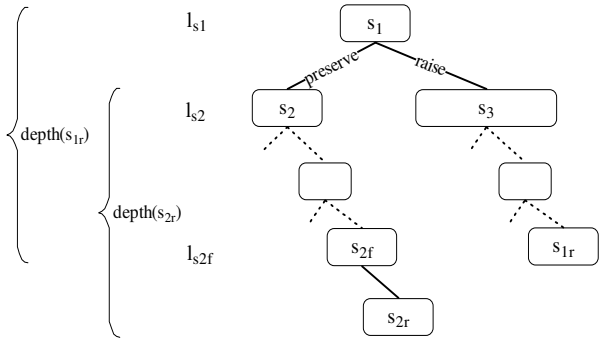

Figure 6. The auctioneer's revenues in case that $P_b \geq (depth(S_{1r})+1)\cdot\Delta+l_{s1}$

Figure 7 illustrates the details of step 3 of the algorithm. Starting from the current state of the auction, denoted by S_1, compute $depth(S_{1r})$ and $rev(S_{1r})$. This is done by computing each state produced along S_1 raise branch until S_{1r} is reached. Then, compute $depth(y_r)$ and $rev(y_r)$, where y_r is the terminating state reached by traversing from S_1 to its preserve descendent and then traversing along its descendent raise branch. The computation of $depth(y_r)$ and $rev(y_r)$ is immediate (as shown in Theorem 2). In case that the revenue expected by reaching y_r is higher then the one expected by reaching x_r, traversing to $y=preserve\_desc(x)$[3] is preferable. That is, it is better to preserve the number of units offered. Otherwise, unless y is a terminating state, it is necessary to check whether y can lead to a better revenue than $rev(x_r)$ could. This means

[3] $preserve(x)$ appears as $preserve\_desc(x)$ in Figure 7.

that it is necessary to compute the optimal strategy as if y is the current state (x←y). Since we already know the value of $depth(y_r)$ and $rev(y_r)$, there is no need to perform the first step of the algorithm, which is time-consuming. The number of states computed along the execution of the algorithm is composed of $(l_{max}\text{-}l_0)/\Delta$ states computed at the initial phase of the algorithm and $(l_{max}\text{-}\ l_0)/\Delta$ states computed until reaching a terminating state. Summing up the number of states we compute during the algorithm we find out that this number is linear bounded by $O((l_{max}\text{-}l_0)/\Delta)$. This result proves Theorem 3.

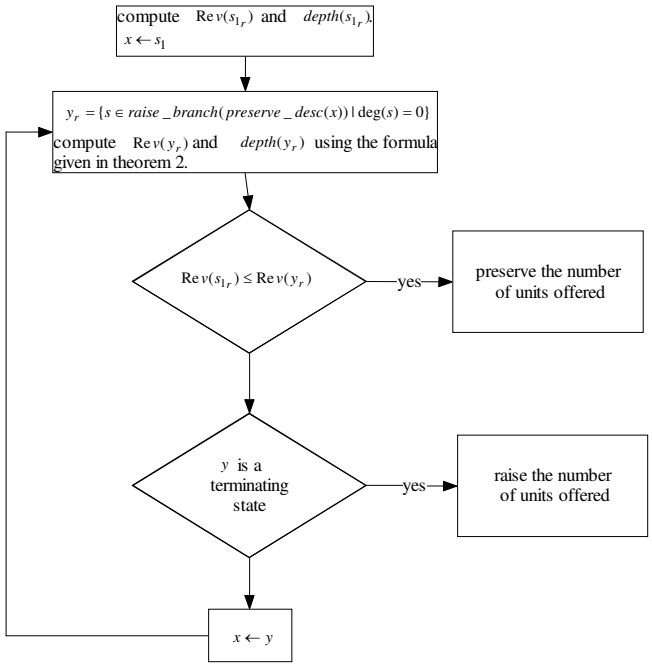

Figure 7. Illustration of step 3 of the informed decision strategy algorithm.

5. EXPERIMENTAL EVALUATION

The theoretical model presented above was tested experimentally to assess its added value compared to other techniques for running auction sites in the context of conducting expanding auctions.

Our simulation captured the dynamics of the expanding auction mechanism discussed above. Two strategies have been tested with such auctions:

- The informed decision strategy we propose.
- A post optimal decision strategy – this strategy is equivalent to the IDS except that here instead of sampling a MBV vector based on statistical knowledge gathered, the strategy considers the real MBV generated for each bidder participating in the auction. This strategy is superior compared to the IDS and serves as a measure for evaluating the quality of the solution offered by the IDS.

Both strategies have been tested in two types of environments: a homogenous environment in which bidders participating are sharing the same probability distribution function, and; heterogeneous environment in which the probability distribution function of each bidder is distinct.

For each setting, the parameters of the experiment were set to allow producing statistically significant results. For example, for an experiment in which the bidders' MBV distribution has a low variance to expectation ratio, 1000 trials were sufficient to arrive at statistical significance. Testing the same feature in the case of a high variance vs. expectation ratio required 4000 trials to produce stable results.

We have conducted a series of experiments in which all bidders originated from a homogenous distribution function; the variance/expectation ratio of the distribution function was set to 0.25. The number of bidders participating in the auction was set to 100. The results show that the IDS gains 70-80 percent of the post-optimal strategy in terms of revenue. Increasing the variance/expectation ratio shows degradation in the results compared to the post-optimal strategy. This is expected as the uncertainty of the sample MBV vectors produced increases.

The experiments with homogeneous distribution functions served as a reference. We have also performed experiments where we mixed homogenous and heterogeneous bidders. The results obtained when conducting experiments in mixed environments were highly dependent on the variance/expectation ratio, the portion of bidder types participating in the auction and the bidder selection distribution function. Interestingly, for experiments where the mutual variance/expectation ratio was set to 0.25, the portion of bidder types was 50% of each, and the bidder selection distribution function was uniform, the results can be computed from results of other experiments. In particular, one can average the results of similar experiments performed on fully homogenous and fully heterogeneous bidder populations.

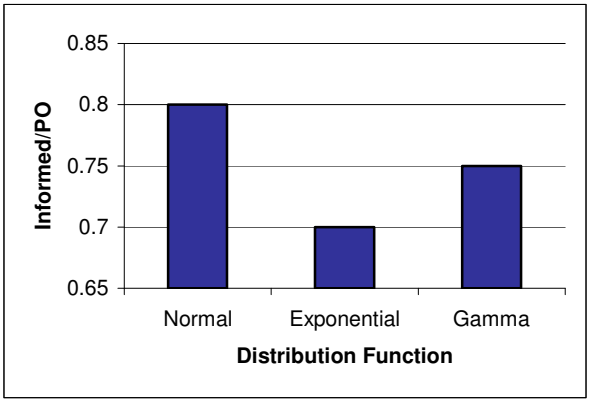

Figure 8. Informed Decision Strategy vs. Post-optimal strategy (variance/expectation ratio=0.25).

In a set of experiments, using settings as stated above, we have performed experiments in which normally distributed bidders, exponentially distributed bidders and Gamma distributed bidders participate in the same auction. The expected revenue arrived at was 0.7-0.8 of the post-optimal results (cf. Figure 8).

Note that we did not perform experiments that compare our strategy to the naive step strategy currently used in web implementations of the expanding auction. Such experiments could have further exemplified the advantage of our strategy. However, the reason for not performing such experiments is that, as we have shown by example, the step function can lead to results far from optimal. In contrast, because our strategy selects the best possible action given the knowledge available, it would always outperform the step strategy.

6. CONCLUSION

The expanding auction mechanism discussed in this paper is different from other mechanisms, such as the ascending clock mechanism or the GVA mechanism, in the sense that it does not require that the auctioneer set the number of units he/she is willing sell before the auction starts. This property makes the expanding multi-unit auction mechanism suitable for B2C commodities sales, where the auctioneer might prefer flexibility in the number of units offered to the participants.

The study performed here introduces a practical solution to the management of expanding multi-unit auctions. The informed decision strategy proposed was proven, theoretically and empirically, to address computation and time constraints that must be met by real life auctions. It was shown that the optimal strategy for searching the problem space—seemingly exponentially bounded—can be solved in linear time. The naïve step function strategy used in B2C expanding auction sites provides a sub-optimal mechanism to establish the price levels in which the auctioneer should raise the number of units offered. The revenues obtained by our new strategy outperform this naïve strategy.

Empirical results have shown that under diverse probability distribution functions the informed decision strategy we introduced produces significant gains. The auctioneer's expected revenues constitute 70%-80% of the post-optimal revenues. This is an excellent result given the probabilistic nature of the information used by our strategy. Future research needs to examine the effect of rational bidder strategies on our result. Regardless, IDS is very useful by itself, as bidders in contemporary dynamic sales sites hardly implement rational bidding.

ABSTRACT

This paper presents a method for discovering and detecting shill bids in combinatorial auctions. The Vickrey-Clarke-Groves Mechanism is one of the most important combinatorial auctions because it can satisfy the strategy-proof property, individual rationality, and Pareto efficiency, that is, it is the only mechanism that simultaneously satisfies these properties. As Yokoo et al. pointed out, false-name bids and shill bids pose an emerging problem for auctions, since on the Internet it is easy to establish different e-mail addresses and accounts for auction sites. Yokoo et al. proved that VCG cannot satisfy the false-name-proof property, and they also proved that no auction protocol can satisfy all three of the above properties and the false-name proof property simultaneously. Their approach concentrates on designing a new mechanism that has desirable properties, but this is quite complicated. As a new approach against shill-bids, in this paper, we design a mechanism that utilizes VCG and an algorithm for finding potential shill bids. Our mechanism is quite simple compared with Yokoo's approaches [11][12][13]. Our mechanism can judge whether there might be a shill bid from the results of the VCG procedure. We prove a theorem stating that shill bidders cannot increase their utilities unless all shill bidders win in the auction. Based on this theorem, our proposed mechanism compares the agents' utilities in a conventional auction with those in an auction where a shill bidder does not join in the auction. When these agents' utilities are different between the above cases, such agents might be shill bidders. Then, our mechanism allocates items to the shill bidders as a group from the set of items obtained through successful bids by the agent in the conventional auction. This process prevents shill bidders from increasing unfair profits. Furthermore, even though shill bidders participate in the auction, the seller's profit does not decrease using our proposed method. Thus, our mechanism detects shill bids when it only detects the possibility of shill bids. Our proposed method has the following three key advantages. First, we propose a method to detect shill bidders by comparison between bidders utilities. Our method is superior than existing complex mechanisms in the point of view of generalization and wide-use, because our auction mechanism employs only VCG. Second, even though there are shill bidders in an auction, incentive compatibility property is preserved using our mechanism. Finally, the schemer, in our mechanism, does never have incentive to make shill bidders. The schemer's utility does not increase in our mechanism even though a schemer make shill bidders. Namely, not to make shill bidders is dominant strategy for the schemer.

1. INTRODUCTION

This paper presents a method for detecting shill bids and for the allocation of items in combinatorial auctions. Auction theory has received much attention from computer scientists and economic scientists in recent years [7]. One reason for this interest is the fact that Internet auctions such as Yahoo Auction and eBay have developed very quickly and widely. Also, auctions in B2B trades are increasing rapidly. Moreover, there is growing interest in using auction mechanisms to solve distributed resource allocation problems in the field of AI and multi-agent systems. Combinatorial auctions have been studied very widely as one of most important auction formats. In a combinatorial auction, bidders can make bids on multiple bundles of different items[9].

The Vickrey-Clarke-Groves (VCG) Mechanism is one of the combinatorial auction mechanisms that are strategy-proof, i.e., the dominant strategy is for bidders to declare their true evaluation value for a good, and its allocation is Pareto efficient. Many scientists in the field of auction

theory have focused on VCG because of its strategy-proof property. The details of VCG are described in Section 2.

As Yokoo et al. pointed out, false-name bids and shill bids are an emerging problem for auctions, since on the Internet it is easy to establish different e-mail addresses and accounts for auction sites [13]. Bidders who make false-name bids and shill bids can benefit if the auction is not robust against false-name bids. A method to prevent false-name bids and shill bids is a major issue that auction theorists need to resolve.

Yokoo et al. proved that VCG cannot satisfy the false-name-proof property [13]. Moreover, they proved that there is no auction protocol that can satisfy all of the three major properties, i.e., false-name-proof property, Pareto efficiency, and strategy-proof property. They have developed several other complicated auction protocols that can satisfy at least the false-name-proof property. Their approach is to find alternative auction protocols and mechanisms. However, satisfying the false-name proof property prevents them from developing Pareto efficient and strategy-proof protocols.

On the contrary, in this paper we propose a new approach to detecting shill bidders as well as an allocation method in combinatorial auctions. Even though there exist shill bidders, our method can employ the VCG mechanism without using complicated mechanisms such as the protocol proposed by Yokoo et al. Our mechanism can determine whether there might be a shill bid from the results of the procedure of a VCG mechanism.

The mechanism proposed in this paper consists mainly of the following two steps. First, our mechanism judges the possibility of shill bidders based on the result of an auction. Auctions where some bidders bid their valuations as zero are attempted, and other bidders' utilities are calculated in this situation. The utility of each bidder is compared between a conventional VCG and the altered outcome. When there are bidders whose utilities change with the situation, our mechanism judges that such bidders might be shill bidders. Then, items are allocated to successful bidders. However, in this step, the following method of allocation is used, the items are allocated to bidders who are not shill bidders. On the other hand, some items are allocated as a set to a group of shill bidders and bidders who might be shill bidders, for a merged valuation function. This prevents shill bidders from making unfair profits and decreasing total revenue for sellers. Namely, in our approach, we build a mechanism to find shill bids in order to avoid them in VCG. This differs from the approach of Yokoo et al., which builds mechanisms to avoid shill bids. In Yokoo's approach, they have been trying to design a different mechanism that can satisfy desired properties (e.g. false-name proofness). However, the resulting mechanisms have been complicated due to the difficulty of this approach. On the other hand, our mechanism detects shill bidders and regards them as a single bidder. In our mechanism, VCG is employed without any complicated modifications. This gives our mechanism more generic usefulness since VCG is a well known protocol compared with Yokoo's proposed protocols.

A shill bid is defined as two or more bids created by a single person, who can unfairly gain a benefit from creating such bids. The straightforward way to find shill bids is to find a bidder whose utility becomes negative when his/her bids and those of another bidder are merged. The merging method is described in Section 3. However, this straightforward method requires an exponential amount of computing power, since we need to check all possible combinations of bidders. Thus, we use a theorem involving the characteristics of shill bids and propose a new method for detecting shill bidders. The theorem shows that a group of shill bidders cannot increase their utilities when a shill bidder cannot be a successful bidder. Using this method, the computational costs are reduced dramatically compared with the merge investment method. Comparing bidders utilities between the normal VCG and the above method, the group of shill bidders is detected. Our mechanism allows a set of items to be allocated to a shill bidders group for merged investments. In addition to detecting shill bidders, the VCG's properties are preserved. Further, a seller's revenue never decreases, even though shill bidders bid in the auction.

Our proposed method has the following properties and advantages. First, we propose a method to detect shill bidders by comparison between bidders utilities. Our method is superior than existing complex mechanisms in the point of view of generalization and wide-use, because our auction mechanism employs only VCG. Second, even though there are shill bidders in an auction, incentive compatibility property is preserved using our mechanism but efficiency is not preserved in some cases. Finally, the schemer, in our mechanism, does never have incentive to make shill bidders. The schemer's utility does not increase in our mechanism even though a schemer make shill bidders. Namely, not to make shill bidders is dominant strategy for the schemer.

The rest of this paper consists of the following six parts. In Section 2, we give preliminaries, explaining several terms and concepts of auctions. In Section 3, we explain shill bids and show the characteristics of shill bidding in VCG. In Section 4, the method of detecting shill bidders and allocating items used in this paper is introduced. In Section 5, discussions are presented to show the properties of our mechanism. Finally, we give our concluding remarks.

2. PRELIMINARIES

2.1 Model

Here, we describe the model and definitions needed for the present work. The auction participants of trading consist of a seller and bidders. The seller prepares multiple items for sale, and bidders place bids for bundles they want to purchase.

- In an auction, we define that a set of bidders/agents is $N = \{1, 2, \ldots, i, \ldots, n\}$ and a set of items is $A = \{a_1, a_2, \ldots, a_k, \ldots, a_m\}$.
- $v_i^{a_k}$ is bidder i's value, at which the ith bidder bids for the kth item ($1 \leq i \leq n$, $1 \leq k \leq m$).
- $v_i(B_i^{a_k,a_l})$ is bidder i's value, at which the ith bidder bids for the bundle including the kth and lth items ($1 \leq i \leq n$, $1 \leq k, l \leq m$). This notation is used when a bidder evaluates more than two items.
- $p_i^{a_k}$ is the payment when agent i can purchase an item a_k. When bidder i purchases the set of bundles of items, the payment is shown as $p_i(B_i^{a_k,a_l})$.
- G_i is the bundle of items allocated to agent i.

- The set of choices is $G = \{(G_1, \ldots, G_n) : G_i \cap G_j = \emptyset, G_i \subseteq G\}$.

ASSUMPTION 1 (QUASI-LINEAR UTILITY). *Agent i's utility u_i is defined as the difference between the value v_i of the allocated good and the monetary transfer p_i for the allocated good. $u_i = v_i - p_i$. Such a utility is called a quasi-linear utility.*

ASSUMPTION 2 (PRIVATE VALUE). *In this paper, we employ the assumption that the characteristics of items are private value for all bidders. Each agent's type is independent of the types of the other bidders.*

ASSUMPTION 3 (SINGLE-MINDED VALUATION). *We assume single-minded valuation, that is, bidders never bid as substitute values for each item.*

Namely, in this paper, when the number of items in a bundle increases, the total value for the bundle decreases. This means that free disposal is assumed.

Each bidder i has preferences for the subset $G_i \subseteq G$ of goods. Formally, each bidder has type θ_i, that is, in a type's set Θ. Based on the type, we show that the bidder's utility is $v_i(G_i, \theta_i) - p_i^{G_i}$ when the bidder purchases item G_i for $p_i^{G_i}$. Note that $(v_i(G_i, \theta_i))$ is bidder i's value for bundle $G_i \subseteq G$.

2.2 VCG: Vickrey-Clarke-Groves Mechanism

The Vickrey-Clarke-Groves mechanism [2][4][10] has some key properties, that is, it's strategy-proof and Pareto efficient if there exists no false-name bid. We say an auction protocol is Pareto efficient when the sum of all participants' utilities (including that of the auctioneer), i.e., the social surplus, is maximized. If the number of goods is one, in a Pareto efficient allocation, the good is awarded to the bidder having the highest evaluation value corresponding the quality of the good.

In the VCG, first each agent tells his/her value $v_i(G_i, \theta_i)$ to the seller. We omit the "type" notation and simply write $v_i(G_i, \theta_i) = v_i(G_i)$. The efficient allocation is calculated as an allocation to maximize the total value:

$$G^* = arg \max_{G=(G_1,\ldots,G_n)} \sum_{i \in N} v_i(G_i).$$

The auctioneer informs the payment amount to the bidders. Agent i's payment p_i is defined as follows.

$$p_i = \sum_{i \neq j} v_j(G^*_{\sim i}) - \sum_{i \neq j} v_j(G^*).$$

Here, $G^*_{\sim i}$ is the allocation that maximizes the sum of all agents' values other than that of agent i. This is the allocation in which the total value is maximum when all agents, other than agent i, bid their values:

$$G^*_{\sim i} = \arg \max_{G \setminus G_i} \sum_{N-i} v_j(G_j).$$

3. SHILL BIDS

3.1 Weakness against shill bids

In auction research, some papers have reported the influence of false name bids in combinatorial auctions, such as VCG [13]. These are called "shill bids." Here, we show an example of shill bids.

Assume there are two bidders and two items. Each agent bids for a bundle, that is, $\{a_1, a_2, (a_1, a_2)\}$.

Agent 1's value $v_1(B_1^{a_1,a_2}) : \{\$6, \$6, \$12\}$
Agent 2's value $v_2(B_2^{a_1,a_2}) : \{\$0, \$0, \$8\}$

In this case, both items are allocated to agent 1 for 8 dollars. Agent 1's utility is calculated as $12 - 8 = 4$.

If agent 1 creates a false agent 3, his/her utility increases.

Agent 1's value $v_1(B_1^{a_1,a_2}) : \{\$6, \$0, \$6\}$
Agent 2's value $v_2(B_2^{a_1,a_2}) : \{\$0, \$0, \$8\}$
Agent 3's value $v_3(B_3^{a_1,a_2}) : \{\$0, \$6, \$6\}$

Agent 1 can purchase item a_1 and agent 3 can buy item a_2. Each agent's payment amount is $8 - 6 = 2$, and each agent's utility is calculated as $6 - 2 = 4$. Namely, agent 1's utility is 8 dollars (because agent 3 is the same as agent 1).

Yokoo et al. examined the effect of false-name bids on combinatorial auction protocols [13]. False-name bids are bids submitted by a single bidder using multiple identifiers such as multiple e-mail addresses. They showed a formal model of combinatorial auction protocols in which false-name bids are possible. The obtained results can be summarized as follows: (1) the Vickrey-Clarke-Groves (VCG) mechanism, which is strategy-proof and Pareto efficient when there exists no false-name bid, is not false-name proof; (2) there exists no false-name-proof combinatorial auction protocol that satisfies Pareto efficiency; (3) one sufficient condition where the VCG mechanism is false-name-proof is identified, i.e., the concavity of a surplus function over bidders.

3.2 Schemer's utility

In this paper, a "schemer" is an auction participant who contrives shill-bids and creates "shill bidders". When shill bidders are not successful bidders, the schemer's utility never increases. Namely, the schemer cannot increase his/her utility by using a "decoy" bidder. The schemer's utility does not increase unless all shill bidders and the schemer become successful bidders. The following theorem shows the characteristics of shill-bids.

THEOREM 1 (SHILL-BIDDERS MUST BE WINNERS). *An agent who creates shill bidders cannot increase his/her utility unless a shill bidder wins.*

[Proof] We prove that bidder agent i's utility u_i does not increase when the agent's shill bidder does not win in an auction. When bidder i does not create any shill bidders, bidder i's payment p_i can be illustrated as $p_i = \sum_{i \neq j} v_j(G^*_{\sim i}) - \sum_{i \neq j} v_j(G^*)$. When the bidder agent creates shill bidders, bidder i's payment p'_i is $p'_i = \sum_{i \neq j} v_j(G'^*_{\sim i}) - \sum_{i \neq j} v_j(G'^*)$.

Here, we show $p'_i \geq p_i$, assuming that bidder i's shill bidders do not win in the auction. Also, the set of allocations in the auction does not change. Namely, $G' = G \not\ni s$ holds. The difference between p'_i and p_i is shown as follows. $p'_i - p_i = \sum_{i \neq j} v_j(G'_{\sim i}) - \sum_{i \neq j} v_j(G') - (\sum_{i \neq j} v_j(G_{\sim i}) - \sum_{i \neq j} v_j(G)) = \sum_{i \neq j} v_j(G'_{\sim i}) - \sum_{i \neq j} v_j(G_{\sim i})$.

The objective function of the winner determination problem solved over a strictly larger set of bids (that is, one with additional shill bids) cannot decrease. By adding bids the winner determination value never goes down. Thus, shill bidders' utilities do not increase when the shill bidder does not win.

□

3.3 Characteristics of shill bids

Shill bids are characterized by the fact that a successful shill bidder's payment amount is decided based on the other shill bidders and the schemer. Namely, the schemers get unfair profits from the shill bidders' bids because the shill bidders' valuations are used in calculating the schemer's payment amount.

Here, we give the following two lemmas characterized by shill bidding.

LEMMA 1 (SHILL BIDDER'S UTILITY). *A shill bidder's utility cannot be independent of the values bid by other shill bidders.*

[Proof] Essentially, the lemma can be proven based on the definition of payment in the VCG mechanism. We give an example of this situation. Using the example of the section 2, we consider the situation where bidder 3's valuation changes. The shill bidders group includes bidders 1 and 3. Each bidder bids his/her value as follows.

$v_1(B_1^{a_1,a_2}) : \{\$6, \$0, \$6\}$
$v_2(B_2^{a_1,a_2}) : \{\$0, \$0, \$8\}$
$v_3(B_3^{a_1,a_2}) : \{\$0, \$4, \$4\}$

Bidder 1's payment amount can be calculated as $8 - 4 = 4$ for item 1 and bidder 3's payment amount is $8 - 6 = 2$ for item 3. Thus, the schemer's (bidder 1's) utility can be computed as \$6. In section 2, the schemer's utility is \$8. On the other hand, in this situation, the schemer's utility has a different value. Namely, when shill bidders' valuations for items change, the bidders' payoff in the same shill-bid group changes. A shill bidder's payment is not independent of the other shill bidders' or the schemer's value. □

LEMMA 2 (SHILL BIDDER'S PAYMENT). *Each shill bidder's payment amount is calculated based on the valuations of the other shill bidders in the shill-bid group.*

[Proof] This lemma can be proven easily based on the definition of VCG. In VCG, a successful bidder's payment is shown as $p_i = \sum_{i \neq j} v_j(G^*_{\sim i}) - \sum_{i \neq j} v_j(G^*)$. The $\sum_{i \neq j} v_j(G^*_{\sim i})$ in the right side of the equation means the sum of the winners' total valuations except for bidder i's valuation. This first member of the equation includes all other shill bidders' values. This means that each shill bidder's payment amount is calculated based on the other shill bidders' valuations in the same shill-bid group, as described above. Thus, a shill bid can be characterized by its payment amount being interdependent with other shill bidders' valuations. □

In VCG, bidder i's payment amount is based on the bidders' values in the bidder set $N \setminus i$ in equation as shown in section 2.2. On the another hand, bidder i's valuation is used in calculating the other shill bidders' payment amounts. Let us consider the situation where a schemer does not create shill bidders. In this situation, the schemer's payment increases compared with the situation where there are shill bidders, since there is no shill bidder who can influence to the schemer's payment. Intuitively, we can detect shill bidders by merging investments among winners. We can determine the possibility of shill bidders by comparing the utilities between a calculation using an individual agent's value and one using the merged values. Figure 1 shows a conception of the merged value method. Winners' utilities under normal VCG are reduced than the utilities under the merged investment. Thus, the merged investment method is one of appropriate methods for detecting shill bidders.

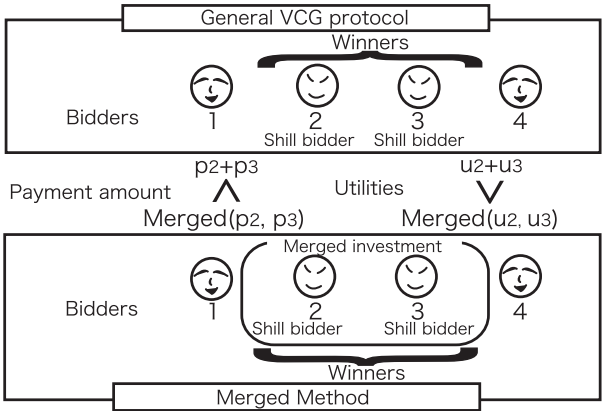

Figure 1: Merged Investment

4. DETECTING SHILL BIDDERS AND ALLOCATING ITEMS

4.1 Merged investment

Shill bidders are detected based on a comparison between bidders' utilities. Concretely, first, each bidder's value is merged with other bidders' values. An auction is conducted under the condition of merged investment. The merged bidder's utility is computed in this situation and compared with the sum of each bidder's utility in general VCG. If the bidder's utility is reduced in the merged case, such a bidder may be guilty of shill bidding. Thus, we construct an artificial situation where a shill bidder cannot influence the other shill bidders through collusion, and then we can detect the shill bidders in VCG. The next section describes our method of detecting shill bidders in detail.

A feature of shill bids is that the scheming agent can increase his/her utility when he/she bids the values divided into multiple bids. We show a straightforward method to determine the possibility of shill bidding by using the winners' values in a combinatorial auction. Shill bidders are created by separating the bids of an original agent. Namely, the original agent can increase utility by dividing his/her bidding actions. When the original bidder and his/her shill bidders are winners of an auction, we can determine how much the agent increases the utility by comparing the utilities of divided bidding with those of merged investment bidding. Intuitively, we apply a winner-based algorithm, which is based on a comparison of utilities between bidding in real auctions and bidding based on our method. Below, we describe our proposed algorithm in detail.

Input: Bids on bundles from each participant.
Output: True if there is a potential shill bid.
False if there is no potential shill bid.

Function Detect a Shill bid
begin
Determine winners and calculate
payments based on VCG.
Create a power set S for a set of participants.
for each $s \in S$
Merge participants' values in s

by merge function $f(s)$.
Determining winners and calculating payments
based on merged values by VCG.
$u_{f(s)}$:= the utility of s after merging.
u_{sum_s} := sum of the utilities in s before merging.
if $u_{f(s)} < u_{sum_s}$
return True
else
return False
end.

In the above method, the number of merged investments is calculated as $2^n - n - 1$ when the number of winner is n, namely the computational cost is $O(2^n)$. Therefore, a huge computational cost is required to judge whether there are shill bidders in the auction. Consequently, we propose a new method for detecting shill bidders. Based on [Theorem 1], a schemer's utility decreases if a shill bidder does not win in the auction, since the shill-bid scheme fails. Assume that there are shill bidders i and j. Bidder i's utility decreases if bidder j does not join the auction because shill bidder j's valuation is used in calculating i's payment. Using this method, the number of computations is just $n - 1$ if all bidders win in the auction.

4.2 Method of detecting shill bidders

Based on [Theorem 1], shill bidders cannot increase their utilities unless their confederates win the auction. Then, how can we detect shill bidders by using this feature? We tentatively try each auction where winners are excluded, one by one. Figure 2 shows a conception of our new proposed method. If there are shill bidders, such bidders' utilities are reduced by the above procedure through comparison between a normal auction and the trial auctions. Thus, shill bidders are detected by comparing the differences in their utilities.

Here, we give an outline of our proposed mechanism. First, an allocation is calculated and successful bidders' utilities are computed in VCG. Second, bidders' utilities are calculated after attempting auctions in which each winner is excluded one by one. Third, each bidder's utility is compared between the first step and the second step. The bidders whose utilities change are classified into a shill-bidder group. Then, the auction is retried among innocent bidders and the shill-bidder group. The bundle is allocated as a set to the shill-bidder group. The reason why we allocate items as a set in this method is that a shill-bidder group sometimes includes false-shill bidders. False-shill bidders, who bid unexpectedly in the manner of shill bidding, are innocent. In this paper, we focus on preventing shill bidding and fraud. We permit the mechanism to allocate items to the shill-bidder group to cope with shill bidding, but we never employ the traditional auction method in which items are allocated to each bidder. Thus, our mechanism cannot only detect shill bidders but also preserve the advantages of VCG.

Here, we concretely explain the procedure of our mechanism.

[**Algorithm**] (**Step 1**) Assume that n bidders join the auction and that the winners are determined based on VCG. Items are allocated to the successful bidders in a combination such that the total of all bidders' valuations is maximum. $G^* = arg\max_{G=(G_1,\ldots,G_n)} \sum_{i \in N} v_i(G_i)$. The successful bidder i's payment amount p_i is calculated based on

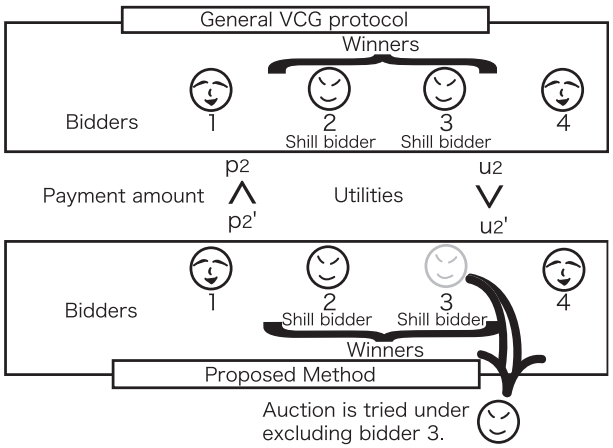

Figure 2: Proposed Method

the following equation. $p_i = \sum_{i \neq j} v_j(G^*_{\sim i}) - \sum_{i \neq j} v_j(G^*)$. $G^*_{\sim i}$ is the combination where all bidders' valuations are maximized except for bidder i's valuation. This allocation is defined as follows. $G^*_{\sim i} = \arg\max_{G \setminus G_i} \sum_{N-i} v_j(G_j)$.

(**Step 2**) Winners' utilities are calculated. We simply define that a set of successful bidders is shown as $W = \{1, 2, \ldots, \iota, \ldots, \theta\}$. Bidder ι's surplus is u_ι.

(**Step 3**) An auction in which a bidder θ does not participate is tried. In this auction, the allocation is described as $G^*_{\sim\theta} = arg\max_{G=(G_1,\ldots,G_n)} \sum_{N-\theta} v_i(G_i)$. The set of winners is $W = \{1, 2, \ldots, \iota, \ldots, \theta - 1\}$. In this allocation, each bidder's utility is compared with his/her utility at the allocation in (**Step 1**).

(**Step 4**) The difference in the winners utilities, $u_\iota - u_\iota^{\sim\theta}$, is calculated. $u_\iota^{\sim\theta}$ is winner ι's utility in an auction that bidder θ does not join. A set of winners $\{w_{\sim\iota}\} \in W$ is detected under $u_\iota - u_\iota^{\sim\theta} > 0$.

(**Step 5**) In (**Step 4**), a winners group $(\{w_{\sim\iota} \setminus \theta\} \in W) = (\{w_{\sim\theta} \setminus \iota\} \in W)$, whose utilities are reduced, is established. Items are allocated to the winners except for bidders in the above winners group (shill bidders), that is, $W \setminus w$.

(**Step 6**) Winners w's values are merged. The payment amount is calculated in the merged investment. For this payment, items are allocated as a set to the shill bidders.

4.3 Example

In this section, an example of our proposed mechanism is shown in the case where five bidders participate in an auction for two items. In this situation, assume that there are a schemer and a shill bidder created by the schemer. Bidders bid their valuations for each item and bundle as follows.

$v_1(B_1^{a_1,a_2})$: {\$8, \$7, \$15}
$v_2(B_2^{a_1,a_2})$: {\$7, \$8, \$15}
$v_3(B_3^{a_1,a_2})$: {\$12, \$0, \$12}
$v_4(B_4^{a_1,a_2})$: {\$0, \$12, \$12}
$v_5(B_5^{a_1,a_2})$: {\$0, \$0, \$20}

In this round, the successful bidders are 3 and 4. Each bidder's payment amount is 8. Namely, u_3 and u_4 are both 4 dollars.

Here, an auction where bidder 3 does not participate is tried based on our proposed mechanism to detect shill bidders. In this case, the winners are bidder 5 or bidders 1 and

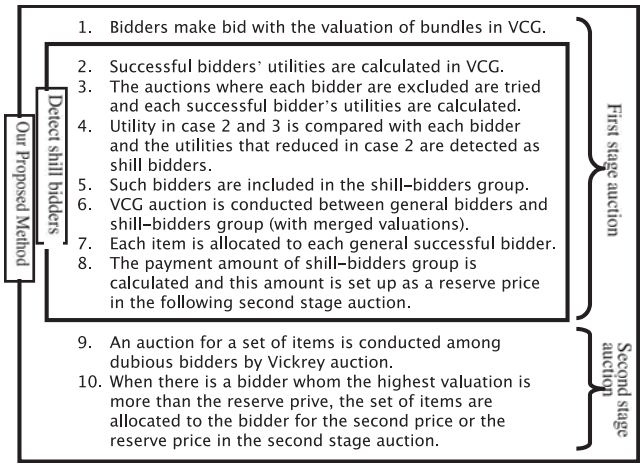

Figure 3: Proposed mechanism

4. Bidder 4's payment amount is 12 dollars. u_4 is 0. Bidder 4's utility is reduced compared with the normal auction.

Similarly, there is the same result when bidder 4 is excluded from a set of bidders. In this case, the winners are bidder 5 or bidders 2 and 3. Bidder 3's payment amount is 12 dollars. u_3 is 0. Bidder 3's utility is reduced compared with the normal auction. Bidders 3's and 4's utilities decrease after the integration of valuations.

In an allocation, bidders 3's and 4's valuations are merged by a certain merge function F. For example, we assume that $v_{f(i,i+1,\ldots,j)}$ is the following maximum function among agents' values for each item. Merged value $v_{f(i,i+1,\ldots,j)}$ is shown as $(\max_{i,i+1,\ldots,j}\{v_i^{a_1}\}, \max_{i,i+1,\ldots,j}\{v_i^{a_2}\},\ldots,$ $\max_{i,i+1,\ldots,j}\{v_i(B_i^{a_1,\ldots,a_m}\})$ for agent i's value $(v_i^{a_1}, v_i^{a_2},\ldots,$ $v_i(B_i^{a_1,\ldots,a_m}))$ in the maximum selection method. In this example, the merged valuation $v_{F(3,4)}$ for bidders 3 and 4 is $\{12, 12, 24\}$. Using this merged valuation, the auction is retried. The integrated bidders group's payment amount $p_{F(3,4)}$ is calculated as $20-0=20$. Both items are allocated to the merged bidders for \$20 as a set.

4.4 Robust auction mechanism against shill bidders

Figure 3 shows an outline of our proposed mechanism. The mechanism is distinguished between two stages. In the first stage, VCG auction is conducted. and shill bidders are detected as shown in the above subsections. Items are allocated to general bidders who are no possibility of shill bidder. After that, the ramained set of items are allocated to shill-bidders group. Here, reserve price is calculated as a result of first stage auction. In the second stage, each dubious bidder as a shill agent bids to a set of items like a Vickrey auction. A bidder who bids the highest valuation makes a successful bid when the valuation is more than the reserve price.

In our mechanism, there are two situation concerned with efficiency. When the set of items is allocated successfully to the bidder for the bidder's reserve value or less, the allocation is Pareto efficient. On the other hand, the false-name proof and strategy-proof property is preserved based on this method.

Here, we give the concrete allocation method. The method employs like the single item auction that is, each bidder bids only one bid value to the set of items. The set of items is allocated based on the second highest value. Thus, the method is essentially same as the Vickrey auction.

We assume that there are bidders $w = \{i'_1, \ldots, i'_\iota, \ldots, i'_n\}$ in shill bidders group. Bidders' valuations are shown as $\{v_{i'_1}, \ldots, v_{i'_\iota}, \ldots, v_{i'_n}\}$. Bidders' payments included in the shill bidders group is shown as $\{p_{i'_1}, \ldots, p_{i'_\iota}, \ldots, p_{i'_n}\}$. Bidders' utilities is shown as $\{u_{i'_1}, \ldots, u_{i'_\iota}, \ldots, u_{i'_n}\}$. We decide a reserve price based on the price (such as the end of subsection 4.3) allocated to the shill bidders group at the first stage. The set of items is shown as $A' \subset A$.

[Algorithm] (**Step 1**) Bidders who are included in the shill bidders group bid their valuations $v_{i'_\iota}$ for the set of items A'.

(**Step 2**) We assume simply higher order of bidders valuations is shown as $\{v_{i'_1} > v_{i'_2} > \ldots > v_{i'_\iota} > \ldots > v_{i'_n}\}$. If the bidder's valuation $v_{i'_2}$ is not more than the reserve price, items are not allocated to the winner. Otherwise, (**Step 3**) is employed.

(**Step 3**) If the bidder's valuation $v_{i'_2}$ is more than the reserve price, the winner of this auction is decided based on the second highest price which is bid by a bidder in the shill bidders group. Namely, bidder i'_1's payment amount $p_{i'_1}$ is $v_{i'_2}$.

5. DISCUSSION

5.1 Properties of protocol

Here, we give a discussion on the properties and validity of our mechanism. Our mechanism preserves the desirable advantages of VCG, that is, Pareto efficiency, individual rationality, and incentive compatibility. First, Pareto efficiency is proven self-evidently because items are allocated in a combination where participants' total utilities are maximum in VCG. The individual rationality property can be shown simply by the definition of VCG. Here, we give the following theorem to prove the incentive compatibility property of our mechanism.

THEOREM 2 (STRATEGY-PROOF PROPERTY). *Incentive compatibility is preserved in our mechanism.*

[Proof] In literature [13], Yokoo et al. proposed a flamework for mechanism design called PORF protocol, that is, designed mechanism is satisfied incentive compatibility property. Mechanisms based on PORF's characteristics are incentive compatible mechanism and strategy-proof mechanism. Our proposed mechanism has the PORF's feacture as shown in the following explanations.

First, we give some definitions for explanations. Bidder i is a ith bidder who participates in an auction. Shill bidders (including innocent bidders in the shill bidders group) are shown as i'. Shill bidders group is shown as w, that is, i' is included in w. In our proposed method, all bidders' payments and shill bidders' payments included in shill bidders group are not depend on their own bid valuations. Thus, our mechanism is satisfied the strategy-proof property.

Second, the bidders i's payment amount is calculated based on VCG. On another hand, the payment amount for shill bidder i' is decided based on the reserve price $r(= p_w)$ in the second stage. The reservation value r is independent with the valuations included in the sholl bidders group.

Finally, an allocation feasibility for bidder i is reserved due to same as VCG. On the other hand, the allocation for shill bidder i' is reserved because items are allocated to a bidder who is in the shill bidders group.

As shown the above issues, our proposed mechanism is satisfied the PORF flamework. Even though a bidder's valuation who is not in the shill bidders gruop can give effects to shill bidders group's payment amount, the payment amount is not reduced by the valuation. □

In our proposed method, a schemer can not increase their utilities if he/she makes shill bidders compared with the situation where the schemer does not make shill bidders. This situation is same as normal VCG auction because shill bidders' values are merged. Considering situations in the real auctions, to make shill bidders puts some costs for the schemer. Thus, if the schemer does not make shill bidders, the schemer's strategy becomes dominant strategy.

When the set of items is allocated successfully, the allocation is efficient. On the other, if the bidder's valuation $v_{i'_2}$ is not more than the reserve price, the allocation is not efficient because items are remained unsold. The efficiency is related the number of bidders in shill-bidders group and the rate of false-shill bidders in the group. The efficiency is shown as a decreasing function with the rate of false-shill bidders in the group. Here, we give a proposition that a schemer never has an incentive to make shill bidders in our mechanism. Schemer's dominant strategy is not to make shill bidders.

ASSUMPTION 4 (STRATEGY SPACE). *We assume the following two strategies, that is, a schcemer makes shill bidders and does not make shill bidders.*

PROPOSITION 1 (DOMINANT STRATEGY). *Schemer's dominant strategy is not to make shill bidders in our mechanism.*

[Proof] After detecting shill bidders, second-price auction is conducted based on bidders' valuations and reserve price for the set of items. In this auction, if there is a winner, his/her payment amount is the reserve price r' or more than the price because the second-price should be more than the reserve price. Namely, the following holds. $p_{i'_1} = v_{i'_2} \geq r'$. The reserve price is essentially same as the payment amount in which bidders do not bid by shill bidding.

First, we consider a situation where shill bidders group is organized by only bidders made by the schemer. If the schemer does not make shill bidders, he/she can purchase items for r'. On the other hand, If the schemer make shill bidders, he/she purchase items for r' or more than the reserve value. Even though a shill bidder can make successful bid and his/her valuation is $v_{i'_1}$, his/her utility $u_{i'_1}$ is calculated as $v_{i'_1} - v_{i'_2}$. On the other hand, when the schemer does not make shill bidders, his/her utility $u_{i'_1}$ is calculated as $v_{i'_1} - r'$. Clearly, the following holds. $v_{i'_1} - v_{i'_2} < v_{i'_1} - r'$. Thus, the schemer, in this case, does never have incentive to make shill bidders.

Second, we consider a situation where shill bidders group is organized by innocent bidders (false-shill bidders) and shill bidders made by the schemer. In this situation, there are following two cases, (1) the case in which the schemer wins the second auction and (2) the case in which the schemer loses the second auction. $p_{i'_1} = v_{i'_2} \geq r'$ holds concerned with the schemer's payment amount. The schemer's utility $u_{i'_1}$ is calculated as $v_{i'_1} - v_{i'_2}$. On the other hand, when the schemer does not make shill bidders, his/her utility $u_{i'_1}$ is calculated as $v_{i'_1} - r'$. Clearly, the following holds. $v_{i'_1} - v_{i'_2} < v_{i'_1} - r'$. In the latter case, the schemer's utility is 0 because he/she can not purchase items. If the schemer does not make shill bidders, he/she can make a successful bid in the first stage auction(VCG). Clearly, the schemer's utility is $v_{i'_1} - r' (> 0)$.

Thus, the schemer, in this case, does never have incentive to make shill bidders. In any case, the schemer's utility does not increase in our mechanism. Namely, not to make shill bidders is dominant strategy for the schemer. □

5.2 Multiple schemes

Our mechanism can cope with multiple schemers in an auction. If there are multiple schemers, our mechanism detects multiple shill-bidder groups created by the schemers.

In our mechanism, some bidders may casually submit bid values that seem like unnatural shill bidders' valuations. Such bidders are included in the shill-bidder group. However, the goal of our protocol is to detect and prevent shill bidding. To solve this problem, our mechanism allocates items to a shill-bidder group as a set of items. When the shill-bidder group consists of all shill bidders, the result of the mechanism is the same as an auction in which the schemer does not commit unfair practices. Even if the shill-bidder group includes an innocent bidder, we can provide many types of methods of allocation and calculation of payment amount. In the shill-bidder group, items are allocated based on the method in which each bidder's payment does not depend on his/her valuation.

6. RELATED WORK

Milgrom analyzed the shill-biddable feature in VCG [7]. Bidders in VCG can profitably use shill bidders, intentionally increasing competition in order to generate a lower price. Thus, the Vickrey auction provides opportunities and incentives for collusion among low-value, losing bidders. This feature is a result of the monotonic increase problem. However, this work does not provide a method of detecting shill bidding in combinatorial auctions.

Yokoo et al. reported the effect of false-name bids in combinatorial auctions [13]. To solve the problem, Yokoo, Sakurai and Matsubara proposed novel auction protocols that are robust against false-name bids [11]. One such protocol is called the Leveled Division Set (LDS) protocol, which is a modification of the VCG. It utilizes the reservation prices of auctioned goods for making decisions on whether to sell goods in a bundle or separately. Furthermore, they also proposed an Iterative Reducing (IR) protocol that is robust against false-name bids in multi-unit auctions [12]. The IR protocol is easier to use than the LDS, since the combination of bundles is automatically determined in a flexible manner according to the declared values of agents. They concentrated on designing mechanisms that could perform as alternatives to VCG. Due to our fundamentally different purpose, we do not simply adopt off-the-shelf methods for mechanism design.

Ausubel and Milgrom referred and characterized shill bidding [1]. They showed a theorem in which the substitute condition is sufficient for shill bidding and loser collusion to be unprofitable. Further, if the set of bidder values is otherwise sufficient inclusive, the condition is also necessary for the theorem. However, in our proposed method, we do not

only show the features of shill bidding, but we also give a concrete mechanism for detecting shill bidding.

Some researchers [3][5][6][8][9] have proposed methods for computing and calculating the efficient solution in combinatorial auctions. These analyses contributed to the pursuit of a computational algorithm for winner determination in combinatorial auctions, but they did not deal with shill bidding and thus are fundamentally different approaches from our work. However, some of these algorithms can be incorporated in our work. Combinatorial auctions have a computationally hard problem in which the number of combinations increases when the number of participants/items increases in an auction, since agents can bid their values as a set of bundled items.

Sandholm [8] proposed a fast winner determination algorithm for combinatorial auctions. Sandholm et al. [9] also showed how different features of a combinatorial market affect the complexity of determining the winners. These works studied auctions, reverse auctions, and exchanges, with one or multiple units of each item, with and without free disposal. We theoretically analyzed the complexity of finding a feasible, approximate, or efficient solution.

Fujishima et al. proposed two algorithms to mitigate the computational complexity of combinatorial auctions [3]. Their Combinatorial Auction Structured Search (CASS) algorithm determines efficient allocations very quickly and also provides good "any-time" performance. Their second algorithm, called Virtual Simultaneous Auction (VSA), is based on a simulation technique. CASS considers fewer partial allocations than the brute force method because it structures the search space to avoid considering allocations containing conflicting bids. It also caches the results of partial searches and prunes the search tree. On the other hand, VSA generates a virtual simultaneous auction from the bids submitted in a real combinatorial auction and then carries out simulation in the virtual auction to find a good allocation of goods for the real auction. In our work, to determine efficient allocations quickly in each VCG, we employ the CASS method. However, Fujishima's paper does not focus on shill bids.

Leyton-Brown et al. proposed an algorithm for computing the optimal winning bids in a multiple-unit combinatorial auction [6]. This paper describes the general problem in which each good may have multiple units and each bid specifies an unrestricted number of units desired for each good. The paper proves the correctness of our branch-and-bound algorithm based on a dynamic programming procedure. Lehmann et al. proposed a greedy optimization method for computing solutions of combinatorial auctions [5]. However, the VCG payment scheme does not provide for a truth-revealing mechanism. Therefore, they introduced another scheme that guarantees truthfulness for a restricted class of auction participants.

7. CONCLUSIONS

This paper proposed a method for detecting shill bids in combinatorial auctions. Our mechanism can judge whether there might be a shill bid from the results of the VCG procedure. We proved a theorem stating that shill bidders cannot increase their utilities unless all shill bidders win in the auction. Based on this theorem, our proposed mechanism compares the agents' utilities in a conventional auction with those in an auction where a shill bidder does not join in the auction. This process prevents shill bidders from increasing unfair profits.

Our mechanism has the three advantages. (1) Our mechanism is more superior than existing complex mechanisms in the point of view of generalization, because our mechanism employs only VCG. (2) Even though shill bidders exist in an auction, incentive compatibility property is preserved using our mechanism. (3) The schemer does never have incentive to make shill bidders in our mechanism. Namely, not to make shill bidders is dominant strategy for the schemer.

ABSTRACT
In this paper we present the internal architecture and bidding mechanisms designed for Mertacor, a successful trading agent, which ended up first in the Classic Trading Agent Competition (TAC) of 2005. TAC provides a realistic benchmarking environment in which different trading agents compete with each other in order to best satisfy their clients' preferences and maximize their total profit. The "travel game" scenario of TAC involves three types of auctions; a) continuous one-sided that sell flight tickets, b) ascending multi-unit auctions for booking hotel rooms, and c) continuous double auctions for entertainment tickets. For each one of these types, we describe the techniques deployed by Mertacor. In flight auctions prices are updated according to a random walk process, thus the accurate prediction of the next update is not feasible. A key element of agent behavior in these auctions is its ability to accurately deduce the specific time in an auction, at which bidding will be profitable. In order to deal with the uncertainty due to price fluctuations in flight auctions and to provide our agent with an efficient decision mechanism, we have designed the *z-heuristic* framework. The goal of *z*-heuristic is to figure out when the price assumes its minimum value and recommend bidding at that moment. In the case of hotel auctions, Mertacor used fuzzy reasoning in conjunction with rule-based reasoning in order to predict the closing prices of hotel rooms, when historical data from past auctions are available. In order to bid efficiently in entertainment auctions, we have designed a bidding strategy whose goal is to preserve a pre-specified long-term profit. We finally present and discuss the results of agent benchmarking in the TAC Classic game.

1. INTRODUCTION
Autonomous agents that participate in electronic marketplaces represent a new paradigm of automated transactions, in which computer programs are faced with the challenge to effectively increase their revenue without human intervention. The successful performance of agents in trading scenarios, measured by the profit or savings they materialize, may introduces a great potential for agent-mediated e-commerce in general and electronic auctions in particular.

This paper presents Mertacor, a trading agent that ended up first in the finals of international Trading Agent Competition for 2005 (TAC-05). The latter provides a competitive environment where a number of autonomous trading agents compete to each other in order to procure travel packages on behalf of a number of customers in online simultaneous and interrelated auctions of different types. In this paper we describe Mertacor's architecture and internal structure, as well as the details of the bidding algorithms designed to deal with the different types of auctions in the context of TAC.

The TAC (http://www.sics.se/tac) provides a competitive trading environment in which, each participating agent operates with the goal of assembling travel packages on behalf of eight clients. Each package refers to a 5-day period travel and consists of a round-trip flight, a hotel reservation and tickets for three different entertainment events. The clients have separate preferences over the arrival and departure dates, the type of hotel and entertainment events they wish to visit, which are randomly assigned to each client at the beginning of the game. The objective of each agent is to maximize the total satisfaction of its clients. In the TAC simulation environment, all three kinds of commodities (flights, hotels and entertainment tickets) are sold in simultaneous online interrelated auctions of three different types, running over a game, which lasts for 9 minutes. TAC has been designed so that no optimal strategy that always wins may exist. On the contrary, the agents that participate in the competition need to deploy tradeoffs between the offered goods in order to best satisfy their clients' preferences. The TAC supported auctions are described in the following.

There is only one Airline Company that sells tickets in single seller continuous one-sided auctions, which close at the end of the game. Each auction sells tickets for a particular day and direction, whereas an unlimited number of seats are available. The first agent that submits a bid in an auction buys the auctioned ticket for its current price and the auction clears. Once a bid is submitted it cannot be withdrawn. Prices in flight auctions are updated according to a random walk process. The initial price is a uniformly distributed variable in the range [250,400]. Each price

update is then perturbed every 10 seconds by a value uniformly drawn from the following intervals:

- $[-10, x(t)]$ if $x(t) > 0$
- $[x(t), 10]$ if $x(t) < 0$
- $[-10,10]$ if $x(t) = 0$.

The bound $x(t)$ is calculated by the following equation:

$$x(t)=10+(t/9{:}00)(x\text{-}10)\,, \quad (1)$$

where x is a hidden random variable drawn uniformly on [-10, 30] and 9:00 denotes the auction duration (9 minutes).

There are two hotels in which clients can stay between the arrival and departure dates: "Tampa Towers" (TT) and "Shoreline Shanties" (SS). TT is more comfortable, clean and preferable than SS, thus it is expected to be more expensive. Hotel rooms are traded in standard ascending multi-unit 16th price English auctions, which close at randomly determined times in the last 8 minutes of the game. In each auction 16 rooms are offered for each combination of hotel and night. A hotel auction clears and matches bids only once, when it closes. On clearing, hotel rooms are allocated to the 16 highest offers with all competitors paying the price of the lowest winning bid. Price quotes are only generated once per minute, on the minute.

Entertainment tickets are traded in continuous double auctions (CDA), which are held between the participants during the game. Each agent holds a randomly chosen number of tickets from the beginning of the game and may operate as either a seller or a buyer. Trade may occur at any time during the game and participants are allowed to continuously update their prices, i.e. buyers may update their offered prices and sellers their ask prices. Entertainment ticket auctions clear continuously. On clearing, bids match immediately. A bid that does not completely match remains standing in the auction.

The score that the agent receives at the end of each game is calculated as the utility minus the expenditure costs. The utility function in its general form is:

$$Utility = 1000 - travelPenalty + hotelBonus + FunBonus,$$

Apart from tackling with the utility optimization problem, TAC participants need to also deal with many uncertainty factors introduced by the different nature of each auction types and the interrelations that hold between them. For example, the agents need to acquire flight tickets, hotel rooms and entertainment tickets so that are all consistent with the preferred arrival and departure dates on behalf of their clients. Agents should also take compound decisions, including how much and when to bid. In order for an agent to operate efficiently it has to monitor its environment and collect sufficient information about the market conditions and the behavior of its opponents.

Since the beginning of the competition in 2000, the TAC problem attracted many participants from different countries and organizations. ATTac-2000 agent [7], [8] made the first key contribution to this challenging area. The intricacies of the game were clarified and attacked in a systematic way. ATTac-2000 was the first agent who won the TAC. The notion of *marginal utility* was then recognized to play an important role in the TAC game framework. In fact it has been proven that bidding marginal values in sequential auctions with deterministic prices is an optimal strategy and a fairly satisfactory one in the TAC environment [2]..

Since the first TAC, teams concentrated their efforts mainly on developing with effective ways of price prediction. A survey of agent prediction methodologies deployed in TAC-02 may be found in [10]. Due to space limitations we only refer here to those approaches that most influenced our work. A novel price prediction method was designed for agent SouthamptonTAC [3] by the application of fuzzy techniques. Walverine [1] on the other hand provided an analytical approach relied on the principles of a competitive economy. Another approach was proposed by whitebear [9], which simply but also interestingly enough, used average prices for prediction. LearnAgents [6] introduced an alternative multiagent architecture as opposed to most competitors' single agent approaches.

Although all of the above efforts generated good results, they had not traced thoroughly the details of the flight ticket price perturbation process. Having realized that the hidden variable x is the most significant parameter in flight auctions, Mertacor's flight bidding component provides a formula that calculates the probability of the fact that x lies on a particular continuous interval. This approach is innovative in the context of TAC flight auctions.

In this paper we describe the implementation details of Mertacor and illustrate the key contributions of our work. In particular, we first present the internal architecture of our agent, in Section 2, which proved to be very stable since the beginning of the competition. An additional feature of the described architecture is that it easily allows rapid changes in agent's internal bidding mechanisms due to its high degree of modularity.

The next key contribution of this paper is the description of a novel decision framework, called *z-heuristic*, designed in order to deal with the problem of optimal bidding in flight auctions.

Section 4 describes the mechanism we have deployed in order to deal with price prediction in hotel auctions. In particular, we adopted a previously known fuzzy approach, originally developed for agent SouthamptonTAC [3], which was a competent in TAC-01 and TAC-02. Further to this approach, we have also slightly modified its functionality, by adding a new set of rules that improve the results of the fuzzy reasoning module.

Another contribution of this paper, described in Section 5, is the introduction of a new bidding strategy for continuous double auctions, which are realized in the form of entertainment auctions in the context of TAC.

Section 6 provides an outline of the benchmarking results taken from TAC-05, as well as independent experiments, while Section 7 concludes the paper and outlines future work.

2. MERTACOR ARCHITECTURE

Mertacor's architecture, which is shown in Figure 1, adopts a typical modular design that supports synchronous intercommunication. Three main units (Flight, Hotel and Entertainment Auction Unit) undertake the responsibility to concurrently handle information related to the three different types of auctions running on the TAC server. Typically, this information includes the prices of the goods that are auctioned off. This configuration adheres to the typical abstract agent architecture, where the three units play the role of Mertacor's sensor components. An additional sensor unit, which also receives game information pertaining user preferences and running auction ids is the *Game Info* component.

All input information perceived by the sensor components of Mertacor goes to the *Bidder* module, which deploys the three bidding mechanisms developed for each of the aforementioned auction types into three separate modules, one for each type of

auction. Once *Bidder* calculates the new bids it sends them back to the TAC server. Thus, *Bidder* implements the main "effector" components of Mertacor. Since there is one direct communication channel to the TAC server, which is served through a TCP connection, it is critical to allow all three parts of Bidder to synchronously send information to the TAC server. For this reason, the three components of *Bidder* are implemented as threads. For instance, the *Hotel Bidder* component instantiates a thread process that places bids in hotel auctions every minute. *Bidder* also provides central control services that are activated when special conditions of emergency arise (e.g. a bid is rejected by the server).

Mertacor relies on the execution of a Linear Programming (LP) model. This is implemented as a separate module used not only to provide the optimal goods allocation but also the marginal value of the traded goods and the shadow prices of the model's constraints [5]. In what follows we provide thorough descriptions of the internal bidding mechanisms of Mertacor with respect to the three separate modules.

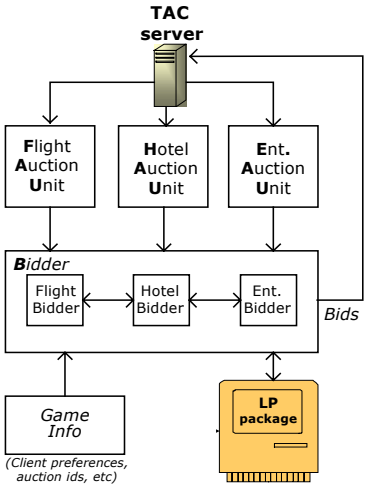

Figure 1. Overview of Mertacor's architecture

3. BIDDING IN FLIGHT AUCTIONS

According to TAC flight auction rules, price perturbations at time t are related to the value of the random variable $x(t)$, which is given by Equation (1). The ranges, from which perturbations are drawn, are determined by the sign of the bound $x(t)$. The main objective of our analysis is to figure out the time at which $x(t)$ changes sign. This time guarantees a profitable buying. This holds because $x(t)$ is a linear function depending on time and on the hidden variable x. Excluding extreme cases, this means that $x(t)$ either decreases or increases, according to x. Moreover, prices are updated either from D_1 =[-10, $x(t)$] or D_2=[$x(t)$, 10]. Since prices are initially updated from D_1, if $x(t)$ increases in a timely fashion, it is easy to show that prices will most likely increase. On the other hand, if $x(t)$ decreases, it is likely for it to change sign. In this case, the interval D_1 decreases, thus prices decrease accordingly. When $x(t)$ changes sign, prices are updated from D_2. Since $x(t)$ changes linearly, at this point it is negative and close to zero. Hence, prices will start rising again. Thus, bidding at this point will potentially result in a profitable transaction.

The goal of the decision framework we describe in the remaining Section, is to make an estimation about the real value of the x parameter and therefore about the change of the variable $x(t)$. For this purpose, we exploit the price updates that are revealed to agents every 10 seconds. These updates provide us with *low bounds,* i.e. with real numbers denoted as B_i that satisfy the inequality $x \geq B_i$.

Knowing the point where $x(t)$ changes sign is very useful. By clustering these bounds into a vector and calculating the probability of appearance of this specific vector we can construct an interval where the hidden parameter lies, with any pre-specified probability

3.1 The *z-heuristic* Decision Framework

In this section we present the z-heuristic, a framework used for estimating the time at which the prices of flight tickets reach their minimum value. For simplicity we introduce the y variable as follows:

$$y = x - 10 ,$$

where x is the hidden variable appeared in Equation (1). Since x is a random variable uniformly drawn on [-10, 30], it is clear that y is also a random variable uniformly distributed in [-20, 20] Each flight auction lasts for 9 minutes and posts a price update every 10 seconds. Therefore, the total number of price updates during a flight auction is $N=54$. Thus, Equation (1) can be rewritten as:

$$x_i = 10 + i \cdot \frac{y}{N}, i \in [1, N] \quad (2)$$

Firstly we will define the point at which $x(t)$ changes sign, as a *corner*. For this purpose we introduce the following definitions.

Definition 1. Consider two updates i_1 and i_2. We define that update i_1 is *earlier* than i_2 (or equivalently, i_2 is *later* than i_1), iff: $i_1 < i_2$.

Definition 2. We define as *corner* i_c of a flight auction the latest update for which we know that price perturbations are drawn from [-10, x_i].

Definition 3. We define as *low bound* B the maximum real number for which we know that $y \geq B$.

Our goal is to calculate the corner. Lemma 1 provides a way to find a candidate low bound that may lead to a corner.

LEMMA 1. *If δp_i is the price variation at the ith update for which is $i \leq i_c$, $B_i=(\delta p_i-10)\cdot\frac{N}{i}$* it holds that

$$y \geq B_i \quad (3)$$

Due to space limitations we skip the proofs of this and the following Lemmas. If $B_i > B$ then we have found a new low bound of the flight auction. This also gives us useful information about the corner of the flight auction, according to the following Lemma.

LEMMA 2. *If a flight auction has low bound B, then the corner i_c is given by* $i_c=\left\lfloor 10\frac{N}{|B|} \right\rfloor$, if $B \leq -10$, or $i_c=N$, otherwise.

It is important to clarify the distinction between the corner that is derived from auction data and the *real corner* of the flight auction, i.e. the update at which the bound x_i really changes sign. Our goal is to calculate the real corner. Since this variable changes linearly, the values of perturbations are drawn from [x_i, 10], after x_i changes from zero to a negative value. In this case,

prices will obviously rise because x_i is much less than 10. Thus, the price changes are positive and generally high. This explains why there is a steeply decreasing stage for flight auctions whose y parameter is below –10. After that stage an increasing one follows. The prices are reduced until the real corner of the flight auction is "crossed" and then they increase. Therefore, it is a good strategy to buy just when an update is estimated to be close to the real corner.

It is likely that the corner calculated by Lemma 2 is different than the real one. For example, let us consider a flight auction that has a real corner i_{rc} = 36. Setting $x_{i_{rc}}=0$ in (2), we get y=-15. In order for a new low bound to occur, price changes should be noticeably big, according to inequality (3). If this is not the case, the only information we are able to know about y is that $y \geq -20$. Therefore, B = -20 and the flight auction's corner is 27, according to Lemma 2. Buying at the 27th update implies that we will miss 9 updates at which price is very likely to decrease. This is of course undesirable. Thus, instead of buying at the auction corner, we define a new buying criterion based on the following Lemma:

LEMMA 3. *If* $B_i=(\delta p_i-10)\cdot\frac{N}{i}$, *B is auction's low bound and* i_c *is the flight auction corner, the following statements cannot be true at the same time:*

- $B_i < B$
- $i > i_c$
- *the real corner has been crossed*

for the ith *price update.*

Therefore, if a flight auction has bound B, corner i_c and for the ith update the following two statements are true:

- $i > i_c$
- $B_i \geq B$,

our agent assumes that the real corner has been crossed, and decides to buy the tickets needed.

Normally, in a flight auction many successively increasing bounds B_i may come up at the ith update. We define as *evidence couples* any couple of the form (B_i,i), and use them to estimate the value of variable y. By recording all evidence couples found during an auction we can provide the following definition.

Definition 4. *Bound evidence* (*BE*) is a vector of the form $BE=\left[(b_1,k_1)\ \ (b_2,k_2)\ \ \cdots\ \ (b_n,k_n)\ \ T\right]$, where $b_i=\frac{B_i}{20}$ and $i \in 1,2,\ldots n$.

Let us also define variable $s = y / 20$. The variable T is an integer equal to the last update of the flight auction.

It is very useful to calculate the probability $p(BE|s)$ of the fact that a specific bound evidence occurs in an auction, when the value of the variable s is known. This is provided by the following Lemma.

LEMMA 4. *If s=y/20, the probability of occurrence of the evidence couples* (b_1, k_1) *and* (b_2, k_2) *with* $b_2 > b_1$ *and* $k_2 > k_1$ *is*

$$\Upsilon(k1,\ k2,\ b1,\ s) = \left\{\prod_{i=k_1+1}^{k_2-1}\frac{(N+i\cdot b1)}{(N+i\cdot s)}\right\}\cdot\frac{k_2\cdot(s-b_1)}{(N+k_2\cdot s)} \qquad (4)$$

By generalizing Lemma 4, the probability $p(BE|s)$ can be calculated, using (4), by the following equation:

$$p(BE \mid s) = \prod_{i=1}^{n-1}\Upsilon(k_i,k_{i+1},b_{i-1},s)\cdot\prod_{j=kn+1}^{T}\frac{(N+j\cdot b_n)}{(N+j\cdot s)} \qquad (5)$$

Equation (5) describes $p(BE|s)$ as a function $g(BE, s)$ of the hidden variable s.

Since $y \in [-20,20]$, it is $s \in [-1,1]$. From probability $p(BE \mid s)$, we can calculate p(s| BE) which will give us an estimation of s and thus y. Using Bayesian probabilities we can write

$$p(s \mid BE) = \frac{p(BE|s)\cdot p(s)}{p(BE)} \qquad (6)$$

Setting s = s_1 and s_2 successively in Equation (6) we create two new equations from which we derive that $p(s_1|\ BE)p(BE|\ s_2) = p(s_2|\ BE)p(BE|\ s_1)$, or:

$$p(s_1|BE)g(BE,s_2)=p(s_2|BE)g(BE,s_1) \qquad (7)$$

Now let us consider a continuous subset $S_1 \subseteq [-1,\ 1]$. Keeping s_2 fixed and having $s_1 \in S_1$ by integrating equation (7) we have:

$$p(s\in S_1|BE)g(BE,s_2)=p(s_2|BE)\int_{S_1}g(BE,s) \qquad (8)$$

Assume that $S_2 = [b_n, 1]$. Since B_n is actually the low bound of the flight auction and b_n is the normalized low bound, it is:

$$p(s \in S_2 \mid BE) = 1 \qquad (9)$$

From Equations (8) and (9) for $s_2 \in S_2$ we have:

$$p(s\in S_1|BE)=\frac{\int_{S_1}g(BE,s)}{\int_{S_2}g(BE,s)}$$

If we consider $S_1 = [b_n, z]$ we can gradually increment z so that $p(s \in S_1 \mid BE)$ becomes equal to a fixed predefined value p. We chose this value to be 0.8. With this algorithm we can find a range $[b_n, z]$ in which the parameter s lies, with probability 0.8. This value of the z is called *z-point***.** The reason for applying such a methodology was motivated by an experimental analysis whose results are graphically described in Figure 2.

In Figure 2 we can see the relationship between the bound of the y parameter found until the 20th update for 50,000 auctions and the real value of y. Obviously, real y values tend to gather around and below the line $y=B$. This is the reason we use the range $[b_n, z]$ in our z-heuristic framework**.**

Having constructed a range in which we assume with sufficient evidence that the hidden parameter s lies, we can make an estimation of its real value. In order to accomplish this, we defined the *sign evidence (SE) vector* as a vector of the signs of all auction price updates. Following a procedure similar to the one used for the calculation of probabilities of occurrence of the *BE* vector we can calculate $p(SE)$ and $p(SE|s)$.

The estimation of s is enabled through the following equation**:**

$$\hat{s}=\frac{1}{z-b_n}\cdot\int_{S_1}s\cdot\frac{p(SE|s)}{p(SE)}ds \qquad (10)$$

Thus, the estimation of y is simply derived by the equation:

$$\hat{y}=20\cdot\hat{s} \qquad (11)$$

Equations (10) and (11) provide an approximation of y that can be used in conjunction with statistical methods, in order to enable an estimation of the price change from the arbitrary update i_a to the

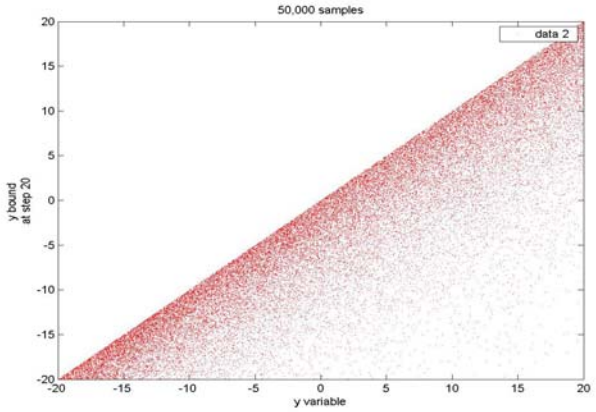

Figure 2. Low bounds found until the 20th update for 50,000 games. Samples are gathered around line $y=B$ which provides a good estimation of the real y value.

later update i_b, where $i_b < i_a$. By considering the mean value in the range [-10, x_i], we receive:

$$\widehat{\Delta p}(i_a, i_b) = \hat{y} \cdot \frac{(i_a+i_b)\cdot(i_b-i_a+1)}{4\cdot N}$$

Finally, we determine which values of the above estimations play a significant role in the bidding process. For this reason, we define the following decision criteria, considering a flight auction with current price *CP*, initial price *IP*, current update *i* and low bound *B*:

1. Is $T>52$?
2. Is $CP<160$\$?
3. Is *Corner* crossed?
4. Is $\hat{y}>4$ AND $B>-3$ AND $CP>IP$?
5. Is $B>7$?

3.2 Flight Auctions Analysis

Each of the previously defined criteria is potentially met according to the current status of the auction parameters. A *decision variable*, which is an integer $d = 0,\ldots,5$ represents one of the previously defined decision criteria. A positive value of d triggers the bidding mechanism, 0 means that no criterion is satisfied. For example, if $d = 5$, criterion 5 is met, hence prices will most probably skyrocket. By using these criteria, our agent may opt to postpone a bid submission or fragment the total quantity for which it intends to bid.

The results of auction analysis are reported in Table 1. This table shows the evolution of a real flight auction during the first 9 updates.

The flight auction starts off with an initial value of \$327. At update no.3 an increment of \$9 gives a new low bound $B = -18$ and the corner becomes 30. At the 5th update a price increment by 10 gives a new bound $B = 0$ and now the corner becomes 54, which implies that until the end of the auction, price fluctuations will be drawn on $[-10,x_i]$. Since bound is zero, it will be $y \geq 0$ and y is estimated to the value 8.99. At this time criterion 3 is fulfilled, therefore the decision variable changes to value 3. This indicates that current time is a good time to buy the auctioned ticket. The final price was ended up to \$388, thus the recommended decision on bidding results to a \$35 profit for our agent.

Table 1. Flight Auctions Analysis table (9 updates)

i	i_c	Initial price	Current price	Last bound	Z-point	Decision	Y est.	Buying Price
1	27	327	327	-20.0	11.88	0	-4	327
2	27	327	332	-20.0	11.60	0	-4.28	332
3	30	327	341	-18.0	15.49	0	-0.73	341
4	30	327	343	-18.0	15.29	0	-0.49	343
5	54	327	353	0.0	17.34	4	8.99	353
6	54	327	352	0.0	17.34	4	8.86	352
7	54	327	345	0.0	17.19	4	8.63	345
8	54	327	350	0.0	17.19	4	8.78	350
9	54	327	361	6.0	18.25	4	12.29	361

4. HOTEL BIDDING STRATEGY

At the beginning of the game, there is little or no information about hotel prices. For this reason we use the following procedure in order to calculate the initial bids to submit. Denoting (*arrival day*, *departure day*) a user preference over the arrival and departure dates, there are 10 possible such travel preferences: (1,2), (1,3), (1,4), (1,5), (2,3), (2, 4), (2, 5), (3, 4), (3, 5) and (4, 5). Four out of ten preferences include an in-flight at day 1, three at day 2, two at day 3 and one at day 4. Thus, we can define a parameter that indicates how likely for an in-flight day is to occur among client preferences. Let us call this parameter *statistical importance factor* of in-flights for the day *i*:

$$s_{in,i}=0.5-0.1i, i\in[1,4]\ ,$$

Similarly, the statistical importance factor of out-flights for the day *j* is:

$$s_{out,i} = 0.1j - 0.1,\ j \in [2,5]$$

Our goal is to estimate hotel closing prices. For this purpose, we use the only information, which is available in the beginning of each game, i.e. the initial flight prices. Our methodology uses these prices to estimate the average hotel room demand, which indicates how far from the statistical balance the game will evolve. The probability that a client will be staying for *i* days is equal to: $p(i) = 0.5 - 0.1 \cdot i$. Thus, the *mean trip duration* equals to $\sum_{i=1}^{4} p(i)\cdot i = \sum_{i=1}^{4} (0.5-0.1\cdot i)\cdot i = 2$ days and hence the average demand for hotel rooms per game is:

$$2\frac{rooms}{client} * 8\frac{clients}{agent} * 8\frac{agents}{game} = 128\frac{rooms}{game}$$

Since 16 rooms are sold in each of the 8 hotel auctions, the *hotel room supply* is equal to the average demand. It is reasonable to assume that in games with demand close to the average demand, a balanced bidding activity will be noticed. Otherwise, the game may become unstable and the hotel prices skyrocket.

Let us assume that the eight competitors need I_i in-flight tickets at day *i* and O_j out-flight tickets at day *j*. Total in-flight and out-flight demand will be $I = \sum Ii = 64$ and $O = \sum Oi = 64$, respectively, since we have 64 clients and one in-flight and out-

flight preference for each client. Let us also define the *relative* in-flight and out-flight ticket demand as $\varepsilon_i = Ii / I$ and $\mu_i = O_j / O$, respectively, with $i \in [1,4]$, $j \in [2,5]$. If the absolute hotel room demand for day i is H_i, then it is easy to prove that the following equations hold: $H_1 = I_1$, $H_2 = I_1 + I_2 - O_2$, $H_3 = -I_4 + O_4 + O_5$ and $H_4 = O_5$, or equivalently:

$$\mathbf{H}=\mathbf{R}\cdot\mathbf{F}, \tag{12}$$

where $\mathbf{H} = (H_1 \quad H_2 \quad H_3 \quad H_4)^{\mathrm{T}}$,

$$\mathbf{R} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix},$$

and $\mathbf{F} = \begin{pmatrix} I_1 & I_2 & I_3 & I_4 & O_2 & O_3 & O_4 & O_5 \end{pmatrix}^{\mathrm{T}}$. Equation (12) maps absolute flight demand to absolute hotel demand.

The estimation of the hotel demand for each day is calculated by the following equation:

$$\hat{\mathbf{H}} = \mathbf{R} \cdot \hat{\mathbf{F}}, \tag{13}$$

where:

$$\hat{\mathbf{F}} = 64 \cdot \begin{pmatrix} \hat{\varepsilon}_1 & \hat{\varepsilon}_2 & \hat{\varepsilon}_3 & \hat{\varepsilon}_4 & \hat{\mu}_2 & \hat{\mu}_3 & \hat{\mu}_4 & \hat{\mu}_5 \end{pmatrix}^{\mathrm{T}},$$

and $\hat{\varepsilon}_i$ $\hat{\mu}_j$ are the relative demand estimates for in-flight and out-flight tickets respectively. In order to calculate $\hat{\varepsilon}_i$ we use the following equations:

$$\hat{\varepsilon}_i = f_{in,i} / \sum_{k=1}^{4} f_{in,k} \text{ and } f_{in,i} = s_{in,i} \cdot (400 - IP_i) / 150,$$

where IP_i is the initial in-flight ticket prices for day i. The $\hat{\mu}_j$ coefficients are calculated in a similar manner.

After estimating hotel room demand we create initial bids by using look-up tables with historical data from previous games. These tables provide mappings between closing prices and hotel room demand estimates. As real information about market demand is being revealed in the game, our agent exploits the fuzzy reasoning method [4] developed for SouthamptonTAC [3] for price prediction. In our implementation, we used the prediction p combined with the mean value m of the closing prices denoted at the previous 14 games. We use a Linear Programming module in order to calculate the optimal allocation of the hotel rooms, when the closing price is estimated to be a linear conjunction of the previous prediction p and the mean value m. In particular, the closing price estimation, denoted I_{LP}, is calculated in a heuristic manner by the following rules:

IF $p \geq 2m$ **THEN** $I_{LP} = p$;
ELSE IF $p \leq m/2$ **OR** $p \geq (3/2)m$ **THEN** $I_{LP} = (2/3)p+(1/3)m$;
ELSE $I_{LP} = (1/2)(p+m)$;
END IF

During the last two minutes of the game, when uncertainty about the market is reduced, using the above estimation of hotel closing prices increases bidding efficiency

5. ENTERTAINMENT BIDDING STRATEGY

Entertainment auctions are continuous double sided auctions, where agents receive new price quotes every 30 seconds and bids are processed continuously. Although the entertainment auctions adhere to the continuous double auction protocol applied in the stock market, they formulate a more simplified auction environment for two reasons. First, the number of eight participants is significantly lower than the ones met in a typical stock market. Second, the agents remain adherent to their initial plans about acquiring the desired tickets. This is not always the case in a real stock market, where traders may deploy totally unpredicted bidding behaviors.

Mertacor's bidding mechanism in entertainment auctions is based on a simple and consistent algorithm that aims to achieve a long-term profit at the end of the auction.

Our selling strategy in the entertainment auctions is implemented by the procedure *MertacorSellStrategy* illustrated in Figure 3. We describe its functionality in what follows.

```
PROCEDURE MertacorSellStrategy
 1:  FOR each entertainment ticket in possession
 2:      Assign a pre-specified value to target;
 3:      mean ← getMeanValue();
 4:      M ← A*target + B*mean;
 5:      IF M ≤ (1/2)*target OR M ≥ (3/2)*target THEN
 6:        M ← relocateM();
 7:      END IF
 8:      V ← calcVal();
 9:      IF V < Vo THEN V ← Vo; END IF
10       profit ← ask– 2*V;
11       Mt ← w(t)*M;
12       Ra ← M;
13       Rb ← 3*M/2;
14       Rc ← rand(M/2, M);
15       IF profit ≥ Mt-Ra THEN sellTicket();
16       ELSE IF profit ≥ Mt-Rb THEN ask (Mt-Ra+2*V);
17       ELSE ask (Mt - Rc +2*V);
18       END IF

```

Figure 3. The selling strategy deployed by Metacor in the entertainment auctions.

The procedure iterates over all tickets that the agents possesses. The *target* variable represents the long-term average profit that the agent aims at achieving. This is set to a pre-specified value for each of the entertainment tickets. Typical values for *target* lie on [5, 12]. The variable *mean* is set equal to the current mean value of profit gained over the previously completed transactions. This is calculated by the function *getMeanValue()* in row 3. Variable M, which is given by the following equation:

$$M = A \cdot target + B \cdot mean \tag{14}$$

is used to determine the range of the profit sought. After experiments, the weights A and B were chosen to be A=0.7 and B=0.3. Thus, our agent seeks for a profit highly influenced by the value of *target*. In order to keep our agent adherent to this goal,

we impose (row 5) the variable M to only take values in the range [(1/2)·*target*, (3/2)·*target*]. For this reason, we use function *relocateM*() (row 6), which returns values in the range [min {*target*, *mean*}, max {*target*, *mean*}]. In order to calculate current ticket's valuation V, our agent calls function *calcVal()*, in row 8, which makes use of the LP model. Since we are interested in always selling higher than a determined reserve price V_o, if $V<V_o$ we set $V=V_o$ in row 9. If we denote *ask* as the ask price, then Mertacor calculates the profit it would make in a potential transaction by using the equation

$$profit = ask - 2V \quad (15)$$

This preserves our agent's goal, which is to keep $E\{profit\}=target$, where the $E\{.\}$ operator denotes the mean value. In row 11 we define a new variable $M_t = w(t)M$ that introduces a time-depended low bound for the desired profit. The $w(t)$ function is graphically represented in Figure 4. The peak that appears in the middle of the game (4.5 minutes) represents the maximum profit sought at that time. The demand for profit decreases and then remains constant at a relatively low value as the game reaches its end. Next, we define three variables, namely R_a, R_b and R_c, in rows 12, 13 and 14 respectively. Function *rand()* in row 14 returns a number uniformly distributed in the range [M/2, M]. These three variables determine, along with the variable M_t the ranges of an acceptable profit. In order to decide when to bid, our agent uses the three decision rules shown in rows 15-17. According to these rules, Mertacor sells the ticket it currently possesses if the profit to be achieved is M_t-R_a or above. This is done by function *sellTicket()*, in row 15. Otherwise, it asks for those prices that will result to a profit equal to or bigger than M_t-R_a or M_t-R_c. Our agent submits its ask price (derived from (15)) for both cases, by invoking the *ask()* function in rows 16 and 17, respectively. Since $R_c \leq R_a$ the expected profit will be at least equal to ($w(t)$-1)M**.**

From Figure 4 we can see that $w(t) \geq 1$ for most of the time. During the last 30 seconds of the game $w(t)$ is fixed to value 0.8 and the profit becomes -0.2M, which is a negative value. Thus, if M has a big value, a transaction occurred during the last 30 seconds of the game, will lead to a big loss. In addition to this, transactions close to the middle of the game are not so likely to happen, since the quantity ($w(t)$-1)M is relatively big. This will lead to a decrease of the overall average profit, and thus M as it is derived from Equation (14). On the other hand, if M is small, transactions that lead to a positive profit are more likely to happen, while negative profit transactions will result to a small loss. The

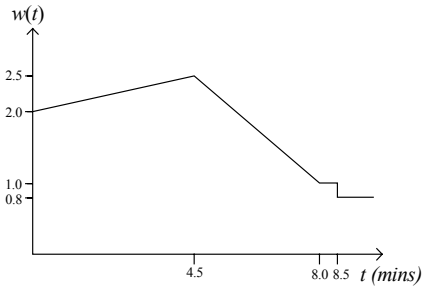

Figure 4. The *w*(*t*) function plotted over time (in minutes). It indicates a time-dependant bidding attitude

aforementioned mechanism is highly adaptive to changes in the market environment, since when a big profit is assumed the number of transactions is reduced and vice versa. The buying bidding strategy of Mertacor is completely symmetrical to the selling strategy.

6. RESULTS

In the 6th TAC, eleven agents participated from the beginning of the competitions. Among these only eight managed to end up to the finals. The agents were evaluated according to the average score they gained at each round. The score of each agent is calculated by the server when a game finishes and it is equal to the utility minus expenditure costs. For each round the average score determines the performance metric for all agents.

TAC-05 consisted of 5 rounds. In the first (qualifying) round of TAC all eleven agents participated in 600 games, running for almost two weeks in a constant 24-hour basis. Our agent ranked fourth, gaining a score of 3918.45, which was 240.33 below the top score achieved by agent whitebear05. In this round Mertacor employed a completed version of the Flight Auctions strategy, while it used a naïve bidding algorithm for hotel auctions and a greedy strategy for entertainment auctions. Next, in the seeding round 688 games were played using the same server configuration. At the beginning of this round we changed our hotel bidding mechanism to the one presented in Section 4 and preserve it until the finals. We also used for the fist time the CDA strategy described in Section 5. We set the parameter *target* in Eq. (14) to value *target* = 12, i.e. our agent was seeking for a big profit. In this round Mertacor improved its overall performance. It finished third with score 4033.32, managing to reduce its distance from the top score agent whitebear05 to 135.29. In the semi-final round ten participants were able to compete in 56 games. Mertacor improved many aspects of all bidding algorithms and mostly fixed many bugs. Thus, it retained its performance by gaining a score of 4023.88.

Eight out of the ten competitors who participated in the semi-finals were invited to the finals held on August 3rd in Edinburgh, Scotland. Table 2 shows the scores of the eight finalists. In the final round all agents played in 80 games, concurrently run in two servers (40 games in each server). Compared to the semi-final round, Mertacor improved its entertainment bidding strategy, by fine-tuning the parameter in the entertainment stategy. In particular, we lowered the value of the *target* parameter to 5. This resulted in both lower profits and losses. This intervention proved to significantly improve our agent's performance who eventually ranked first.

Apart from the overall benchmarking results provided by TAC, we have also conducted an additional analysis of the agents' performance regarding only the entertainment auctions, because fine tuning the *target* parameter in the entertainment bidding algorithm proved to be the key element that increased our agent's performance. In the context of our experiments, we measured the profits that the agents made in their transactions, in all the games of the final round. The results of this analysis are shown in Fig. 5. For each agent we measured the average profit collected in buying, selling and both types of transactions. Fig. 5 shows that the proposed algorithm is particularly efficient in buying transactions. Mertacor performed almost as well as its competitors in selling transactions. In the latter case the best performing agent

is Dolphin. Noticeably, Mertacor and whitebear05 are the only agents that managed to receive a positive profit when participating in buying transactions, with Mertacor outperforming all agents. This resulted in an overall better performance of Mertacor in the entertainment auctions.

Table 2. Score table for TAC-05 final round

Agent	Average Score	Zero Games
Mertacor	4126.49	0
Whitebear05	4105.68	0
Walverine	4058.90	2
Dolphin	4022.79	0
SICS02	3972.29	0
LearnAgents	3899.24	0
e-Agent	3451.25	0
RoxyBot	3167.64	10

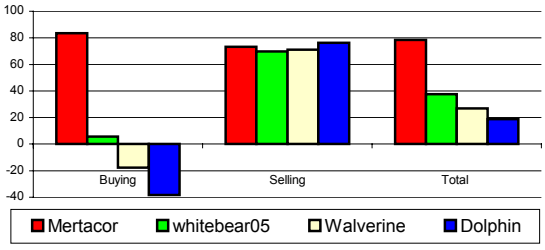

Figure 5. Average Profit collected by the four top-scoring agents in the final round when they participated in buying, selling and in both types of transactions

7. CONCLUSIONS

This paper presented the details of Mertacor, a trading agent which took part in TAC-05 competing against eleven agents in a simultaneous interrelated auctions environment. We analyzed our agent's architecture and provided the details of the internal bidding mechanisms. Specifically, we presented the bidding strategies deployed by our agent per each of the three different types of auctions involved in the TAC game. In flight auctions we tackled with the decision problem of choosing the best time to bid in the auction, i.e. the time that leads to a maximum profit. In order to calculate the time at which bidding is more profitable, we have developed a methodological framework called z-heuristic based on probabilistic reasoning. The outcome of z-heuristic is then used by our agent in conjunction with a set of simple bidding rules in order to decide when to bid. Next, we explained the price prediction method adopted for efficient bidding in the hotel auctions. This method comes from previous related work, and it was slightly enhanced in order to meet our agent's design requirements. Although we developed a new technique for price prediction in hotel auctions, we applied it on Mertacor only at the qualifying round, while we then switched to the adopted methodology, which we kept until in the finals rounds for the sake of performance stability. In order to deal with bidding in double-sided entertainment auctions we developed a strategy with the goal to achieve a long- term profit specified by a target value. This strategy proved to be robust and easily adaptable to market fluctuations, especially when Mertacor participated in buying transactions. Our agent, which exploited a combination of strategies, exhibited outperformed performance in the context of the TAC.

Future work involves further improvement of the presented techniques and continuation of our experiments.

8. ACKNOWLEDGEMENTS

We would like to thank the TAC organizing teams, University of Michigan and SICS for their technical support before and during the competition.

1. INTRODUCTION

This paper describes simulations designed to test the relative efficiency of two different sequential auction mechanisms for allocating compute resources between users in a shared data-center. For each of two possible auction types we apply a genetic algorithm to a broad class of bidding strategies to determine a near-optimal bidding strategy for a specified auction type, and use statistics of the performance of these strategies to determine the most suitable auction type for this domain.

To ground the simulations, we have based our model on the SE3D project [3], in which a select group of up-and-coming film-makers was given access to a state-of-the-art CGI rendering utility owned by HP, and were forced to acquire resources via markets. We hypothesise an extension to SE3D in which animators are given bidding agents to relieve them of the chore of bidding, and seek to understand what appropriate bidding strategies for those agents might be, and what impact market mechanism choice would have.

2. RELATED WORK

The work of Ferguson et al on distributed markets for compute resources [2] is some of the earliest. Like [1] and [4], among many others, allocation in Ferguson's system is done at the level of the individual server, in order to manage distributed resources. The benefit of this approach is that by distributing the mechanism a central point of control (and hence potential failure) is eliminated. The downside of a distributed mechanism is that allocations might be far from optimal, and might have unstable dynamics, depending on the coordination mechanisms used to migrate a job between nodes on the basis of pricing. In any case, since this paper concerns a datacenter in which all compute resources are centrally hosted, there is no benefit to using a distributed mechanism.

Bidding to acquire complex sets of resources is not a novel area of study for agents: the canonical example in this field is of course the Trading Agent Competition [7]. Optimal strategy selection is notoriously dependent on the specific configuration of goods, mechanisms, preferences and so on. Our focus however is not so much on finding good strategies as it is in comparing different mechanisms in the domain of Utility Computing.

A variety of auction mechanisms have been tried as the basis for a market-based resource allocation system. In particular the Proportional Share and Generalized Vickrey mechanisms we use here have both been used before – for example PS in [4], GV in [8]. In addition other mechanisms have been used such as an ascending N^{th} price mechanism (in [5]) similar to GV but in which the price paid is the same for all winners and equal to the highest losing bid; and a first price mechanism in [2], [6]. Almost all the work cited evaluates a particular mechanism rather than comparing alternative market mechanisms.

3. RENDER UTILITY SIMULATOR

3.1 Rendering Model

To simulate the challenges that an agent might be expected to face we have to simulate the operational details of the rendering application acting on a "realistic" payload. The basic unit of rendering is a *frame*, which is defined by its intrinsic work content, measured in server milliseconds. When a frame is assigned to a server, work begins on the frame, and proceeds either until the relevant number of milliseconds has elapsed, or until rendering on the frame is terminated. To be faithful to the SE3D environment the rendering simulator obeys the following constraints:

1. Work already done on a frame cannot be check-pointed, so that if rendering on a frame is terminated before the frame is complete, all work so far done on the frame is lost, and must be done again.

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. To copy otherwise, to republish, to post on servers or to redistribute to lists, requires prior specific permission and/or a fee.

Copyright 2006 ACM 1-59593-303-4/06/0005 ...$5.00.

2. A frame is not parallelizable at all, so that for a single frame two servers would take the same amount of time as one.

The combination of these two properties makes performance non-linear with respect to resource levels, especially if frame workloads are large compared to the timescale of the auctions. The task that each agent has to work on is a *render job*, consisting of a set of frames, and start time, end time (deadline) and total budget.

3.2 Auction Models

In SE3D, resources were sold on a rolling basis both for immediate use and in advance of later use. In these simulations we restricted attention to auctions for resources available immediately. Thus time is divided into "rounds". In each round there are three steps: first bids are gathered from each agents; then an auction is run to determine resource allocations until the next round; then work is done on each job with the resulting number of resources, according to the rendering model described above in Section 3.1.

There were two auction mechanisms tested in the SE3D project, and these were faithfully reproduced in the simulation.

3.2.1 Proportional Share Auction

In a Proportional Share (PS) auction for N servers, each agent submits a bid b^a; the number of resources allocated to each agent a is as close as possible to the share

$$N^a_{lim} = N\frac{b^a}{\sum_{a'} b^{a'}}. \quad (1)$$

Since this number is not in general an integer, we cannot in general give exactly N^a_{lim} servers (which are indivisible). Therefore the actual number N^a allocated is determined in a time-dependent way such that $|N^a - N^a_{lim}| \leq 1$ and such that if all bids remain the same for multiple successive rounds in the auction, then the average allocation $\langle N^a \rangle$ will converge[1] on N^a_{lim}. Before processing, bids are truncated to lie in $[0, B^a]$, where B^a is agent a's total remaining balance.

3.2.2 Generalized Vickrey Auction

In a Generalized Vickrey (GV) auction for N servers, each agent submits a vector of bids, $(b^a(1), b^a(2), \ldots, b^a(N))$. The number $b^a(j)$ represents the maximum amount of money that agent a would be willing to pay to secure exactly j resources. The resource allocation N^a to each agent is calculated so as to maximize the sum of maximum prices $S(N) = \sum_a b^a(N^a)$. The price paid by each agent is set to be the negative impact that the presence of that agent has on this total as calculated over the other agents: with agent a removed we calculate the allocation $N^{a'}_{-a}$ for the other agents a' that maximizes $S_{-a}(N_{-a}) = \sum_{a' \neq a} b^{a'}(N^{a'}_{-a})$. The price paid by agent a is

$$S_{-a}(N_{-a}) - (S(N) - b^a(A_a)) = \sum_{a' \neq a} b^{a'}(N^{a'}_{-a}) - b^{a'}(N^{a'}). \quad (2)$$

If there are several allocations that give rise to the same maximal total $S(N)$, we cycle between those that minimize the difference between allocations to different agents. For example, if two agents bid $(10, 20, 30)$ for a total of 3 resources, any allocation of all the resources has value 30, the two allocations that minimize the difference between agents are $(1, 2)$ and $(2, 1)$ and so we cycle between these. The period of this cycle in time steps is a parameter of the allocation mechanism[1].

In SE3D, to simplify bidding in the GV auction so that bidders were not compelled to enter a complete vector of bids for each time step, we constrained them to use bid vectors from a 3-parameter family, parameterized by the maximum number of units for which they wanted to bid (N_{max}), a total price for all units ($b_{max} = b^a(N_{max})$), and a risk factor (r) in $[-1, 1]$ which determines the rate of decrease of marginal demand $b^a(n) - b^a(n-1)$.

[1]In practice, extra resources cycled around once every three time steps, to avoid too much "thrashing"

4. BIDDING STRATEGIES

4.1 Strategy Space

In its most general form, an agent's bid depends on the current state of its job, the list of past bids it has made and resulting allocations and prices, and any accumulated history of previous runs. In cases of interesting scale the space of strategies is therefore far too large to enumerate.

We chose to restrict the space of bidding strategies by making the fraction of remaining budget bid, dependent only on current time step t and time to deadline d, with rational polynomial dependency. In the PS markets for example, each bidding strategy was defined by six constants $c_1, \ldots, c_6$, via the function

$$b^a/B^a = (c^a_1/d + c^a_2 + c^a_3.d + c^a_4.d^2) \times (1 + c^a_5.t + c^a_6.t^2), \quad (3)$$

where B^a is agent a's remaining funds at the time of bidding.

Likewise in GV markets each of the three strategic parameters, total bid b_{max}, maximum number of units N_{max}, and risk factor r, were represented in this way, leading to an 18-dimensional bidding strategy space.

4.2 Strategy Optimization

It is clear that even within the restricted families described above we have no hope of finding any equilibria analytically. When confronted with this situation, different researchers have taken different approaches. We chose to apply a genetic algorithm to the sets of parameter values in order to evolve appropriate strategies.

To do this, a population of strategies was instantiated to multiple copies of the default strategy ($b/B = 1/d$ for PS markets, $b_{max}/B = 1/d$, $r = 1$, $N_{max} = N$ for GV). In each generation each individual was placed into a run of the simulation with randomly selected opponents drawn from the population; each agent was given a randomly generated job to perform, and the simulation run to determine the performance of the agents – and hence the strategies. After a number of such runs for each individual, the averaged performance data were used as a measure of the fitness of each individual. To generate the next generation, genomes were selected with preferential weighting given to high-fitness individuals, and a new set of parameters generated from the two parents by crossover. Mutation was applied to each parameter, and the resulting parameter-set inserted into the new population. Elitism was used, so that the best individual in a given generation was always transferred to the next generation.

5. RESULTS

The standard simulation environment consisted of 6 agents competing for 15 resources with job start time $\sim U[0, 10]$; time from start to deadline $\sim U[20, 40]$; number of frames $\sim U[10, 20]$; and budget per frame $\sim N(0.8, 0.2)$. Agent performance was measured by the number of frames completed by the job's deadline.

These parameters were chosen to give maximal performance difference between the mechanisms. When the system is under very little contention all agents get all their jobs done all the time; when the system is under very heavy contention, agents fail so often that their performance is not much affected by mechanism choice either. In between the mechanism makes a difference, and this was the parameter zone from which the experimental conditions were selected.

A benchmark resource allocation mechanism is "fair share" (FS) in which each active agent is simply given an equal share of the resources.

With the setup above, using FS, the mean number of frames incomplete at the end of a simulation run was 4.12 with a standard deviation of 5.54 – a significant number given that the total number of frames per job was in the range 10 – 20.

5.1 Performance data

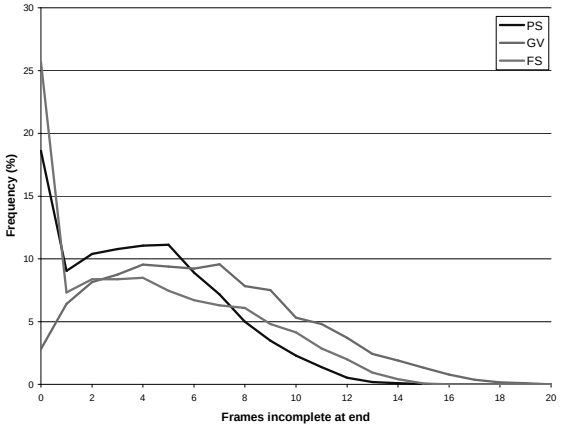

Figure 1: Distribution of number of incomplete frames.

Figure 1 shows the distribution of the number of frames that have not been rendered by the time of the jobs deadline. Although FS has the greatest frequency of runs in which all frames are completed 25.7%, it has a higher proportion of cases in which a large number of frames is incomplete than PS. This is reflected in the standard deviation of frames complete – 5.54 for FS as opposed to 3.85 for PS. In fact PS has both the lowest variance and the lowest mean: 3.85 for PS as opposed to 4.90 for FS. GV has the highest mean 6.38 and the highest standard deviation 7.43.

To try to analyse why mechanisms might give the performance metrics they do, we can examine the statistics of resource allocation. We can examine the difference between runs at a given time. By time 15 all agents' jobs have started and none have ended, so all agents are active. Since there are 6 agents and 15 resources, each agent gets either 2 or 3 with 50% probability, giving a standard deviation of allocation of 0.5. For PS the standard deviation is 0.97, while for GV it is 1.31, demonstrating that the allocations fluctuated more widely with the GV mechanism than PS, which itself varied more widely than FS.

Some of this variability is due to variability in job budget, start time etc. We can control for this by examining the change in allocation from time step to time step throughout the lifetime of each job. The standard deviations of allocation change are 1.12, 1.14 and 1.24 for PS, FS and GV respectively, showing that although the allocations generated by FS have markedly lower variance than the other mechanisms at time 15, over the lifetime of a job FS gives a similar although slightly higher level of variability to PS. Interestingly PS is far ahead when it comes to the number of time steps in which allocation did not change at all: 75%, as opposed to 66% and 67% for GV and FS respectively.

These relative standings with respect to volatility are the same when repeated for for allocation change measured relative to the average allocation given to a job over its lifetime. Here the standard deviations are 0.699 for PS and FS, and 0.881 for GV.

6. CONCLUSION

While it might seem that the choice of market mechanism through which to sell shared compute resources is arbitrary on the grounds that supply and demand should lead to the same equilibrium, in fact we find that when supply and demand fluctuate and are uncertain, and when allocation changes are costly, the precise dynamics of a mechanism can greatly affect the efficiency of the whole system. An inappropriate mechanism – GV in this case – can be worse than simply sharing the resources equally among participants irrespective of need; an appropriate mechanism however can consistently do better for the community as a whole.

Robust Mechanisms for Information Elicitation

{avivz, jeff}@cs.huji.ac.il

ABSTRACT

We study information elicitation mechanisms in which a principal agent attempts to elicit the private information of other agents using a carefully selected payment scheme based on proper scoring rules. Scoring rules, like many other mechanisms set in a probabilistic environment, assume that all participating agents share some common belief about the underlying probability of events. In real-life situations however, underlying distributions are not known precisely, and small differences in beliefs about these distributions may alter agent behavior under the prescribed mechanism.

We propose designing elicitation mechanisms in a manner that will be robust to small changes in belief. We show how to algorithmically design such mechanisms in polynomial time using tools of stochastic programming and convex programming, and discuss implementation issues for multi-agent scenarios.

1. INTRODUCTION

In this paper we examine a scenario in which a principal agent is interested in purchasing information about some event from some other agent (or group of agents) that has private access to that information. The sellers are required to invest some effort in order to learn the information, and may be tempted to guess or report falsely if they expect to benefit from doing so. The buyer of information must therefore design its payments in a way that will induce truthfulness on the part of the sellers. This is ordinarily done using *Proper Scoring Rules* [2]. With a well-designed payment scheme, the expected utility of the sellers is maximized only when they invest the effort to learn the information and reveal it truthfully.

To construct such a mechanism, the designer must take into account the *beliefs* of the sellers about the probabilities of events, since these affect the cost-benefit analysis the sellers make. Unfortunately, these probabilities might not be common knowledge, and may in fact be secret information the agents do not wish to reveal.

We propose to design information elicitation mechanisms to be robust not only against manipulation by the participants, but also against small variations in the beliefs they may hold. The classic approach to dealing with variations in beliefs (or "type") of agents within mechanism design is the use of direct revelation mechanisms. These are mechanisms in which the participants reveal everything to the mechanism, which in turn acts optimally on their behalf — eliminating the need to lie. This approach is not appropriate in scenarios involving information elicitation where information is considered a commodity that is to be sold and not revealed freely.

2. THE SCENARIO

We model the information of agents using discrete random variables. Each seller i is assumed to own a private variable X_i that it can access at a cost of c_i. These variables are not necessarily independent. Once the transaction is complete, the buyer is given access to a random variable denoted Ω. The variable Ω is assumed to be somewhat coupled with the variables X_i, and provides a limited means of verification about their true values. Alternatively, one may think of Ω as some outcome that the buyer is attempting to predict, which eventually becomes known. We denote the governing probability distribution $Pr(\Omega = \omega, X_1 = x_1, \ldots, X_n = x_n)$ by $p_{\omega,x_1\ldots x_n}$. Payments to the agents are made after the value of Ω is revealed and may thus depend on the outcome, as well as the reports of all the agents (it is impossible to create the incentives for truthfulness without some measure of the correctness of the information provided). We denote the payment to agent i by $u^i_{\omega,x_1,\ldots,x_n}$. When dealing with only one agent, we shall drop the script i from all notations.

We require three things from a proper payment scheme. These are presented below in the case of a single agent:

1. **Truth Telling.** Once an agent knows its variable is x, it must have an incentive to reveal it, rather than any lie x'.

$$\forall x, x' \quad s.t. \quad x \neq x' \quad \sum_{\omega} p_{\omega,x} \cdot (u_{\omega,x} - u_{\omega,x'}) > 0 \quad (1)$$

Here $p_{\omega,x}$ is the probability of what actually occurs, while the payment $u_{\omega,x'}$ is based only on what *the agent* reported.

2. **Individual Rationality.** An agent must have a positive expected utility from participating in the game:

$$\sum_{\omega,x} p_{\omega,x} \cdot u_{\omega,x} > c \quad (2)$$

3. **Investment.** The *value of information* for the agent must be greater than its cost. Any guess the agent makes without actually computing its value must be less profitable (in expectation) than revealing the variable:

$$\forall x' \quad \sum_{\omega,x} p_{\omega,x} \cdot (u_{\omega,x} - u_{\omega,x'}) > c \quad (3)$$

When a mechanism is designed for multiple agents, similar requirements should be considered. Their exact nature depends on the level of cooperation possible among the selling agents (transfer of utility, shared information, etc.). They can still be described in the form of linear constraints, but the number of constraints can sometimes be exponentially large in the number of agents.

2.1 Building Non-Robust Mechanisms

The three requirements above can all be characterized using linear constraints and can thus be solved efficiently using linear programming methods. Furthermore, a solution can be found that minimizes some target function such as the expected cost of the mechanism to the buyer.

A great deal of insight into the design problem can be obtained when considering the vectors defined by $\vec{p}_x \triangleq (p_{\omega_1,x} \ldots p_{\omega_k,x})$ and $\vec{u}_x \triangleq (u_{\omega_1,x} \ldots u_{\omega_k,x})$. Using this notation, the truthfulness constraints can be viewed as the requirement that the probability vectors $\vec{p}_x, \vec{p}_{x'}$ will be linearly separated by the vector of payments $\vec{u}_x - \vec{u}_{x'}$.

The following proposition shows necessary and sufficient conditions for the existence of a proper payment scheme.

PROPOSITION 1. *In the single agent case, a proper payment scheme exists iff the probability vectors $\vec{p}_x$ are pairwise independent. Furthermore, if any proper payment scheme exists then there is one with a mean cost as close to c as desired. Such a scheme is optimal, due to the individual rationality constraint.*

PROOF SKETCH. When two vectors $\vec{p}_x$, $\vec{p}_{x'}$ are linearly dependent, there is no way to satisfy the two truthfulness constraints for x, x'. If they are independent, then the truthfulness constraints can be satisfied (for example) by setting for any $\alpha > 0$ and any $\vec{\beta}$, $\vec{u}_x = \frac{\vec{p}_x}{||\vec{p}_x||} \cdot \alpha + \vec{\beta}$. α and $\vec{\beta}$ can be adjusted independently to satisfy the individual rationality and investment constraints tightly. Notice that this implies that the truthfulness constraints are the only things that might prevent us from finding a proper payment scheme. See [3] for a more detailed proof. □

3. DESIGNING ROBUST MECHANISMS

We shall now turn our attention to the case where the probabilities associated with the random variables Ω, X_i are not common knowledge. From now on, $\hat{p}_{\omega,x}$ shall denote the probabilities the principal agent believes in, and $p_{\omega,x}$ will denote the beliefs of an agent. Since beliefs about probabilities are usually grounded by observations, they are not likely to be very far from the truth. We shall assume that different beliefs are "close" to one another according to some distance metric: $\hat{p}_{\omega,x} = p_{\omega,x} + \epsilon_{\omega,x}$ and $||\vec{\epsilon}|| < \epsilon$. We have opted for the use of the L_∞ norm for measuring distance, since it is easily described using linear constraints, but the methods we present can be easily adapted for any other norm.

3.1 The Robustness of a Payment Scheme

Definition 1. We shall say that a given *payment scheme* $u_{\omega,x}$ is *ϵ-robust* with regard to an elicitation problem with distribution $\hat{p}_{\omega,x}$ if it is a proper solution to every elicitation problem with distribution $\hat{p}_{\omega,x} + \epsilon_{\omega,x}$ such that $\|\vec{\epsilon}\|_\infty < \epsilon$, and is infeasible for at least one problem instance of any larger norm.

The definition above is conservative. An ϵ-robust payment scheme will create the proper incentives for truthfulness for *every* possible belief variation of the agent that is within a distance of ϵ. This represents a "large margins" point of view, where the solution is required to satisfy all constraints with enough redundancy to handle small changes in them.

3.1.1 Determining the Robustness of a Given Scheme

Given a payment scheme $u_{\omega,x}$, and an elicitation problem with probabilities $p_{\omega,x}$, we can determine the robustness level of $u_{\omega,x}$ by finding out how much the probabilities must be perturbed to violate one of the constraints required for a truthful mechanism. We can do this by solving a linear program for every constraint. For example, the following program finds a perturbation that violates the truth-telling constraint for a secret x and a lie x'.

$$\begin{array}{ll} \min & \epsilon \\ \text{s.t.} & \\ & \sum_{\omega} (\hat{p}_{\omega,x} + \epsilon_{\omega,x})(u_{\omega,x} - u_{\omega,x'}) \leq 0 \\ \forall x, \omega & \hat{p}_{\omega,x} + \epsilon_{\omega,x} \geq 0 \\ & \sum_{\omega,x} \epsilon_{\omega,x} = 0 \\ \forall x, \omega & -\epsilon \leq \epsilon_{\omega,x} \leq \epsilon \end{array}$$

A solution to this program will be a small perturbation $\epsilon_{\omega,x}$ with a small norm ϵ that manages to violate the constraint. The requirements on $\epsilon_{\omega,x}$ assure us that the perturbed values are still legal probabilities. Once we solve a linear program for every constraint, we simply take the minimal value of ϵ that was found. This is the robustness level of the mechanism.

3.1.2 Efficiently Finding Some ϵ-Robust Mechanism

From a design point of view, we may be interested in finding a solution that is at least ϵ-robust for some ϵ and has a minimal cost. We can do this using tools for *Stochastic Programming*. A stochastic program is simply a mathematical program that contains uncertainty about the exact constraints that need to be satisfied, or the function that is optimized. The following stochastic program describes our problem:

$$
\begin{aligned}
\min \quad & \sum_{\omega,x} \hat{p}_{\omega,x} \cdot u_{\omega,x} \\
\text{s.t.} & \\
\forall x \neq x' \quad & \sum_{\omega} p_{\omega,x}(u_{\omega,x} - u_{\omega,x'}) > 0 \\
& \sum_{\omega,x} p_{\omega,x} \cdot u_{\omega,x} > c \\
\forall x' \quad & \sum_{\omega,x} p_{\omega,x}(u_{\omega,x} - u_{\omega,x'}) > c \\
\text{where:} & \\
\forall x, \omega \quad & p_{\omega,x} = \hat{p}_{\omega,x} + \epsilon_{\omega,x} \\
& p_{\omega,x} \geq 0 \\
& \sum_{\omega,x} p_{\omega,x} = 1 \\
& -\epsilon \leq \epsilon_{\omega,x} \leq \epsilon
\end{aligned}
$$

Stochastic programs with the conservative solution we require can be solved efficiently. [1] presents methods for doing so by treating the problem as a regular convex programming problem. Naturally, there can be cases where no solution exists for the given robustness level.

3.2 The Robustness Level of a Problem

Definition 2. We define the *robustness level* ϵ^* *of the problem* $\hat{p}$ as the supremum of all mechanism robustness levels ϵ for which there exists a proper mechanism:

$$\epsilon^* \triangleq \sup_{\vec{u}} \{\epsilon | \exists \vec{u} \text{ that is an } \epsilon\text{-robust mechanism for } \hat{p}\} \quad (4)$$

To find the robustness level of a problem, one can simply perform a binary search. The robustness level is certainly somewhere between 0 and 1. One may test at every desired level in between to see if there exists a mechanism with some specified robustness by solving the stochastic program above. The space between the upper and lower bounds is then narrowed according to the answer that was received.

3.2.1 A Bound for Problem-Robustness

A simple bound for robustness of the problem can be derived from examining the truthfulness conditions. In fact, Proposition 1 for non-robust mechanisms can be viewed as a private case of the following proposition when applied to 0-robust mechanisms:

PROPOSITION 2. *The robustness level* ϵ^* *of a problem* $\hat{p}$ *can be bounded by the smallest distance between a vector* $\hat{p}_x$ *and the optimal hyper-plane that separates it from* $\hat{p}_{x'}$*:*

$$\epsilon^* \leq \min_{x,x'} ||\hat{p}_x - (\hat{p}_x^{tr} \cdot \vec{\varphi}_{x,x'}) \cdot \vec{\varphi}_{x,x'}||_\infty \quad ; \quad \vec{\varphi}_{x,x'} = \frac{\hat{p}_x + \hat{p}_{x'}}{||\hat{p}_x + \hat{p}_{x'}||_2}$$

The optimal separating hyper-plane is a hyper-plane that separates the points and is of maximal (and equal) distance from both of them.

PROOF SKETCH. If there exist x, x' that give distance ϵ to the hyperplane then the vectors $\hat{p}_x, \hat{p}_{x'}$ can be perturbed towards the hyperplane with a perturbation of norm ϵ, until they are linearly dependent. For this problem instance, according to Proposition 1, there is no possible mechanism. □

In the case where $|\Omega| = 2$, the vectors $\hat{p}_x$ are situated in a two-dimensional plane, and it can be shown that the bound given above is tight — the problem robustness is determined exactly by the closest pair of vectors.

3.3 Mechanisms for Multiple Agents

We assume here that sellers cannot collude, share information, or transfer utility among themselves. Models that allow for collusion are interesting to explore from the viewpoint of robustness, but are beyond the scope of this paper.

When designing mechanisms for multiple agents, the designer has to choose the solution concept it wishes to achieve. It is sometimes possible to design mechanisms that will provide the agents with dominant strategies of truth telling — each agent is better off telling the truth no matter what the other agents do. However, in some cases this is not possible, and the designer must implement a mechanism that provides for good behavior only in equilibrium, when *all* players are behaving well. In these cases the payments made to the players utilize the information given by their peers. Each solution concept translates into a different linear program that may provide a different answer.

In this case, the design of a robust mechanism becomes even more difficult. The designer must now take into account not only the possible beliefs of agents about the probabilities of events, but also their beliefs about the beliefs of other agents. For an agent to believe that some strategy is in equilibrium, it must also be convinced that its counterparts believe that their strategies are in equilibrium, or are otherwise optimal. This will only occur if the agent believes that they believe that it believes that its strategy is in equilibrium — and so on to infinity. Any uncertainty about the beliefs of other agents grows with every step up the belief hierarchy. If agent A knows that all agents have some radius ϵ of uncertainty in beliefs, and its view of the world consists of some probability distribution p it assigns to events, then it is possible that agent B believes the distribution is p' and further believes that agent A believes the distribution is some p'' which is at a distance of up to 2ϵ from p. With an infinite belief hierarchy, it is therefore possible to reach any probability if we go high enough in the hierarchy.

A possible solution to this problem is to use a mixture of solution concepts. The mechanism can often be designed to make each agent's payment depend only on a subset of agents that precedes it. In this case it only needs to take their beliefs into consideration when deciding on a strategy. The necessary belief hierarchy is then finite, which limits the possible range of beliefs about beliefs. The most extreme case of this is to design the mechanism for dominant strategies only. Naturally, a solution constructed in such a way may be less efficient or may not exist at all. Another possibility is to consider only bounded agents that can only consider a finite number of levels in the belief hierarchy.

ABSTRACT

This paper compares the sequential and simultaneous auctions for the following scenario. There are multiple similar objects for sale, each object is sold in a separate auction, and each bidder needs only one object. We use English auction rules and first determine equilibrium bidding strategies for the simultaneous and sequential cases. We do this for both common and private value objects by treating a bidder's information about these values as *uncertain*. We then consider the case where the private and common values have a uniform distribution and compare the two mechanisms in terms of three key properties: a bidder's ex-ante expected profit, the auctioneer's expected cumulative revenue, and the total expected surplus. For both common and private value objects, our study shows the following result. The expected cumulative revenue and the expected total surplus is higher for the sequential mechanism. However, a bidder's exante expected profit depends on the number of objects being auctioned and the number of participating bidders, and it is sometimes higher for the sequential mechanism and sometimes for the simultaneous one.

1. INTRODUCTION

Multiple objects can be auctioned using a number of mechanisms. Now the bidding behaviour is different for different mechanisms. So the outcome of such auctions (i.e., who wins and at what price) is also different for different mechanisms. Hence, the auctioneer and the bidding agents want to know which mechanism will be the most beneficial to them. To this end, we study and compare two different mechanisms: *sequential* and *simultaneous*. To date, considerable research effort has been devoted to the study of these mechanisms. But the main limitation of existing work is that it has studied sequential and simultaneous auctions in isolation and so far there has been very little work on the comparison of these two mechanisms in terms of their outcomes. Our objective is therefore to provide a comparative analysis of sequential (SEQ) and simultaneous (SIM) auctions in an incomplete information setting. We do this for both common value (CV) and private value (PV) objects. For both CV and PV objects, our study shows the following result. The expected cumulative surplus and the auctioneer's cumulative revenue is higher for the SEQ mechanism. However, the mechanism that generates a higher ex-ante expected profit for the bidders depends on the number of objects being auctioned and the number of participating bidders, and it is sometimes higher for SEQ mechanism and sometimes for the SIM one.

Section 2 determines equilibrium for the SEQ and SIM mechanisms. Section 3 compares the outcomes for the two mechanisms. Section 4 concludes.

2. EQUILIBRIUM BIDDING STRATEGIES

Equilibrium bidding strategies for a single object with both common and private values have been obtained in [4]. We therefore briefly summarize its key results and then determine the equilibrium for our m objects case.

2.1 Single object

We first describe the CV case. For a single object with CV V_1, the equilibrium obtained in [4] is as follows. Let f^n denote the first order statistic of the surplus for the n bidders and s^n the second order statistic. Then the bidder with the highest surplus wins and the winner's expected profit is $EP_w(n) = E(f^n) - E(s^n)$. The expected surplus is $ES(n) = E(V_1)$. Finally, the expected revenue is $ER(n) = ES(n) - EP_w(n)$.

On the other hand, for PV objects [6], the winner's expected profit is $\overline{EP}_w(n) = E(\overline{f}^n) - E(\overline{s}^n)$. The expected surplus is $\overline{ES}(n) = E(\overline{f}^n)$ and the expected revenue is $\overline{ER}(n) = E(\overline{s}^n)$ where $\overline{f}^n$ and $\overline{s}^n$ denote the first and second order statistic for the private value of the object.

2.2 Multiple sequential auctions

The m similar objects are sold in m separate English auctions conducted sequentially one after another. Each bidder needs only one object and draws its CV/PV for an auction just before that auction begins. Since a bidder needs only one object, it participates in the series of auctions until it wins an object. After that, it does not take

part in any of the remaining auctions[1]. In our model, there is a single probability distribution function for the CVs and PVs of all the objects and each bidder receives its signals for an object before the auction for that object begins (like in [5, 1]).

The English auction rules are as follows. The auctioneer continuously raises the price, and bidders publicly reveal when they withdraw from the auction. Bidders who drop out from an auction cannot re-enter that auction. A bidder's strategy for the jth (for $1 \leq j \leq m-1$) auction depends on its expected profit from the $(m-j)$ future auctions. Since the mth auction is the last one, a bidder's strategy for this auction is the same as the single object case. But the bidding behaviour for the first $(m-1)$ auctions is different from the single object case.

We first obtain the equilibrium bids for CV objects and then extend it to PVs. For the former case, a bidder's strategy for an individual auction depends on its probability of winning any one of the remaining auctions that are yet to be conducted. If the number of bidders for the first auction is n, then let $\beta(y, j, m, n)$ denote a bidder's ex-ante probability of winning the yth (for $j \leq y \leq m$) auction in the series from the jth to the mth auction before the jth one begins. This probability is:

$$\beta(y, j, m, n) = [\Pi_{k=j}^{y-1}(1 - 1/(n-y+k+1))] \times (1/(n-y+1))$$

For CV objects, let $EP_w(j, m, n)$ denote the winner's expected profit for the jth auction in a series of m auctions with n bidders for the first one. Also, let $\alpha(j, m, n)$ denote a bidder's ex-ante expected profit for winning any one auction in the series from the jth (for $1 \leq j \leq m$) to the mth auction where

$$\alpha(j, m, n) = \Sigma_{y=j}^{m} \beta(y, j, m, n) EP_w(y, m, n)$$

For CV objects, the n-tuple of strategies $(B(\cdot), \ldots, B(\cdot))$ with $B(\cdot)$ defined below constitutes a symmetric equilibrium for the jth (for $1 \leq j < m$) auction at a stage where k bidders have dropped out (see [3] for details):

$$B_0^j(x_{ij}) = E(v_{ij}|S_{ij} = x_{ij}) - \alpha(j+1, m, n)$$

$$B_k^j(x_{ij}; b_1, \ldots, b_k) = \frac{n-j+1-k}{n-j+1} E(v_{ij}|S_{ij} = x_{ij}) + \frac{1}{n-j+1} \sum_{y=0}^{k-1} E(v_{ij}| \; B_y(x_{ij}; b_1, \ldots, b_y) = b_{y+1}) - \alpha(j+1, m, n)$$

where x_{ij} is bidder i's surplus for the jth object.

Let $ER(j, m, n)$ denote the expected revenue from the jth auction in a series of m CV auctions with n bidders for the first one. Also, let $ES(j, m, n)$ denote the expected surplus for the jth auction. Then for the jth (for $1 \leq j \leq m$) auction, the winner's expected profit ($EP_w(j, m, n)$), the expected surplus ($ES(j, m, n)$), and the expected revenue ($ER(j, m, n)$) are:

$$EP_w(j, m, n) = E(f^{n-j+1}) - E(s^{n-j+1}) + \alpha(j+1, m, n)$$
$$EP_w(m, m, n) = E(f^{n-m+1}) - E(s^{n-m+1})$$
$$ES(j, m, n) = E(V_j)$$
$$ER(j, m, n) = ES(j, m, n) - EP_w(j, m, n)$$

[1]This model is an extension of [1]: [1] analyses a sequence of two private value auctions while we analyse $n \geq 2$ auctions for common and private values.

We now find the cumulative revenue, the cumulative surplus, and a bidder's ex-ante expected profit from all m auctions. For $n > m$, let $X_{seq}(m, n)$ denote the cumulative revenue and $Y_{seq}(m, n)$ a bidder's exante profit from all m auctions where $X_{seq}(m, n) = \Sigma_{j=1}^{m} ER(j, m, n)$ and $Y_{seq}(m, n) = \alpha(1, m, n)$. In general (i.e., $n > m$ or $n \leq m$), the cumulative revenue ($ECR_{seq}(m, n)$) is as follows:

$$ECR_{seq}(m, n) = \begin{cases} 0 & \text{if } n = 0, \text{ or } n = 1 \\ X_{seq}(m, n) & \text{if } n > m \\ X_{seq}(n-1, n) & \text{if } n \leq m \end{cases}$$

This is because if $n \leq m$, then the number of bidders for the first $n-1$ auctions is at least 2. For the nth auction there is only one bidder and so it wins the object for nothing resulting in a revenue of zero. For all the remaining $m-n$ auctions, there are no bidders and so the revenue is zero again.

Let $EEP_{seq}(m, n)$ denote a bidder's ex-ante expected profit for all the m auctions where

$$EEP_{seq}(m, n) = \begin{cases} E(V) & \text{if } n = 1 \\ Y_{seq}(m, n) & \text{if } n > m \\ Y_{seq}(n-1, n) + \beta(n, 1, n, n)E(V) & \text{if } n \leq m \end{cases}$$

This is because if ($n \leq m$) for the first $n-1$ auctions there are at least two bidders. But for the nth auction, since there is only one bidder, it gets the object for nothing. For this auction, the winner's expected profit is the expectation of the CV. Since the CVs of all the objects are drawn from a single distribution function (F), we drop the subscript in $E(V)$.

Finally, the expected cumulative surplus is:

$$ECS_{seq}(m, n) = \begin{cases} mE(V) & \text{if } n \geq m \\ nE(V) & \text{if } n < m \end{cases}$$

We now turn to PV objects. For these objects, we denote the first and second order statistic of the PV for the jth auction as $\overline{f}^{n-j+1}$ and $\overline{s}^{n-j+1}$ respectively. For these objects, a bidder's bid for an auction is obtained by subtracting its ex-ante expected profit for the future auctions from its bid for the current one. Hence, for the jth auction, the winner's expected profit (denoted $\overline{EP_w}(j, m, n)$) is:

$$\overline{EP}_w(j, m, n) = E(\overline{f}^{n-j+1}) - E(\overline{s}^{n-j+1}) + \overline{\alpha}(j+1, m, n)$$
$$\overline{EP}_w(m, m, n) = E(\overline{f}^{n-m+1}) - E(\overline{s}^{n-m+1})$$

where $\overline{\alpha}(j, m, n)$ is a bidder's ex-ante expected profit for winning any one auction in the series from the jth (for $1 \leq j \leq m$) to the mth auction and is:

$$\overline{\alpha}(j, m, n) = \Sigma_{y=j}^{m} \beta(y, j, m, n) \overline{EP}_w(y, m, n)$$

The expected revenue and the expected surplus are:

$$\forall_{j=1}^{m-1} \overline{ER}(j, m, n) = E(\overline{s}^{n-j+1}) - \overline{\alpha}(j+1, m, n)$$
$$\overline{ER}(m, m, n) = E(\overline{s}^{n-m+1})$$
$$\forall_{j=1}^{m} \overline{ES}(j, m, n) = \overline{ER}(j, m, n) + \overline{EP}_w(j, m, n)$$

For $n > m$, let $\overline{X}_{seq}(m, n)$ denote the expected cumulative revenue for all the m objects and $\overline{Y}_{seq}(m, n)$ a bidder's ex-ante expected profit from all the m auctions where $\overline{X}_{seq}(m, n)$ is equal to $\Sigma_{j=1}^{m} \overline{ER}(j, m, n)$ and $\overline{Y}_{seq}(m, n) = \overline{\alpha}(1, m, n)$. In general, (i.e., for $n > m$ or $n \leq m$), the cumulative revenue is:

$$\overline{ECR}_{seq}(m, n) = \begin{cases} 0 & \text{if } n = 0, \text{ or } n = 1 \\ \overline{X}_{seq}(m, n) & \text{if } n > m \\ \overline{X}_{seq}(n-1, n) & \text{if } n \leq m \end{cases}$$

and a bidder's ex-ante expected profit ($\overline{EEP}_{seq}(m,n)$) is:

$$\overline{EEP}_{seq}(m,n) = \begin{cases} E(\overline{f}^1) & \text{if } n = 1 \\ \overline{Y}_{seq}(m,n) & \text{if } n > m \\ \overline{Y}_{seq}(n-1,n)+ & \\ \beta(n,1,n,n)E(\overline{f}^1) & \text{if } n \leq m \end{cases}$$

Finally, the expected cumulative surplus is:

$$\overline{ECS}_{seq}(m,n) = \begin{cases} \sum_{j=1}^{m} E(\overline{f}^{n-j+1}) & \text{if } n \geq m \\ \sum_{j=1}^{n} E(\overline{f}^{n-j+1}) & \text{if } n < m \end{cases}$$

2.3 Multiple simultaneous auctions

As before, we have $m > 1$ similar objects, n risk-neutral bidders, and each bidder needs only one object. Given this, the SIM auctions game is played as follows. The m objects are sold in m different auctions conducted simultaneously and independently of each other. Each bidder randomly selects one of the m auctions and bids in it. It is obvious that after a bidder selects an auction, its equilibrium bids are the same as that for a single object.

This game has been analysed in [2] for private value objects for the limiting case where both m and n tend to infinity. The analysis is done by assuming complete information. Here, we extend this analysis to a more realistic case where both m and n are finite, the objects are either CV or PV, and there is uncertainty about these values. For this SIM auctions game, the equilibrium outcome depends on how the n bidders arrive at the m auctions. We let T_m^n denote the number of different ways in which n bidders can be distributed between m auctions where

$$T_m^n = \begin{cases} 1 & \text{if } n = 0 \text{ or } m = 1 \\ \Sigma_{k=0}^{n} C(n,k) & \text{if } m = 2 \\ \Sigma_{k=0}^{n} C(n,k) T_{m-1}^{n-k} & \text{if } m > 2 \end{cases}$$

For m SIM auctions, the probability that k bidders arrive at an auction ($P(m,k)$) is:

$$P(m,k) = (C(n,k)T_{m-1}^{n-k})/T_m^n$$

Consider any one auction. The number of bidders for this auction can vary between 0 and n. If no bidders arrive at the auction, the object remains unsold. If only one bidder arrives, it gets the object for nothing. If $k \geq 2$ bidders arrive, then the expected revenue is greater than zero.

Consider CV objects. For these objects, the expected cumulative revenue from all the m auctions ($ECR_{sim}(m,n)$) is:

$$\begin{aligned} ECR_{sim}(m,n) &= \Sigma_{k=0}^{n} P(m,k)[ER(k)+ \\ &\quad ECR_{sim}(m-1,n-k)] \end{aligned}$$

Also, for an individual auction, the winner's expected profit is:

$$\begin{aligned} EP_w(m,n) &= P(m,1)[E(V)]+ \\ &\quad \Sigma_{k=2}^{n} P(m,k)[E(f^k) - E(s^k)] \end{aligned}$$

and hence a bidder's ex-ante expected profit ($EEP_{sim}(m,n)$) is:

$$\begin{aligned} EEP_{sim}(m,n) &= P(m,1)[E(V)]+ \\ &\quad \Sigma_{k=2}^{n} P(m,k)(1/k)[E(f^k) - E(s^k)] \end{aligned}$$

Finally, the total expected surplus (denoted $ECS_{sim}(m,n)$) is:

$$\begin{aligned} ECS_{sim}(m,n) &= \Sigma_{k=1}^{n} P(m,k)[ES(k)+ \\ &\quad ECS_{sim}(m-1,n-k)] \end{aligned}$$

Now consider PV objects. For these objects, the expected cumulative revenue is:

$$\begin{aligned} \overline{ECR}_{sim}(m,n) &= \Sigma_{k=0}^{n} P(m,k)[\overline{ER}(k)+ \\ &\quad \overline{ECR}_{sim}(m-1,n-k)] \end{aligned}$$

Also, for an auction, the winner's expected profit is:

$$\begin{aligned} \overline{EP}_w(m,n) &= P(m,1)[E(\overline{f}^1)]+ \\ &\quad \Sigma_{k=2}^{n} P(m,k)[E(\overline{f}^k) - E(\overline{s}^k)] \end{aligned}$$

and hence a bidder's ex-ante expected profit is:

$$\begin{aligned} \overline{EEP}_{sim}(m,n) &= P(m,1)[E(\overline{f}^1)]+ \\ &\quad \Sigma_{k=2}^{n} P(m,k)(1/k)[E(\overline{f}^k) - E(\overline{s}^k)] \end{aligned}$$

Finally, the total expected surplus is:

$$\begin{aligned} \overline{ECS}_{sim}(m,n) &= \Sigma_{k=1}^{n} P(m,k)[\overline{ES}(k)+ \\ &\quad \overline{ECS}_{sim}(m-1,n-k)] \end{aligned}$$

3. A COMPARISON OF THE TWO AUCTION MECHANISMS

We now compare the two mechanisms in terms of three key properties: the expected cumulative revenue, the expected cumulative surplus, and a bidder's ex-ante expected profit. To do this, we consider the uniform distribution function for both PVs and CVs. For this distribution, our study shows that from an auctioneer's perspective, the SEQ mechanism is better because it generates a higher revenue. From a global perspective too, the SEQ mechanism is better (because it generates a higher expected cumuative surplus). However, from a bidder's perspective, the ex-ante expected profit depends on the number of participating bidders and the number of objects being auctioned, and it is sometimes higher for the SEQ mechanism and sometimes for the SIM one.

4. CONCLUSIONS

This paper analyses two key auction mechanisms for multiple objects: *sequential* and the *simultaneous*. This analysis is done for both common and private value objects by treating a bidder's information about these values as uncertain. We used the English auction rules and determined equilibrium for the two mechanisms. We then considered the case where the private and common values have a uniform distribution and compared the mechanisms in terms of their expected cumulative revenues, their expected cumulative surplus, and a bidder's ex-ante expected payoff. For both common and private values, our study shows that, the sequential mechanism is better both from the auctioneer's and also from a global perspective. However, from a bidder's perspective, the choice of a mechanism depends on the number of objects and the number of bidders.

ABSTRACT

In this paper, we consider competition between sellers offering similar items in concurrent online auctions, where each seller must set its individual auction parameters (such as the reserve price) in such a way as to attract buyers. We show that there exists a pure Nash equilibrium in the case of two sellers with asymmetric production costs. In addition, we show that, rather than setting a reserve price, a seller can further improve its utility by shill bidding (i.e., pretending to be a buyer in order to bid in its own auction). But, using an evolutionary simulation, we show that this shill bidding introduces inefficiences within the market. However, we then go on to show that these inefficiences can be reduced when the mediating auction institution uses appropriate auction fees that deter sellers from submitting shill bids.

1. INTRODUCTION

Online markets are becoming increasingly prevalent and extend to a wide variety of areas such as e-commerce, Grid computing, recommender systems, and sensor networks. To date, much of the existing research has focused on the design and operation of individual auctions or exchanges for allocating goods and services. In practice, however, similar items are typically offered by multiple independent sellers that compete for buyers and set their own terms and conditions (such as their reserve price and the type and duration of the auction) within an institution that mediates between buyers and sellers. Examples of such institutions include eBay, Amazon and Yahoo!, where at any point in time multiple concurrent auctions with different settings are selling similar objects, often resulting in strong competition. Given this competition, a key research question is how a seller should select their auction settings in order to best attract buyers and so increase their expected profits. In this paper, we consider this issue in terms of setting the seller's reserve price (since the role of the reserve price has received attention in both competitive and non-competitive settings). In particular, we extend the existing analysis by considering how sellers may improve their profit by shill bidding (i.e. bidding within their own auction as a means of setting an implicit reserve price). Moreover, we investigate how the institution can deter this undesirable shill bidding through the use of appropriate auction fees.

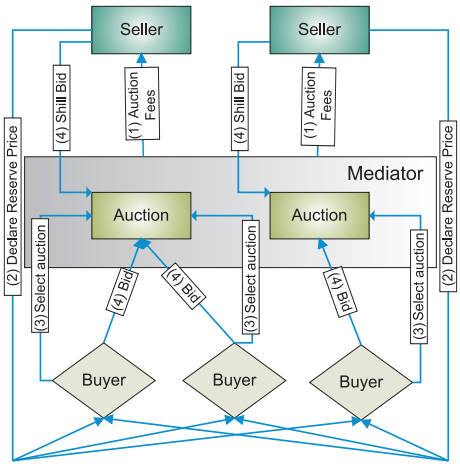

Figure 1: The competing sellers game.

2. MODEL OF COMPETING SELLERS

The model of competing sellers proceeds in four stages (see figure 1). First, the mediator (an institution such as eBay or Yahoo! that runs the auctions) announces the auction fees to the sellers. The sellers then simultaneously post their reserve prices in the second stage. In the third stage, the buyers simultaneously select an auction (or, equivalently, a seller) based on the observed reserve prices. In the final stage, the buyers (and possibly the sellers who are shill bidding) submit bids and the auctions are executed concurrently.

3. ANALYSIS

A complete analysis of equilibrium behaviour and market efficiency for the complete model is intractable [3]. Therefore, in this section, we analyse a simplified version with

two sellers and no auction fees (in section 4 we address the complete model). We assume that there are N risk neutral buyers, each of whom requires just one item. Each buyer has valuation v independently drawn from a commonly known cumulative distribution F with density f and support $[0, 1]$. Each risk neutral seller offers one item for sale, has production costs x_i, and decides upon a reserve price r_i and shill bid s_i. The preferences of buyers and sellers are described by von Neumann and Morgenstern utility functions.

3.1 Buyer Equilibrium Behaviour

The buyers' behaviour for two sellers has been analysed in [2]. A rational buyer with valuation $v < r_1$ will not attend any auction. Furthermore, if $r_1 < v < r2$, the buyer will always go to seller 1. The interesting case occurs when $v > r2$. In a symmetric Nash equilibrium, there is a unique cut-off point $1 \geq w \geq r2$ where buyers with $v < w$ will always go to seller 1, and buyers with $v \geq w$ will randomize equally between the two auctions. The cut-off point w is exactly where a buyer's expected utility is equal for both auctions, and is thus found by solving:

$$r_1\mathcal{F}(r_1, w)^{N-1} + (N-1)\int_{r_1}^{w} y\mathcal{F}(y, w)^{N-2}dF(y) = r_2\mathcal{F}(w, w)^{N-1}$$

where $\mathcal{F}(y, w) = F(y) + [1 - F(w)]/2$. Given the buyers' cut-off point, we can now calculate the sellers' expected revenue.

3.2 Seller Equilibrium Behaviour

To calculate the equilibrium behaviour of the sellers, we derive a general expression for the sellers' expected utility. This is calculated by considering the probability of one of three events occurring: (i) no bidders having valuations above the reserve price and the item does not sell, (ii) only one bidder having a valuation above the reserve price and the item sells at the reserve price, or (iii) two or more bidders having valuations above the reserve price and the item sells at a price equal to the second highest valuation. Thus, the expected utility of seller i who has a production cost of x_i and sets a reserve price of r_i is

$$U_i(r_i, x_i) = N(r_i - x_i)\mathcal{G}(r_i)(1 - \mathcal{G}(r_i))^{N-1} + N(N-1)\int_{r_1}^{1}(x_i - y)\mathcal{G}'(y)\mathcal{G}(y)(1 - \mathcal{G}(y))^{N-2}dy \quad (1)$$

where $\mathcal{G}(y)$ is the probability that a bidder is present in the auction *and* that this bidder has a valuation greater than y.

Now, in the standard auction with no competing sellers, we have the standard result that $\mathcal{G}(y) = 1 - F(y)$ and $\mathcal{G}'(y) = -f(y)$. However, for two competing sellers, we must account for the fact that the number and valuation of the bidders in the auction is determined by the bidders' cut-off point w. Thus, for sellers 1 and 2 (where seller 1 has the lower reserve price), $\mathcal{G}_1$ and $\mathcal{G}_2$ are given by:

$$\mathcal{G}_1(y) = \begin{cases} \frac{1+F(w)}{2} - F(y) & y < w \\ \frac{1-F(y)}{2} & y \geq w \end{cases} \quad \mathcal{G}_2(y) = \begin{cases} \frac{1-F(w)}{2} & y < w \\ \frac{1-F(y)}{2} & y \geq w \end{cases} \quad (2)$$

Thus, the sellers' expected utility depends on the reserve price of both sellers and the equilibrium behaviour is complex. We now apply this result to three different cases: (i) where both sellers declare public reserve prices, (ii) where one seller declares a public reserve price and the other submits a shill bid, and (iii) where both sellers shill bid[1].

[1]When a seller shill bids, the declared reserve price has no additional benefit. Thus we assume they declare no reserve price (or, equivalently, declare a zero reserve price).

		Seller 2	
		RP	SB
Seller 1	RP	0.452 , 0.189	0.403 , 0.220
	SB	0.457 , 0.188	0.423 , 0.220

Table 1: Sellers' expected utility when either declaring a reserve price (RP) or to shill bidding (SB).

Both Sellers Announce Public Reserve Prices. In this case, the equilibrium strategy of each seller is given by a Nash equilibrium at which each seller's reserve price is a utility maximising best response to the reserve price of the competing seller. When $x_1 = x_2$, no pure strategy Nash equilibrium exists [2]. However, when the sellers have sufficiently different production costs, we find that a pure Nash equilibrium exists where the reserve price of both sellers is higher than their production costs. We find this equilibrium numerically by iteratively discretising the space of possible reserve prices. That is, for all possible values of r_1 and r_2 that satisfy the conditions $x_1 \leq r_1 \leq 1$ and $r1 \leq r_2 \leq 1$, we calculate w and hence the expected utility of the two sellers. We then search these reserve price combinations to find the values of r_1^* and r_2^* that represents the utility maximising best responses to one another. By iterating the process and using a finer discretisation at each stage, we are able to calculate the Nash equilibrium to any degree of precision. The outcomes show that the symmetric case is very much a special case, and the majority of possible production cost combinations yield unique pure strategy Nash equilibria.

One Seller Shill Bids. Rather than announce a public reserve price, either seller may choose to announce a reserve price of zero to attract bidders, and then submit a shill bid to prevent the item from selling at too low a price. Thus, the seller who does not shill bid (seller 2 since r_2 will be greater than r_1) should declare a reserve price that is a best response to the zero reserve price announced by the bidder who does shill bid. This reserve price is simply given by the value of r_2 that maximises $U_2(r_2, x_2)$, given that we calculate $\mathcal{G}_2(y)$ as in equation 2 and take $r_1 = 0$ in order to calculate w. Given the best response reserve price of seller 2, and the resulting value of w, we can also calculate the shill bid that seller 1 should submit in order to maximise its own expected utility. By substituting s_1 for r_1 in equation 1, and using $\mathcal{G}_1(y)$ as given in equation 2, we find the shill bid that maximises $U_1(s_1, x_1)$.

Both Sellers Shill Bid. Finally, when both sellers declare a zero reserve price and shill bid, the bidders will randomise equally between either auction, since there is no reserve price information to guide their decision. Thus we find the equilibrium shill bids of both sellers by again substituting s_i for r_i in equation 1 and hence finding the value of s_i that maximises $U_i(s_i, x_i)$ when $w = 0$.

Table 1 shows an example of the resulting four strategy combinations as a normal form game (in this case $N = 10$, $x_1 = 0.25$, and $x_2 = 0.5$). Note that both sellers have a dominant strategy to submit shill bids (this result holds in general in the absence of auction fees). At this equilibrium, seller 2 achieves its maximum possible utility. However, seller 1 receives more when neither seller shill bids and is thus better off with a mechanism that deters all parties from submitting shill bids.

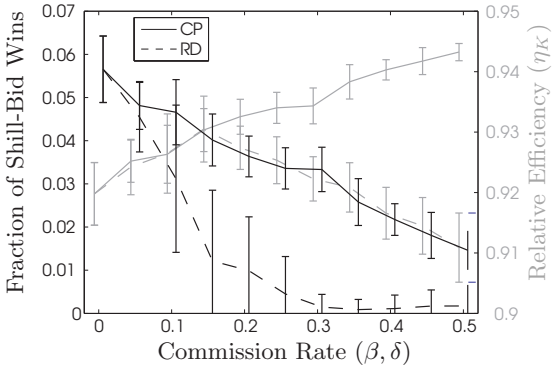

Figure 2: Average fraction of shill-bid wins (black) and relative efficiency (grey) for CP & RD auction fees ($N = 10$ and $x_1 = x_2 = 0$). The error-bars indicate the standard deviation.

4. AUCTION FEES

We now consider auction fees and market efficiency in the competing sellers game. We compare two types of auction fees: a closing price (CP) fee that is a fraction, β, of the selling price (where β is the CP commission rate), and a reserve-difference (RD) fee that is calculated as a fraction, δ, of the difference between the selling price and the seller's declared reserve price, (where δ is the RD commission rate). The first type of fee is the most common in online auctions such as eBay, Yahoo! and Amazon. The second type of fee was introduced in previous literature, and is shown to prevent shilling for particular bidder valuation distributions in a single multi-stage auction [4].

Auction fees add considerable complexity to the analysis of the competing sellers game since a seller now needs to optimally set both the reserve price and the shill bid. Therefore, we investigate auction fees using a simulation based on evolutionary algorithms (EAs) [1]. The EA maintains a population of possible seller strategies, where a strategy determines the shill bid and reserve price for each auction. At each generation, M seller strategies are randomly selected from the population and compete against one another in a number of consecutive games. The fittest strategies survive and are transferred to the next generation, whereas poor performing strategies are removed from the population. New strategies are explored by slightly modifying existing individuals using a mutation operator. This evolutionary process is repeated for a fixed number of iterations.

We compare auction fees by considering the fraction of *shill-bid wins* (i.e., the fraction of auctions that result in a shill bid being the highest bid), and a measure of the relative efficiency η_K of an allocation K, where η_K is given by:

$$\eta_K = \frac{\sum_{i=1}^{N} v_i(K) + \sum_{i=1}^{M}(x_i - x_i(K))}{\sum_{i=1}^{N} v_i(K^*) + \sum_{i=1}^{M}(x_i - x_i(K^*))}, \qquad (3)$$

where $K^* = \arg\max_{k \in \mathcal{K}}[\sum_{i=1}^{N} v_i(k) - \sum_{i=1}^{M} x_i(k)]$ is an efficient allocation, $\mathcal{K}$ is the set of all possible allocations, $v_i(k)$ is bidder i's utility for an allocation $k \in \mathcal{K}$, and $x_i(k)$ is seller i's production costs for a given allocation (in order to prevent a negative value we add production costs x_i in both the denominator and the numerator).

Now, in order to directly compare the auction fees, we first consider the case without production costs. To this end, figure 2 shows the fraction of shill-bid wins and relative efficiency for the two types of auction fees. These results show that the RD fee is better able to reduce shill bidding for this setting. However, in case of high commission rates, a higher efficiency is obtained using the CP fee. Since the RD fee is effectively a combination of a CP fee and a negative RD fee, it rewards a high reserve price. If the commission rate is sufficiently high, the reserve price is set higher than the equilibrium price without any auction fees, and thus, results in an inefficient outcome. The CP fee, on the other hand, is neutral with regard to the reserve price.

In case of production costs we find similar results. However, if both production costs and CP commission rates are very high (e.g. above 30%), a sharp decline in efficiency is observed using the CP fee. A seller will then set a very high reserve price to prevent making a loss in case it sells, and, as a result, efficiency becomes very low. Using the RD fee, on the other hand, efficiency does not decrease because sellers never make a loss as long as they report a reserve price above their production costs. The latter type of fee is therefore more robust to high production costs.

To conclude, the experiments show that in most cases highest efficiency is obtained by the commonly applied CP auction fees. The RD auction scheme, however, is more effective in deterring shill bidding and is also more robust to high production costs. This is consistent with earlier results showing that RD auction fees can deter shill bidding for isolated auctions [4]. However, our results show, for the first time, that these fees are also effective for a setting where sellers compete and in case of production costs. Moreover, we see that, when using the RD fee, sellers pay much less to the mediator overall compared to CP auction fees. The latter is especially important in a larger setting where multiple mediating institutions compete to attract sellers, since high fees will deter potential sellers.

5. CONCLUSIONS

Traditionally, competition among sellers has been ignored when designing auctions and setting auction parameters. However, when faced with competition, we have shown that auction parameters are important in determining the number and type of buyers that are attracted to an auction. We have also shown that such competition provides an incentive for sellers to shill bid, but this can be avoided by a mediator that applies appropriate auction fees. These results are particularly relevant for online markets and multi-agent systems, where competition is strong due to the ease with which a buyer (or a software agent) can search for particular goods. Thus, in these settings, our results can be used by sellers seeking to maximise their profit, or alternatively, by the auction institution itself, who wishes to use appropriate auction fees to deter shill bidding and thus increase the efficiency of the market as a whole.

Evaluating Bidding Strategies for Simultaneous Auctions

ABSTRACT

Bidding for multiple items or bundles on online auctions raises challenging problems. We assume that an agent has a valuation function that returns its valuation for an arbitrary bundle. In the real world all or most of the items of interest to an agent is not present in a single combinatorial auction. We study the problem of bidding for multiple items in a set of simultaneous auctions, each of which sell only a single unit of a particular item. Hence an agent has to bid in multiple auctions to obtain preferred item bundles. While an optimal bidding strategy is known when bidding in sequential auctions, only suboptimal strategies are available when bidding for items sold in auctions running simultaneously. To decide on an agent's bid for simultaneous auctions, we investigate a multi-dimensional bid improvement strategy, which is optimal given an infinite number of restarts, . We provide a comparison of this algorithm with existing ones, both in terms of utilities generated and computation time, along with a discussion of the strengths and weaknesses of these strategies.

bidding, simultaneous auctions

1. INTRODUCTION

Auction theory has received significant attention from researchers following the development of electronic auctions on the Internet. Researchers are interested both in designing auctions with desirable properties [5, 6] and designing automated agents to represent interests of human users [3, 4, 7].

In a multi-auction setting, multiple single-item auctions are run concurrently or sequentially. A potential bidder needs to estimate closing prices of such auctions to compute optimal bids. The bidder incurs the computational cost of estimating closing prices and calculating optimal bids given its valuation for items and the expected closing prices. The problem of computing optimal bids is complex. While an optimal bidding strategy is known for sequential auctions [3, 8], none is known for simultaneous auctions.

We have developed a multidimensional bid improvement strategy for bidding in simultaneous auctions. We use an optimization techniques to determine bids that maximize the expected utility function. The focus of this paper is a comparative evaluation of our proposed algorithm with existing ones in terms of time complexity and the quality of the solutions generated.

2. RELATED WORK

Bidding for bundles in simultaneous auctions has received a lot of attention partly due to the Trading Agent Competition (TAC)[1]. Stone *et al.* and Greenwald and Boyan have studied the possibility to bid in multi-auctions in the context of the TAC [4, 2, 8, 7], which resulted in the design of two top-scoring agents. Their approaches, however, were fundamentally different from the one we have developed [1]. Our multi-dimensional bid improvement algorithm is motivated by optimization techniques, where, given any bid vector, we generate the next bid vector by sequentially optimizing the bid for each item while assuming the bid for the other items are held constant. The approaches used by both Stone *et al.* and Greenwald involve assigning valuations to individual items based on expected marginal utilities of the items. The marginal utility of an item i is the extra-profit generated by the acquisition of i at price equal to zero. The idea behind the marginal utility is that one is willing to pay for an item up to the benefit of getting it. We provide a more detailed description of Stone *et al*'s and Greenwald and Boyan's algorithms in Section 4 and offer a comparison of the effectiveness of their algorithms and ours in Section 5.

3. SIMULTANEOUS AUCTION MODEL

We consider a bidder which plans to acquire items from the set $\mathcal{I} = \{1, \ldots, N\}$. A valuation function ϑ represents the bidder's preference by assigning a value the bidder is

willing to pay for each bundle. Item i is available in only one single-item single-unit auction a_i. An auction is modeled by the cumulative probability distribution F_i of the closing prices in the range $[\underline{p_i}, \overline{p_i}]$. We assume these distributions to be continuous, independent, and known to the bidder. When a_i closes, the bidder gets the item if it has placed a bid b_i greater than or equal to the closing price p_i ($b_i \geq p_i$) and the payment is equal to the closing price. All auctions are run in parallel and their closing times are not known by the bidder. $B = (b_1, \ldots, b_N)$ represents the bids placed simultaneously in all auctions by the bidder and $P = (p_1, \ldots, p_N)$ are the closing prices. We assume the bidder to be rational, i.e., it wants to maximize its expected utility from the purchases, if any. Hence it tries to find a bid vector B^* such that $B^* = \underset{B \in \mathcal{B}}{\operatorname{argmax}}\ \bar{\alpha}(B)$ where $\mathcal{B}$ is the bid space and $\bar{\alpha}(B)$ is the expected utility of bidding B.

4. BIDDING STRATEGIES

We review some prominent bundle bidding strategies before discussing our approach.

4.1 Marginal utility bidding ($\overline{MU}$)

We first present the optimal bidding strategy for bundles in sequential auctions[2, 8]. In the remainder of this paper, we will refer to this method as *expected marginal utility bidding* or $\overline{MU}$. When bidding for the ith item, the bidder places the bid $b_i = \bar{\mu}(i, I_h, I_r)$ in auction a_i. I_h contains items held by the bidder, I_r contains items to be auctioned, $\bar{\mu}(i, I_h, I_r)$ is the expected marginal utility of item i which can be viewed has the extra-profit due to the acquisition of i at zero-cost.

$\overline{MU}$ is optimal when bidding in sequential auctions as shown by Greenwald and Boyan in [2]. $\overline{MU}$ is suboptimal for simultaneous auctions. In particular, when items are substitutable, the bidder may acquire two items it may not desire to acquire together. Another downside of $\overline{MU}$ is its complexity. The calculation of the marginal utility is exponential since it requires the knowledge of the profit generated by each possible bundle.

To adopt $\overline{MU}$ for simultaneous auctions, a bidder has to compute all bids simultaneously. In that case, $\mathcal{I}_h = \emptyset$. The bidder bids for each item as if it is the first item to be auctioned. In other words, the bidder places $b_i = \bar{\mu}(i, \emptyset, \mathcal{I} \setminus \{i\})$ in auction a_i.

4.2 Expected Value Marginal Utility bidding (EVMU)

In this section, we present a variant of $\overline{MU}$ introduced by Greenwald and Boyan [2]. This variant tries to overcome the issue raised by leaving out of consideration some bidder preferences. To prevent the bidder from obtaining two "similar" items, a set of preferred items is precomputed. We refer to this set as the *acquisition set* $\mathcal{I}_{evmu}$. The acquisition set is the optimal set of items to be obtained assuming that items are auctioned at deterministic prices equal to the expected closing prices for these items. The bidder places a bid for all items in $\mathcal{I}_{evmu}$ and the bids are equal to the expected marginal utility of the items. Like $\overline{MU}$, the computation of marginal utility in EVMU is exponential.

4.3 Multi-Dimensional Bid Improvement (MDBI)

Now we present an approach to bidding in simultaneous auctions based on an incremental optimization technique [1]. Assume that the bidder has decided, by some means, to bid the vector B. We try to improve B replacing b_i by $\beta_i(B_{-i})$ where $\beta_i(B_{-i})$ is the best bid for item i holding other bids constant ($\beta_i(B_{-i}) = \underset{b_i \in [\underline{p_i}, \overline{p_i}]}{\operatorname{argmax}}\ \bar{\alpha}(b_i \vee B_{-i})$). We exclude the proof due to space limitations but observe that $\beta_i(B_{-i})$ is such that $\frac{\partial \bar{\alpha}}{\partial b_i}(\beta_i(B_{-i}) \vee B_{-i}) = 0$, i.e., $\beta_i(B_{-i})$ is the *marginal expected welfare* of bidding B_{-i}.

To use this approach the bidder has to choose an initial bid vector B_0 by some means, e.g., randomly. Let B_t be the bid after t iterations. B_{t+1} is obtained from B_t by sequentially improving bids for each of the N items in turn. While considering the improvement of the bid for an item, we keep the bids for other items constant in B_t. We call this $N-step$ perturbation an $N-sequential$ improvement and the algorithmic process a multi-dimensional bid improvement (MDBI) scheme. The process is stopped when $||B_{t+1} - B_t|| < \varepsilon$ where ε is a positive constant defined by the user and $||\cdot||$ is any vectorial norm.

To improve the bid for item i, we need to calculate β_i. The formula, however, requires exponential computation. It is possible to approximate β_i by price sampling. The following presents the pseudo-code to approximate β_i, where K is the number of price samples generated from the closing price distributions for all the items.

$\beta \leftarrow 0$
for $k = 1..K$ **do**
  $P \leftarrow \text{generatePriceSamples}(F_1, \ldots, F_N)$
  $\beta \leftarrow \beta + \left(\vartheta\left(\mathcal{I}_{ac}(\overline{p_i} \vee B_{-i}, P)\right) - \vartheta\left(\mathcal{I}_{ac}(\underline{p_i} \vee B_{-i}, P)\right)\right)$
end for
return $\frac{\beta}{K}$.

Three variants of MDBI are available: **Random Start Bid Improver (RSMDBI):** RSMDBI starts with a randomly chosen bid vector and does not use restarts. **Random Start Bid Improver With Restart (RSMDBIWRn):** RSMDBIWRn restarts the improvement process with random bid vectors $n-1$ times and outputs the bid vector with the highest expected utility. **Valuation Start Bid Improver (VSMDBI):** VSMDBI uses the initial bid $B_0 = (v_1, \ldots, v_N)$ where $v_i = \vartheta(\{i\})$ and does not use restarts.

The complexity of the approximation of $\beta_i(B_{-i})$ is linear given K, the number of samples. In MDBI, each N-sequential improvement requires N approximations of $\beta_i(B_{-i})$. The number of N-sequential improvements, $C(\varepsilon, N)$, correspond to the number of iterations of the improvement loop. Thus, the complexity of MDBI is $O(K\,N\,C(\varepsilon, N))$. Experimental results presented in Section 5 shows that the actual run-time complexity of MDBI is satisfactory.

5. EXPERIMENTAL RESULTS

Our experimentation goal is to compare the efficiency of different variants of the MDBI scheme with variants of MU bidding both in terms of the quality of the solution generated and time efficiency. To assess the absolute performances of these algorithms, we use an exhaustive search-based brute force algorithm (BF) which is asymptotically optimal

We ran our experiments in an environment containing four single-item single-unit auctions. All closing prices are drawn from selected discrete closing price distributions. A simulation consists of one bidder with the knowledge of all closing price distributions. A run of our experiment consists

of seven simulations, one for each of the bidders RSMDBI, RSMDBIWRn with n=5 or 10, VSMDBI, BF, $\overline{MU}$, EVMU. For a run, bidders in each simulation share the same valuation function. We generate four kinds of valuation functions: (a) SI, where items are substitutable, (b) CI, where items are complementary, (c) NRI, where items are non-related, and (d) RI, where valuations for bundles are random.

5.1 Quality of solutions generated by algorithms

We present the cumulative average profit of the bidders using each algorithm in Table 1. The algorithms are ordered by the profits they generate. Algorithms with no statistical performance difference are grouped together. To obtain such groupings, we consider the average profits obtained by our algorithms as random variables and use the Wilcoxon test to identify the significance of the difference in their values.

We highlight the following observations from Table 1: (1) RSMDBI performs similar to or better than previously known algorithms. (2) VSMDBI performs similar to RSMDBI except for RI valuations where performances are worse. (3) With few random restarts our algorithm always performs similar to BF which is asymptotically optimal. (4) RSMDBIWRn, $n = 5, 10$ has better performances than RSMDBI except for non-related items where performances are equal. (5) Every algorithm is optimal when items are non-related except EVMU, (6) EVMU performs better than $\overline{MU}$ except when items are non-related when its performance is worse.

5.2 Time efficiency of MDBI variants

We discussed the complexity of MDBI in Section 4.3. The expression of this complexity contains an unknown function $C(\varepsilon, N)$. We wanted to find out the complexity of MDBI variants in practice. We run experiments using the RSMDBI and VSMDBI by varying the number of items, N. The time complexity of VSMDBI and RSMDBI appears to be linear in N. Since the complexity of MDBI is equal to $O(K\,N\,C(\varepsilon,\,N))$, $C(\varepsilon,\,N)$ is constant for VSMDBI given N. We also collected the average value of $C(\varepsilon,\,N)$ from our experiments and can highlight the following observations: (1) Except for non-related items, the number of N-sequential improvements ($C(\varepsilon,\,N)$) increases very slowly. The largest range is [2, 4], (2) The number of N-sequential improvements is always better for VSMDBI, (3) $C(\varepsilon,\,N) = 1$ for VSMDBI and $C(\varepsilon,\,N) = 2$ for RSMDBI when items are non-related.

6. CONCLUSION

We compared the performance of an optimization based bidding algorithm for obtaining bundles of items in simultaneous auctions, MDBI, that we have recently developed with existing algorithms from literature. We discuss variants of the basic iterative bid-improvement algorithm: an approach with finite number of restarts and one with no restarts but a carefully chosen starting bid vector. Performance similar to or better than existing algorithms in literature, $\overline{MU}$ and EVMU, is achieved without restarts when items are substitutable, complementary or non-related. We additionally observe that a small number of restarts can be used to approximate optimal expected utility.

Another strong point of the MDBI variants is their polynomial time complexities whereas existing algorithms have exponential complexity. While exact calculation of bid improvement needs combinatorial number of operations, we approximate such calculations in linear time by a constant number of price samples. We are currently working on formally characterizing the process and the properties of the MDBI algorithms.

ABSTRACT

Current computational trust models are usually built either on an agent's direct experience of an interaction partner (interaction trust) or reports provided by third parties about their experiences with a partner (witness reputation). However, both of these approaches have their limitations. Models using direct experience often result in poor performance until an agent has had a sufficient number of interactions to build up a reliable picture of a particular partner and witness reports rely on self-interested agents being willing to freely share their experience. To this end, this paper presents *Certified Reputation* (CR), a novel model of trust that can overcome these limitations. Specifically, CR works by allowing agents to actively provide third-party references about their previous performance as a means of building up the trust in them of their potential interaction partners. By so doing, trust relationships can quickly be established with very little cost to the involved parties. Here we empirically evaluate CR and show that it helps agents pick better interaction partners more quickly than models that do not incorporate this form of trust.

1. INTRODUCTION

A wide variety of networked computer systems (such as the Grid, the Semantic Web, and peer-to-peer systems) can be viewed as multi-agent systems (MAS) in which the individual components act in an autonomous and flexible manner in order to achieve their objectives. An important class of these systems are those that are *open*; here defined as systems in which agents can freely join and leave at any time and where the agents are owned by various stakeholders with different aims and objectives. From these two features, it can be assumed that in an open MAS: (1) the agents are likely to be self-interested and may not always complete tasks that are requested of them; (2) no agent can know everything about its environment; and (3) no central authority can control all the agents. Given such uncertainties, trust is central to effective interactions between the agents [7]. Indeed, this recognition accounts for the large number of computational models of trust (here defined as the subjective probability with which an agent a assesses that another agent b will perform a particular action, both before a can monitor such action and in a context in which it affects its own action [2]) that help agents to determine the most reliable interaction partner (see Section 4 for more details).

Although there are many differences in the way these models are implemented, the majority of them are built on an agent's direct experience of an interaction partner (interaction trust) or reports provided by third parties about their experiences with a partner (witness reputation). However, both these approaches have their shortcomings. First, when an agent first enters an environment, it has no history of interactions (with the other agents in that environment). In such circumstances, if its trust model is based solely on direct experience, it would need to explore the environment by interacting with other agents to learn about their performance. However, in so doing, the agent also inevitably risks making losses if it encounters unreliable partners. Moreover, because it can learn about only one agent per interaction, trust models using direct experience typically require a long time to be able to achieve stable performance. Second, models based on witness reports usually implicitly assume the altruism of agents in sharing their experiences. Now, this cannot be guaranteed in all cases because self-interested agents are unlikely to be willing to sacrifice their resources in order to provide witness reports. Moreover, in the distributed and open environments we consider, the required witnesses for any given agent can be difficult to locate. This is usually addressed by using some form of centralised mechanism to collect all the witness reports [13] or implementing a distributed search process to look for witnesses in an agent's social network [12]. However, the former is not compatible with an open MAS since agents representing different owners may well question the trustworthiness of a central authority and the latter may well involve high costs of time

and resources to locate witnesses.

Against this background, in this paper we present a novel type of trust called *certified reputation* (CR) whose mechanism overcomes the limitations of current trust models described above. Hence, CR can be used complementarily to other sources of trust information (e.g. direct experience, witness reports) to build a versatile composite trust model (which benefits from all the advantages of its components). In more detail, the CR of an agent is the reputation that is derived from third-party references about its previous performance. Agents that adopt the CR mechanism will actively collect and present such references in order to seek the trust of their potential partners. This, in turn, moves the burden of obtaining and maintaining trust information from the trust evaluator to the agent being evaluated (who is incentivised to do so)[1]. Hence, trust information (references) about a particular agent becomes available to those who want to interact with it. Moreover, agents using CR have neither to interact first with the agent being evaluated (as they do with direct experience), nor to locate its witnesses (as they do with witness reports). The potential downside, however, is that third-party references might not be reliable (since referees can collude with particular agents by providing falsely inflated references for them and negative ones for the others). Now, this is an inherent problem of using any type of third-party information and so it is important to be able to evaluate the credibility of a referee and to use this to weigh its information. To this end, we also develop such a model that records the history of a referee's performance in terms of providing accurate references (by comparing an agent's actual observations with the references it receives). Such histories of referees are then used to derive their credibility.

In so doing, we advance the state of the art in the following ways. First, we develop a new process of obtaining information for trust evaluation. This process addresses the inherent shortcomings of interaction trust (the lack of direct experience) and witness reputation (the difficulty in finding witness reports). Second, as CR allows agents to be able to evaluate trust themselves, without relying on a central mechanism, it is compatible with a wide range of open and distributed environments. Third, from empirical evaluation, it is shown that using CR improves an agent's utility gain by helping it to quickly pick good interaction partners. Finally, it is shown that our model is robust against various types of collusion.

The rest of the paper is organised as follows. Section 2 presents our model of certified reputation. This model is then empirically evaluated in Section 3. Section 4 presents related work and Section 5 concludes.

2. CERTIFIED REPUTATION

A trust model is typically used by an agent, say agent a, to evaluate the trustworthiness of another agent, say agent b, when it considers establishing an interaction with b. In this case, we call a the *evaluator* and b the *target*. Now, most trust evaluation is based on past experience of the target agent's performance. Such experience is here recorded in the form of *ratings* which are tuples of the following form: $r = (a, b, i, c, v)$, where a and b are the agents that participated in interaction i, and v is the rating a gave b for the term c. For instance, the quality of a news provider can be rated in terms of topicality, quality, and honesty. Here, the range of v is $[-1, +1]$, where -1, $+1$, and 0 means absolutely negative, absolutely positive, and neutral respectively. Each agent has a local *rating store* to collect the ratings it makes and the ones that it receives from others. Since ratings are context-dependent (described in the rating terms), each trust evaluation is also about a specific term. Here, we use $\mathcal{T}(a, b, c)$ to denote the trustworthiness of b in terms of c that is evaluated by a. In order to make such a trust evaluation, a needs to obtain a set of relevant ratings. We call this set $\mathcal{R}(a, b, c)$.

Now, having defined the basic notions, we turn to the CR model itself. The mechanism of CR is given in Section 2.1, which also describes how CR is calculated. Then Section 2.2 shows how the credibility of referees is evaluated.

2.1 The Mechanism of Certified Reputation

Certified reputation of a target agent b consists of a number of certified references[2] about its behaviour on particular tasks that are provided by third-party agents. Such information is obtained and stored by the target agent itself and made available to any other agent that wishes to evaluate its trustworthiness for further interactions (somewhat like a reference when a person is applying for a job). The agents giving references are called the *referees*. Here, references are in the form of ratings given by b's partners about its performance in (past) interactions between them. These ratings allow b to prove its (achievable) performance as viewed by its previous interaction partners and then to gain the trust of its potential partners. However, since b can choose which ratings to put forward, a rational agent will only present its best ones. Therefore, it should be assumed that CR information probably overestimates an agent's expected behaviour. Thus, although it cannot guarantee b's minimal performance in future interactions, the CR information does reveal a partial perspective on agent b's capabilities (which is certainly useful for trust evaluation in the absence of other sources of information).

Though CR may have lower predictive power than the other types of trust/reputation (where all bad and good ratings can be collected), it is useful because of its wide applicability. With the cooperation of its partners, agent b can obtain their references from just a small number of interactions[3]. From our evaluation, for instance, in a society where 100 agents provide a service to 500 others, agents using direct experience to evaluate trust require more than 100 interactions to achieve a reasonable level of utility gain,

[1]It can reasonably be assumed that agents want to have more interactions because of their potential utility gain. Hence, agents have incentives to provide trust information about themselves so that they can gain the trust of other agents which, in turn, will facilitate more interactions.

[2]It is assumed that some form of security mechanism (such as a public-key infrastructure) is employed to ensure that the provided references cannot be tampered with. For instance, all references could be accompanied by digital signatures from the issuers using their private keys [14]. By so doing, any change to a reference will be easily detected. Digital signatures are also a means to verify the references' origins.

[3]In many scenarios, such as those in the Internet, established service providers (e.g. news service, online merchants) usually have high volumes of interactions (at any time). Therefore, if they adopt the CR process outlined here, we can reasonably expect that such providers will have an abundance of performance ratings readily available.

which is still less than that achieved by agents using CR after 5 interactions (see Section 3 for more detail). In addition to its high availability, since references are stored by the target agent and provided directly to the evaluator, CR has a very low running cost (i.e. time, communication, processing cost) compared to sources like witness reputation.

In more detail, the process of CR is as follows:

- After every transaction, agent b asks its partners to provide their certified ratings about its performance from which it can choose the best ratings to store in its (local) rating store.
- When agent a contacts b to express its interest in using b's service, it asks b to provide references about its past performance with respect to an interested term c.
- Agent a receives the set of certified ratings of b from b, which we call $\mathcal{R}_{\mathsf{C}}(a,b,c)$ (C to denote this set is obtained via the CR mechanism), and calculates the CR of b based on this set.

In this process, since agent b relies on its interaction partner's cooperation to get references, agents may refuse to give out their ratings (as in the case of witness reputation). However, this is a much smaller problem than that in witness reputation because this information is requested far less frequently (each referee is requested to give its rating only once). Moreover, giving such information could be made a standard part of any agreement for task allocation and so agents could be forced to give it. The most notable point in this process is that when agent a makes the trust evaluation, it only involves agents a and b. Since the certified ratings about b are stored by b itself, they are immediately available to a as in the case when a uses its own experience.

Having obtained the references of b, a can estimate b's future behaviour, or more specifically, the expected rating value b is likely to receive in a future interaction. A common way to estimate that value is to calculate it as the arithmetic mean of all the rating values in the set. However, these ratings are usually not equally relevant when estimating the expected rating value. For example, some ratings may be older than others and, thus, may be out-of-date; and some may come from a more reliable source that suggests a higher level of credibility compared to others. Therefore, like many contemporary models [8, 10, 12], we use a *rating weight function* $\omega_{\mathsf{C}}(r_i)$ ($\omega_{\mathsf{C}}(r_i) \geq 0$) which calculates the relevance of each given certified rating r_i. Then, instead of considering all ratings equally, the trust value is calculated as the weighted mean of all the ratings available[4]:

$$\mathcal{T}_{\mathsf{C}}(a,b,c) = \frac{\sum_{r_i \in \mathcal{R}_{\mathsf{C}}(a,b,c)} \omega_{\mathsf{C}}(r_i) \cdot v_i}{\sum_{r_i \in \mathcal{R}_{\mathsf{C}}(a,b,c)} \omega_{\mathsf{C}}(r_i)} \quad (1)$$

where $\mathcal{T}_{\mathsf{C}}(a,b,c)$ is the CR value of b that agent a calculates with respect to term c, which is calculated from the rating set $\mathcal{R}_{\mathsf{C}}(a,b,c)$, and v_i is the value of the rating r_i. In short, the CR value is calculated as the sum of all the available ratings weighted by the rating relevance and normalised to the range of $[-1,1]$ (by dividing the sum by the sum of all the weights).

Now, we need to determine the relevancy of a given rating ($\omega_{\mathsf{C}}(r_i)$). Since an agent's environment may change rapidly, resulting in out-of-date ratings, we use the recency of ratings as one measure of their relevance. Specifically, the recency relevance of a rating r_i is calculated by an exponential decay function based on its recency [5]:

$$\omega_{\mathsf{Re}}(r_i) = e^{-\frac{\Delta t(r_i)}{\lambda}} \quad (2)$$

where $\omega_{\mathsf{Re}}(r_i)$ is the relevance value for the rating r_i in terms of recency, $\Delta t(r_i)$ is the time difference between the current time and the time when the rating r_i is recorded, and λ is the recency factor which is used to scale $\Delta t(r_i)$ according to a particular application's time unit.

As certified ratings are digitally signed, their authenticity can be verified and their content cannot be tampered with. However, since there is no guarantee about the honesty of agents in an open MAS, a referee can still collude with the target agent and provide falsely inflated references about its performance. Moreover, even if the referee is honest in providing references, its references can be inaccurate (either because of its incapability of making accurate ratings or because it has a different view to that of the evaluator). In either case, these inaccurate references will result in inaccurate CR values. Therefore, we need measures to prevent or to minimise the adverse effects of such references. To this end, we use the credibility of referees as another measure of rating relevance. In more detail, for a reference r_i from referee w, w's credibility value is calculated by a (called $\mathcal{T}_{\mathsf{RCr}}(a,w) \in [-1,1]$, RCr denotes referee credibility). Then, the relevance of r_i in terms of referee credibility (denoted by $\omega_{\mathsf{RCr}}(r_i)$) is defined as follows:

$$\omega_{\mathsf{RCr}}(r_i) = \begin{cases} 0 & \text{if } \mathcal{T}_{\mathsf{RCr}}(a,w) \leq 0 \\ \mathcal{T}_{\mathsf{RCr}}(a,w) & \text{otherwise} \end{cases} \quad (3)$$

Both the above measures of rating relevancy are then taken into account in weighing a rating:

$$\omega_{\mathsf{C}}(r_i) = \omega_{\mathsf{RCr}}(r_i) \cdot \omega_{\mathsf{Re}}(r_i) \quad (4)$$

It should be noted that, from Equations 3 and 4, references whose referees have negative credibility are discarded (by setting $\omega_{\mathsf{C}}(r_i) = 0$). Only references whose referees have positive credibility are taken into account when calculating CR. In such cases, they are weighted both by their referees' credibility and by their recency. In so doing, ratings from the more credible referees make a bigger impact on the CR value than those from the less credible ones. In cases where all the certified ratings collected are disregarded, due to negative credibility of their providers, no trust value will be produced. In such circumstances, agent a can give b a default low trust value (e.g. -0.5) because b fails to provide reliable references. Otherwise, agent a can re-request b for more reliable references.

2.2 Referee Credibility

The credibility of a referee in reporting its ratings about another agent can be derived from a number of sources. These include knowledge about: the relationships between the referee and the rated agent (e.g. cooperating partners may exaggerate each other's performance, competing agents may underrate their opponents, no relationship may imply impartial ratings); the reputation of the referee for being honest and expert in the field in which it is doing the rating (e.g. a reputable and independent financial consultant should provide fair ratings about the services of various banks); the relationships between the referee and the querying agent (e.g.

[4]We choose the weighted mean method here because it allows us to take the relevance of each rating into account. Other aggregation methods could equally well be used if desired.

agents with the same owner should provide honest reports to one another); and so on. Unfortunately, however, such types of knowledge are very application specific and may not be readily available in many cases. Therefore, although they could certainly be used to enhance the precision of a referee credibility measure, they are not suitable as a generic basis (although they could complement a generic measure in particular contexts). Therefore, here, we base our solution on a modified version of the witness credibility model we devised for evaluating witness reputation in [4] to assess a referee's credibility. We choose this model because it does not require such domain-specific information about relationships and because providing witness reports and references are of the same broad nature. Specifically, in this model, we view providing references as a service an agent provides. Thus its performance (i.e. trustworthiness and reliability) can be evaluated and predicted by a trust model. By so doing, the credibility model can benefit from a trust model's ability of learning and predicting an agent's behaviour (in this case, the behaviour of providing accurate reports) without having to implement its own method.

In more detail, after having an interaction with agent b, agent a records its rating about b's performance, denoted by r_a ($r_a = (a, b, i_a, c, v_a)$). Now, if agent a received a reference (i.e. a certified rating) from agent w, it then rates the credibility of w by comparing the actual performance of b (i.e. v_a) with w's rating about b. The smaller the difference between the two rating values, the higher agent w is rated in terms of providing accurate references (mutatis mutandis for bigger differences). For each certified rating that a received from w in evaluating the CR of b (denoted by $r_k = (w, b, i_k, c, v_k)$), the credibility rating value v_w for agent w is given in the following formula:

$$v_w = \begin{cases} 1 - |v_k - v_a| & \text{if } |v_k - v_a| < \iota \\ -1 & \text{if } |v_k - v_a| \geq \iota \end{cases} \quad (5)$$

where ι is called the *inaccuracy tolerance threshold* ($0 \leq \iota \leq 2$, 2 is the maximal difference since $v_k, v_a \in [-1, 1]$). Thus if the difference between a certified rating value and the actual performance is higher than ι, the referee is considered to be inaccurate or lying, and, therefore, receives a negative rating of -1 for its credibility. On the other hand, if the difference is within the tolerance threshold, it can be viewed as resulting from a subjective viewpoint and is deemed acceptable. In this case, the credibility rating value v_w is set to be inversely varied to the difference (e.g. higher difference, lower credibility). Since $0 \leq |v_n - v_a| \leq 2$, v_w is also in the range $[-1, 1]$ regardless of ι. The rating about w's credibility — $r_w = (a, w, i_w, \text{term}_{\mathsf{RCr}}, v_w)$ — is then recorded by a, where $\text{term}_{\mathsf{RCr}}$ is the rating term for performance in providing references and i_w is the interaction of agent w providing agent a the certified rating r_k about agent b.

Having recorded ratings about w's performance on providing references, a can evaluate w's credibility based on those ratings. As mentioned above, a can use its own trust model for so doing. Specifically, here we calculate a's trust on w's capability of providing accurate references similarly as per CR (Equation 1), except that we use only ratings retrieved from a's ratings store (instead of obtaining them via the CR mechanism) and weigh the ratings only by their recency[5] (Equation 2). This type of trust is here called interaction trust (IT) since it is based solely on a's direct experience from its interactions. The IT value of a on b in terms of c is denoted by $\mathcal{T}_{\mathsf{I}}(a, b, c)$ and is calculated as follows:

$$\mathcal{T}_{\mathsf{I}}(a, b, c) = \frac{\sum_{r_i \in \mathcal{R}_{\mathsf{I}}(a,b,c)} \omega_{\mathsf{I}}(r_i) \cdot v_i}{\sum_{r_i \in \mathcal{R}_{\mathsf{I}}(a,b,c)} \omega_{\mathsf{I}}(r_i)} \quad (6)$$

where $\omega_{\mathsf{I}}(r_i)$ is the rating weight of r_i and $\omega_{\mathsf{I}}(r_i) = \omega_{\mathsf{Re}}(r_i)$. Then, in order to determine the referee credibility of w ($\mathcal{T}_{\mathsf{RCr}}(a, w)$), we need to calculate $\mathcal{T}_{\mathsf{I}}(a, b, \text{term}_{\mathsf{RCr}})$. This is calculated from the set of $\text{term}_{\mathsf{RCr}}$ ratings — $\mathcal{R}_{\mathsf{I}}(a, b, \text{term}_{\mathsf{RCr}})$. However, if no such rating has been recorded, and, thus, the IT value is not available, we assign w the default referee credibility trust value, denoted by $\mathcal{T}_{\mathsf{DRCr}}$:

$$\mathcal{T}_{\mathsf{RCr}}(a, w) = \begin{cases} \mathcal{T}_{\mathsf{I}}(a, w, \text{term}_{\mathsf{RCr}}) & \text{if } \mathcal{R}_{\mathsf{I}}(a, w, \text{term}_{\mathsf{RCr}}) \neq \emptyset \\ \mathcal{T}_{\mathsf{DRCr}} & \text{otherwise} \end{cases} \quad (7)$$

It should be noted here that, at first, every referee receives the default credibility value since it has not provided references to agent a before. Hence, end users can set the value of $\mathcal{T}_{\mathsf{DRCr}}$ to reflect their policy towards newly encountered referees. For example, $\mathcal{T}_{\mathsf{DRCr}}$ can be set to 0 so that newly encountered referees are disregarded until they prove to be credible (by providing ratings in the acceptable accuracy threshold) or it can be set to 1 so that all referees are considered to be accurate and honest until proven otherwise.

3. EMPIRICAL EVALUATION

In order to empirical evaluate our CR model, we use the testbed designed in [5] with a few changes. In more detail, in order to verify our intuitions about CR, it will be evaluated in ideal (honest) environments where agents do not collude with each other (Section 3.3). It will then be evaluated in (biased) environments where colluding agents give high ratings to each other (Section 3.4) to determine its robustness for open multi-agent contexts. Before doing this, however, a brief description of the testbed is given in Section 3.1 (see [5] for a complete description and for justifications of the choices we made in it) and Section 3.2 presents the methodology and experimental settings for our experiments.

3.1 The Testbed

The testbed is a multi-agent system consisting of agents providing services (called *providers*) and agents using those services (called *consumers*). Without loss of generality, it is assumed that there is only one type of service in the testbed. Hence, all the provider agents offer the same service. However, their performance (i.e. the quality of the service) differs. The agents are situated randomly on a spherical world whose radius is 1.0. Each agent has a *radius of operation* r_o that models its capability in interacting with others (e.g. the available bandwidth or the agent's infrastructure). In addition, each consumer agent has a maximum number of friend providers (N_{FP}) that it may collude with when providing references about their performance. Such providers are selected randomly from a consumer's nearby providers when it enters the testbed.

Simulations are run in the testbed in rounds (of agent interactions), and the round number is used as the time unit. In each round, if a consumer agent needs to use the service it can contact the environment to locate nearby provider agents (in terms of the distance between the agents on the

[5]Since a makes the ratings itself, weighing them in terms of referee credibility is irrelevant.

spherical world). The consumer agent will then select one provider from the list to use its service. The selection process relies on the agent's trust model to decide which provider is likely to be the most reliable. Consumer agents without a trust model randomly select a provider from the list. The consumer agent then uses the service of the selected provider and gains some utility from the interaction (called UG). The value of UG is in $[-10, 10]$ and depends on the level of performance of the provider in that interaction. A provider agent can serve many consumers at a time.

After an interaction, the consumer agent will rate the service of the provider based on the level of performance it received and provide the rating to the provider to be potentially used as a reference. A provider will select $\mathsf{N_R}$ best references from those that it receives to store and to present when requested. Since a provider knows very old references are unlikely to be valued highly by its consumers, when selecting references to store, it takes into account both a reference's rating value (i.e. saying how well the provider performed) and the time when that reference is made. In particular, when comparing two references r_1 and r_2, the value of r_1 is biased by an amount of $\frac{t_1 - t_2}{\mathsf{TIMESCALE}}$, where t_i is the time that reference r_i is given, and TIMESCALE is selected to be 20.0 given the time unit used in the testbed[6].

In addition, since a referee may make biased references, we model this phenomenon by introducing five types of referees. Agents in the Hon group always give out their actual ratings as references. *Exaggerating referees* in groups Exag1 and Exag2, however, give falsely higher ratings than those they actually recorded for their friend providers[7] (and their actual ratings for the others). In addition to giving falsely inflated references for their friends, *extreme referees* in Extr1 and Extr2 also deliberately underrate the other providers. The difference between an actual rating value and its inaccurate one in Exag1 and Extr1 is randomly set in the range $[0.3, 1.0]$ (i.e. representing marginally inaccurate referees) and the respective range of Exag2 and Extr2 is $[1.0, 2.0]$ (i.e. representing extremely inaccurate referees).

In our testbed, the only difference in each interaction situation is the performance of the provider agents. Here, we consider four types of providers: good, ordinary, bad, and intermittent. Each of them, except the last, has a mean level of performance, denoted by μ_P. Its actual performance follows a normal distribution around this mean. The values of μ_P and the associated standard deviation (σ_P) of these types of providers are given in Table 1. Intermittent providers, on the other hand, yield unpredictable (random) performance levels in the range [PL_BAD, PL_GOOD]. In addition, the service quality of a provider is also degraded linearly in proportion to the distance between it and the consumer to reflect the greater uncertainties associated with service delivery (e.g. lower service quality resulting from increased delays or losses in information exchanges between two agents when they are far away from each other). Hence, from the same provider, each consumer may receive a different level of service quality depending on its location. This means honest ratings about that provider's performance by its consumers can be different; reflecting the phenomenon that every agent has its own context making its own view different.

Profile	Range of μ_P	σ_P
Good	[PL_GOOD, PL_PERFECT]	1.0
Ordinary	[PL_OK, PL_GOOD]	2.0
Bad	[PL_WORST, PL_OK]	2.0

Performance level	Utility gained
PL_PERFECT	10
PL_GOOD	5
PL_OK	0
PL_BAD	−5
PL_WORST	−10

Table 1: Profiles of provider agents.

3.2 Experimental Methodology

In each experiment, the testbed is populated with provider and consumer agents. Each consumer is equipped with a particular trust model, which helps it select a provider when it needs to use a service. Since the only difference among consumer agents is the trust models that they use, the utility gained (UG) by each agent reflects the performance of its trust model in selecting reliable providers for interactions. Hence, the testbed records the UG of each interaction along with the trust model used. In order to obtain an accurate result for performance comparisons between trust models, each one will be employed by a large number of consumer agents ($\mathsf{N_C}$). In addition, the average UG of agents employing the same trust models (called consumer groups) are compared with each other's using the two-sample t-test [1] (for means comparison) with a confidence level of 95%. The result of an experiment is then presented in a graph with two y-axes (see Fig. 1 for an example); the first plots the UG means of consumer groups in each interaction and the second plots the corresponding performance rankings obtained from the t-test (prefixed by "R.", where the group of rank 2 outperforms that of rank 1). The experimental variables are presented in Table 2 and these will be used in all experiments unless otherwise specified.

Simulation variable	Symbol	Value
Number of simulation rounds	N	500
Total number of provider agents:	$\mathsf{N_P}$	100
+ Good providers	$\mathsf{N_{PG}}$	10
+ Ordinary providers	$\mathsf{N_{PO}}$	40
+ Bad providers	$\mathsf{N_{PB}}$	45
+ Intermittent providers	$\mathsf{N_{PI}}$	5
Number of consumers in each group	$\mathsf{N_C}$	500
Max. number of friend providers	$\mathsf{N_{FP}}$	4

Table 2: Experimental variables.

Now, in each experiment, we include several groups of consumers in order to compare their performance. These include one group employing CR, one employing the SPORAS model[8] (see Section 4 for details), one employing IT[9],

[6]This is obviously just one way of comparing two references but it is a way that is effective in our system. If we wanted to make rating recency less relevant then we could make TIMESCALE smaller, or if we wanted to make rating recency more relevant then we could make it bigger.

[7]This is motivated by examples where referees provided exaggerated reports about their friends.

[8]SPORAS is chosen as the control benchmark because it is a successful, independently developed trust model which several other researchers have used for benchmarking.

[9]IT is defined in Equation 6. It is calculated from a con-

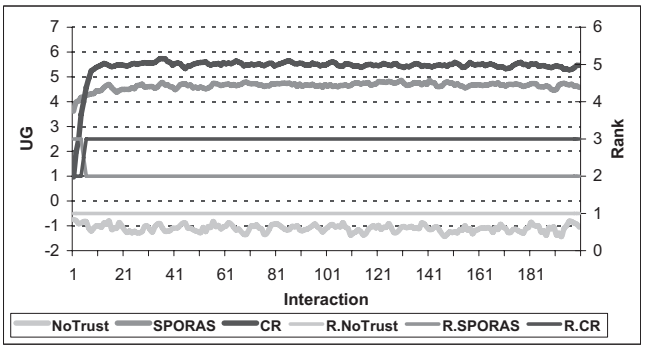

Figure 1: Performance of CR vs SPORAS and NoTrust.

and one consisting of agents with no trust model. We name these groups CR, SPORAS, IT and NoTrust. A summary of the parameters of CR is provided in Table 3. The recency factor λ is selected such that a 5-time-unit-old rating will have a recency weight of 0.5 (to suit the time unit used in the testbed). The default referee credibility $\mathcal{T}_{\mathsf{DRCr}}$ is set to 0.5 so that all ratings from newly encountered referees will be taken into account in calculating CR, but their weights are smaller than those of any proven accurate referee (which are typically greater than $\iota = 0.5$, see Equation 7) and larger than that of a proven inaccurate one (which is typically negative). The value of ι is handpicked based on the actual variability of honest rating values in the testbed (which never exceeds 0.5).

Parameters	Symbol	Value
Recency factor	λ	$-\frac{5}{\ln(0.5)}$
Number of stored references	$\mathsf{N_R}$	10
Referee credibility parameters:		
+ Default referee credibility	$\mathcal{T}_{\mathsf{DRCr}}$	0.5
+ Inaccuracy tolerance threshold	ι	0.5

Table 3: CR's parameters.

3.3 Honest Environments

Having defined the testbed and the evaluation methodology, we now turn to the experiments themselves. The first thing to test is whether CR helps consumer agents select profitable providers (i.e. those yielding positive UG) from the population and, by so doing, helps them gain better utility than without using CR. Hence, in this experiment we evaluate the performance of CR against that of NoTrust. SPORAS is also included in this experiment to compare the performance of CR with that of an independent benchmark that does not use CR. Here, Fig. 1 shows that the NoTrust group, selecting providers randomly without any trust evaluation, performs consistently the lowest (as we would expect). On the other hand, both SPORAS and CR prove to be beneficial to consumer agents, helping them obtain significantly high UG. This shows that the tested trust models can learn about the provider population and allow their agents to select profitable providers for interactions. In particular, SPORAS, being a centralised service, is able to gather ratings about all interactions in the system. This allows agents using it to achieve high performance right from the first interactions.

sumer's ratings about a provider's performance which that consumer collects in its rating store after every interaction.

In contrast, since each provider only shows a small number of ratings to agents using CR, they spend the first few interactions learning about their environment. Hence their initially lower performance than that of SPORAS. However, agents using CR quickly catch up with those in SPORAS (after 5 interactions) and they then maintain a higher stable performance thereafter (after the first 5 interactions, the average UG per interaction of SPORAS and CR are 4.65 and 5.48, respectively). The t-test also confirms that this difference is statistically significant as the ranks of SPORAS and CR switch after the first 5 interactions. Here, it should be noted that consumers may have different views on the same provider's performance because of the different distances between them and the provider (see Section 3.1). Therefore, although all the agents are honest, their ratings about that provider can be different due to their particular experience. Now, SPORAS takes all ratings equally and, thus, such differences are merely noise to it. This is the main reason that limits its performance. In contrast, the referee credibility model of CR compares each referee's ratings with an agent's own ratings and gives higher weights to those referees that have similar views to it. By so doing, the relevancy of each rating is determined and taken into account in calculating CR, making it more accurate than SPORAS.

Having shown that CR can outperform a centralised trust model based on witness reports, we now test CR against IT, which uses an agent's direct experience. Here, there are two groups of consumer agents, IT and CR, using IT and CR, respectively, as their trust models. The t-test results in Fig. 2 shows that CR outperforms IT in all interactions. The chart also shows that while it only takes agents using CR 5 interactions to achieve a stable level of performance, agents using IT need more than 100 interactions to obtain a reasonably stable level of performance. This is clearly because agents in IT do not have adequate ratings to quickly learn about their environment (i.e. the performance of providers). Moreover, even the maximum UG of IT (4.85) is lower than the average UG of CR (around 6.0). The reason is that agents using IT can miss identifying the best providers because ratings about them are less available than in the case of CR and because agents in our testbed will stick to choosing the highest trusted provider after a period of learning about the environment[10] (resulting in locally sub-optimal provider selections). Meanwhile, agents using CR always receive the most recent and the best references that are actively presented by providers. Moreover, the high availability of these references helps CR greatly increase its learning speed and, thus, avoid the problems associated with IT.

In summary, we have shown that in honest environments, CR provides a robust trust measure that is also highly available. However, we now go onto consider the more realistic situations in which collusion can occur.

3.4 Biased Environments

In this section, we evaluate CR in a wider range of environments. In particular, the consumers in each experiment consist of honest referees and those from one of the four colluding referee groups (Exag1, Exag2, Extr1, and Extr2 — see Section 3.1). For example, Fig. 3 presents the result from the experiment where the consumers consist of 20% honest referees and 80% colluding referees from the Extr2 group.

[10]Agents in our testbed use a Boltzmann exploration strategy to explore (i.e. try the service of) unknown providers.

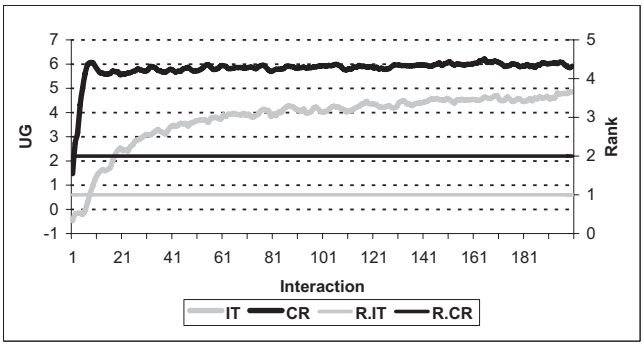

Figure 2: Performance of CR vs IT.

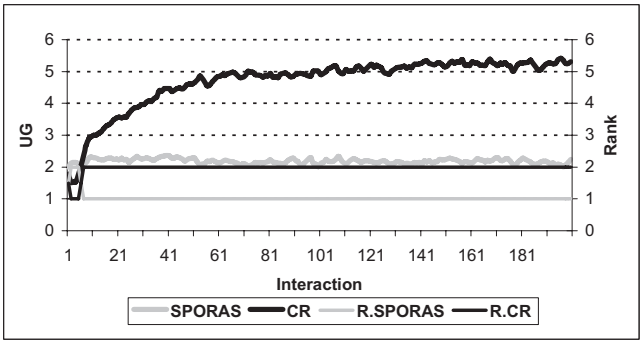

Figure 3: 80% Extr2 referees.

Since NoTrust performs consistently poorly in all the experiments, its results are omitted from our charts for the sake of simplicity. Moreover, because of space constraints, we cannot provide a detailed result of every experiment as in Fig. 3. Instead, we plot the average UG per interaction of SPORAS and CR in each experiment on the summary charts in Figs. 4 and 5. In these charts, the plots are named as GroupName.RefereeType. For example, SPORAS.Extr1 is the plot for the average UG of agents in the SPORAS group when the colluding referees in the testbed are of type Extr1.

The first thing these charts show is that collusion adversely affects the performance of trust models (as we would expect). For instance, Fig. 3 shows that it takes longer for CR to reach a stable level of performance (i.e. to learn about the colluding agents) and this performance is also lower than that in an honest environment. In such circumstances, SPORAS also yields a low UG and, without a credibility model, it cannot improve its performance over time. We can also see that the average performance of both SPORAS and CR generally decreases when the number of colluding agents increases (Figs. 4 and 5). However, CR always outperforms SPORAS except in the case when 100% of the consumers are Extr2 agents. In this particular experiment, since all consumers are identified by CR as lying (because all of them provide highly distorted references for all the providers), CR stops using their references, thus, depressing performance. However, this particular case (i.e. 100% extreme collusion) is highly unlikely to happen in practice (and if it did one might just retract trust from the population altogether). In the remaining experiments, CR can easily detect referees providing highly distorted references and maintain a generally high performance (see plots CR.Exag2 and CR.Extr2). CR is less effective in filtering out the colluding agents in

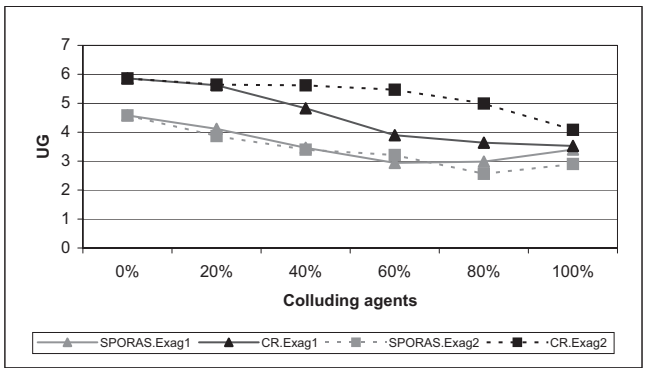

Figure 4: Performance with exaggerating referees.

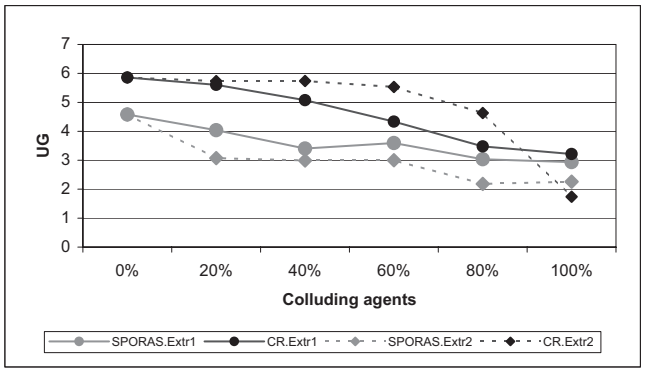

Figure 5: Performance with extreme referees.

Exag1 and Extr1 since their colluded references are less distorted than in the case of Exag2 and Extr2 (i.e. more difficult to detect lying). This suggests that the inaccuracy tolerance threshold ι should be carefully selected to reflect the nature of biased behaviours in a particular environment, or better, learning techniques could be used to enable an agent to adjust this parameter according to the prevailing context.

In sum, this section shows that the credibility model of CR enables it to outperform SPORAS in dealing with biased behaviours. Specifically, it allows agents using CR to maintain a robust and high performance in a variety of cases, especially when the level of collusion is less than 50% (which is, in our opinion, the most likely case in realistic scenarios).

4. RELATED WORK

Many trust and reputation models have been devised in recent years due to the increasing recognition of their roles in controlling social order in open systems [7]. SPORAS [13] is one of the most notable of these models. In this model, each agent rates its partner after an interaction and reports its ratings to the centralised SPORAS repository. The received ratings are then used to update the global reputation values of the rated agents. The model uses a learning function for the updating process so that the reputation value can closely reflect an agent's performance. In addition, it also introduces a reliability measure based on the standard deviations of the rating values. However, it has been designed without considering the problem of inaccurate reports and so it suffers disproportionately when false information is collected (as shown in Section 3).

Speaking more generally, as many trust models are built

on witness reports, the problem of disinformation has come to the fore in several recent works on trust. Regret [8] models a witness' credibility based on the difference between that witness' opinion and an agent's past experience. This differs to our approach in that it depends on the availability of an agent's past experience. Moreover, this approach cannot deal with the situations where the target agent's behaviour changes since it does not take the new behaviour into account in its witness credibility assessment. Thus, it can falsely punish honest witnesses (who report the target agent's new behaviour). In Whitby et al.'s system [11], the "true" rating of an agent is defined by the majority's opinions. In particular, they model the performance of an agent as a beta probability density function (PDF) which is aggregated from all witness ratings received. Then a witness is considered unreliable and filtered out when the reputation derived from its ratings is judged to be too different from the majority's (by comparing the reputation value with the PDF). Due to the dependency on PDFs of witness reports, if these reports are scarce and/or too diverse it is not able to recognise lying witnesses. Moreover, it is possible that a witness can lie in a small proportion of their reports without being detected. In addition, isolated honest opinions (i.e. different than that of the majority) can be falsely punished. To rectify this, TRAVOS uses an approach that is similar to ours [10]. However, as it uses beta PDFs for representing trust derived from binary outcomes (i.e. 0 for 'failed', 1 for 'success'), it is not suitable for our CR model because we require a more fine-grained and continuous range for trust values. In our earlier work [5], we presented a preliminary model of CR. However, this model could not cope with collusion and did not take the variance of referees situations (see Section 3.3) into account.

The mechanism of CR has similarities to trust policy management engines such as PolicyMaker [3] and Trust-Serv [9]. These engines grant rights (i.e. trust) to an agent based on its certificates of its identity according to predefined policies (i.e. rules, such as 'if a is a registered user and it possesses a valid credit card then it can book flights'). However, these engines are designed to determine the access rights of agents, rather than to determine the expected performance of these agents (i.e. how the agents behave after they can access a particular service). Similarly, the PGP web of trust model [14] allows a person to prove the authenticity of his public key by others' digital signatures, but not that person's behaviour. Certified ratings are also similar to the concept of endorsements in [6] — certificates endorsing that a service (provider) is trusted and preferred by their issuers. However, such endorsements are one-value ratings and therefore cannot show how good that service is (as our certified ratings can by having values in $[-1, +1]$ in a context sensitive way using rating terms). Moreover, the work in [6] does not consider the problem of collusion.

5. CONCLUSIONS AND FUTURE WORK

This paper has presented a novel mechanism for a new type of trust — certified reputation. This model provides a number of advantages over current approaches. First, its mechanism addresses the problem of the lack of direct experience (since agents can typically collect a large number of references themselves and they are incentivised to present these to establish new trust relationships). Second, agents are freed from the various costs involved in locating witness reports (e.g. resource, time, and communication costs). Third, since CR allows agents to evaluate trust for themselves it does not require a centralised service and, thus, is compatible with open multi-agent environments. In addition, in our evaluation we have shown CR performs significantly better than both a direct experience only model and a successful centralised trust mechanism. We have also shown that our CR model is robust against various types of collusion between agents.

In the future, we aim to devise a method to automatically adjust the accuracy tolerance threshold during the system's operation (instead of handpicking a value as at present). This can be achieved by analysing the recorded performance levels of service providers that an agent has interacted with to determine the likely variability of honest ratings. With respect to the CR mechanism itself, we plan to elevate the current presenting references process into a full dialog between the evaluator and the target agent. In so doing, the evaluator can specify what type of reference it wants to see (e.g. only the most recent ones, only references about transactions of high values, or those from a selected set of referees). This dialog can be a full negotiation process in which the evaluator can ask why a reference is bad and the target agent can explain a plausible reason for that. This will further allow both agents to learn more about each other, which clearly facilitates the trust evaluation process.

ABSTRACT

An argumentation based negotiation model is supported by information theory. Argumentative dialogues change the models of agents with respect to ongoing relationships. Trust and Honour are key components. Trust measures expected deviations of behaviour in the execution of commitments. Honour measures the expected integrity of the arguments exchanged. We understand rhetorical moves in dialogues as actions to project the current relationships into the future.

1. INTRODUCTION

Negotiation dialogues have been traditionally organised around the basic illocutionary particles *Offer*, *Accept* and *Reject*. Previous work has been centred on the design of negotiation strategies and on proposing agent architectures able to deal with the exchange of offers [8, 4]. Game theory [13], possibilistic logic [5] and first-order logic [9] have been used for this purpose. Some initial steps in proposing rhetoric particles have been made, especially around the idea of *appeals*, *rewards* and *threats* [15]. However, no formal model of the meaning of these speech acts has been proposed yet. Expanded negotiation dialogues, including these rhetoric moves, are known as *argumentation-based negotiations*[1]. *Argumentation* in this sense is mainly to do with building (business) relationships. When we reward or threaten we refer to a future instant of time where the reward or threat will be effective, its scope goes beyond the current negotiation round. We will understand argumentation in this paper as an information exchange process between agents. Every illocution that an agent utters gives away valuable information. To evaluate each illocution exchanged we base our information-based agent architecture on information theory.

We distinguish between the *trust* that an agent displays through the enactment of its contracts, and the *honour* that an agent displays in sustaining its trading relationships. The enactment of a contract is uncertain to some extent, and trust, precisely, is a measure of how uncertain the enactment of a contract is. Trust is therefore a *measure of expected deviations of behaviour* along a dimension determined by the type of the contract [14]. In this sense, the higher the trust the lower the expectation that a (significant) deviation from what is signed occurs.

A (business) *relationship* between a set of agents consists of a historical sequence of related trades together with expectations of fair, trusted and honourable trade in the future. These expectations are established by the trading history and by the information exchanged [in appeals] and conditional promises made [in threats and rewards]. Exchanged information may turn out to be partly false, and promises may be partly broken. We introduce the concept of Honour to measure the *expected integrity of the information and promises exchanged*. This leads to a natural hierarchy: individual deals, (business) relationships and businesses.

We first introduce an argumentation language in Section 2. Then, after giving our intuitions on building relationships in Section 3 we define an information based model in Section 4 that supports our model of Honour in Section 5. How the information is managed is explained in Section 6. Finally, the agent architecture is explained in Section 7.

2. AN ARGUMENTATION LANGUAGE

In order for communication to be effective agents need to agree upon an ontology and a communication language.

2.1 Ontology

To model the agent dialogues we define *ontology* to include a (minimum) repertoire of elements: a set of *concepts* organised in an *is-a hierarchy*, captured by a partial order relation, a set of *relations* defined over these concepts, and a set of

[1]Not to be confused with argumentation in a classical sense: the generation of arguments, usually as logical proofs, for and against a given course of action that support decision making processes.

axioms defined over the concepts and relations. We model ontologies following an algebraic approach and present ontologies as logical theories in the form of pairs $O = (S, A)$ where S is the *ontological signature*, representing the vocabulary, and A is a set of ontological axioms, specifying the interpreation of the vocabulary in a given context. The signature is usually represented as a mathematical structure and the set of axioms are usually written in a logical formalism. In our case, we define an ontology signature as a tuple $S = (C, R, \leq, \sigma)$ where C is a finite set of concept symbols (including basic data types); R is a finite set of relation symbols; $\leq$ is a reflexive, transitive and anti-symmetric relation on C (a partial order); and, $\sigma : R \to C^+$ is the function assigning to each relation symbol its arity. Concepts play somehow the role of *type*, and the is-a hierarchy is the notion of subtype. Thus, type inference mechanisms can be used to type all symbols appearing in expressions. Once the basic ontology signature is fixed we need to define a language to express, in our case, contracts, promises, rewards and so on. We denote that language as L_S. The axioms in the ontology will be written in that language, $A \subseteq L_S$, a first order language defined over the ontological expressions.

In our dialogues an essential concept is that of *contract*. Contracts are usually thought of as having a number of issues (dimensions) associated with values (or regions). Thus an (incomplete) example of ontology[2] for contracts could be defined as $\mathcal{S} = (C, R, \leq, \sigma)$ where
– $C = \{contract, quantity, integer, money, free, payment, date, plastic, wood, material, animal, crocodile\}$
– $R = \{price, made\_of, delivery, number, signed\}$
– $money \leq payment, free \leq payment, plastic \leq material, wood \leq material, crocodile \leq animal, integer \leq quantity$
– $\sigma(price) = contract \times payment, \sigma(made\_of) = contract \times material, \sigma(delivery) = contract \times date, \sigma(number) = contract \times quantity, \sigma(signed) = contract \times date$

For instance, the contract "3 plastic crocodiles at the price of €10" can be represented as:

$number(c_1, 3) \wedge made\_of(c_1, plastic) \wedge price(c_1, €10)$

A contract saying "3 crocodiles of any material, and at a maximum price of €10" becomes:

$number(c_1, 3) \wedge made\_of(c_1, material) \wedge price(c_1, [€0, €10])$

And, the expression "in all future contracts, I'll give you a free bottle of wine"

$\forall c : Contract\ .\ signed(c, [now, \infty]) \to present(c, bottle)$

We define the *ontological context* of formula $\varphi \in L_S$, denoted $O(\varphi)$, as the set of concepts in C used by the literals of φ. In the previous example, $O(\varphi) = \{contract, quantity, plastic, payment\}$. We extend the subtype relationship, $\leq$, in the following way,

$$\varphi \leq \psi \iff \forall c_i \in O(\varphi)\ (\exists c_j \in O(\psi).c_i \leq c_j)$$

We base the definition of the *semantic distance* between two concepts on the path length over the $\leq$ of the signature (more distance in the graph is more semantic distance), and the *depth* of the subsumer concept on the shortest path between the two concepts (the deeper in the hierarchy, the closer the meaning of the concepts) [10]:

$$Sim(c_1, c_2) = e^{-\kappa_1 l} \cdot \frac{e^{\kappa_2 h} - e^{-\kappa_2 h}}{e^{\kappa_2 h} + e^{-\kappa_2 h}}$$

[2]generic concepts and particular domains concepts are mixed in this example.

where l is the shortest path between the concepts, h is the depth of the deepest concept subsuming both concepts, and κ_1 and κ_2 are parameters scaling the contribution of shortest path length and depth respectively.

From the semantic distance between two concepts we define the semantic distance between formulae as the maxmin distance between concepts in their ontological context.

$$Sim(\varphi, \psi) = \max_{c_i \in O(\varphi)} \min_{c_j \in O(\psi)} \{Sim(c_i, c_j)\}$$

2.2 Communication language

Agent α is in a trading relationship with an agent β. They aim to strike deals $\delta = (a, b)$ where $a \in L_S$ is α's commitment and $b \in L_S$ is β's. Our agents share a communication language, $\mathcal{C}$, where the propositional content is expressed in L_S and the illocutionary particles are: [3]
– Offer(α, β, δ). Agent α offers agent β a deal $\delta = (a, b)$ with action commitments $a \in L_S$ for α and $b \in L_S$ for β.
– Accept(α, β, δ). Agent α accepts agent β's previously offered deal δ.
– Reject$(\alpha, \beta, \delta[, info])$. Agent α rejects agent β's previously offered deal δ. Optionally, information $info \in L_S$ explaining the reason for the rejection can be given.
– Withdraw$(\alpha, \beta[, info])$. Agent α breaks down negotiation with β. Extra $info \in L_S$ justifying the withdrawal may be given.
– Inform$(\alpha, \beta, info)$. Agent α informs β about $info \in L_S$ and commits to the truth of *info*.
– Reward$(\alpha, \beta, \delta, \varphi[, info])$. Intended to make the opponent accept a proposal with the promise of a future compensation. Agent α offers agent β a deal δ. In case β accepts the proposal, α commits to make $\varphi \in L_S$ true. The intended meaning is that α believes that worlds in which φ is true are somehow desired by β. Optionally, additional information in support of the deal can be given.
– Threat$(\alpha, \beta, \delta, \varphi, [info])$ Intended to make the opponent accept a proposal with the menace of some sort of retaliation. Agent α offers agent β a deal δ. In case β does not accept the proposal, α commits to make $\varphi \in L_S$ true. The intended meaning is that α believes that worlds in which φ is true are somehow not desired by β. Optionally, additional information in support of the deal can be given.
– Appeal$(\alpha, \beta, \delta, info)$ Intended to make the opponent accept a proposal as a consequence of the belief update that the accompanying information might bring about. Agent α offers agent β a deal δ. Additionally, α passes a pack of information in support of the deal. An Appeal can be understood as a combination of an offer and an inform, that is Appeal$(\alpha, \beta, \delta, info)$ = Offer(α, β, δ);Inform$(\alpha, \beta, info)$ — we borrow ';' from Dynamic Logic to mean action concatenation.

The accompanying information, *info*, can be of two basic types: (i) referring to the process (plan) used by an agent to solve a problem, or (ii) data (beliefs) of the agent including preferences. When building relationships, agents will therefore try to influence the opponent by changing their

[3]It is commonly accepted since the works by Austin and Searle that illocutionary acts are actions that succeed or fail. We will abuse notation in this paper and will consider that they are predicates in a first order logic meaning 'the action has been performed'. For those more pure-minded an alternative is to consider dynamic logic.

processes (plans) or by providing new data.

Dialogues, especially in Electronic Institutions [3], tend to be structured in order to facilitate the decision making of the participants. This structuring of dialogues is what is usually called a *protocol*. We will not detail it here, but will assume that such a protocol exists.

2.3 Information model predicates

The predicate $\text{Acc}(\alpha, \beta, \delta)$ means "agent α finds the deal δ with agent β acceptable", and $\text{Build}(\alpha, \beta, \rho)$ means "agent α considers agent β to be a potential trading partner for deals in a relationship ρ". Where ρ is a super type (more abstract set of concepts) than δ, that is $\delta \leq \rho$. ie: a relationship ρ could be "supply of chops", and a particular deal δ could be "supply 6 lamb chops today". Our agent estimates probabilities that are attached to $P(\text{Build}(\alpha, \beta, \rho))$ representing the certainty that it has in this proposition. Thus, if $P(\text{Build}(\alpha, \beta, \rho)) > P(\text{Build}(\alpha, \gamma, \rho))$ then it does *not* mean that β is better than γ. It *does* mean that for ρ-deals α is more certain that β is OK than that γ is OK.

To estimate $P(\text{Build}(\cdot))$ we express $\text{Build}(\cdot)$ in terms of a *social model* comprising:

– $\text{Capable}(\alpha, \beta, \rho)$ is a measure of the ability of an agent to do what it says it can do for deals of type ρ. Eg: "If β *says* he can supply both sausages and chops then he *can* supply both sausages and chops.".

– $\text{Trust}(\alpha, \beta, \rho)$ is a measure of expected deviations of behaviour along a given dimension (ρ). The assessment of Trust incorporates $\text{Reputation}(\beta)$ = "the reputation of β reported by other agents — not necessarily truthfully".

– $\text{Honour}(\alpha, \beta, \rho)$ measures the expected integrity of the arguments exchanged. That is, α's expectation that "β will honour previously issued appeals, threats and rewards when negotiating deals of type ρ". We expect rewards to compensate for bad proposals, and threats when our own position is seen to be dishonourable.

– $\text{Rel}(\alpha, \beta, c)$ measures the reliability of the information that β provides — this measure is keyed to sections of the ontological context, $c \in C$. For example, how reliable is β's information about wine, or about the stock market.

3. BUILDING RELATIONSHIPS

A simple bargaining agent α can only do three things: submit and respond to proposals, and "walk away". The only way in which a simple bargaining agent α can "reward or threaten" is to submit proposals that are more or less attractive to β than α would normally do so. A negotiation can "breakdown", and α may be interested in estimating $p_{b,\beta}$ — the probability that β will walk away in the subsequent negotiation round.

An argumentation agent extends the capacity of a simple bargaining agent by using threats, rewards and appeals to sustain trading relationships. An argumentation agent is concerned both with future single trades and with *trading relationships* that encapsulate expectations of future acceptable trades. Just as a negotiation can "breakdown", a trading relationship can *collapse*. So, just as a bargaining agent is interested in $p_{b,\beta}$, an argumentation agent will also be interested in estimating the probability that a trading relationship with β will collapse: $p_{c,\beta}$.

Our agent α uses argumentation to maintain a reliable set of potential trading partners, $\{\beta_i\}_{i \in \mathcal{B}_\rho}$, for each type of deal ρ. α considers β to be a reliable trading partner for ρ-deals if $P(\text{Build}(\alpha, \beta, \rho)) \geq \epsilon$ for some threshold constant ϵ. $\mathcal{B}_\rho = \{\beta \mid P(\text{Build}(\alpha, \beta, \rho)) \geq \epsilon\}$ will have an optimal size which is difficult to specify analytically due to dependencies between the probabilities. The size of the set $\mathcal{B}_\rho$ will be bounded by: first the difficulty in locating β_i for whom the p_{c,β_i} are "moderately" independent, and second the larger $\mathcal{B}_\rho$ the less opportunity α has to estimate $\{p_{c,\beta_i}\}_{i \in \mathcal{B}_\rho}$ directly. α may maintain these estimates indirectly by sharing information in a *trading pact*, but if α shares information about her trading partners then that may reduce the value of those partners to α.

Under what circumstances will α decide to "walk away" from a negotiation or a trading relationship? This is dealt with in α's negotiation plans, and α's plans for choosing potential trading partners — these are not described here. Presumably α will exercise her outside options if she believes that they will improve her position. α will only do this if $P(\text{Build}(\cdot))$ for her current partners are worse than the expected value for an untried partner. An argumentation agent's threat, reward and appeal illocutions are its weapons against collapse, as we discuss in Section 7.1.

4. AN INFORMATION-BASED MODEL

We ground our argumentation model on information-based concepts. *Entropy*, H, is a measure of uncertainty [11] in a probability distribution for a discrete random variable X: $H(X) \triangleq -\sum_i p(x_i) \log p(x_i)$ where $p(x_i) = P(X = x_i)$. Maximum entropy inference and minimum relative entropy inference are chosen partly because of their encapsulation of common sense reasoning [12].

Maximum entropy inference is used to derive sentence probabilities for that which is not known by constructing the "maximally noncommittal" [7] probability distribution, and minimum relative entropy inference is used to update these distributions. These forms of inference are criticised [6] for their dependence on the representation chosen — such as the way in which values for a continuous variable are represented as intervals. We argue to the contrary, that this choice enables the tailoring of the model in fine detail.

Given a prior probability distribution $\underline{q} = (q_i)_{i=1}^n$ and a set of constraints, the *principle of minimum relative entropy* chooses the posterior probability distribution $\underline{p} = (p_i)_{i=1}^n$ that has the least relative entropy with respect to $\underline{q}$, and that satisfies the constraints[4].

[1] describes the estimation of both $P(Acc(\alpha, \beta, \delta))$ and the estimation of $P(Acc(\beta, \alpha, \delta))$ which is α's estimate of β's willingness to accept δ. These estimates are derived by applying maximum entropy inference to the observed behaviour of the agents. In the subsequent subsection we'll see how α updates its sentence probabilities for $\text{Honour}(\cdot)$ by observation following receipt of the illocutionary particles described in Section 2.

4.1 Updating honour from observations

[4]Ie: $\arg\min_{\underline{p}} \sum_{i=1}^n p_i \log \frac{p_i}{q_i}$. The principle of minimum relative entropy is a generalisation of the principle of maximum entropy. If the prior distribution $\underline{q}$ is uniform, the relative entropy of $\underline{p}$ with respect to $\underline{q}$ differs from $-H(\underline{p})$ only by a constant. So the principle of maximum entropy is equivalent to the principle of minimum relative entropy with a uniform prior distribution.

The choice of trading partner is influenced by the observation of the fulfilment of informs, rewards and threats. Such illocutions are a *conditional commitment* to act. Eg: $\text{Reward}(\alpha, \beta, \delta, \varphi)$ when uttered by α has the meaning that α becomes socially committed to make φ happen if β enacts the illocution $\text{Accept}(\beta, \alpha, \delta)$. Similarly, $\text{Threat}(\alpha, \beta, \delta, \varphi)$ when uttered by α has the meaning that α becomes socially committed to make φ happen if β does *not* enact the illocution $\text{Accept}(\beta, \alpha, \delta)$ — usually by a given deadline. Finally, $\text{Inform}(\alpha, \beta, \varphi)$ means that α is socially committed to the truth of φ.

Agent α has the opportunity to observe the extent to which agent β sticks to his word in $\text{Reward}(\cdot)$, $\text{Threat}(\cdot)$ and $\text{Inform}(\cdot)$ illocutions, and to observe how accurate his *info* is. We base our measure of honour as the negative entropy of the probability distribution of possible outcomes following such a given illocution — honour measures the relationship between commitment and execution of promises. More precisely, between issued illocutions and their *perceived* execution. In this way, a natural way to base our modelling of honour is on a conditional probability, P^t, between commitment and observation given a context e as:

$$P^t(\text{Observe}(\alpha, \varphi') \mid (\text{Reward}(\beta, \alpha, \delta, \varphi); \text{Accept}(\alpha, \beta, \delta)), e)$$

where every reward execution represents a point in that distribution. For threats and informs the distributions are:

$$P^t(\text{Observe}(\alpha, \varphi') \mid (\text{Threat}(\beta, \alpha, \delta, \varphi); \neg\text{Accept}(\alpha, \beta, \delta)), e)$$

$$P^t(\text{Observe}(\alpha, \varphi') \mid (\text{Inform}(\beta, \alpha, \varphi)), e)$$

For simplicity, we denote these relationships between the commitment, φ, and the observation, φ', as $P^t(\varphi'|\varphi, e)$.

An important aspect that we want to model is the fact that beliefs 'evaporate' as time goes by. If we don't keep an ongoing relationship, we become unsure how *honourable* a trading partner is. If I stop buying meat from my butcher, I'm not sure anymore that he will commit to his promises. This decay is what justifies a continuous relationship between individuals. In our model, the conditional probabilities should tend to ignorance as represented by the *decay limit distribution* $\{d_i\}$. If we have the set of observations $\Phi = \{\varphi_1, \varphi_2, \ldots, \varphi_n\}$ then complete ignorance of the opponent's expected behaviour means that given the opponent commits to φ the conditional probability for each observable outcome φ' becomes $d_i = \frac{1}{n}$ — i.e. the unconstrained maximum entropy distribution — but α may be prepared to make assumptions about β's decay limit distribution so that its entropy is less than this. This natural decay of belief is offset by new observations.

We define the evolution of the probability distribution that supports the previous definition of decay using an equation inspired by pheromone like models [2]:

$$P^{t+1}(\phi'|\phi) = \kappa \cdot \left((1-\nu) \cdot d_i + \nu \cdot \left(P^t(\phi'|\phi) + \Delta^t P(\phi'|\phi)\right)\right) \quad (1)$$

where κ is a normalisation constant and $\{d_i\}$ is the decay limit distribution for β. This equation models the passage of time for a conveniently large $\nu \in [0, 1]$ and where the term $\Delta^t P(\phi'|\phi)$ represents the increment in an instant of time according to the last experienced event as the following shows.

Similarity based. The question is how to use the observation φ' given a commitment φ (generated by a sequence of illocutions $\text{Reward}(\alpha, \beta, \delta, \varphi)$; $\text{Accept}(\beta, \alpha, \delta)$ — similarly for others) in the context of a deal $\delta \leq \rho$ in the update of the overall probability distribution over the set of all possible outcomes defined over L_C. Here we use the idea that given a particular deviation in a region of the space, *similar* deviations should be expected in other regions. The intuition behind the update is that if my butcher has not honoured commitments with respect to red meat, then I might expect similar deviations with respect to poultry.

This idea is built upon the previously defined Sim function (see Section 2) to take into account the difference between acceptance probabilities and similarity between the perception of the execution x of a reward (or threat) y. Thus, after the observation of φ' the increment of probability distribution at time $t+1$ is:

$$\Delta^t P(\phi'|\phi) = (1 - \mid Sim(\varphi', \varphi) - Sim(\phi', \phi) \mid) \quad (2)$$

Entropy based. Suppose that α has a business relationship ρ with agent β, that β promises ϕ, and this promise is sound. The material value of ϕ to ρ will depend on the future use that α makes of it, and that is unlikely to be known. So α estimates the value of ϕ to the honour he holds for β in ρ using a probability distribution $(p_1, \ldots, p_n)$ over a relationship evaluation space $E = (e_1, \ldots, e_n)$ that could range from "that is what I expect from the perfect trading partner" to "it is totally useless" — E may contain hard or fuzzy values. $p_i = w_i(\rho, \phi)$ is the probability that e_i is the correct evaluation of the enactment ϕ in the context of relationship ρ, and $\underline{w} : L_S \times L_S \to [0, 1]^n$ is the promise *evaluation function*.

Let $L_S = (\phi_1, \ldots, \phi_m)$ in some order. Then for a given ϕ_k, $(P^t_\beta(\phi_1|\phi_k), \ldots, P^t_\beta(\phi_m|\phi_k))$ is the prior distribution of α's estimate of what will actually occur if β promised that ϕ_k would occur and $\underline{w}(\rho, \phi_k) = (w_1(\rho, \phi_k), \ldots, w_n(\rho, \phi_k))$ is α's evaluation over E with respect to the relationship ρ of β's promise ϕ_k. α's expected evaluation of what will occur given that β has promised that ϕ_k will occur is: $\underline{w}^{\exp}(\rho, \phi_k) =$

$$\left(\sum_{j=1}^{m} P^t_\beta(\phi_j|\phi_k) \cdot w_1(\rho, \phi_j), \ldots, \sum_{j=1}^{m} P^t_\beta(\phi_j|\phi_k) \cdot w_n(\rho, \phi_j)\right).$$

Now suppose that α observes the event $(\varphi'|\varphi)$ in another relationship ρ' also with agent β. Eg: α may buy wine and cheese from the same supplier. α may wish to revise the prior estimate $\underline{w}^{\exp}(\rho, \phi_k)$ in the light of the observation $(\varphi'|\varphi)$ to: $(\underline{w}^{\text{rev}}(\rho, \phi_k) \mid (\varphi'|\varphi)) =$

$$\underline{g}(\underline{w}^{\exp}(\rho, \phi_k), \underline{w}(\rho', \varphi), \underline{w}(\rho', \varphi'), \rho, \rho', \phi, \varphi, \varphi'),$$

for some function $\underline{g}$ — the idea being, for example, that if the promise, φ, concerning the purchase of cheese, ρ', was not kept then α's expectation that the promise, ϕ, concerning the purchase of wine, ρ, will not be kept should increase. The entropy based approach estimates $\Delta^t_\beta P(\phi'|\phi)$ by applying the principle of minimum relative entropy[4]. Let:

$$\left(P^t_{\beta,C}(\phi_j|\phi)\right)_{j=1}^m = \arg\min_{\underline{p}} \sum_{i=1}^{m} p_i \log \frac{p_i}{P^t_\beta(\phi_i|\phi)} \quad (3)$$

satisfying the n constraints C, and $\underline{p} = (p_j)_{j=1}^m$. Then:

$$\Delta^t P(\phi'|\phi) = P^t_{\beta,C}(\phi'|\phi) - P^t_\beta(\phi'|\phi) \quad (4)$$

Where the n constraints C are: $\sum_{j=1}^{m} p_j \cdot w_i(\rho, \phi_j) =$

$$g_i(\underline{w}^{\exp}(\rho, \phi_k), \underline{w}(\rho', \varphi), \underline{w}(\rho', \varphi'), \rho, \rho', \phi, \varphi, \varphi')$$

for $i = 1, \ldots, n$. This is a set of n linear equations in m unknowns, and so the calculation of the minimum relative entropy distribution may be impossible if $n > m$. In this case, we take only the m equations for which the change from the prior to the posterior value is greatest. That is, we attempt to select the most significant factors.

5. AN HONOUR MODEL

Honour as expected behaviour. Consider a distribution of expected fulfilment of promises that represent α's "ideal" for a relationship with β, in the sense that it is the best that α could reasonably expect β to do. This distribution will be a function of β, α's history with β, anything else that α believes about β, and general environmental information including time — denote all of this by e, then we have $P_I^t(\varphi'|\varphi, e)$. For example, if α considers that it is unacceptable for the execution φ' to be less preferred than the promise φ then $P_I^t(\varphi'|\varphi, e)$ will only be non-zero for those φ' that α prefers to φ. The distribution $P_I^t(\cdot)$ represents what α expects, or hopes, β will do. Honour is the relative entropy between this ideal distribution, $P_I^t(\varphi'|\varphi, e)$, and the distribution of the observation of fulfilled promises, $P_\beta^t(\varphi'|\varphi)$. That is:

$$H(\alpha, \beta, \varphi) = 1 - \sum_{\varphi'} P_I^t(\varphi'|\varphi, e) \log \frac{P_I^t(\varphi'|\varphi, e)}{P_\beta^t(\varphi'|\varphi)} \quad (5)$$

where the "1" is an arbitrarily chosen constant being the maximum value that honour may have. This equation defines honour for one, single promise φ — for example, my honour in my butcher if he promises me a 10% discount for the rest of the year. It makes sense to aggregate these values over a class of promises, say over those φ that are subtypes of a particular relationship ρ, that is $\varphi \leq \rho$. In this way we measure the honour that I have in my butcher in relation to the promises he makes for red meat generally:

$$H(\alpha, \beta, \rho) = 1 - \frac{\sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi) \left[\sum_{\varphi'} P_I^t(\varphi'|\varphi, e) \log \frac{P_I^t(\varphi'|\varphi, e)}{P_\beta^t(\varphi'|\varphi)}\right]}{\sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi)}$$

where $P_\beta^t(\varphi)$ is a probability distribution over the space of promises that the next promise β will make to α is φ. Similarly, for an overall estimate of α's honour in β:

$$H(\alpha, \beta) = 1 - \sum_{\varphi} P_\beta^t(\varphi) \left[\sum_{\varphi'} P_I^t(\varphi'|\varphi, e) \log \frac{P_I^t(\varphi'|\varphi, e)}{P_\beta^t(\varphi'|\varphi)}\right]$$

Honour as expected 'preferability'. The previous notion of honour requires that an ideal distribution, $P_I^t(\varphi'|\varphi, e)$, has to be specified for each φ. The idea behind honour as expected 'preferability' is that in a trading relationship, ρ, if the execution φ' of a promise is preferable to that that was promised φ then α will honour β more. The extent to which an enactment, φ', can be 'preferable' to a promise, φ, is limited. For example, if my grocer promises me a 10% discount on tomatoes and gives me 15% then I may be delighted, but if he gives me a 95% discount then my desire to trade with him may diminish. Given a predicate $\text{Prefer}(c_1, c_2, e)$ meaning that α prefers c_1 to c_2 in environment e. An evaluation of $P^t(\text{Prefer}(c_1, c_2, e))$ may be defined using $Sim(\cdot)$ and the evaluation function $\underline{w}$ — but we do not detail it here. Then if $\varphi \leq \rho$:

$$H(\alpha, \beta, \varphi) = \sum_{\varphi'} P^t(\text{Prefer}(\varphi', \varphi, \rho)) P_\beta^t(\varphi' \mid \varphi)$$

and:

$$H(\alpha, \beta, \rho) = \frac{\sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi) \left[\sum_{\varphi'} P^t(\text{Prefer}(\varphi', \varphi, \rho)) P_\beta^t(\varphi' \mid \varphi)\right]}{\sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi)}$$

Honour as certainty in promise execution. Honour is consistency in expected acceptable executions of promises, or "the lack of expected uncertainty in those possible executions that are better than the promise as specified". Then if $\varphi \leq \rho$ let: $\Phi_+(\varphi, \rho, \kappa) = \{\varphi' \mid P^t(\text{Prefer}(\varphi', \varphi, \rho)) > \kappa\}$ for some constant κ. The idea here is that α will honour β more if variations, φ', from expectation, φ, are not random. The Honour that an agent α has on agent β with respect to the execution of a promise φ is:

$$H(\alpha, \beta, \varphi) = 1 + \frac{1}{B^*} \cdot \sum_{\varphi' \in \Phi_+(\varphi, \rho, \kappa)} P_+^t(\varphi'|\varphi) \log P_+^t(\varphi'|\varphi)$$

where $P_+^t(\varphi'|\varphi)$ is the normalisation of $P_\beta^t(\varphi'|\varphi)$ for $\varphi' \in \Phi_+(\varphi, \rho, \kappa)$,

$$B^* = \begin{cases} 1 & \text{if } |\Phi_+(\varphi, \rho, \kappa)| = 1 \\ \log |\Phi_+(\varphi, \rho, \kappa)| & \text{otherwise} \end{cases}$$

As above we aggregate this measure for those promises of a particular type ρ:

$$H(\alpha, \beta, \rho) = 1 + \frac{\sum_{\varphi:\varphi\leq\rho} \left[P_\beta^t(\varphi) \cdot \sum_{\varphi' \in \Phi_+(\varphi, \rho, \kappa)} P_+^t(\varphi'|\varphi) \log P_+^t(\varphi'|\varphi)\right]}{B^* \cdot \sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi)} = 1 + \frac{\sum_{\varphi:\varphi\leq\rho} \sum_{\varphi' \in \Phi_+(\varphi, \rho, \kappa)} \left[P_+^t(\varphi', \varphi) \log P_+^t(\varphi'|\varphi)\right]}{B^* \cdot \sum_{\varphi:\varphi\leq\rho} P_\beta^t(\varphi)}$$

where $P_\beta^t(\varphi', \varphi)$ is the joint probability distribution, and $P_+^t(\varphi', \varphi)$ is the normalisation of it as above. And, similarly as before:

$$H(\alpha, \beta) = 1 + \frac{\sum_{\varphi} \left[P_\beta^t(\varphi) \cdot \sum_{\varphi' \in \Phi_+(\varphi, \rho, \kappa)} P_+^t(\varphi'|\varphi) \log P_+^t(\varphi'|\varphi)\right]}{B^*} = 1 + \frac{\sum_{\varphi} \sum_{\varphi' \in \Phi_+(\varphi, \rho, \kappa)} \left[P_+^t(\varphi', \varphi) \log P_+^t(\varphi'|\varphi)\right]}{B^*}$$

Evaluating honour. The various expressions for honour given above involve extensive calculations. For example, Eqn. 5 contains $\sum_{\varphi'}$ that sums over *all* possible enactments φ'. To develop the above into a more computationally friendly model we appeal to the structure of the ontology described in Sec. 2.1. For example, Eqn. 5 may be approximated to:

$$H(\alpha, \beta, \varphi) = 1 - \sum_{\varphi': Sim(\varphi', \varphi) \geq \eta} P_{\eta,I}^t(\varphi'|\varphi, e) \log \frac{P_{\eta,I}^t(\varphi'|\varphi, e)}{P_{\eta,\beta}^t(\varphi'|\varphi)}$$

where $P^t_{\eta,I}(\varphi'|\varphi,e)$ is the normalisation of $P^t_I(\varphi'|\varphi,e)$ for $Sim(\varphi',\varphi) \geq \eta$, and similarly for $P^t_{\eta,\beta}(\varphi'|\varphi)$. The extent of this calculation is controlled by the parameter η. An even tighter restriction may be obtained with: $Sim(\varphi',\varphi) \geq \eta$ *and* $\varphi' \leq \psi$. For example, if β promises a 10% discount on tomatoes next month, we may choose to evaluate $H(\alpha,\beta,\varphi)$ for promises φ' that are *both* close to this promise, φ, *and* that concern tomatoes, ψ.

6. DEALING WITH [*INFO*].

In this section we discuss how to deal with the information that β communicates in the illocutions, $info \in L_C$. We will base this treatment on β's *reliability* as an estimate of the extent to which this *info* is correct. For example, β may send α the *info* that "the price of fish will go up by 10% next week", and it may actually go up by 9%. α's argumentation and relationship building strategies are based on plans that are not described here. Those plans determine a set of probability distributions from which a world model is derived. *info* is represented as a set of linear constraints on one or more of those probability distributions. A chunk of *info* may not be directly related to one of those distributions, or may not be expressed naturally as constraints, and so some inference machinery is required to derive these constraints — this inference is performed by a set of model building function, J_s, for each active plan s chosen by α. If a plan s calls for the distribution D then J^D_s is the model building function for D, and $J^D_s(info)$ is the set of constraints on D derived from *info*.

6.1 Updating the world model with *info*

If at time u, α receives a message containing *info* it is time-stamped and source-stamped $info_{(\beta,\alpha,u)}$, and placed in a repository $\mathcal{Y}^t$. If α has an active plan, s, then the model building function, J_s, is applied to $info_{(\beta,\alpha,u)}$ to derive constraints on some, or none, of α's distributions. The extent to which those constraints are permitted to effect the distributions is determined by a value for the *reliability* of β, $R^t(\alpha,\beta,O(info))$.

An agent may have models of integrity decay for some particular distributions, but general models of integrity decay for, say, a chunk of information taken at random from the World Wide Web are generally unknown. However the values to which decaying integrity should tend in time *are* often known. For example, a prior value for the truth of the proposition that a "22 year-old male will default on credit card repayment" is well known to banks. As described in Sec. 4.1, if α attaches such prior values to a distribution D they are called the *decay limit distribution* for D, $(d^D_i)^n_{i=1}$. No matter how integrity of *info* decays, in the absence of any other relevant information it should decay to the decay limit distribution.

In the absence of new *info* the integrity of distributions decays. If $D = (q_i)^n_{i=1}$ then we use a geometric model of decay:

$$q^{t+1}_i = (1-\nu^D) \times d^D_i + \nu^D \times q^t_i, \text{ for } i = 1,\ldots,n \qquad (6)$$

where $\nu^D \in (0,1)$ is the decay rate. This raises the question of how to determine ν^D. Just as an agent may know the decay limit distribution it may also know something about ν^D. In the case of an information-overfed agent there is no harm in conservatively setting ν^D "a bit on the low side" as the continually arriving *info* will sustain the estimate for D.

We now describe how new *info* is imported to the distributions. A single chunk of *info* may affect a number of distributions. Suppose that a chunk of *info* is received from β and that α attaches the epistemic belief probability $R^t(\alpha,\beta,O(info))$ to it. Each distribution models a facet of the world. Given a distribution $D = (q_i)^n_{i=1}$, q_i is the probability that the possible world ω_i for D is the true world for D. The effect that a chunk *info* has on distribution D is to enforce the set of linear constraints on D, $J^D_s(info)$. If the constraints $J^D_s(info)$ are taken by α as valid then α could update D to the posterior distribution $(p^{info}_i)^n_{i=1}$ that is the distribution with least relative entropy with respect to $(q^t_i)^n_{i=1}$ satisfying the constraint:

$$\sum_i \{p^{info}_i : J^D_s(info) \text{ are all } \top \text{ in } \omega_i\} = 1. \qquad (7)$$

But $R^t(\alpha,\beta,O(info)) = r \in [0,1]$ and α should only treat the $J^D_s(info)$ as valid if $r = 1$. In general r determines the extent to which the effect of *info* on D makes it closer to $(p^{info}_i)^n_{i=1}$ or to the prior $(q^t_i)^n_{i=1}$ distribution by:

$$p^t_i = r \times p^{info}_i + (1-r) \times q^t_i \qquad (8)$$

But, we should only permit a new chunk of *info* to influence D if doing so gives us new information. For example, if 5 minutes ago a trusted agent advises α that the interest rate will go up by 1%, and 1 minute ago a very unreliable agent advises α that the interest rate may go up by 0.5%, then the second unreliable chunk should not be permitted to 'overwrite' the first. We capture this by only permitting a new chunk of *info* to be imported if the resulting distribution has more information *relative to* the decay limit distribution than the existing distribution has. Precisely, this is measured using the Kullback-Leibler distance measure[5], and *info* is only used if:

$$\sum_{i=1}^n p^t_i \log \frac{p^t_i}{d^D_i} > \sum_{i=1}^n q^t_i \log \frac{q^t_i}{d^D_i} \qquad (9)$$

In addition, we have described in Eqn. 6 how the integrity of each distribution D will decay in time. Combining these two into one result, distribution D is revised to:

$$q^{t+1}_i = \begin{cases} (1-\nu^D) \times d^D_i + \nu^D \times p^t_i & \textit{if} \text{ usable } \textit{info} \text{ is} \\ & \text{received at time } t \\ (1-\nu^D) \times d^D_i + \nu^D \times q^t_i & \textit{otherwise} \end{cases}$$

for $i = 1,\cdots,n$, and decay rate ν^D as before. We have yet to estimate $R^t(\alpha,\beta,O(info))$ — that is described in Sec. 6.2. We now illustrate the above by showing how an important class of *info* illocutions, namely preference information, is managed.

Preferences. Preference information is a statement by an agent that it prefers one class of deals to another where deals may be multi-issue. Preference illocutions may refer to particular issues within deals — e.g. "I prefer red to yellow", or to combinations of issues — e.g. "I prefer a car with a five year warranty to the same car with a two year warranty than costs 15% less". Here α receives preference information, *info*, from β through an $\text{Inform}(\beta,\alpha,info)$ illocution, or through one of the other argumentation illocutions — see Sec. 2 — and attaches $R^t(\alpha,\beta,O(info))$ to it.

[5]This is just one criterion for determining whether the *info* should be used.

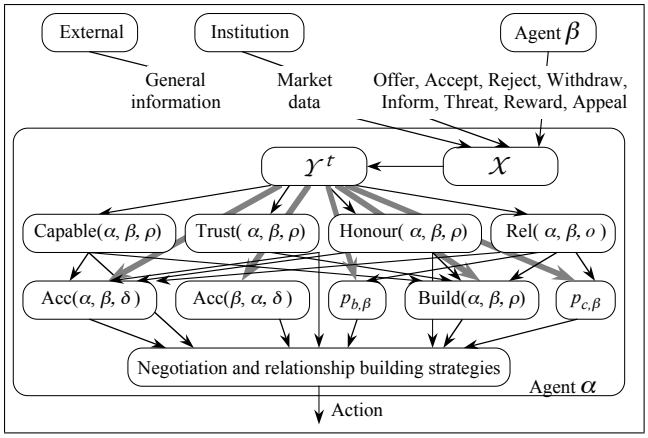
What happens next will depend on α's plans. Suppose that α has a plan s that constructs the probability distribution $P^t(\text{UPrefer}(\beta, \alpha, \delta))$ over all δ meaning that "δ is the deal that β prefers most". α may know the decay limit distribution for UPrefer$(\cdot)$. Suppose α has a prior distribution $(q_i^t)_{i=1}^n$ for UPrefer$(\cdot)$. Now suppose that α learns the *info* "x% of the time β prefers deals with property Q_1 to those with property Q_2". J_s^{UPrefer} derives the following linear constraint on the $P^t(\text{UPrefer}(\beta, \alpha, \delta))$ distribution:

$$\frac{x}{100} = \frac{\sum_{\delta:Q_1(\delta)} p_\delta}{\left(\sum_{\delta:Q_1(\delta)} p_\delta\right) + \left(\sum_{\delta:Q_2(\delta)} p_\delta\right) - \left(\sum_{\delta:Q_1 \wedge Q_2(\delta)} p_\delta\right)}$$

and the procedure described above follows as described. Note that this manages two different probabilities: first, the probability within the *info* "x% of the time...", and second α's estimate of β's reliability in providing information of this sort, $R^t(\alpha, \beta, O(info))$, that is determined by the ontological context $O(info)$ of the *info*.

6.2 A reliability model

We estimate $R^t(\alpha, \beta, O(info))$ by measuring the error in information. α's plans will have constructed a set of distributions. We measure the 'error' in information as the error in the effect that information has on each of α's distributions. Suppose that a chunk of *info* is received from agent β at time u and is verified at some later time t. For example, a chunk of information could be "the interest rate will rise by 0.5% next week", and suppose that the interest rate actually rises by 0.25% — call that correct information *fact*. What does all this tell agent α about agent β's reliability? Consider one of α's distributions D that is $\{q_i^u\}$ at time u. Let $(p_i^{info})_{i=1}^n$ be the minimum relative entropy distribution given that *info* has been received as calculated in Eqn. 7, and let $(p_i^{fact})_{i=1}^n$ be that distribution if *fact* had been received instead. Suppose that the reliability estimate for distribution D was R_D^u. This section is concerned with what R_D^u should have been in the light of knowing *now*, at time t, that *info* should have been *fact*, and how that knowledge effects our current reliability estimate for D, $R^t(\alpha, \beta, O(info))$.



The idea of Eqn. 8, is that the current value of r should be such that, *on average*, $(p_i^u)_{i=1}^n$ will be seen to be "close to" $(p_i^{fact})_{i=1}^n$ when we eventually discover *fact* — no matter whether or not *info* was used to update D, as determined by the acceptability test in Eqn. 9 at time u. That is, given *info*, *fact* and the prior $(q_i^u)_{i=1}^n$, calculate $(p_i^{info})_{i=1}^n$ and $(p_i^{fact})_{i=1}^n$ using Eqn. 7. Then the *observed reliability* for distribution D, $R_D^{(info|fact)}$, on the basis of the verification of *info* with *fact* is the value of r that minimises the Kullback-Leibler distance between $(p_i^u)_{i=1}^n$ and $(p_i^{fact})_{i=1}^n$:

$$\arg\min_r \sum_{i=1}^n (r \cdot p_i^{info} + (1-r) \cdot q_i^u) \log \frac{r \cdot p_i^{info} + (1-r) \cdot q_i^u}{p_i^{fact}}$$

If E^{info} is the set of distributions that *info* affects, then the overall *observed reliability* on the basis of the verification of *info* with *fact* is: $R^{(info|fact)} = 1 - (\max_{D \in E^{info}} |1 - R_D^{(info|fact)}|)$. Then for each ontological context o_j, at time t when, perhaps, a chunk of *info*, with $O(info) = o_k$, may have been verified with *fact*:

$$R^{t+1}(\alpha, \beta, o_j) = (1-\nu) \times R^t(\alpha, \beta, o_j) + \nu \times R^{(info|fact)} \times \text{Sim}(o_j, o_k)$$

Figure 1: Trust, Honour and Reliability in the informed agent. The figure shows the social model and a sample world model. The social model consists of the four components: Capable$(\cdot)$**,** Trust$(\cdot)$**,** Honour$(\cdot)$ **and** Rel$(\cdot)$ **standing for 'reliability'. The sample world model contains just five distributions with the thick arcs representing the five model building functions J_s^D.**

where Sim measures the semantic distance between two sections of the ontology, and ν is the learning rate. Over time, α notes the ontological context of the various chunks of *info* received from β and over the various ontological contexts calculates the relative frequency, $P^t(o_j)$, of these contexts, $o_j = O(info)$. This leads to a overall expectation of the *reliability* that agent α has for agent β:

$$R^t(\alpha, \beta) = \sum_j P^t(o_j) \times R^t(\alpha, \beta, o_j)$$

7. AGENT ARCHITECTURE

The agent architecture developed so far is summarised in Fig. 1. α's actions are determined by its relationship-building strategy that identifies trading partners, and by its negotiation strategy that manages individual negotiations. The complete apparatus in Fig. 1 is revised when any illocution is received.

The *social model*: Capable$(\cdot)$, Trust$(\cdot)$, Honour$(\cdot)$, and Reliability$(\cdot)$, presents a summary of the interaction history weighted towards recent observations. It provides the foundation for α's relationship building strategy. The estimation of Capable$(\cdot)$ depends on the commitments involved — for example, estimating whether β is capable of raising a sum of money presents a different problem to estimating whether β can supply 100 kilos of sausages — the estimation of Capable$(\cdot)$ is not discussed here. An estimation of Trust$(\cdot)$ is discussed in [14], and herein Honour in Sec. 5 and Reliability in Sec. 6. The world model is described following.

7.1 World Model

Agent α acts by activating a plan s that invokes model building functions J_s^D and uses one of the two entropy inference methods [see Sec. 4] to "fill in the gaps" in probability dis-

tribution D. The *world model* is then aggregated from these distributions. Fig. 1 shows a sample world model consisting of: $\text{Acc}(\alpha, \beta, \delta)$, $\text{Acc}(\beta, \alpha, \delta)$, $p_{b,\beta}$, $\text{Build}(\alpha, \beta, \rho)$ and $p_{c,\beta}$. The components of the world model estimate of α's belief that a proposition is true.

$P^t(\text{Acc}(\alpha, \beta, \delta))$ is α's estimate that δ is an acceptable deal from agent β — this probability expresses the certainty that α has in this proposition. So $P^t(\text{Acc}(\alpha, \beta, \delta_1)) > P^t(\text{Acc}(\alpha, \beta, \delta_2))$ does not mean that δ_1 is an intrinsically better deal than δ_2 — it means that α is more certain that δ_1 is acceptable than δ_2 is acceptable.[6] A framework for estimating the $P^t(\text{Acc}(\alpha, \beta, \delta))$ distribution, derived from subjective, market and general observations, is described in [1].

$P^t(\text{Acc}(\beta, \alpha, \delta))$ is α's estimate that δ is an acceptable deal to β. [1] estimates $P^t(\text{Acc}(\beta, \alpha, \delta))$ by observing the Offer$(\cdot)$, Accept$(\cdot)$ and Reject$(\cdot)$ illocutions received from β.

$p_{b,\beta}$ is estimated by observing β's behaviour. A simple method is to measure the local entropy of the $P^t(\text{Acc}(\beta, \alpha, \delta))$ distribution — that is, the entropy of the normalisation of that distribution for δ restricted to the negotiation region. If that entropy measurement does not fall in time as the negotiation proceeds then this may indicate β's intention to withdraw from the negotiation. [1] describes the estimation of $p_{b,\beta}$.

A natural way to define $\text{Build}(\alpha, \beta, \rho)$ is by combining the four concepts we claimed were its pillars:

$$P(\text{Build}(\alpha, \beta, \rho)) = k(\text{Capable}(\alpha, \beta, \rho), \text{Trust}(\alpha, \beta, \rho), \text{Honour}(\alpha, \beta, \rho), \text{Rel}(\alpha, \beta, O(\rho)))$$

for some function k, where $O(\rho)$ denotes the ontological context of relationship ρ. This characterisation of Build is defined in terms of (commitment, observation) pairs for each of its four components.

A simple negotiation agent aims to strike a deal δ with agent β whilst avoiding the risk of negotiation breakdown. Similarly, an argumentation agent aims to build a trading relationship ρ with agent β whilst avoiding the risk of relationship collapse. To estimate $p_{c,\beta}$ we observe β for odd behaviour. Indications of collapse include: individual negotiations that have a high number of rounds or that take a significant time, reluctance to benefit from attractive terms offered in α's Reward$(\cdot)$s, β offers unrealistic Reward$(\cdot)$s, β issues Threats$(\cdot)$s, or, if the structure of the electronic institution permits general observation of β's trading, that β has taken his business elsewhere.

8. CONCLUSION

We introduced in this paper two new concepts: Honour$(\cdot)$ and Reliability$(\cdot)$. Honour$(\cdot)$ models the fulfilment of the promises derived from the use of argumentative particles such as *appeals*, *rewards* and *threats*. This concept plays a similar role to that that the concept of Trust$(\cdot)$ plays with respect to the fulfilment of contract agreements, as developed in [14]. Reliability$(\cdot)$ models the reliability of the information tabled by an opponent. We have proposed a semantics for these two concepts based on information theory. Also, an agent architecture to support this model is proposed.

[6]We differ from game-theory-based agents in that our agent is not necessarily "utility aware".

ABSTRACT

Online communities increasingly rely on reputation information to foster cooperation and deter cheating. As rational agents can often benefit from misreporting their observations, explicit incentives must be created to reward honest feedback. Reputation side-payments (e.g., agents get paid for submitting feedback) can be designed to make truth-telling optimal. In this paper, we present a new side-payment scheme adapted for settings where agents repeatedly submit feedback. We rate the *feedback set* of an agent, rather than individual reports. The *CHI-Score* of the feedback set is computed based on a Chi-square independence test that assesses the correlation between the agent's feedback and the feedback submitted by the rest of the community. The mechanism has intuitive appeal and generates significantly lower costs than existing incentive-compatible reporting mechanisms.

reputation mechanisms, honest reporting

1. INTRODUCTION

Reputation mechanisms emerge as a promising solution for building trust in online communities lacking objective monitoring and enforcing authorities. The experience of previous interactions (i.e., reputation information) is an indicator of future performance; when feedback is shared within the community, agents can accurately identify malicious partners and thus protect themselves against cheating. The *Feedback Forum* of eBay is a notorious example of how reputation mechanisms make business possible in a decentralized environment where two agents have few a priori reasons to trust each other.

In a service-oriented market, reputation mechanisms can do more than just identify and isolate malicious providers. Perfect service is impossible, or prohibitively expensive to provide. Occasional failures happen against the best intention of service providers; excluding such providers from the market would be unfair and inefficient. Instead, reputation information can be used to approximate the real quality of service (QoS) delivered by a provider, and consequently, to dynamically scale the price paid for service [10]. Such a flexible pricing scheme allows service providers with different characteristics to reach the best compromise between delivered quality (hence revenue) and costs. Jurca and Faltings [11] show how reputation information can become part of the Service Level Agreements (SLAs) and efficiently substitute external monitoring of Quality of Service (QoS). They prove that such *reputation-based* SLAs make it rational for service providers to keep their promises, leading to an efficient and trustworthy market.

In this paper, we address a similar scenario. Autonomous agents (clients) contract services from the different providers available in the market. The contract (i.e., the SLA) specifies the price of service, the promised QoS and a monetary penalty, paid back to the agent, when the delivered QoS is lower than promised (see [2, 11] for a framework and detailed description of such interactions). Assuming that all clients in a given group are treated equally within a certain period of time, their aggregated feedback estimates the real QoS delivered to them as a group. Reputation information (i.e., aggregated feedback) can therefore replace external monitoring of QoS, and serve to compute the penalty due by the providers.

This leaves the problem of obtaining true feedback from self-interested agents. Reporting the truth is not optimal: by submitting false negative reports, the agents can decrease the reputation of the provider and thus decrease the total price (i.e., the price specified by the SLA minus the reputation-based penalty) paid for service. Misreporting incentives can be counterbalanced by explicit rewards for honest feedback. The reputation mechanism can use side-payments to pay for the agents' reports. As no objective information is available in the market, the *reputation* side-payments are computed by correlating one agent's report

with reports submitted by peers. When carefully designed, these payments make it optimal for every agent to reveal the true feedback. Moreover, they can be scaled such that reporting costs or other external benefits obtained from lying (e.g., a price decrease) are accounted for. [12, 11].

However, existing side-payment schemes assume that every agent interacts only once with a service provider (in a given time period), and can therefore submit only one feedback. When a client interacts several times with the same provider, coordinated lying in multiple feedback reports can still be profitable.

Take, for example, a web service providing stock quotes. The client requests the price of a specified stock at a given time: e.g., *"Request the price of an IdealCompany share at 11:00AM on Oct 18, 2005"*. The provider promises an answer within a certain deadline: e.g., *information is delivered within 1 minute from the request time* (i.e., before 11:01 AM for the previous request). The daily SLA specifies (a) the cost of a service request, (b) the promised QoS (i.e., the probability that the request is answered before the deadline) and (c) a penalty if the delivered QoS is lower than promised, for the considered day.

One agent a that constantly monitors (e.g., once every ten minutes) the price of a share, will issue $6 \cdot 8 = 48$ service requests during one 8-working-hours day. This agent is therefore entitled to submit 48 binary feedback reports by the end of the day, where every report signals that one of the requested answers was received or not before the deadline. By misreporting only one feedback (negative instead of positive; the other 47 reports remain unchanged) the agent expects:

- to lose amount ΔSP due to the side-payment for that report;
- to decrease the price of every service invocation by Δp

Existing side-payment schemes make sure that ΔSP is always greater than Δp; however, the total price decrease of agent a is $48\Delta p$, as the price decrease also applies to the other 47 service invocations where a reported true feedback. By a similar argument, a will find it profitable to misreport all other positive reports, and she will end up reporting a clean set of 48 negative reports. Eliminating the lying incentives of agent a requires $\Delta SP \geq 48\Delta p$, which translates into a 480% increase of the original reputation side-payments.[1] The cost of reputation management simply becomes too big.

In this paper we present a new mechanism for rewarding truth-telling in settings where agents have several interactions and can submit several reports within a given time-window. The first idea behind our mechanism is to group all reports of an agent from a given time period into a *feedback set*, and pay the agent only once based on her feedback set. Second, we introduce *CHI-Scores* as a basis for computing the side-payments. The CHI-Score for a feedback set is computed based on a *Chi-square independence test* [18] applied to the feedback set itself, and the set containing the feedback of all other agents. The CHI-Score reflects the correlation between the reports of one agent and those of the entire group. Third, we use CHI-Scores not only to pay the reporter, but also to weigh different feedback sets when computing the reputation of the provider. Finally, we explicitly model external lying incentives (e.g., decrease in price) to make sure that the side-payments based on CHI-Scores makes honest reporting optimal.

Like other agreement-based (between the considered report and the general opinion) side-payment schemes (see Section 2) the mechanism we propose is not incentive compatible in general. Truthful reporting is the optimal strategy only when an agent's beliefs regarding the reports of other agents are entirely determined by her direct experience (i.e., the agent does not have any prior information). This is a common assumption for software agents in multi-agent systems and therefore we particulary address our work to such environments. Moreover, the scheme is intuitive, computationally cheap, robust against small numbers of irrational reporters, and generates significantly lower costs than existing schemes (Section 4).

Section 2 discusses related work, Section 3 formally introduces the setting and our mechanism. An experimental evaluation of the mechanism is presented in Section 4, followed by future work and the conclusion.

2. RELATED WORK

The contribution of reputation information in dynamically scaling the prices of goods and services has been established both theoretically and experimentally. Dellarocas [3] studies an "eBay-like" market where sellers can strategically choose whether to ship or not the good purchased by a buyer. He proves the existence of an equilibrium where the reputation of the seller from the last N transactions determines the present price of the good. Experimental studies of eBay transactions [5, 15] confirm that the reputation of a seller affects the selling price of the auctioned goods.

Jurca and Faltings extend the analysis of reputation-based pricing to service oriented environments where providers with different capabilities coexist [10, 11]. Their results are based on two observations. First, all clients in a given group are probably treated equally[2]. Second, service providers cannot change the quality of the delivered service infinitely often. Therefore, the reputation information obtained by aggregating the feedback from the immediate past offers an accurate estimation of the real QoS delivered by the provider. In [10], client's pay the price corresponding to yesterday's reputation. In [11], a reputation-based SLA allows clients to be refunded at the end of a given time period if the provider's reputation is lower than promised. Both mechanism promote trustworthy behavior, as service providers have the incentive to deliver the promised QoS.

The question of honest reporting has been extensively addressed by Miller et al. in [12]. The mechanism uses the feedback of a future client (called the *rater*) to rate (and compute the payment for) a submitted report. The present report is first used to update a probability distribution for the report of the rater. The payment is then computed by a scoring rule[3] that assesses how the actual report of the rater relates to the probability distribution induced by the rated report. Truthful reporting is a Nash equilibrium in all contexts: it is always optimal for an agent to report the truth

[1] for one given side-payment scheme, multiplication by a constant is the only method for increasing the side-payment loss due to misreporting

[2] note that providers can have several customer groups that are treated differently: e.g., silver/gold/platinium clients

[3] see [1] for a detailed description of scoring rules. The logarithmic function is an example of a scoring rule

given that all other agents report the truth. Moreover, the side-payments can be scaled to account for reporting costs and external benefits obtained from cheating.

Prelec [14] considers a similar approach. His mechanism asks every agent two questions: the first, regarding the observed feedback, the second regarding the feedback other agents are likely to submit. Agents are rewarded if the feedback they report is "unexpectedly common" compared with the overall prediction made by the group about the feedback likely to occur. This *information scoring* makes truthful reporting pareto optimal.

[12] discusses the danger associated with using *agreement* for computing side-payments. When the report of an agent is paid according to how well it "agrees" with the general opinion, the optimal reporting strategy is to adhere to the expected majority. Take an eBay buyer cheated by a seller with a large positive *feedback score*. Despite the negative experience, the buyer continues to believe that most of the future buyers will experience good transactions. Therefore, the report that maximizes the agreement with future feedback is the false positive one.

Agreement-based payments can therefore reward honest feedback only when the agent's expectation of future transactions coincides with her direct experience. In the case of one interaction per agent, this is possible when the outcome of successive interactions are correlated. [7] documents such a scenario where the behavior of service providers is modeled by a Markov chain satisfying certain conditions.

When agents get feedback from several direct interactions, agreement-based payment does encourage truth-telling as long as agents do not have external, trusted third-party information. This assumption is common for multi-agent systems, and has been extensively used in social networks to filter out malicious reports. In TRAVOS [16], the weights of peer reports are computed based on a Bayesian model assessing the agreement between previous recommendations and the direct experience. In CREDENCE [17] malicious reporters are filtered based on a distance measure between the agent's own observations and those of the reporter. Similar techniques are described in [20, 6, 19].

A different approach to honest feedback elicitation is presented in [8] and [13]. They rate feedback for each transaction separately, independent of other transactions. The mechanism punishes both the client and the provider if they have conflicting reports regarding the outcome of the transaction in question. [8] proves that (in any equilibrium) the number of false reports collected by such a mechanism is limited by an upper bound. [13] show an implementation of the mechanism for the Peer-to-Peer environment.

3. USING CHI-SCORES TO REWARD HONEST FEEDBACK

We propose a new side-payment scheme to explicitly reward honest feedback, based on the following ideas: first, feedback reports submitted by one agent about the same provider (within a relevant time window) are treated unitarily as one feedback set of the agent. Second, each feedback set is rated against the set of all other relevant reports available in the market for the considered time period. The CHI-Score assigned to a feedback set is computed using a Chi-square independence test applied to the two sets: the rated feedback set and the reference set containing all other

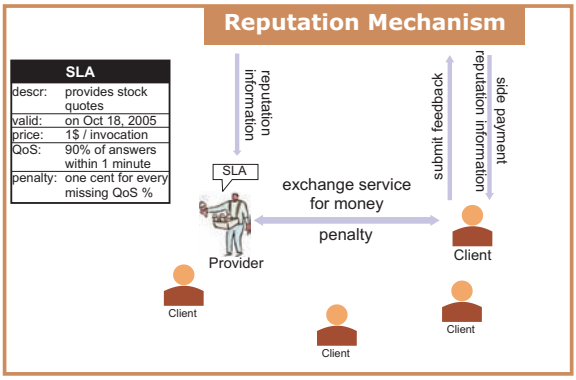

Figure 1: An online market of services.

available feedback reports. Finally, the CHI-Score is used (a) to compute the monetary reward paid to the reporting agent, and (b) to weigh the feedback when computing the reputation information. The external benefits from lying (e.g., price cuts) are factored in so that truth-telling is a Nash equilibrium.

3.1 The Scenario

We consider an online market pictured in Figure 1 where service providers repeatedly offer the same service (having the same functional interface) to the interested clients (autonomous agents), in exchange for money. Agents choose the desired providers based on the Service Level Agreement (SLA) advertised by the latter. The SLA specifies:

- the description of the service
- a period of validity,
- the quality parameters of the delivered service (i.e., the QoS),
- the price for every service invocation,
- the monetary penalty to be refunded when the actual QoS is lower than the advertised one.

A precise definition of such SLAs is presented in [11]. A practical framework supporting such interactions is documented in [2].

We assume that clients have two degrees of satisfaction: they perceive either *high* or *low* quality service. For example, high quality service means that the client obtains the answer before the deadline. QoS can therefore be defined as the probability that one service request is answered successfully (i.e., the client perceives high quality).

The QoS actually delivered to clients depends on the fixed infrastructure (e.g., computing power, bandwidth, etc) and on the strategic choices of the service provider (e.g., number of accepted requests, allocation of resources, etc). The provider can anticipate the implications of his[4] decisions on the perceptions of the clients; therefore we say that the provider can choose (within the limits imposed by the infrastructure) the QoS he is actually going to deliver.

[4]as a convention, we will refer to the provider as "he" and to the client as "she"

A service provider cannot change his decisions infinitely often. We split time into equidistant periods (indexed according to t) such that all services delivered within one period will share the same QoS. We also assume that a large enough group of clients will request the service in any period, and that their observations will be independently identically distributed according to the delivered QoS. Note that a provider can have several customers groups (i.e., silver/gold/platinium) as long as all clients in a given group are treated identically within a given period of time.

An independent reputation mechanism requests binary feedback (1 for a high quality service, 0 otherwise) about every interaction. The reputation of a provider is computed as the average satisfaction rate of the clients for a given period of time. When clients report truthfully, reputation information accurately estimates the real QoS delivered by the provider in that period.

At the end of each period, the reputation mechanism publishes the reputation of every provider, and service providers are expected to refund every client the monetary penalty specified in the SLA. The penalty is positive if the delivered QoS (i.e., the reputation) is lower than advertised, and zero otherwise. When the penalty is large enough, [11] proves that rational service providers keep their promises and the market is efficient.

The feedback submitted during one period has no influence over future periods of time. We can therefore separately analyze the reporting incentives of rational clients for each period. Let us consider the time period t where one provider advertises the SLA, $sla_t = \big[p_t, \bar{q}_t, \lambda(\bar{q}_t, R_t)\big]$ where p_t is the price of one service invocation, $\bar{q}_t$ is the advertised QoS, and $\lambda(\bar{q}_t, R_t)$ is the penalty refunded to the client at the end of the period if the reputation R_t is lower than $\bar{q}_t$. For simplicity, we take a linear penalty function:

$$\lambda(\bar{q}_t, R_t) = \max\big(C \cdot p_t \cdot (\bar{q}_t - R_t), 0\big);$$

where C is a constant. We assume that N_t agents require the service from the provider, each of them issuing M service requests during period t. We use the notation a_i, $i = 1, \ldots, N_t$ to refer to one client agent, and a_{-i} to refer to the group of all agents except a_i.

By the end of the period, every agent will have M binary feedback reports, each describing the quality of one service request. Let $o_i = \{s_1, s_2, \ldots, s_M\}, s_j \in \{0, 1\}$ be the feedback set *observed* by agent a_i. As the order of the reports is not relevant, the feedback set can be represented by one integer value counting the number of positive reports: $o_i = \sum_{j=1}^{M} s_j$.

Client agents do not necessarily report true feedback to the reputation mechanism. We denote by $r_i \in \{0, 1, \ldots, M\}$ the feedback set *reported* by agent a_i. Similarly, $r_{-i} \in \{0, 1, \ldots (N_t - 1)M\}$ denotes the union of the feedback sets of the agents a_{-i}.

3.2 Computing the CHI-Scores

At the end of the time period, the reputation mechanism obtains N feedback sets, each containing M binary reports. Based on this information, the reputation mechanism will (a) compute the reputation of the provider for the past period, and (b) reward agents for their feedback such that it is in their best interest to report the truth. For both task, the reputation mechanism will use the CHI-Scores of the feedback sets.

The CHI-Score of the feedback set r_i belonging to the agent a_i is computed based on a Chi-square independence test applied to the sets r_i and r_{-i}. The Chi-square independence test is a well established statistical tool that helps decide if the results of an inquiry are independent from the sample group. Consider, for example, the vacation preferences (seaside or mountains) of the citizens of Switzerland and Italy. m_S out of the N_S inquired Swiss citizens prefers a vacation in the mountains, compared to m_I out of the N_I inquired Italian citizens. Applied to this data, a Chi-square independence test allows us to decide if the vacation preferences of Swiss citizens are really different from those of the Italian citizens.

We use the Chi-square independence test in a similar manner: for every agent, we try to establish if her feedback set is really different from the one of the rest of the agents. However, instead of outputting a binary decision (i.e., reporting pattern is different or not), we modify the test to output a continuous value: the CHI-Score of the feedback set.

We define, χ^i_{Sc}, the CHI-Score of the feedback set r_i as:

$$\begin{aligned} \chi_i^{Sc}(r_i) &= \chi_i^{Sc} = 1 - chi2cdf(\chi_i^2, 1); \\ \chi_i^2 &= \frac{\big(r_i - r_{-i}/(N_t-1)\big)^2}{r_{-i}/(N_t-1)} \\ &\quad + \frac{\big(M - r_i - M + r_{-i}/(N_t-1)\big)^2}{M - r_{-i}/(N_t-1)} \\ &= \frac{M\big(r_i(N_t-1) - r_{-i}\big)^2}{r_{-i}\big(M(N_t-1) - r_{-i}\big)} \end{aligned} \tag{1}$$

where χ_i^2 is the Chi-square value associated with the Chi-square independence test applied to the sets r_i and r_{-i}, and $chi2cdf(\cdot, 1)$ is the chi-square cumulative distribution function with one degree of freedom.

Intuitively, the CHI-Score of r_i is equal to the probability that honest reports of agent a_i could be even further away from r_{-i} than r_i is. The CHI-Score takes values between 0 and 1; the higher the CHI-Score, the "closer" are the sets r_i and r_{-i} and therefore the lower the probability that a_i's reports are distributed differently than the reports of the rest of the agents. We take the CHI-Score to be a direct measure of the agent's honesty, and therefore use it to compute the agent's side-payment, and the weight of the feedback set when computing the reputation of the provider.

3.3 Incentives for Honest Reporting

The reputation of the provider is computed as a weighted average of the feedback sets submitted by the agents:

$$R_t = \frac{1}{M} \frac{\sum_{j=1}^{N_t} \chi_j^{Sc} r_j}{\sum_{j=1}^{N_t} \chi_j^{Sc}}; \tag{2}$$

PROPOSITION 1. *When agents honestly report feedback, the reputation R_t of the provider accurately approximates the actual QoS delivered in the time period t.*

SKETCH OF PROOF. Let q be the real QoS delivered by the service provider during time period t. For all agents a_i, the number of positive reports in the observed feedback set o_i will be distributed according to the binomial distribution with parameters M and q. As all agents report truthfully, the number of positive reports in the set r_{-i} follows a binomial distribution with parameters $(N_t - 1)M$ and q. The

expected CHI-Score of agent a_i can be computed from the distributions of r_i and r_{-i}, and is equal for all agents. Since all weights in Equation (2) have the same values, the expected value of the reputation R_t, is equal to the expected ratio of positive reports submitted by all agents: i.e., the delivered QoS, q. ■

Proposition 1 proves that the use of CHI-Scores to weigh feedback sets does not bias the value of the reputation information (i.e., reputation accurately estimates delivered QoS). Therefore, the efficiency results of [11] still apply.

The final price agents pay for the M service invocations in period t is:

$$\begin{aligned} p &= M \cdot \big(p_t - \lambda(\bar{q}_t, R_t)\big) \\ &= M \cdot p_t \Big(1 - max\big(C(\bar{q}_t - R_t), 0\big)\Big); \end{aligned} \tag{3}$$

The price directly depends on the reputation of the provider. By reporting only negative feedback, rational clients decrease the reputation of the provider as much as possible, and thus minimize their payments.

Side-payments for feedback reports can make truth-telling rational. The payment proposed by our mechanism is directly proportional to the CHI-Score of the feedback set submitted by an agent. When all other agents report the truth (hence r_{-i} contains true feedback), a_i expects that r_{-i} follows a similar distribution as o_i, her direct observations. Therefore, the expected CHI-Score of r_i is maximized when $r_i = o_i$: any misreporting increases the "distance" between r_i and r_{-i}. The expected reputation side-payment is therefore maximized when a_i reports honestly; this makes truthful reporting a Nash equilibrium.

The external reward obtained from lying (i.e., the price decrease) imposes supplementary constraints on the reputation side-payments. Truthful reporting remains a Nash Equilibrium only when the price decrease obtained by lying is smaller than the expected side-payment loss. Let $SP(o_i, r_i)$ be the expected side-payment obtained by agent a_i when reporting r_i instead of the observed feedback o_i. $\Delta SP(o_i, r_i) = SP(o_i, o_i) - SP(o_i, r_i)$, $r_i \neq o_i$ is the expected side-payment loss due to misreporting. If $\Delta p(o_i, r_i)$ is the corresponding price decrease, we must have:

$$\Delta SP(o_i, r_i) \geq \Delta p(o_i, r_i); \forall r_i \neq o_i; \tag{4}$$

To compute the potential price decrease obtained by lying, let us consider the effect of misreporting on the reputation of the provider. By reporting r_i instead of o_i, the reputation of the provider becomes:

$$R_t^* = \frac{1}{M} \frac{\chi_i^{Sc}(r_i) r_i + \sum_{j \neq i} \chi_j^{Sc} r_j}{\chi_i^{Sc}(r_i) + \sum_{j \neq i} \chi_j^{Sc}}$$

When N_t is large enough, the misreporting of a_i does not affect the CHI-Scores of other agents, and therefore the expected decrease in reputation can be approximated by:

$$R_t - R_t^* \simeq \frac{o_i \chi_i^{Sc}(o_i) - r_i \chi_i^{Sc}(r_i)}{M \cdot N_t \cdot \chi_i^{Sc}(o_i)}$$

Assuming providers advertise the intended QoS, (i.e., $\bar{q}_t \simeq R_t$), the expected price decrease (due to misreporting) for the M service invocations is:

$$\Delta p(o_i, r_i) = C \cdot p_t \frac{o_i \chi_i^{Sc}(o_i) - r_i \chi_i^{Sc}(r_i)}{N_t \cdot \chi_i^{Sc}(o_i)}$$

Computing the expected side-payment loss due to misreporting requires an explicit model for the beliefs of the agents. We assume agents do not have any prior information about the service provider. Having observed o_i successful service invocations during one time period, the best estimate a_i has about the real QoS delivered by the provider is o_i/M.[5]

We denote by $\phi(r_i, r_{-i})$ the actual payment received by a_i when she reports the feedback set r_i, and the rest of the agents report r_{-i}. Let $\phi(r_i, r_{-i}) = K \cdot \chi_i^{Sc}(r_i)$, where K is a constant, greater than 0. The expected payment of a_i can now be computed by considering the probability distribution of r_{-i} given the real observation o_i:

$$SP(o_i, r_i) = \sum_{r_{-i}=0}^{(N_t-1)M} Pr[r_{-i}|o_i] \phi(r_i, r_{-i}); \tag{5}$$

where $Pr[r_{-i}|o_i]$ follows a binomial distribution for $(N_t - 1)M$ trials with probability o_i/M.

PROPOSITION 2. *Truthful reporting is a Nash Equilibrium when:*

$$K \geq \max_{r_i \neq o_i} \frac{\Delta p(o_i, r_i)}{\Delta SP(o_i, r_i | K = 1)};$$

where $\Delta SP(o_i, r_i|K = 1)$ is the expected side-payment loss for reporting r_i instead of o_i, computed for $K = 1$.

SKETCH OF PROOF. The proof has two parts. First, we show that $\Delta SP(o_i, r_i) \geq 0$ for all $o_i \neq r_i$, and $K > 0$. Then, given the lower bound for K, we show that the price decrease obtained by misreporting is always smaller than the loss caused by the side-payments.

Note that $SP(o_i, r_i) = K \cdot SP(o_i, r_i|K = 1)$ where:

$$SP(o_i, r_i|K = 1) = \sum_{r_{-i}=0}^{(N_t-1)M} Pr[r_{-i}|o_i] \chi_i^{Sc}(r_i, r_{-i});$$

is the expected CHI-Score of the report r_i given the observation o_i. $SP(o_i, r_i|K = 1)$ can be seen as the inter-correlation of two signals: $Pr[x|o_i]$ and $\chi_i^{Sc}(x|r_i)$. When all other agents report the truth, both signals have only one maximum (for $x = o_i(N_t - 1)$ and $x = r_i(N_t - 1)$ respectively) and are (approximately) symmetrically decreasing around the maximum point. The maximum correlation is reached when the maximum points of the two signals are aligned, i.e., $o_i = r_i$, and therefore $SP(o_i, o_i|K = 1) \geq SP(o_i, r_i|K = 1)$ for all $o_i \neq r_i$.

When K satisfies the hypothesis, we have:

$$\begin{aligned} \Delta SP(o_i, r_i) &= K\Big(\Delta SP(o_i, r_i|K = 1)\Big) \\ &\geq \Delta p(o_i, r_i) \text{ for all } o_i \neq r_i; \end{aligned}$$

Therefore it is optimal for a_i to report honestly, given that all other agents also report the truth. This makes truthful reporting a Nash Equilibrium. ■

3.4 Extension to N-ary Feedback

Binary feedback about a transaction can sometime cause the loss of valuable information. For agents using the stock-quote web service, late information (i.e., received after the

[5]for $o_i = 0$ and $o_i = M$, the actual estimate of the QoS is actually ε respectively $1 - \varepsilon$ for ε small

deadline) could still be more valuable than no information at all. One can therefore imagine a finer-grained reporting system where the feedback also gives some information about the delay of the answer: one feedback is submitted when the request was answered on time, another when the answer was no more than 1 minute late, etc.

In general, one can consider an N-ary reporting scheme where feedback can take any value from the predefined set $\mathcal{S} = \{s_1, \ldots s_S\}$ of cardinality S. Agents share a common ontology about the elements of $\mathcal{S}$ (i.e., they interpret feedback in the same way). The feedback set observed by an agent becomes a vector $o_i = (o_i^1, \ldots, o_i^S)$ where o_i^j is the number of service requests where a_i perceived the feedback value s_j. Similarly, the reported feedback set of an agent (i.e., r_i), as well as the feedback set of all other agents (i.e., r_{-i}) are vectors with S elements. The QoS and the reputation of the provider become probability distributions over the possible feedback values: $\bar{q}_t = (q_{s_1}, \ldots, q_{s_S}) \in [0,1]^S$ such that $\sum_{j=1}^{S} q_{s_j} = 1$.

The extension of the mechanism to N-ary feedback is straightforward: the CHI-scores are computed in the same way and become:

$$\chi_i^{Sc}(r_i) = \chi_i^{Sc} = 1 - chi2cdf(\chi_i^2, S-1);$$

$$\chi_i^2 = \sum_{j=1}^{S} \frac{\left(r_i^j(N_t-1) - r_{-i}^j\right)^2}{(N_t-1)r_{-i}^j}$$

where the Chi-square value is a summation over the dimensions of the feedback set, and the chi-square cumulative distribution function has $S-1$ degrees of freedom. The qualitative results of Proposition 1 and Proposition 2 remain the same.

4. EXPERIMENTAL EVALUATION

In this section we experimentally evaluate the mechanism described above, using several criteria. First, we study the accuracy of the reputation information in the presence of irrational clients that misreport feedback regardless of the monetary loss they incur. Second, we investigate the robustness of the honest-reporting incentives in the presence of such irrational agents. Finally, we compare the cost of our mechanism against existing side-payment schemes.

We consider the same example presented in the introduction, where a web service delivers stock quotes to interested agents. Every morning, the web service advertises a SLA specifying the price of a service request, the promised QoS (as a probability of delivering the information within a given deadline), and the coefficient C of the linear reputation-based penalty function λ. Clients subscribe to the service before the opening time of the market. Each subscription specifies (a) the code of the desired share and (b) the set of M time points when an information update is requested. An example of a subscription is: *"Request the price of the share X every 15 minutes starting at 9:00 AM and ending at 5:PM"*. Every subscription generates M service invocations.

The real QoS delivered to clients depends on the infrastructure of the provider and on the number of accepted requests. The provider can choose the intended QoS by limiting the total number of subscribers for a given day. When the stock market opens, all requests have already been registered and the delivered QoS remains fixed for the entire day. The reputation information is computed by the reputation mechanism at the end of every day, and all penalties are paid to the clients before the beginning of the next day.

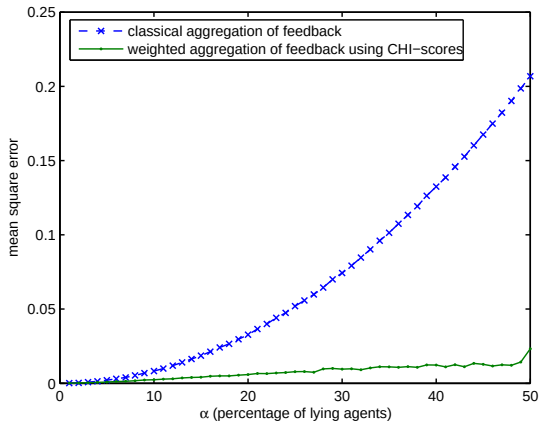

Figure 2: Mean square error of reputation information.

We take one day and one web service. We assume the total number of clients is N, and that all client requests are similar: the price of a share is requested every m minutes. The total number of requests per client during one day is therefore $M = 8hours \times 60min/m$.

As a first experiment, we study the accuracy of the reputation mechanism when irrational clients lie, despite the guarantees provided by Proposition 2. Figure 2 plots the mean square error between the expected and real reputation information when α percent of the agents lie (submit only negative feedback). The performance of our mechanism is compared against a classical (un-weighted) aggregation scheme for $N = 100$ agents, $M = 40$ interactions per agent, and the real QoS equal to 0.9. The average is taken over 100 runs. As it can be seen, using CHI-Scores to weigh feedback sets dramatically improves the robustness of the mechanism against lying agents.

Irrational lying also affects the honest reporting incentives for the rational agents. The most extreme lying strategy (worst-case scenario) is when irrational agents constantly submit negative feedback. Depending on the number of irrational reporters, rational agents find it optimal to slightly down-bias their real report. Figure 3 plots the probability that a rational agent will report something else than the true observation as the number of lying agents increases. For this experiment we took the same delivered quality value (i.e QoS $= 0.9$) but we considered only $M = 20$ interactions per client. The total number of clients varied from $N = 100$ to $N = 400$. The graph reveals an almost instantaneous switch from the truthful strategy to some lying strategy. For up to 2.5% liars, truth-telling is optimal; from that point onward, every supplementary liar makes down-biasing rational for an increasing set of observations (some observations are still reported truthfully, but the probability of such observations appearing decreases rapidly with the number of liars). With 3.5% liars, down-biassing becomes rational for all observations. This low threshold is mostly due to the extreme lying strategy we have considered. In reality, dishonest agents will lie only once every L reports, and consequently, the toler-

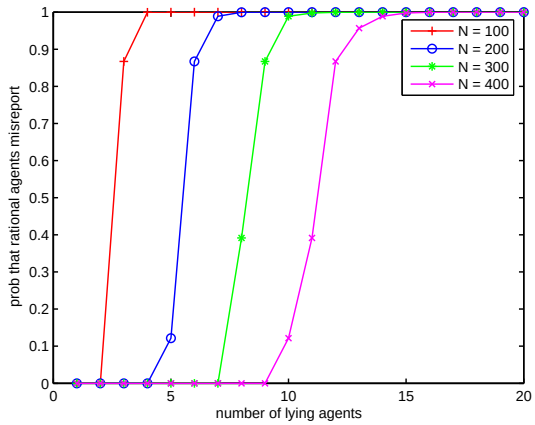

Figure 3: Misreporting incentives in the presence of irrational liars.

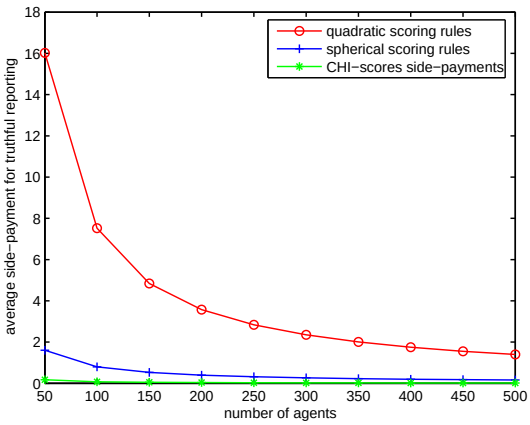

Figure 5: Average side-payment per client per transaction for truthful reporting.

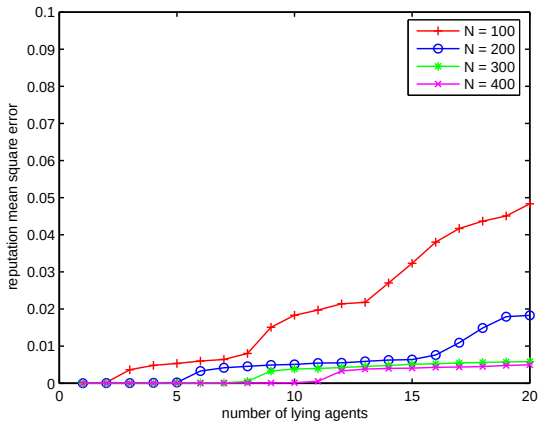

Figure 4: Reputation mean square error when rational agents are aware of the presence of irrational reporters.

ance threshold will be multiplied by L.

Even when truth-telling is not optimal, the submitted reports are not too far from the truth, and thus do not greatly distort reputation information. Figure 4 plots the corresponding mean square error for the reputation value when rational agents are aware of the presence of irrational reporters and consequently adapt their reports.

The reputation side-payments contribute substantially to the global cost of the reputation mechanism. In theory, all side-payment mechanisms can be made budget balanced by asking fixed (or periodically updated) fees from the client agents (i.e., clients also pay for using the reputation mechanism). However, none of the existing online markets charges clients for access to reputation information. The cost of reputation management is absorbed by the market and later distributed to service providers. Moreover, Dellarocas [4] theoretically proves that increasing amounts of truthful feedback helps rational service providers cut down costs (e.g., advertising costs) and thus justifies the providers' contribution to reputation management costs.

It therefore becomes an important objective for mechanism designers to minimize such costs, by minimizing the side-payments. We compare the costs of our mechanism with existing side-payment schemes based on scoring rules [12, 11]. We consider two of the best-known scoring rules: the spherical and quadratical scoring rule. The resulting side-payments are scaled (by addition and multiplication with a constant) to the minimum positive side-payments that counterbalance the price decrease obtained from misreporting. We take the average expected side-payment for truthful reporting, $\bar{SP} = \sum_{o_i} SP(o_i, o_i)$, per client, per transaction. Figure 5 plots the averages for the three mechanisms when $M = 20$ interactions per day per client, the price of service and the penalty constant are unitary (i.e., $p_t = C = 1$) and N varies from 50 to 500 clients per day. The side-payments based on CHI-Scores are one order of magnitude lower than the cheapest of the side-payments based on the considered scoring rules. When one service invocation costs 1 dollar, the average side-payment based on CHI-Scores is 7.5 cents for $N = 50$ clients and 1.3 cents for $N = 500$ clients. In the same conditions, the average side-payment computed using the spherical scoring rule is 79 respectively 15 cents.

5. DISCUSSION AND FUTURE WORK

One of the important assumptions behind our mechanism is that all customers in a certain group receive the same QoS within one period of time. In real systems, however, request arrival rates as well as other real-time factors might trigger non-negligible short term fluctuations in the service quality. Certain clients will thus receive better service than others.

However, most of these fluctuations will look random for the clients. Even though quality observations are no longer independently identically distributed, one client, due to the limited number of observations, will not be able to model the stochastic behavior of the service provider. Thus, the clients' beliefs remain as described in this paper, and the CHI-Scores encourage truthful reporting.

On the other hand, easily-identifiable QoS fluctuations patterns should not exist in a rational market. When ser-

vice providers can identify the clients that are likely to receive higher quality, it makes sense to treat those clients as part of a different, "preferred" group. Providers can thus offer different conditions (QoS and price) to each group, and clients within the same group continue to be treated "approximately equally". As a last resort, the mechanism designer can of course solve the problem by shortening the length of the time period.

A related problem comes from subjective interpretations of quality. Different agents might have different criteria for high quality, and this will affect our scoring mechanism. For this reason, our paper targets specific markets where autonomous agents request (web-)services. Interactions in such environments are usually regulated by SLA's that consider objective measures of QoS (such as response time, availability, etc). Dealing with subjective perceptions is a challenging direction for future work.

Truthful reporting is guaranteed as a Nash equilibrium by Proposition 2. However, honest reporting is not the only equilibrium strategy: e.g., reporting only negative experiences is also a Nash equilibrium. The problem of multiple reporting equilibria has been formally identified in [9]. Fortunately, there is a simple way of enforcing truth-telling by using a small number of trusted, third-party reports.

As future work, we plan to extend this mechanism along several dimensions. First, we plan to increase the robustness of the mechanism against irrational liars. In a future version we envisage to rate the feedback set of one agent against the reports of a fraction (not all) of the remaining agents. By carefully choosing the "reference" set for every agent, we plan to increase the threshold for the percentage of tolerated irrational reports.

Second, we plan to extend the set of contexts where the mechanism can be successfully used, by allowing some limited amounts of external information. As before, we expect to be able to group agents according to their prior information, and rate the feedback set of an agent against the reports submitted by other agents in the same group.

Third, we plan to investigate other distance metrics for scoring set of reports.

Last, but not least, we plan to address the problem of collusion. In the present mechanism, two or more agents can benefit by coordinating their false reports. To solve this problem we plan using the idea in [11] where a small number of trusted reports (i.e., reports that are true with high probability) can deter collusion.

6. CONCLUSION

When client agents can submit several feedback reports within a certain period of time, existing payment schemes that reward honest feedback are either inefficient, or extremely expensive. In this paper we present a novel side-payment scheme based on CHI-Scores. We consider the entire feedback set of an agent, not her individual reports. The CHI-Score of a feedback set results from a Chi-square independence test and reflects the correlation between the reports of one agent and those of the rest of the group. The score is used to weigh feedback sets when computing reputation information, and to scale the reputation side-payments. We prove that such monetary rewards make truth-telling rational, and show how external benefits obtained from lying can be counterbalanced. The mechanism can be extended to finer-grained feedback systems, and generates significantly lower costs. Experimental results show that a small number of irrational liars, does not significantly degrade the performance of the mechanism.

ABSTRACT

An agent's *trust decision strategy* consists of the agent's policies for making trust-related decisions, such as who to trust, how trustworthy to be, what reputations to believe, and when to tell truthful reputations. In reputation exchange networks, learning trust decision strategies is complex, compared to non-reputation-communicating systems. When potential partners may exchange reputation information about an agent, the agent's interactions with one partner are no longer independent from interactions with another; partners may tell each other about their experiences with the agent, influencing future behavior. This research enumerates the types of decisions an agent faces in reputation exchange networks, explains the interdependencies between these decisions, and correlates rewards to each decision. Experimental results using the Agent Reputation and Trust (ART) Testbed demonstrate the success of strategy-learning agents over agents employing naive strategies. The variation in performance of reputation-based learning vs. experience-based learning over different opponents illustrates the need to dynamically determine when to utilize reputations vs. experience in making trust decisions.

1. Introduction

When an agent does not have the resources to accomplish its goals alone, it may seek needed resources from other agents in a multi-agent system. These resources are acquired through transactions, which expose at least one party to risk, since a transaction partner might not follow through on the (implicitly or explicitly) agreed upon contract, either by choice or inability. An agent can protect itself against this risk of transaction failure by learning estimates of partner trustworthiness.

Learning trust from transaction experiences [5, 12, 16] is advantageous when agents have opportunities for numerous repeated interactions. When the outcome of interactions are observable, transaction experiences provide a trust-strategy-learning agent with trustworthiness feedback that is certain. Unfortunately, basing trust on transaction experiences means risk exposure is unavoidable; interactions must take place while partners' trustworthiness characteristics are being learned [7].

Reputation exchange is useful for quickly learning trustworthiness characteristics of other agents [14]. Adapted from [8], a reputation is a (not necessarily truthful) communication from one agent to another about the sender's trust in a third subject-agent. A multi-agent system whose communication protocols permit the exchange of reputations [11, 17, 18, 20, 21] is advantageous in systems with large populations and sparse transactions. Further, reputation exchange reduces an agent's risk exposure; an agent risks only the price of reputations it purchases, rather than the value of resources exchanged in a potential transaction. Agents entering a multi-agent system can quickly learn trust models by requesting reputations from more knowledgeable agents.

An agent's *trust decision strategy* consists of the agent's policies for making trust-related decisions with the aim of achieving greatest benefit. The simplest trust decision strategy, in systems without reputation exchange, encompasses decisions regarding both 1) who to trust (to minimize risk of failed transactions), and 2) how trustworthy to be (to exploit others). But the advantage of agents communicating reputation information adds another dimension to an agent's trust decision strategy; in reputation exchange networks, an agent must make additional decisions regarding 1) which reputations to believe (to better choose who to trust) and 2) how truthful to be in communicating reputations to others (to manipulate what others think about who to trust).

Reinforcement learning has been successfully applied to simple trust decision strategies for deciding who to trust—and how trustworthy to be—in agent transactions [3, 13]. This research seeks to apply similar techniques to help agents learn more

comprehensive trust decision strategies required in networks of agents exchanging reputation information. However, in reputation exchange networks, the complexity of the learning problem increases dramatically, compared to systems in which agents do not communicate reputation information. The agent must make more trust-related decisions, regarding not only who to trust and how trustworthy to be, but also regarding which reputation information to believe and how truthful to be when communicating reputations to others. Compounding the problem, the effects of these decisions may not be immediately observable, since the agent cannot easily gauge the nature and extent of reputation exchange occurring among its potential partners. Further, when potential partners may exchange reputation information about an agent, the agent's interactions with one partner are no longer independent from interactions with another; partners may tell each other about experiences with the agent, influencing how each behaves with the agent in the future.

Toward the goal of enabling agents to learn comprehensive trust decision strategies in reputation exchange networks, this research first enumerates the types of decisions an agent faces in systems with reputation exchange. Next, using the Agent Reputation and Trust (ART) Testbed [10] as a case study, the interdependencies between these decisions are explained. This research employs a learning approach for each decision; by establishing assumptions to ease interdependencies, rewards are correlated to each decision type. Experimental results demonstrate the success of strategy-learning agents over agents employing naive strategies. The variation in performance of reputation-based learning vs. experience-based learning over different opponents illustrates why agents must be able to dynamically determine when to utilize reputations vs. experience in making trust decisions.

2. Trust Decision Strategies

A trust decision strategy describes an agent's choices regarding four trust-related decision types, defined according to agent role (trustee or truster) and transaction (fundamental or reputation), as shown in Figure 1. Fundamental transactions are the basic transactions driving the need for trust modeling in the multi-agent system. Reputation transactions are distinct from fundamental transactions because the outcome of reputation transactions directly impacts decisions regarding fundamental transactions (this impact is shown later). An agent's trust-based decisions are:

1) *Should I trust?* For each potential fundamental transaction, the agent must decide whether to participate in—and expose itself to the risk of— the transaction.
2) *How trustworthy should I be?* For each agreed upon fundamental transaction, the agent must identify the degree to which cheating or honesty yields the greatest benefit.
3) *Should I believe this reputation?* For each potential reputation transaction, the agent must decide whether to conduct the transaction, then use the reputation to determine whether it should trust regarding fundamental transactions.
4) *How accurate should the reputation I tell be?* For each agreed upon reputation transaction, the agent must identify its level of truthfulness in communicating a reputation. The agent can only control the accuracy of reputations it communicates to the extent of its own trust model accuracy.

		Transaction	
		Reputation	Fundamental
Agent Role	Trustee	How accurate should the reputation be?	How trustworthy should I be?
	Truster	Should I believe this reputation?	Should I trust?

Figure 1. Trust decision types by transaction and agent role.

How the agent makes these decisions depends, in part, on the characteristics of the transaction. If the transaction protocol calls for sequential action between the two partners (for example, payment then delivery), the first partner to act serves as truster, and the second as trustee. If the transaction protocol dictates simultaneous action, both partners concurrently act as both trustee and truster. Future decisions are also impacted by the observability of a transactions outcome. For example, if an agent receives a payment as the transaction outcome, most likely it can tell if the payment is satisfactory. However, an agent may be unable to tell whether a reputation transaction is successful (the received reputation is accurate) if it has little knowledge about the trustworthiness of the reputation's subject agent.

2.1 The Complexity of Learning Trust Decision Strategies

This research proposes a method by which agents can learn trust decision strategies using a q-learning technique. Q-learning [15] is a well-known tool for learning best decision-making strategies by associating actions with expected rewards. Several researchers [3, 4, 9, 13, 19] have employed reinforcement learning techniques to discover strategies for trust decisions. However, these trust decisions only relate to fundamental transactions, as in the Prisoner's Dilemma [2]. Learning trust decision strategies in reputation-transaction systems is significantly more difficult, since in these systems, fundamental transaction decisions are not independent from each other and from reputation transaction decisions. An agent's fundamental transactions with one partner may influence its fundamental transactions with another, if its two partners are able to communicate reputation information. Learning an agent's trust decision strategy is also complex because multiple decisions can affect common results. For example, falsely spreading negative reputations about a trustworthy partner might cause other agents to trust the lying agent while isolating the falsely accused agent. Similarly, falsely spreading positive reputations about untrustworthy partners might hurt those agents receiving the reputations, thus improving the standing of the lying agent. Or, an agent might perform truthfully in hopes of receiving better treatment from partner agents, yet truthful behavior might benefit the agent's partners too much.

Considering the interdependent nature of these trust-related decisions, an agent attempting to learn the best combination of decisions faces a complexity problem. When making decisions about "should I trust?" an agent faces $O\left(2^{ae}\right)$ decision combinations from which to choose, assuming that choosing to trust is a binary decision, a represents the number of agents in the system, and e represents the number of possible transaction categories for which agents might have different expertise. When deciding "how trustworthy should I be?" an agent has n^p decision combinations, where n describes a number of possible, discrete degrees of fundamental-transaction trustworthiness and p describes the number of fundamental transaction requests

received from other agents. Since p can be as large as $(a\text{-}1)e$, the complexity of this decision is $O\left(n^{ae}\right)$.

When deciding "should I believe this reputation?" an agent faces $O\left(2^{a^2e}\right)$ decisions, assuming that choosing to believe a reputation is a binary decision, a (signifying the number of agents in the system) represents the number of reputation providers and the number of subject agents about whom reputations may be provided, and e (the number of possible transaction expertise categories) represents the number of categories for which each subject agent's trustworthiness can be questioned. When deciding "should I tell an accurate reputation?" an agent has m^q decision combinations, where m describes a number of possible, discrete degrees of reputation-transaction trustworthiness and q describes the number of reputation transaction requests received from other agents. Since q can be as large as $(a\text{-}1)ae$, the complexity of this decision is $O\left(m^{a^2e}\right)$.

Each decision of a given type is interdependent, but further, each decision type is interdependent. Therefore, in a given discrete timestep, in which an agent has the opportunity to interact with each other agent, as both truster and trustee, for both fundamental and reputation transactions, the agent's trust decision strategy has a complexity of $O\left(2^{ae+a^2e}n^{ae}m^{a^2e}\right)$. It is not feasible for an agent to learn its trust decision strategy without introducing some assumptions to relax interdependencies between decisions. The following section demonstrates how an agent can introduce these assumptions yet still learn a useful trust decision strategy.

3. Case Study: The ART Testbed

The Agent Reputation and Trust (ART) Testbed [1] is used as a case study for learning trust decision strategies. A brief overview of the ART Testbed game is described here. Readers are referred to [10] for more detail; all ART Testbed notation described here is consistent with that reference.

In the ART Testbed's artwork appraisal domain, agents act as appraisers who are hired by clients to deliver *appraisals* about paintings, each for a fixed client fee f. Agents compete for clients, who are assigned based on agents' past appraisal accuracy. In attempting to produce accurate appraisals, appraiser agents may purchase *opinions* (valuations of the painting by other agents) for a fixed fee, c_p. Opinion providers choose an amount, c_g, to pay (to the system) to generate an opinion, symbolizing the effort to perform a valuation; the amount c_g corresponds to the accuracy of the generated opinion. Appraiser agents may also purchase *reputations* (for a fixed fee c_r) from each other to help assess the trustworthiness of opinion providers. Agents compete to achieve the highest bank balance.

Designed as a tool for experimentation and competition, the ART Testbed has earned the attention of numerous researchers in the international trust research community. The Testbed design allows variation of agent strategies and game parameters for easy experimentation, as well as competition against and experiment replication by other researchers. Transactions are conducted sequentially, permitting the separate examination of truster and trustee decisions. Opinion purchases correlate to fundamental transactions, the outcomes of which (opinion accuracy) are observable at the end of each timestep, when true painting values are revealed. The outcomes of reputation purchases are not observable, though reputation receivers may estimate the accuracy of the reputations they receive against previously built trust models. Most importantly, the game's complexity illustrates the interdependencies of trust-related decisions.

The four trust-related decisions translate to the ART Testbed domain as shown in Figure 2. As an Opinion Requester, an agent must decide which opinions to purchase. As an Opinion Provider, an agent must decide how much payment, c_g, to invest in the opinions it communicates. As a Reputation Requester, an agent must decide which reputations to purchase. As a Reputation Provider, an agent must decide how truthful to be, compared to its own trust models, when communicating reputations.

		Transaction	
		Reputation	Fundamental
Agent Role	Provider	How accurate a reputation should I provide?	How accurate an opinion should I provide?
	Requester	Should I purchase this reputation?	Should I purchase this opinion?

Figure 2. Trust decision types in the ART Testbed domain.

Several assumptions are made to the ART Testbed game to remove details unnecessary to this research purpose. First, agent transaction protocols are simplified: Opinion Providers do not communicate opinion certainties, and Opinion and Reputation Providers always satisfy requests, though provided opinions and reputations may be untruthful. Further, agents do not generate opinions for their own clients, and they weight all received opinions equally when calculating their final appraisals. To eliminate non-agent-controlled variances in opinion accuracy, all agents are assigned the same expertise levels for all painting eras (fundamental transaction types).

3.1 Identifying Decision Interdependencies

Figure 3 shows a diagram of interdependencies between the ART Testbed's four trust-related decisions (darkened diamonds in the figure) and resulting observable feedback (costs and earnings, darkened boxes in the figure), enumerated here:

1) *Opinion Requester:* The Opinion Requester's decision regarding which opinions to purchase determines its opinion costs and the accuracy of its resulting final appraisals, which, in turn, impact its client revenue.
2) *Opinion Provider:* The Opinion Provider's decision regarding the accuracy of appraisals to provide determines its opinion order costs (c_g). This decision also affects Opinion Requesters' accuracy of final appraisals and client revenue. Since appraiser agents compete for client revenue, effects on Opinion Requesters' client revenue also impact the client revenue of Opinion Providers. Finally, the Opinion Provider's opinion accuracy influences the number of future requests from Opinion Requesters, which determines the Opinion Provider's future opinion revenue.
3) *Reputation Requester:* The Reputation Requester's decision regarding which reputations to purchase impacts its

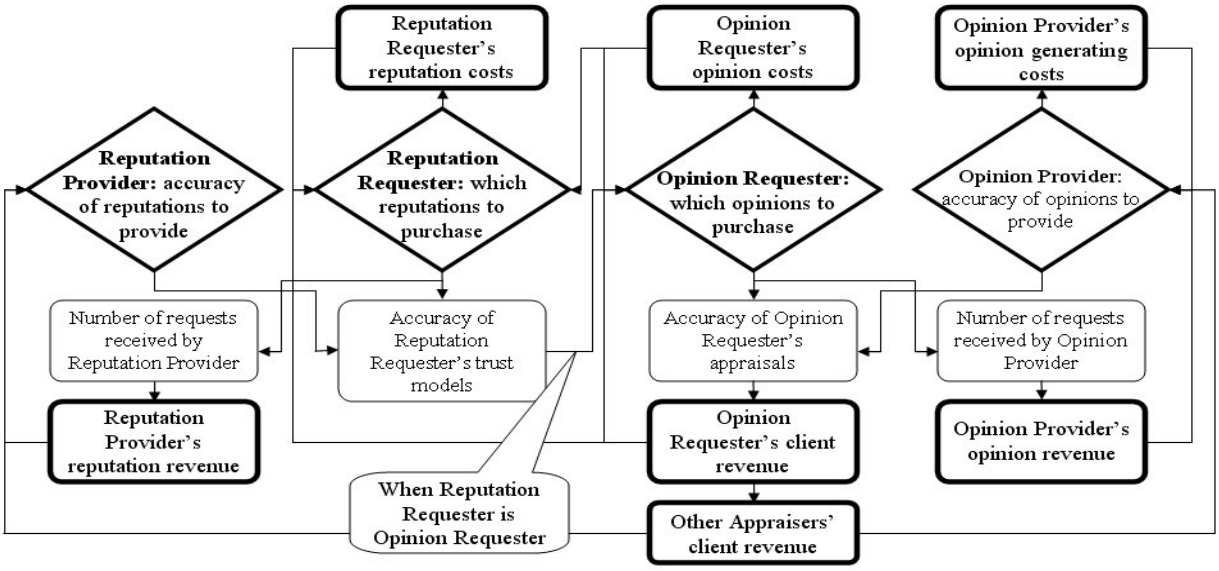

Figure 3. Trust decision interdependencies in the ART Testbed domain.

own reputation costs, as well as its ability to determine which opinions to request, which (as mentioned for the Opinion Requester's role) impacts both the Reputation Requester's opinion costs and client revenue.

4) *Reputation Provider:* The Reputation Provider's decision regarding the accuracy of reputations to provide influences the Reputation Requesters' ability to determine which opinions to request, which affects the Reputation Requester's, and ultimately the Reputation Provider's, client revenue. Also, the Reputation Provider's reputation accuracy influences the number of future requests from Reputation Requesters, which determines the Reputation Provider's future reputation revenue.

Multiple decisions, over all four agent roles, influence multiple feedback elements, making the correlation of specific decisions to their resulting rewards difficult. The following section introduces dependency-eliminating assumptions and proposes methods for calculating rewards associated with each decision.

3.2 Trust Decision Rewards

To conduct q-learning for each trust-related decision, a reward must be assigned to each decision. Since decisions are interdependent, and observable costs and revenues are aggregated, two assumptions are presented to ease these interdependencies and divide observable earnings into per-decision rewards:

Assumption 1: Individual decisions of a single decision type are assumed independent of each other (i.e. all of an agent's opinion-requesting decisions are independent of each other, regardless of opinion provider or era).

Assumption 2: Client revenue is only influenced by the Opinion Requesting decision (thus agents' client revenues are independent of each other).

3.2.1 Opinion Requester Rewards

The Opinion Requester's choice regarding the purchase of a single opinion is binary: either request or not request the opinion. The choice to not request an opinion is assumed to yield a reward of zero, but calculating a reward ($Q_{OR}(true)$) associated with choosing to request an opinion is more complicated. Utilizing the assumptions above, a reward associated with each choice to request an opinion can be estimated by attributing a portion of the Opinion Requester's resulting client revenue first to each computed appraisal, then to each opinion composing that appraisal. First, the total client revenue, v_{total}, attributed to all client appraisals, is calculated as the number of Opinion Requester's clients in the next timestep, n_c, times the earned, per-client fee, f:

$$v_{total} = n_c f \ .$$

Next, the estimated client revenue portion, v_c, attributed to a single appraisal, for client c, is calculated as:

$$v_c = v_{total}\left(\frac{\frac{1}{\varepsilon_{p_c^*}}}{\sum_{i \in C}\left(\frac{1}{\varepsilon_{p_i^*}}\right)}\right),$$

where C represents the set of the Opinion Requester's client appraisals and $\varepsilon_{p_c^*}$ represents the normalized error of the client's painting appraisal, p_c^*, from the painting's true value, t_c:

$$\varepsilon_{p_c^*} = \left|\frac{p_c^* - t_c}{t_c}\right| .$$

An estimated client revenue portion, $v_{c,a}$, is attributed to each opinion (by opinion provider a for client c's painting):

$$v_{c,a} = v_c\left(\frac{\frac{1}{\varepsilon_{p_{c,a}}}}{\sum_{i \in A}\left(\frac{1}{\varepsilon_{p_{c,i}}}\right)}\right),$$

where A represents the set of Opinion Providers for painting c and $\varepsilon_{p_{c,a}}$ represents the normalized error of a single opinion, $p_{c,a}$, from the painting's true value, t_c:

$$\varepsilon_{p_{c,a}} = \left| \frac{p_{c,a} - t_c}{t_c} \right|.$$

Finally, the reward, $w_{OR,c,a}$, associated with requesting the opinion from Opinion Provider a about client c's painting is calculated as the estimated client revenue portion, $v_{c,a}$, minus the cost, c_p, of requesting the opinion:

$$w_{OR,c,a} = v_{c,a} - c_p .$$

This reward is averaged for all requested opinions from a given Opinion Provider a and era e, to which paintings c belong.

3.2.2 Opinion Provider Rewards

The Opinion Provider must choose the accuracy of the opinion it provides to an Opinion Requester. More precisely, the Opinion Provider must choose the amount, c_g, to pay to generate an opinion, where c_g is related to opinion accuracy. First, it is assumed that the Opinion Provider makes the same opinion accuracy decision for all opinion requests from the same Opinion Requester about paintings from the same era. Thus, using the independence assumptions, the reward, $w_{OP,a,e}$, associated with choosing an amount, c_g, to pay to generate an opinion, is calculated as:

$$w_{OP,a,e} = n_{p,a,e}\left(c_p - c_{g,a,e}\right),$$

Where $n_{p,a,e}$ represents the number of opinion requests received in the next timestep from agent a about paintings from era e, c_p represents the per-opinion cost received for providing opinions, and $c_{g,a,e}$ represents the chosen amount paid to generate each opinion for requester a about paintings from era e.

3.2.3 Reputation Provider Rewards

The Reputation Provider must choose the accuracy of the reputation it provides to a Reputation Requester. For this research, it is assumed that all agents have a mutual understanding that reputation values correspond to q-values ($Q_{OR}(true)$) for deciding in the affirmative to request opinions. Since the ART Testbed only permits the exchange of reputations as values between zero and one, q-values are converted from a scale between $-f$-c_p (the assumed worst-case penalty for requesting an opinion) and f-c_p (the assumed best-case reward for requesting an opinion). Therefore, the conversion from $Q_{OR,s,e}(true)$ (the Reputation Provider's actual q-value for requesting opinions from opinion provider (subject-agent) s for expertise era e) to $r_{s,e}$ (the scaled, believed reputation about s for e) is given by:

$$r_{s,e} = \frac{Q_{OR,s,e}\left(true\right) + f + c_p}{2f}.$$

Reputation accuracy is parameterized using the δ variable to describe the relationship between the Reputation Provider's believed reputation, $r_{s,e}$, and the actual reputation, $r^*_{a,s,e}$, it provides to Reputation Requester a. Intuitively, $\delta_{a,s,e}$ represents the percent difference between the believed reputation $r_{s,e}$ and the limits of permissible reputation values, where negative δ values imply pessimistic reputations and positive δ values imply optimistic reputations. Formally, $r^*_{a,s,e}$ is calculated as:

$$r^*_{a,s,e} = \begin{cases} r_{s,e}\left(\delta_{a,s,e} + 1\right), \text{if } -1 \le \delta_{a,s,e} < 0 \\ r_{s,e}\left(1 - \delta_{a,s,e}\right) + \delta_{a,s,e}, \text{if } 0 \le \delta_{a,s,e} \le 1 \end{cases}.$$

Using the independence assumptions, the reward, $w_{RP,a,s,e}$, associated with providing a reputation whose accuracy correlates to $\delta_{a,s,e}$ is given by:

$$w_{RP,a,s,e} = n_{r,s,a,e} c_r ,$$

where c_r is the fixed reputation purchase cost and $n_{r,s,a,e}$ is the number of reputations requested in the next timestep by a about s for era e. Since the maximum possible value of $n_{r,s,a,e}$ is 1 (in a single timestep, a Reputation Requester can only request one reputation from a given provider about a given subject-agent and expertise era), an $n_{r,s,a,e}$ value of zero or one is recorded in each timestep for a chosen δ value, until the timestep in which a new reputation provider decision must be made for the given requester, subject-agent, and era.

3.2.4 Reputation Requester Rewards

The Reputation Requester's decision to purchase reputations is binary. As in the case of the opinion-requesting decision, the reward of not requesting a reputation is assumed to be zero. The reward associated with requesting a reputation is based on the indirect benefit of making savvy opinion requests based on quality reputations, and is estimated as follows. The error of a reputation, $\varepsilon_{r^*_{a',s,e}}$, is estimated by averaging the error between the reputation and computed rewards for requested opinions in C_e (the set of opinions whose paintings belong to this reputation's era e):

$$\varepsilon_{r^*_{a',s,e}} = \frac{\sum_{i \in C_e} \left| r^*_{a',s,e} - w_{OR,i,s} \right|}{\left| C_e \right|},$$

where a' represents the provider of the reputation about opinion provider (subject-agent) s.

An estimated client revenue portion, $v_{r,a',s,e}$, is attributed to each reputation (by reputation provider a' about subject-agent s and era e) in this way: a portion of the client revenue ($w_{OR,c,s}$, attributed to requesting an opinion c) is attributed to each requested reputation according to the reputation's estimated error (A' is the set of reputation providers about s for e). These client revenue portions are averaged over all opinions whose paintings belong to era e:

$$v_{r,a',s,e} = \frac{\sum_{i \in C_e} \left(w_{OR,i,s} \left(\frac{\frac{1}{\varepsilon_{r^*_{a',s,e}}}}{\sum_{j \in A'} \left(\frac{1}{\varepsilon_{r^*_{j,s,e}}} \right)} \right) \right)}{\left| C_e \right|}.$$

The reward, $w_{RR,a',s,e}$, attributed to requesting a given reputation is simply its calculated client revenue portion minus its cost:

$$w_{RR,a',s,e} = v_{r,a',s,e} - c_r .$$

The Reputation Requester must make a second decision which brings to light a significant problem [6]: how should reputation information influence the agent's existing experience-based trust model (the Opinion Requester's $Q_{OR}(true)$ values)? Since a Reputation Requester purchases reputations for the purposes of making better opinion requesting decisions, an agent in the reputation requesting role should be jointly considered in the opinion requesting role. This research employs a weighting parameter λ to perform a weighted average between aggregated reputations and the existing $Q_{OR,s,e}(true)$ value. When λ is 0, no weight is given to reputations, and opinion request decisions are made using only previous experience according to Section 3.2.1. Conversely, when λ is 1, the Opinion Requester's $Q_{OR}(true)$ values are given no weight, instead, the Opinion Requester makes opinion requests based on an average of q-values received as reputations. Reputation request rewards are multiplied by λ since reputations are only responsible for λ fraction of the opinion requesting decision. Note that when an agent serves as a Reputation Provider, it provides reputations from its experience-based $Q_{OR}(true)$ values, excluding any reputations it may have received.

4. Experiments

Once rewards are associated with each trust-related decision as in Section 3.2, q-learning is performed. Experiments are conducted to compare the resulting trust-strategy-learning technique against several standard strategies.

4.1 Experimental Setup

The ART Testbed parameters [10] for these experiments include client fee (f) of 100, opinion cost (c_p) of 10, and reputation cost (c_r) of 1. The accuracy of generated opinions is governed by the parameters s^* (related to appraiser expertise, the standard deviation of opinion error distribution) and α (determines the impact of the opinion-generating cost, c_g). For these experiments, s^* equals 0.1 for all agents regarding all eras, and α is set to 5.0. In each experiment, the simulation assigns client paintings from three eras. The parameter q, which determines the influence of previous client shares on current client shares, equals 0.5. Agents are permitted to select c_g values in one-unit increments between zero and ten (since ten is the opinion purchase price c_p, investments larger than that amount are impractical).

Table 1 displays the seven strategy variations compared. The Naïve-Honest strategy requests opinions from all other agents in the system and provides very accurate opinions, investing $c_g = 10$ to generate each opinion. This strategy is naïve in that reputations are not utilized, therefore none are requested, and default, optimistic reputations of 1.0 are provided to requesters. The Naïve-Cheating strategy is similar to the Naïve-Honest strategy except that it provides very inaccurate opinions (investing $c_g = 0$ in the opinions it provides) and pessimistic reputations (0.0). The Op-Learning-Honest strategy learns opinion requesting decisions from experience (Section 3.2.1) and opinion providing decisions as in Section 3.2.2, while requesting reputations from all agents and providing truthful reputations. The Op-Learning-Cheating strategy behaves similarly to Op-Learning-Honest, but consistently provides pessimistic reputations of 0.0. The Random strategy randomly makes decisions for each of the four decision types. The two Learning strategies demonstrate the learning techniques described in this paper, one with a λ value of 0.0 (learning opinion requesting decisions based on experience only), and the other using λ of 1.0 (learning opinion requesting decisions based on reputations only). All Learning agents employ the same q-learning parameters for each learned decision: learning rate of 0.5, discount factor of 0.0, and temperature, or degree of exploration, of 0.5.

Table 1. Agent strategies.

Strategy Name	Opinion Req.	Opinion Prov.	Reputation Req.	Reputation Prov.
Naïve Honest	request from all	accurate (c_g=10)	none	1.0 (δ= 1)
Naïve Cheating	request from all	inacc. (c_g=0)	none	0 (δ= -1)
Op-Learning Honest	learn by experience	learn	request from all	truthful (δ= 0)
Op-Learning Cheating	learn by experience	learn	request from all	0 (δ= -1)
Random	random	random	random	random
Learning (λ = 0)	learn by experience	learn	learn	learn
Learning (λ = 1)	learn from reputations	learn	learn	learn

In each of ten experiments, a single Learning agent (λ=0 or λ=1) competes against five agents, all of a single strategy: Naïve-Honest, Naïve-Cheating, Op-Learning-Honest, Op-Learning-Cheating, or Random. Each experiment of six agents is run for ten thousand timesteps (for three independent runs) to demonstrate strategy convergence. Each agent's performance is gauged in terms of converged, per-timestep earnings.

4.2 Experimental Results

Results from all ten experiments are shown in Figure 4. In each experiment, per-timestep earnings for each agent converged within approximately the first one hundred timesteps. In all cases, the Learning agent's five opponents (all of like strategy) achieved per-timestep earnings which were statistically similar to each other; these earnings were averaged to arrive at the opponent's average per-timestep earnings (white bars) shown in Figure 4. The opponents' earnings are compared against the Learning agent's earnings (black bars). All differences between Learning agents and their opponents are statistically significant ($\alpha = 0.1$).

In the first pair of experiments, a Learning agent (λ=0 or λ=1) competes in a system with five Naïve-Honest agents. The Learning agent increases its bank balance at nearly twice the rate of each Naïve-Honest agent. Because the Learning agent purchases fewer reputations when λ=0 than when λ=1, the λ=0 agent achieves slightly higher per-timestep earnings than the λ=1 case, and its opponents' earnings are slightly lower (failing to utilize reputations does not penalize the Learning agent, because its opponents are honest). The Learning agent's behavior converges to always requesting opinions from the Naïve-Honest agents, while investing little in the opinions it provides and, in the λ=0 case, rarely requesting reputations.

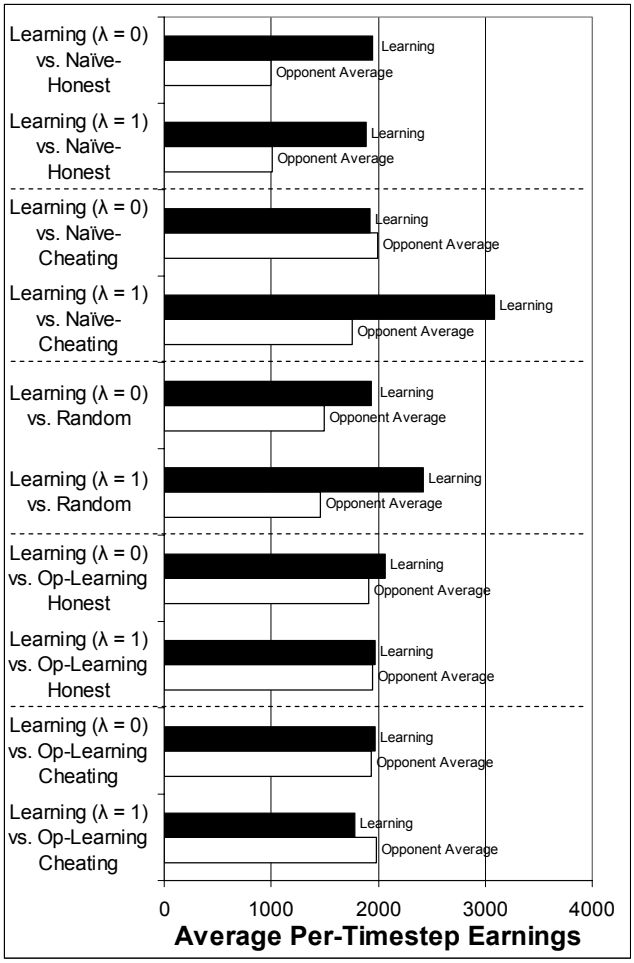

Figure 4. Average, per-timestep earnings for learning strategies (λ=0 and λ=1) versus opponents.

In the second pair of experiments, a Learning agent (λ=0 or λ=1) competes against five Naïve-Cheating agents. The Learning agent with λ=0 maintains per-timestep earnings slightly less than those of the Naïve-Cheating agents. The Learning agent with λ=1 maintains much higher earnings than the Naïve-Cheating agents; it makes use of its opponents' pessimistic reputations, an accurate reflection of the opponents' tendency to cheat.

The third pair of experiments demonstrate that the Learning agent achieves higher earnings than its five Random strategy opponents in both the λ=0 and λ=1 cases. The λ=1 Learning agent achieves higher per-timestep earnings than the λ=0 agent, but Random agents' earnings are the same between the two cases. The Learning agent succeeds by employing a mixed strategy for each of its four decision types.

The fourth pair of experiments compares the Learning agent against five Opinion-Learning-Honest agents. In both cases (λ=0 and λ=1), the Learning agent maintains greater earnings than its opponents. All agents learn to always request opinions and to provide opinions with accuracy that is both beneficial to competitors (to ensure repeated transactions) yet not too costly to generate. Because their opponents naively always request reputations, the Learning agents provide randomly-accurate reputations. As in the Naïve-Honest experiments, the Learning agent yields higher earnings when λ=0 than when λ=1 because the agent purchases fewer reputations in the λ=0 case.

In the last pair of experiments, the Learning agent competes against five Opinion-Learning-Cheating agents. When λ=1, the Learning agent earns lower earnings than its opponents, because it is misled by its opponents' inaccurate reputations. When λ=0, the Learning agent achieves earnings higher than its opponents, relying on the experience-based learning, rather than reputations, to decide which opinions to purchase.

The experiments demonstrate that in only two cases (Learning λ=0 vs. Naïve-Cheating and Learning λ=1 vs. Op-Learning Cheating), the Learning agent earns less than its opponents. However, in both cases, adjusting the λ value (to λ=1 against Naïve-Cheating and to λ=0 against Op-Learning Cheating) allows the Learning agent to outperform its opponents. Further, generalizations can be made about when certain λ values are beneficial: learning from experience (λ=0) achieves higher earnings when opponents tend to be trustworthy, while learning from reputations (λ=1) is beneficial when reputations accurately reflect opponent trustworthiness.

5. Conclusions

Experimental results demonstrate that learning trust decision strategies, either from experience or reputations, yields higher earnings than several static strategies in the ART Testbed domain Further, the variation in earnings of reputation-based learning (λ=1) vs. experience-based learning (λ=0) over different opponents demonstrates successful agents must be able to dynamically determine when to utilize reputations vs. experience in making trust decisions.

This research yields a domain independent contribution by enumerating decisions—and their resulting complexity—that make up a trust decision strategy (who to trust, how trustworthy to be, what reputations to believe, and how truthful to be in telling reputations). Other contributions of this work are adaptable to various types of problems in which trust must be evaluated and reputations may be exchanged. The work identifies interdependencies (which exist since potential partners can influence each other by exchanging reputations about an agent) between those decisions. By introducing assumptions to ease these interdependencies, rewards are attributed to each decision to facilitate reinforcement learning of trust decision strategies. Reward allocation can be adapted to other domains by adjusting transaction costs and earnings associated with domain-introduced interdependencies.

Approaching the complexity of learning trust decision strategies requires the introduction of numerous assumptions. However, these assumptions pave the way for future investigation, which will seek to relax the independence assumptions of Section 3.2 to improve the overall rewards a learning agent achieves. The authors plan to use learning techniques to help an agent learn the best λ, the degree of reliance on experience- versus reputation-based trust, relative to each opinion-requesting decision. The performance of the strategy-learning techniques described in this research requires further analysis against more advanced opponent agents with dynamic strategies. Also, more agent combinations must be tested—including agent self-play—since

trust strategies may yield different results as the composition of the system (strategies and numbers of opponents) change. Since, at the time of writing, the ART Testbed is still awaiting its first competition, sophisticated strategies have yet to be uncovered for comparison. However, the experiments conducted in this research will serve as a benchmark for future progress.

Monopolizing Markets by Exploiting Trust

ABSTRACT

We investigate trust-based relationships in electronic supply chains where trust is a measure of consistency in meeting negotiated contract deadlines. We consider scenarios where contractors assign contracts to contractees who are significantly more successful in meeting deadlines. The task deadlines are drawn from a known distribution. We present a probabilistic analysis that enables contractees to strategically bid on only certain tasks to earn the trust of their contractors. Once a contractee achieves a high level of trust, it can then exploit that trust to increasingly corner a larger portion of the market share of all tasks. We present a trust exploitation scheme that monopolizes the market against greedy contractees who bid on all announced tasks. We also show that such market monopolization is not possible in the presence of a trusted, but non-exploiting, contractee. The exploiter can, however, effectively "starve" the non-exploiting trusted agent.

1. INTRODUCTION

Supply chains form distributed, dynamic networks of agile, adaptive entities. As a result, supply chain management where rational agents represent interests of individual entities and organizations have been an area of active research [16, 21, 23]. From the multiagent systems perspective, a supply chain is often modeled using a decentralized network of agents where each agent can do a part of a task. Typical approaches try to optimize the profitability of entities with emphasis on pricing and scheduling [7].

Researchers in business and management science, however, have recognized that a key component of decision-making in real-world supply chains is the consideration of trust between the contracting organizations [12, 24]. Though the use of information technology and computer systems to facilitate trust-building between organizations have been proposed in mid-80s [14], little work has been done in this area.

We believe an agent based supply chain can effectively capture the needs and constraints faced by real-life B2B systems, and hence, can become an integral part of fielded applications only when such higher level issues like trust are adequately addressed. In our previous work we focused on the aspect of developing stable, long term, trusted partnerships that allow organizations to have more accurate predictions of the time and cost requirements to meet market demands [18]. This work measured trust as the likelihood of completing contracted tasks by their deadlines. Agents that were sufficiently more trusted were always awarded contracts over others. Task deadlines were drawn from a known distribution, and strategic agents bid only on tasks for which they were sufficiently more confident of meeting deadlines. Over time, such an agent would be recognized as more trustworthy by the contractor(s) and would be preferred over other agents who bid for all tasks. We refer to such trust-building agents as *trust-building (TB)* agents.

In this paper, we investigate how a trusted contractee agent can exploit the trust of its contractor(s) to eliminate the competition and monopolize market share. From a self-interested viewpoint, trust is like any other resource that can be leveraged to gain competitive advantage. We propose that once an agent has build sufficient trust, the next logical step would be to exploit that to incrementally take over the entire market. This process mirrors the development of a monopolist in a marketplace though practical scenarios are more complex and involve aspects beyond trust. We refer to agents who exploit their trust as *trust exploiting (TE)* agents.

We further evaluate the performance of such a monopolistic agent in the presence of a non-exploiting TB agent who has no intention to monopolize. The presence of the TB agent presents a major impediment to the TE agent's goal of monopolizing the market directly. We motivate, implement, and evaluate two variations of TE agent that tries to corner as much of the market share as possible even if

monopolization is precluded.

We use a contracting framework for connecting the suppliers to the manufacturers: manufacturers announce contracts for tasks with given deadlines; suppliers bid on these tasks; and the contract is allocated to one of the bidders based on its past performance history. We use a simplified contracting model where contractors prefer to assign tasks to contractees who have significantly higher success rates in meeting deadlines. We assume that the trust preferences of the contractor, the task deadline distribution and the performance distribution of the contractees are known. We then develop a precise bidding strategy for trust-building contractees. The motivation is to bid only on those tasks for which they have a high likelihood of meeting deadlines. However, not bidding on tasks also reduces the success rate of completing tasks. We provide a probabilistic analysis to handle this tradeoff. We then augmented this strategy to incorporate strategic shifts in the bidding range, once trust has been established, to monopolize the market. Further, we investigate the different scenarios which may occur when another trusted agent is present in the market. Finally we provide experimental verification of our formal analysis.

We emphasize that we are not pursuing, in this paper, a game-theoretic approach to equilibrium analysis in the context of trust-based contracting. While such an analysis is critical and necessary under the assumption of all bidders being rational, we are more interested in approximately modeling real world situations. In typical market environments, participants have a varying degree of knowledge, longevity, resources, strategic reasoning capability, etc. In particular, we model market situations where almost of all of the contractors use a myopic or greedy approach to bidding for tasks. This myopic behavior can stem from short market lifetime, financial exigencies, resource constraints, lack of knowledge or reasoning capability, etc. The research question we are pursuing is how should a rational contractor, with long-term market presence, approximate knowledge about market conditions, and no limiting resource constraint, etc. choose its bidding strategy to maximize its long-term utility. While we follow intuitive guidelines while developing and exploiting trust, the technical contribution of this work lies in formally developing precise bidding strategies with accurate performance predictions followed by experimental verification. Whereas trust and reputation in agent based systems is a very active research area in multiagent systems [5, 6, 10, 15, 20, 22, 25], to date there exists very little work on formal derivation of strategies to build or exploit trust.

2. CONTRACTING MODEL

We assume a trust-based model for task allocations by a contractor to bidders in a marketplace.

2.1 Task and performance distributions

We assume a task distribution $\mathcal{T}$ from which the deadline of different tasks are drawn. $\mathcal{P}_j$, defined over the closed interval $[l, h]$, represents the distribution from which the actual time taken by supplier j to process tasks is drawn. For continuous distributions, this means $\int_l^h \mathcal{P}_j(x)dx = 1$ and $\int_l^h T(y)dy = 1$. The corresponding discrete distributions, where T and $\mathcal{P}_j$ represent probability mass functions, are $\sum_{x=h}^{l} \mathcal{P}_j(x) = 1$ and $\sum_{y=h}^{l} T(y) = 1$ respectively.

2.2 Use of trust in selecting contractees

Each contractor maintains a trust rating, t_c for each possible contractee, c, which is the proportion of time that contractee could meet an assigned task deadline. For any two bidders, $\underline{b}, \overline{b} \in B_i$, we say $\overline{b}$ γ-dominates $\underline{b}$ (equivalently, $\underline{b}$ is γ-dominated by $\overline{b}$) if

$$\gamma * t_{\underline{b}} < t_{\overline{b}}, \tag{1}$$

where $\gamma > 1$ is a trust constant, chosen by the contractor. The basic motivation or incentive for the contractor to use a trust measure for selecting suppliers is to ensure reliability. If a supplier fails to deliver the required materials or products by the negotiated deadline, the manufacturer may not be able to meet its own production schedules and delivery deadlines and hence may face stiff penalties.

Each task announcement, T_i, contains an associated deadline $d(T_i)$ drawn from the distribution $\mathcal{T}$. Each supplier decides to bid or not bid on an announced task. As we are concentrating only on the trust evaluation of the bidders in awarding tasks, a bid from a bidder j can just be a default message signaling js interest in the task. The contractor of a task assigns it to a contractee randomly chosen from the set of non-γ-dominated bidders in the set of bidders for the task, B_i.

Note that this is a deliberate simplification of the real-world contracting process. In particular, we have left out the consideration of the price in the bid while awarding contracts! We believe that real-world stable supply chains incorporate trust considerations as a key metric for awarding contracts. We acknowledge that even in such situations, trust is one of several key parameters, including price, that determines contract awards. In this study, however, we wanted to focus exclusively on trust considerations as there has been very little work in agent based systems on the use of trust in supply chain contracting. Another way of situating this work is to assume that the contractor is choosing, based on trust, between all bidders with the same price. The issues we are studying can also be analyzed effectively with only one manufacturer and several suppliers and contractees, and hence we do not use a full supply chain. The techniques presented, however, readily transfers to more elaborate supply chains.

2.3 Goal of contractee

Let there be N contractees. The goal of a contractee j is to maximize its success in procuring and delivering contracts. The objective criterion to be maximized, the *success rate*, is[1]:

$$\int_{bl}^{bh} r(j, y)T(y) \left(\int_l^y \mathcal{P}_j(x)dx \right) dy, \tag{2}$$

where $r(j, y)$ is the probability that a task of length y is assigned to supplier j by the contractor (depends on the set of bidders for the task and their respective trust values), the integration within the parenthesis represents the likelihood of meeting the deadline y and bl, bh are respectively the minimum and maximum deadlines for tasks on which j will bid. The *success rate* represents the expected number of assigned tasks successfully delivered by their deadline.

[1]Most of the analysis presented in the following uses notations corresponding to continuous distributions. The equivalent expressions for discrete distributions can be similarly derived.

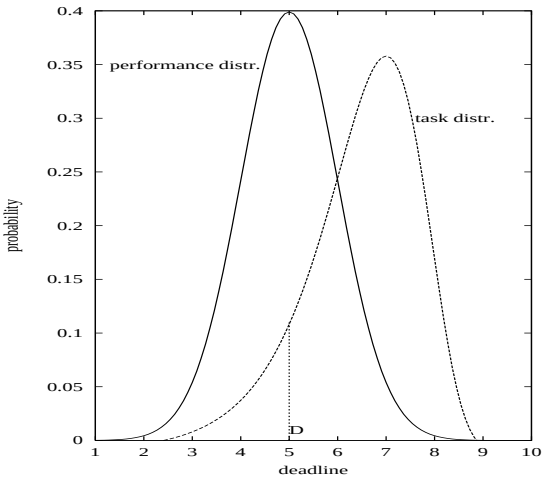

Figure 1: Example continuous task deadline and performance distributions.

3. BUILDING TRUST

We assume that the contracting model is common knowledge between the contractor and the suppliers and that each supplier j is cognizant of the task deadline distribution $\mathcal{T}$, its performance distribution $\mathcal{P}_j$ and the trust constant γ. We now present two types of bidding strategies for a contractee j in response to an announcement for a task t_i with deadline $d(T_i)$:

Greedy (G): This strategy bids for a task whenever there is a non-zero probability of meeting the deadline, i.e., $\int_l^{d(T_i)} \mathcal{P}_j(x)dx > 0$.

Trust-building (TB): This strategy focuses on building trust, which is measured as the likelihood of meeting the deadline of an assigned task. This strategy is elaborated in the rest of this section.

The number of contractees using the G and TB strategy are known and given by N_G and N_T respectively. Let $N = N_G + N_T$.

The key consideration for a TB agent is the choice of the minimum deadline threshold, D, for bidding such that it is viewed by the contractor to be sufficiently more trustworthy, in the sense of γ-domination, than a G contractee. We assume that performance distribution $\mathcal{P}$ is the same for all agents. The Figure 1 presents a typical situation with task and performance probability distributions and the deadline D below which TB agents will not bid.

The average expected success likelihood or *trustworthiness* of an agent j who wins, i.e., is awarded, all tasks in the region $[bl, bh]$ is given by

$$\bar{P}(bl, bh) = \frac{1}{\mathcal{T}_{bl,bh}} \int_{bl}^{bh} T(y) \left(\int_l^y \mathcal{P}_j(x)dx \right) dy, \quad (3)$$

where $\mathcal{T}_{x,y} = \int_x^y T(z)dz$, is the cumulative probability of tasks arriving with deadlines in the region $[x, y]$. The above expression is obtained using Equation 2 with $r(j, y) = 1$, i.e., agent j wins the contract with certainty. If an agent wins only a fraction f of tasks in that region, the corresponding average success likelihood is $f\bar{P}(bl, bh)$.

To facilitate the presentation of the analysis of strategic bidding for tasks, we consider the steady state case, where TB agents always win the contract when they bid (as they have been recognized to be more trustworthy than greedy contractees), and at other times one of the G agents win the contract. First we note that the TB agents should be more inclined to bid on tasks at the higher end of the task deadline distribution as they are more likely to be able to meet the corresponding deadlines. Hence, the upper limit of the range of task deadlines a TB agent will bid, bh_{TB} is equal to h, the maximum task deadline. Let the minimum deadline for which a TB agent bids at steady state be D_{ss}. Therefore, at steady state, the TB agents will win all the tasks for deadlines in the range $[D_{ss}, h]$ and G agents will win all contracts in the region $[l, D_{ss})$. From Equation 1, the following inequality holds if the TB agents were to γ-dominate the greedy agents at steady state:

$$\bar{P}(D_{ss}, h) > \gamma \bar{P}(l, D_{ss}). \quad (4)$$

Equations 3 and 4 can be used to calculate D_{ss}.

The assumption implicit in Equation 4, that the TB agents win whenever they bid, is not valid initially, when they are yet to be recognized as γ-dominant. Hence D_{ss} is not the appropriate choice for the initial minimum task deadline to bid for, D_I, by TB agents. To calculate D_I, we assume that tasks are initially assigned randomly between all bidders. So, while all the tasks with deadlines in the range $[l, D_I)$ will be assigned to G contractees, tasks in the region $[D_I, h]$ will be assigned to G versus TB bidders in the ratio of N_G to N_{TB}. The choice of D_I should be such that it allows a TB agent to have at least γ times higher trust than G agents when tasks are being assigned randomly between bidders:

$$\frac{N_{TB}}{N} \bar{P}(D_I, h) > \gamma \left(\frac{\mathcal{T}_{l,D_I} \bar{P}(l, D_I) + \mathcal{T}_{D_I,h} \frac{N_G}{N} \bar{P}(D_I, h)}{\mathcal{T}_{l,h}} \right). \quad (5)$$

The left hand side of the inequality represents the proportion of tasks expected to be successfully delivered by TB agents when tasks are randomly assigned between all bidders and the TB agents bid only in the interval $[D_I, h]$. The term within the parenthesis on the RHS of the inequality denotes the proportion of tasks successfully delivered by G agents in this period. The terms $\mathcal{T}_{l,D_I}$ and $\mathcal{T}_{D_I,h}$ are used to normalize the trustworthiness in the regions $[l, D_I]$ and $[D_I, h]$ respectively. To calculate D_I we simplify Equation 5

$$\bar{P}(D_I, h) > \frac{N\gamma\mathcal{T}_{l,D_I}}{N_{TB} - \gamma N_G \mathcal{T}_{D_I,h}} \bar{P}(l, D_I), \quad (6)$$

where the simplification uses the fact that $\mathcal{T}_{l,h} = 1$ and that

$$N_{TB} > \gamma N_G \mathcal{T}_{D_I,h}. \quad (7)$$

The inequality in Equation 6 can be satisfied for a range of D_I values. The TB agent uses the minimum value in the range which also satisfies the inequality in Equation 7.

In this paper we use equal number of TB and G agents and hence Equation 6 simplifies to

$$\bar{P}(D_I, h) > \frac{2\gamma\mathcal{T}_{l,D_I}}{1 - \gamma\mathcal{T}_{D_I,h}} \bar{P}(l, D_I), \quad (8)$$

and Equation 7 simplifies to $\mathcal{T}_{D_I,h} < \frac{1}{\gamma}$.

The goal of the contractee is to maximize its success rate as described in Section 2.3. Hence, a contractee must evaluate whether it will have a better success rate, in the long

run, if it decides to be a TB or a G agent. If all agents were of type G, each contractee will be awarded tasks with equal probability, i.e., $\forall j, r(j,y) = \frac{1}{N}$. With N_{TB} TB agents, the probability of such an agent winning a contract when it bids, and after it becomes γ-dominant, is $\frac{1}{N_{TB}}$. Hence, in addition to satisfying the inequality in 6 and 7, the D_I value chosen must satisfy the following inequality

$$\int_{D_I}^{h} T(y) \left(\int_{l}^{y} \mathcal{P}_j(x)dx \right) dy > \frac{N_{TB}}{N} \int_{l}^{h} T(y) \left(\int_{l}^{y} \mathcal{P}_j(x)dx \right) dy. \quad (9)$$

Given T and $\mathcal{P}$ distributions, we designate by γ_{max} the maximal γ value for which there exists a D_I that satisfies all these conditions.

3.1 Bidding strategy of Trust Exploiting Agents

We now present the strategy of the *trust exploiting (TE)* agent. Whereas the TB agent picks a D_I and bids only for tasks above it, TE will progressively bid over larger parts of the task distribution, i.e., for smaller task deadlines, until it monopolizes the market. The key to understanding how such a monopoly can be achieved is to recognize that as a TE agent shifts its deadline to bid, D_I, to the left, i.e., for tasks with shorter deadlines, its trust level drops but so does that of greedy agents who now win only on even more riskier tasks. The following discussion assumes that the TE agents first enter a market with G agents and have achieved γ-domination by bidding for tasks in the range $[D_I, h]$. At this stage, the trust ratings of TE and G agents are $t_{TE} = \bar{P}(D_I, h)$ and $t_G = \bar{P}(l, D_I)$ respectively. Actually, t_{TE} should be much more than the value required to γ-dominate t_G because D_I was calculated assuming half the tasks in the safer task deadline range $[D_I, h]$ go to G agents, which is not true after TE agents achieve γ-domination. Hence it is possible for TE agents to use a lower task deadline, D_{new} to bid on and still maintain γ-domination over the G agents, i.e., $D_{new} < D_I$ and $\bar{P}(D_{new}, h) > \gamma \bar{P}(l, D_{new})$. After sticking with this new deadline for sometime to stabilize new trust values, the TE agents can again expand its bidding range, and continue to do so until it bids over the entire range, effectively monopolizing all task contracts! This process of expanding the bid range after achieving γ-domination over the G agents is described in Algorithm 1.

Algorithm 1 Selecting increasingly larger bidding range to achieve market monopoly.

while $D_I > l$ **do**
  Find D_{new} such that $\bar{P}(D_{new}, h) > \gamma \bar{P}(l, D_{new})$.
  $D_I \leftarrow D_{new}$
  Bid in the range $[D_I, h]$ for a sufficient period to settle on new trust values
end while

The situation is more challenging for the TE agent if it enters the market when a TB agent is already γ-dominating G agents. The first task for the TE agent to gain a foothold is to γ-dominate the TB agent. The corresponding bidding deadline for tasks, D_{TE} can be calculated from the inequality, $\bar{P}(D_{TE}, h) > \gamma \bar{P}(D_I, D_{TE})$ (we assume here that newcomers to the marketplace are given some tasks to evaluate their trustworthiness). Once it has achieved that domination, there are two possibilities for further exploitation:

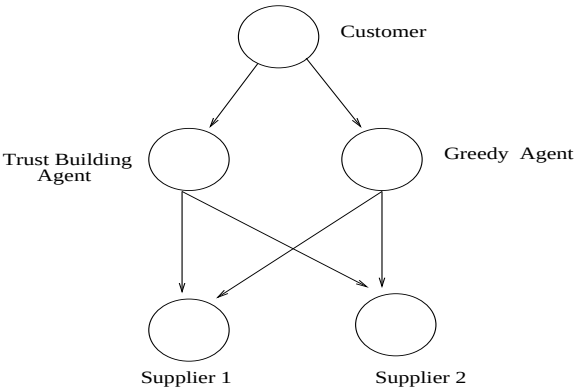

Figure 2: A simple supply chain.

TE1: TE1 expands to bid for all tasks. As a result it will lose γ-domination over TB. When this happens, it switches back to original D_{TE}. Thus the TE1 agent switches its low-end bid deadline between D_{TE} and l.

TE2: TE2 expands to coincide its bidding deadline with that of the TB agent. It may eventually lose γ-domination over TB agent, depending on the task deadline distribution. When this happens, it switches back to original D_{TE}. Thus the TE2 agent switches its low-end bid deadline between D_{TE} and D_I.

A TE2 agent can, depending on the task distribution, "starve" the TB agent out of the market. If the TB agent then leaves the market, we have the scenario of a TE agent against G agents, which will eventually lead to the TE agent monopolizing the market. In other situations, a TE2 agent may outperform a TE1 agent when facing the same TB and G competitors, but not each other.

4. EXPERIMENTAL FRAMEWORK

We use a simple two-level supply chain consisting of a single contractor at the top level, two to three contractees in the second level, and two suppliers under each such contractee at the third level. A representative instance is presented in Figure 2. We ran our experiments in two discrete phases. In the first phase we compared the behavior of two agents bidding, one TB and one TE agent when they play separately against the same G agent, for a contract offered by the customer, the contractor. In the next phase we allow all three agents to operate simultaneously and compared their performances. The deadlines for the contracts are generated randomly from a discretized triangular distribution. We used triangular distribution as an approximation of likely real-life distributions because of easy calculations of the cumulative probabilities. There are two suppliers under each of these two contractees, and the contractee agents must procure supplies from these downstream suppliers before it can process an assigned task.

Since the total time taken by the contractee is the sum of the time taken by its supplier to produce the necessary supplies plus the time it takes to use these supplies to process the tasks, the corresponding task distributions are chosen so that the resultant performance distribution range matches that of its task distribution. We have used identical triangular distributions for the contractee and the suppliers

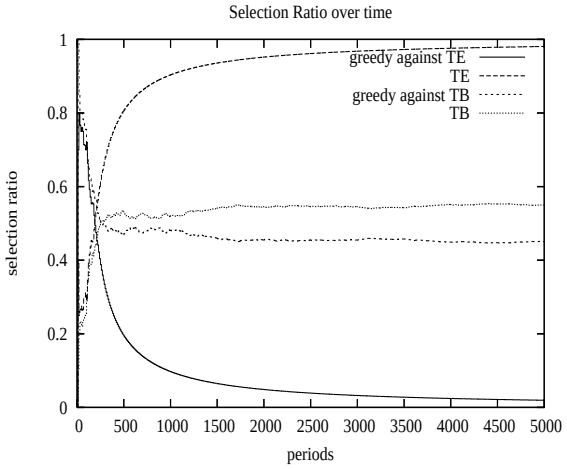

Figure 3: Selection Ratio ($T_p = 8$, $\gamma = 1.29$).

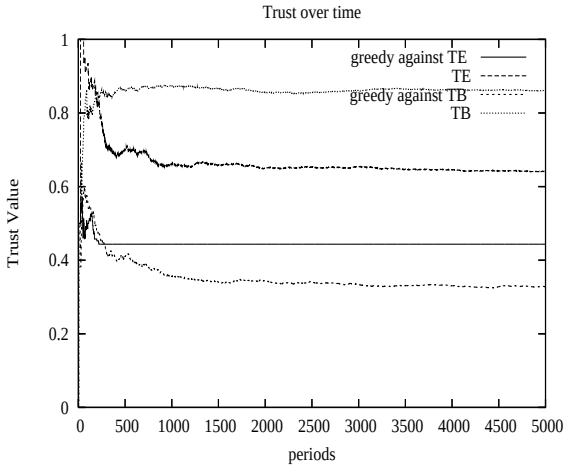

Figure 4: Trust over time ($T_p = 8$, $\gamma = 1.29$).

defined over the range [0,6] with the highest point of the distribution at the midpoint of the range. The resultant performance distribution of the contractee then ranges over [0,12].

In our experiments, we iteratively generated new task deadlines from the task distribution. In a particular iteration, the TB agent decides to bid if the deadline is greater than D_I. The G agent bids on all tasks and TE agent bids if the deadline is greater than its current D_I value.

In the first 100 iterations the customer randomly selects between the agents with bids to estimate the trustworthiness of the contractees. Thereafter a contractee for a task is chosen using the selection criteria specified in Section 2.2. We also assume that the customer selects any new bidder entering the marketplace with a small probability, ϵ, to estimate its performance. After the new agent is selected 50 times using this ϵ-exploration, the customer reverts back to its previous selection strategy using the computed trust values based on these exploration phase. This exploration phase is used only when the TE agent enters the market after TB agent is γ-dominating the G agents.

When a contractee is awarded a task, it generates a task announcement to procure necessary supplies from the suppliers. The time taken by the suppliers followed by that of the selected contractee are then generated from their performance distributions using the standard inverse transform method and are added to calculate the contract fulfillment or delivery time. The agent succeeds if the delivery time is less than or equal to the contract deadline, and fails otherwise.

5. EXPERIMENTAL RESULTS

In our first experiment, we compare the selection ratio and the trust value of the greedy and trust-based contractees over 5000 iterations, where the selection ratio is the proportion of time the agent is selected. The experiment is repeated on three different task distributions: T_p= 4, 6 and 8 and for $\gamma = 1.29$. The results from the $T_p = 8$ scenario is shown in Figure 3 (plots for other values used for T_p are similar and are omitted due to space constraints).

From Figure 3 we observe that though TB agents are selected more often than the greedy agents, it can never get

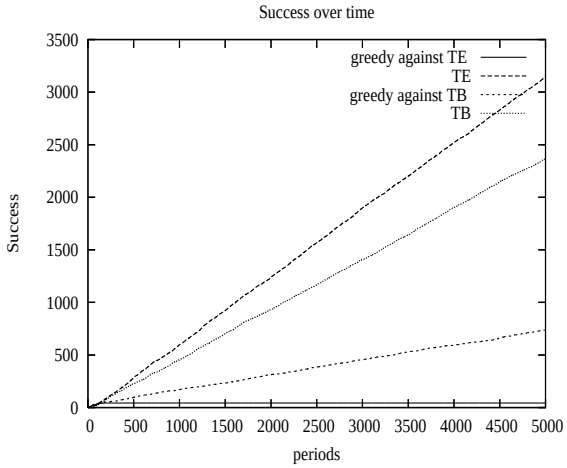

Figure 5: Success over time ($T_p = 8$, $\gamma = 1.29$).

more than 60% of the task as it never bids on a task whose deadline is less than D_I. On the other hand, the selection ratio of the TE agent asymptotically reaches 1 as it starts taking over the market once it has gained sufficient trust. To ensure that, it observes the market continuously and after winning successive 20 bids it sets its new D_I at 2 forcing the G agent to operate only on the high-risk tasks having deadline from 0 to 1. This causes the greedy agent to fail more often and thus loose its trust even more. The trust value of TE agent also decreases and is less than that of TB as shown in Figure 4. But the rate of decrease of trust for the TE agent is much slower than that of the G agent which enables the former to maintain γ-domination. As a result it continues winning all the tasks it bids, and after 20 wins it shifts D_I to 0 and takes over the entire market. From this point onward the G agent does not win any bid, and as a result its trust value remains constant (Figure 4).

We observe from Figure 5 that the TE agent receives more success compared to the TB agent when they play separately against the greedy agent. Also note that, the G agent wins no contracts once TE takes over the market.Due to sampling

biases, a sequence of tasks with short deadlines may be generated which the TE agent may fail to meet, thereby loosing γ-domination over G agents. To counter this problem, the monopolist TE agent monitors the situation and whenever it looses enough bids to loose γ-domination over the greedy agent, it reverts back to its initial D_I value to rebuild the lost trust. Once it gains back the trust, it uses Algorithm 1 to re-monopolize the market.

In our next set of experiments, only the TB and G contractee agents are in the system for the first 400 iterations. Once the TB contractee gain γ-domination over G, a TE contractee is introduced. Here again we assume that the customer uses ϵ-exploration to evaluate the new entrant. We used two different versions of TE agent: TE_1 and TE_2. Both of these agents choose a higher task deadline threshold D_{TE} to achieve γ-dominance over not only the G agent, but also the TB agent. Once it gains the required trust, TE_1 tries to monopolize the market by setting its D_I to 0 and oscillates back and forth to maintain its trust domination. From the results (see Figure 6) we observe that the success of TE_1 depends on the nature of the task distribution; it does well for the distribution with $T_p = 4$, but for task distributions with $T_p = 6$ and higher, TB outperforms TE_1. This is because, in order to γ-dominate the TB agent, the TE_1 bids on a very small range of the task spectrum for such distributions when tasks with longer deadline is common. In such situations, it is not able to win sufficient number of tasks to outperform the TB agent.

TE_2 behaves less greedily than TE_1: after it gains γ-domination over the TB agent, instead of monopolizing the market it sets its D_I at the same position as the TB agent. The TB agent, therefore, loses some of its market share to the TE_2 agent. From Figures 6 and 7 we observe that the success rates of TE_2 are better than that of TE_1. The TE_2 agent, however, loses out to the TB agent for task distributions with $T_p = 8$ and above. In such situations, eventually TE_2 loses γ-domination over TB and moves its bidding deadline to D_{TE}, and after regaining trust switches it back to D_I of TB agent, and the cycle repeats. TE_2 also retains its γ-domination over the greedy agent through this entire process. But this oscillation does not happen for all task distributions, e.g., for $T_p = 4$ and 6, TE_2 never needs loses γ-domination over TB even when it continues to play in the range $[D_I, h]$. This is because, when TE_2 becomes γ-dominant over TB while playing in the range $[D_{TE}, h]$, the TB agent is only awarded tasks with deadline in the range $[D_I, D_{TE})$. For $T_p = 4$ and 6, not only is $\bar{P}(D_{TE}, h) > \gamma\bar{P}(D_I, D_{TE})$ required for establishing γ-domination, but $\bar{P}(D_I, h) > \gamma\bar{P}(D_I, D_{TE})$, i.e., the TE_2 agent continues to maintain γ-domination even after bidding over the range on which the TB agent was bidding when the TE agent enters the market. As a result we observe that in these situations (see the middle and left plots in Figure 7), the TB agent receives no contracts after some time, i.e., it is effectively "starved". Note that the TE_2 agent cannot monopolize all the contracts, and hence the G agent continues to receive the more riskier contracts on which none of the trust-based agents are bidding. Ironically, the presence of the TB agent benefits the G agent: TB starves, but prevents TE from starving G as well!

6. RELATED WORK

More recently the problem of supply chain management has drawn the attention of multiagent systems (MAS) researchers. In MAS, a supply chain is conceptualized as a group of collaborative autonomous software agents [11]. It is argued that managers can better coordinate and schedule processes by distributing the organization-wide business management system into autonomous problem solving agents. This approach is more appropriate when the participating enterprises are geographically distributed and manually controlling $B2B$ trading is not possible. Tackling coordination in supply chains using partial constraint satisfaction problems by mediating agents is investigated by [2].

Swaminathan *et al.* has provided a framework for efficient supply chain formation [21]. MAS researchers have paid attention to the emergence of the optimal supply chain configuration. Walsh *et al.* has shown the optimal dynamic task allocation in a supply chain using combinatorial auctions [23]. Given a task, composed of a group of subtasks, they provide a mechanism for dynamic formation of a supply chain to produce maximum profit. Collins and Gini have provided a testbed, MAGNET, for multiagent contracting for supply chain formation using multiple criteria [7]. A few years back, the Trading Agent Competition (TAC) [16] introduced a realistic supply chain framework where the challenges include the design of strategies for effectively handling factory schedules, efficiently contracting with the suppliers, competitively and profitably bidding to the customers, reducing the inventory cost and penalty for late delivery or order cancellation.

In recent research, trust is established as a key factor to build profitable and long term B2B and B2C collaborations in the Industry [12]. Trust plays an even more critical and important role in the domain of Electronic commerce [3]. Several trust management systems have been proposed to handle the development of trust and its impact in such systems [9].

Use of trust as a basis for interaction strategies has been widely used in multiagent systems. Marsh was one of the first to attempt a computational model of trust [13]. Sen *et al.* have developed a comprehensive reciprocity-based reputation framework for learning to trust like-minded agents and outperform exploitative agents in fully distributed environments like P2P networks [17, 19, 1]. Castelfranchi and colleagues have argued for the necessity of trust in social interactions between agents with complex mental attitudes [5]. Brainov and Sandholhm [4] have shown that trust based contracting can significantly increase market efficiency measured by social welfare, trade volume and agent utilities. Yu and Singh [26] have proposed a mechanism for combining reputation from multiple sources to obtain trust ratings. Glass and Grosz present the SPIRE framework [8], where agents who fulfill social obligations are treated favorably by other members of the society. Sen *et al.* have developed a comprehensive reciprocity-based reputation framework for using trust in

7. CONCLUSIONS AND FUTURE WORK

In this paper, we have argued for the use of trust models to award contracts in the context of supply chains. We work with a particular trust-based contracting framework where contractees with significantly higher historical success rates in meeting contract deadlines are preferentially selected over less "punctual" agents. Our proposed trust-building agents bid less often for tasks, but win and suc-

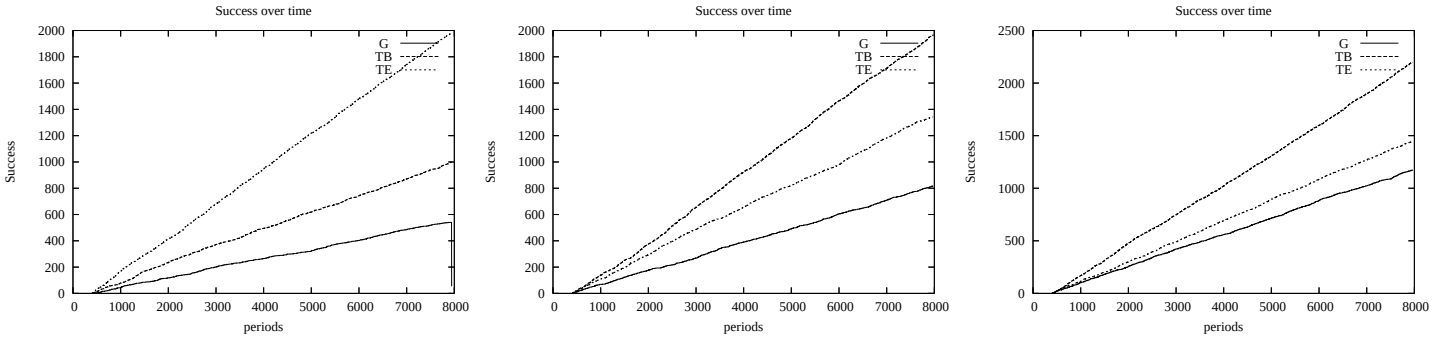

Figure 6: Success of G, TB, and TE_1 agents over time for different task distributions: T_p = 4 (left), 6 (middle), 8 (right); $\gamma = 1.15$.

cessfully meet the deadline of tasks they bid for more often than "greedy" agents who bid for all tasks.

Given task deadline and performance, i.e., task processing distributions, we use a probabilistic analysis to analytically derive the task deadline threshold below which a trust-building contractee will not bid for a task. We expand on this analysis to develop exploitative agents who incrementally take over the entire market from greedy agents. We also propose variations of exploitative agents when competing against both greedy and non-exploiting trust-building agents. We provide experimental verification on a small supply chain to demonstrate the competitive advantage of these trust-exploiting strategies.

While the basic motivations and outlines for trust-exploitation strategies presented in this paper are intuitive, the contribution of our paper lie in formally specifying the trust-exploitation problem and deriving precise strategies for exploiting trust. We present implementable strategies with predictable performance given task deadline and performance distributions and the trust-based contract allocation criterion. We first derived a trust-based strategy that trades off short-term loss (not bidding on certain tasks) for long-term profits (higher success rates after achieving γ-domination). Following this we introduced variants of aggressive trust-exploitation schemes that not only establishes trust as the previous scheme, but then leverages it strategically to monopolize the market. We show that though such market monopolization is not possible if non-exploitative trust-based agents are present, the latter can be effectively dominated under certain task deadline distributions.

In this paper, the trust constant, γ, and the contract allocation procedure are assumed to be common knowledge. The task distribution is assumed to be constant and known *a priori*. Similarly, the performance distribution is fixed and is assumed to be identical for all contractees. Some or all of those assumptions may be violated in a real environment. For example, the contractor may not be consistent in either maintaining or enforcing the trust-based contract award scheme, task distribution may vary over time, agents may be heterogeneous in their capabilities, etc. We plan to relax some of this approaches in future work. In particular, we plan to explore various adaptive mechanisms to cope with dynamic, uncertain environments.

ABSTRACT
The Semantic Web, conceived as a collection of agents, brings new opportunities and challenges to trust research. Enabling trust to ensure more effective and efficient interaction is at the heart of the Semantic Web vision. We propose a composite trust model based on statistical decision theory and Bayesian sequential analysis to balance the costs and benefits during the process of trust evaluating and combine a variety of sources of information to assist users with making the correct decisions in selecting the appropriate service providers according to their preferences. The model proposed by this paper gives trust a strict mathematical interpretation in terms of probability theory.

Keywords
Trust Model, Semantic Web, Bayesian Sequential Analysis.

1. INTRODUCTION
In our model, the quality of a provider agent can be considered to be an unknown numerical quantity, and will represent it by θ and it is possible to treat θ as a random quantity with a probability distribution. Consider the situation of an agent A try to make an estimate of trust value for provider agent B. A holds a prior information (subjective) of B, represented by distribution $\pi(\theta)$, and request A's acquaintance to give opinions on B's quality. After A receives the assessments of B's quality from his acquaintances, A takes these statements as sample about θ. Outcome of these sample is a random variable and will be denoted $\boldsymbol{X}$. A particular realization of $\boldsymbol{X}$ will be denoted x and $\boldsymbol{X}$ will be assumed to be a random variable, with density $f(x|\theta)$. Then, we can compute "posterior distribution" of θ given x, denoted $\pi(\theta|x)$. $\pi(\theta|x)$ reflects the update beliefs about θ after (posterior to) observing the sample x. We take the posterior distribution of θ, $\pi(\theta|x)$, as the estimate of B's trust. If we want to take further investigation on B's quality for more accuracy, $\pi(\theta|x)$ will be used as prior distribution for the next stage of investigation instead of original $\pi(\theta)$.

When several provider agents exist, A need to decide which one should be selected. At that time, the preferences of agent A's owner should be considered properly to make this decision. Therefore, *utility function* should be constructed for agent A's owner, which represented by $U_A(r)$, to express his preferences, where r represents rewards of the consequences of a decision. Supposing that $\pi(\theta|x)$ is the posterior distribution of agent B, the expected utility of function $U_A(r)$ over $\pi(\theta|x)$, denoted $E^{\pi(\theta|x)}[U_A(r)]$, is possible gain of consequence of selecting B.

2. COMPOSITE TRUST MODEL
By treating an agent as a node, the "knows" relationship as an edge, a directed graph emerges. To facilitate the model description, agents and their environment are to be defined. To clarify the idea of our trust model, we begin with a simple illustration. Consider the scenario that agent A is evaluating trust value of B and C for being business. The set of all consultant agents that A requests for this evaluation as well as A, B, C can be considered to be a unique society of agents. In our example (see Figure 1) it is called a "closed society of agents" with respect to A.

2.1 Closed Trust Model
We will treat the service quality, θ, as a continuous variable here, and suppose that the service charges of B and C are 250 and 210 units respectively (SC_B = 250, SC_C = 210, where SC denotes *service charge*). As shown in Figure 1, the agent A feels that θ_B, the service quality of B, has a normal prior density, $N(0.64, (0.08)^2)$. We also suppose that the prior density of θ_C is $N(0.5, (0.15)^2)$ here. The probability distribution of $\boldsymbol{X}$ that represents the assessments of service quality from consultant agents will, of course, depend upon the unknown state of nature θ. Therefore, we assume that $\boldsymbol{X}$ is another continuous random variable with density $f(x|\theta) \sim N(\theta, (0.05)^2)$. We also assume that the agent A's owner has a utility function $U_A(r) = 208.4 + 459.8r - 17.95r^2 - 99.84r^3$.

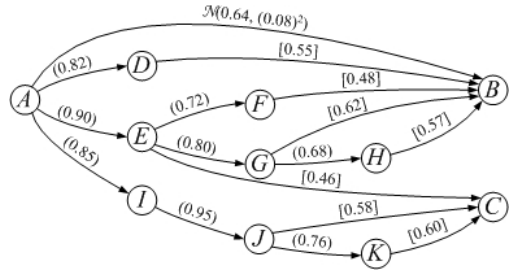

Figure 1. A "closed society of agents" with respect to agent *A*

Assume $X \sim N(\theta, \sigma^2)$, where θ is unknown but σ^2 is known. Let be prior information, $\pi(\theta)$, a $N(\mu, \tau^2)$ density, where μ and τ^2 are known. Note that the marginal distribution of $\boldsymbol{X}$, $m(x)$, is $N(\mu, \sigma^2 + \tau^2)$ and the posterior distribution θ of give x is $N(\mu(x), \rho)$, where

$$\mu(x) = \frac{\sigma^2}{\sigma^2 + \tau^2}\mu + \frac{\tau^2}{\sigma^2 + \tau^2}x \qquad \rho = \frac{\tau^2\sigma^2}{\tau^2 + \sigma^2} \qquad \textbf{(1)}$$

We take the assessments of *B*'s quality from the consultant agents as sample about θ_B and combine these sample information (x) and prior information into posterior distribution of θ_B given x. In order to answer the question of which sample information should be used with higher priority, we propose following order rules: (1) The sample from the agent with shorter referral distance should be used first; (2) If the samples come from the agents that have the same referral distance, which with larger reliability factor is prior to that with smaller one.

Now, we can evaluate trust value of *B* for *A* by using above formulas and information. Firstly, we use the sample information from *D* through the path $A \rightarrow D \rightarrow B$, and the posterior distribution $\pi_B(\theta|x = 0.55) \sim N(0.5753, (0.0424)^2)$, where

$$\frac{0.05^2}{0.08^2 + 0.05^2} \times 0.64 + \frac{0.08^2}{0.08^2 + 0.05^2} \times 0.55 = 0.5753$$

$$\frac{0.08^2 \times 0.05^2}{0.08^2 + 0.05^2} = 0.0424^2$$

However, the reliability factor has not been considered during the process of calculating this posterior distribution. We used following formula to rectify above $\pi_B(\theta|x = 0.55)$, where p_{old}, p and p_{new} represent the parameter of prior distribution, the posterior distribution before rectification and the posterior distribution after rectification respectively (p is mean or variant for normal distribution), and R is reliability factor.

$$p_{new} = p_{old} + (p - p_{old}) \times R \qquad \textbf{(2)}$$

Hence, after rectification, $\mu_B = 0.64 + (0.5753 - 0.64) \times 0.82 = 0.5869$ and $\tau_B = 0.08 + (0.0424 - 0.08) \times 0.82 = 0.0492$. Then the posterior distribution $\pi_B(\theta|x = 0.55)$ is $N(0.5869, (0.0492)^2)$. The residual calculating process of *B* and the whole the process of *C* are shown in Table 1 and 2. Note that we employ multiplying to merge two or more than two reliability factors. The reason behind using multiplying is that if the statement is true only if the agents who propagate this statement all tell the truth and it is considered to be independent for any two agents to lie or not to lie. Expected utility of *B* is:

$$\begin{aligned}\text{utility of } B &= \int_{-\infty}^{+\infty} U_A(r)\pi_B(\theta \mid x)d\theta - SC_B \\ &= \int_{-\infty}^{+\infty}(208.4 + 459.8\theta - 17.95\theta^2 - 99.84\theta^3) \times \\ &\quad \frac{1}{\sqrt{2\pi} \times 0.0309} e^{-\frac{(\theta - 0.5696)^2}{2 \times 0.0309^2}} d\theta - 250 \\ &= 195.82\end{aligned}$$

$$\begin{aligned}\text{and utility of } C &= \int_{-\infty}^{+\infty} U_A(r)\pi_C(\theta \mid x)d\theta - SC_C \\ &= 225.34\end{aligned}$$

hence (225.34 > 195.82), *C* is more appropriate than *B* in the eyes of *A* .

2.2 Open Trust Model

Above discussion is under the condition that the "closed society of agents" must be defined at first, but it is nearly impossible for inherent open and dynamic Web. Our idea is that at every stage of the procedure (after every given observation) one should compare the (posterior) utility of making an immediate decision with the "expected" (preprosterior) utility that will be obtained if more observations are taken. If it is cheaper to stop and make a decision, that is what should be done.

The goal of preposterior analysis is to choose the way of investigation which minimizes overall cost. This overall cost consists of the decision loss (*opportunity cost*) and the cost of conducting observation (*consultant fee*). Note that these two quantities are in opposition to each other, we propose an approach to balance these two costs.

Table 1. The process of evaluating *B*'s trust

Step	Path	Statement	Reliability Factor	Prior Distribution		Posterior Distribution		Utility
				μ	τ	μ	τ	
1	$A \rightarrow D \rightarrow B$	0.55	0.8200	0.6400	0.0800	0.5869	0.0492	201.39
2-1	$A \rightarrow E \rightarrow G \rightarrow B$	0.62	0.7200	0.5869	0.0492	0.5986	0.0390	205.46
2-2	$A \rightarrow E \rightarrow F \rightarrow B$	0.48	0.6480	0.5986	0.0390	0.5695	0.0337	195.75
3	$A \rightarrow E \rightarrow G \rightarrow H \rightarrow B$	0.57	0.4896	0.5695	0.0337	0.5696	0.0309	195.82

Table 2. The process of evaluating *C*'s trust

Step	Path	Statement	Reliability Factor	Prior Distribution		Posterior Distribution		Utility
				μ	τ	μ	τ	
1	$A \rightarrow E \rightarrow C$	0.46	0.9000	0.5000	0.1500	0.4676	0.0577	198.72
2	$A \rightarrow I \rightarrow J \rightarrow C$	0.58	0.8075	0.4676	0.0577	0.5194	0.0416	218.06
3	$A \rightarrow I \rightarrow J \rightarrow K \rightarrow C$	0.60	0.6137	0.5194	0.0416	0.5396	0.0357	225.34

Table 3. The process of Bayesian sequential analysis

Stage	Agent *B*				Agent *C*				Consultant Fee	Utility		Decision
	Prior Distribution		Marginal Distribution		Prior Distribution		Marginal Distribution			Immediate Decision	Further Investigation	
	μ_B	τ_B	$\mu_{x\|B}$	$\tau_{x\|B}$	μ_C	τ_C	$\mu_{x\|C}$	$\tau_{x\|C}$				
1	0.6400	0.0800	0.6400	0.0943	0.5000	0.1500	–	–	3	217.78	219.24	Continue
2	0.5869	0.0492	0.5869	0.0701	0.4676	0.0577	–	–	3	201.39	201.80	Continue
3	0.5695	0.0337	–	–	0.5194	0.0416	0.5194	0.0650	2	218.06	216.09	Stop

We continue above example used in the illustration of the closed trust model. As shown in Figure 2, we begin at the stage 1 when *A* only holds the prior information of *B* and has no any information about *C* (even the existence of *C*, but it is more likely that an agent with the prior distribution of $N(0.5, (0.15)^2)$ and the expected service charge of 210 is near in the network). Agent *A* either can make an immediate decision (to select *B*) or can send request to his acquaintances for their opinions by extending the tree of Figure 2 down to the next layer.

Suppose that the cost of consultant services is determined by how much agents will be requested at the next stage and the consultant fee is the constant of 1 for each times (for example, at the stage 1, agent *A* can ask Agent *D*, *E* and *I* for their opinions, so the consultant fee of the stage 1 will be 3).

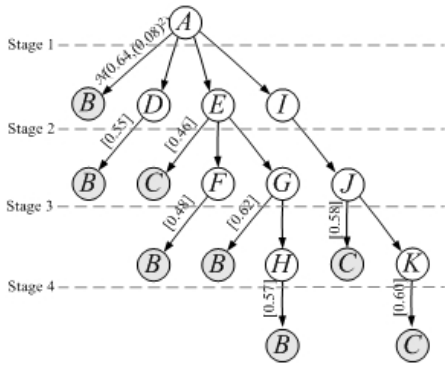

Figure 2. The process of trust evaluating

The utility of an immediate decision is the larger of

$$\int_{-\infty}^{+\infty} U_A(r)\pi_B(\theta)d\theta - SC_B = 217.78$$

here, $\pi_B(\theta) \sim N(0.64, (0.08)^2)$.

and $\int_{-\infty}^{+\infty} U_A(r)\pi_C(\theta)d\theta - SC_C = 207.54$

here, $\pi_C(\theta) \sim N(0.5, (0.15)^2)$.

Hence the utility of an immediate decision is 217.78.

If the request message is sent and x observed, the posterior density $\pi_B(\theta|x)$, is $N(\mu(x), \rho)$, where

$$\mu(x) = \frac{0.05^2}{0.08^2 + 0.05^2} \times (0.64) + \frac{0.08^2}{0.08^2 + 0.05^2}(x) \cong 0.1798 + (0.7191)x$$

$$\rho = \frac{0.08^2 \times 0.05^2}{0.08^2 + 0.05^2} \cong 0.0018$$

However, that we do not know which x will occur, but we know the relevant distribution for $\boldsymbol{X}$ is the "predictive" or marginal distribution, $m_B(x)$, which in this situation is $N(0.64, (0.08)^2 + (0.05)^2)$. Note that if $x < 0.5914$ is observed, the expected utility of $\pi_B(\theta|x)$ is less than 207.54, so we prefer to select *C* instead of *B*. Hence expected utility of not making immediate decision is

$$\int_{-\infty}^{0.5914} 207.54\, m_C(x)dx +$$

$$\int_{0.5914}^{+\infty} (\int_{-\infty}^{+\infty} U_A(r)\pi_B(\theta \mid x)d\theta - SC_B)m_B(x)dx - 3 = 219.24$$

This just is the opportunity cost. Because 219.24 > 217.78, and then further investigation would be well worth the money, in other words, *A* should send request to his acquaintances for their opinions. The residual process of Bayesian sequential analysis are shown in Table 3 and remember that the further exploiting should be terminated immediately along the path on which a cycle is detected. As shown in Table 3, at the stage 3, the expected utility of *C* begins to larger than that of *B*, and because 218.06 > 216.09, making an immediate decision is more profitable. Therefore, *A* should stop investigating and select *C* as a decision. The advantage of sequential analysis should be clear now. It allows one to gather exactly the correct amount of data needed for a decision of the desired accuracy.

ABSTRACT

There exist a number of similarity-based recommendation communities, within which similar users' opinions are collected by users' agents to make predictions of their opinions on a new item. Similarity-based recommendation communities suffer from some significant limitations, such as scalability and susceptibility to the noise. In this paper, we propose a trust-based community to overcome these limitations. The trust-based recommendation community incorporates trust into the domain of item recommendation. Experimental results based on a real dataset show that trust-based community manages to outperform its similarity-based counterpart in terms of prediction accuracy, coverage, and robustness in the presence of noise.

1. INTRODUCTION

The past few years have seen the emergence of the online recommendation communities, such as Epinions[1] and Movielens[2]. Users join the community to collect others' opinions (usually in the form of ratings), which are then used to make predictions of new items' ratings, which recommend the users whether to browse the new items.

Traditionally, similarity-based approach is applied to make predictions in communities, i.e. only opinions from agents[3] with similar preferences are taken into account when making the predictions. The similarity between a pair of agents is generally measured according to the "agreements" between individual items over all the items co-rated by the two agents [6]. However, the similarity-based communities have major limitations, for example:

(1) Agents usually rate few items [2]. It is thus not unusual that agents do not co-rate the minimum number of items required to compute the similarity. For example, it is required that agents co-rate at least two items to calculate the Pearson correlation coefficient, which is a widely used similarity metric. Hence, the number of similar agents is small. In some cases, agent even cannot find similar agents. As a consequence, a large number of agents are not able to make predictions.

(2) By intentionally rating only a small number of items, malicious agents are easier to achieve high similarity since the number of co-rated items is small. For example, Pearson correlation gives a similarity of either 1, -1 or 0 when the number of co-rated items is 2. Consequently, malicious agents' noisy ratings[4] can easily outweigh others' ratings, leading to the biased predictions on given items.

(3) Typically, there is a centralized server that collects the opinions and makes predictions for the agents. The computation burden of the centralized server increases quickly with the increase of the number of agents.

To overcome the aforementioned limitations, we propose a trust-based community by incorporating *trust* into the domain of item recommendation. This paper adapts Barber's definition[1] which defines *trust* to be *the expectation of technically competent role performance*. More specifically, *trust* is interpreted as an agent's expectation of another agent's competence in providing opinions to reduce its uncertainty in predicting new items' ratings. The main components of the trust-based community are as follows:

(1) Agents in trust-based communities take opinions of *trustworthy* agents into account when making predictions. A trust metric is designed to help an agent to quantify the degrees of trust it should place on other agents. Unlike the similarity metric, the trust metric is computable on most agents. It is even computable on pairs of agents who only co-rate one item. A new approach is also proposed to make predictions based on trustworthy agents' opinions.

(2) Each agent collects others' opinions actively when it encounters new items, and then makes predictions of the new items' ratings with local computations. At the

same time, each agent contributes to the community by sharing its opinions when it is contacted by others for opinions. Hence, each agent is in fact a peer servent, and the community is basically a P2P overlay network. The P2P-based architecture avoids the need for centralized server.

The outline of the rest of this paper is as follows. The main components of the trust-based community are described in Section 2. Experimental results are presented in Section 3. Finally, Section 4 concludes the paper.

2. COMPONENTS OF THE TRUST-BASED COMMUNITY

There are two sets of entities within the communities.

(1) a set of uniquely identifiable *items* $O = \{O_1, O_2, \ldots, O_j, \ldots, O_m\}$,

(2) a set of uniquely identifiable *agents* $Ag = \{Ag_1, Ag_2, \ldots, Ag_i, \ldots, Ag_n\}$, who have their opinions $r_{i,j}$ on the *items*.

Here $r_{i,j}$ denotes Ag_i's *opinion* (in the form of rating) on O_j after browsing O_j. Agents' predictions of items' ratings are also given in the form of ratings. Ag_i's prediction on O_j's rating is denoted as $Pr_{i,j}$. When contacted by other agents, agents' opinions on the items, but not the predictions, are shared.

As discussed earlier, each agent is treated equally as a peer servent. Without loss of generality, the rest of this paper is presented from the perspective of a particular agent Ag_s.

2.1 Design of the Trust Metric

The proposed trust metric is experience-based, i.e., the trustworthiness of a given agent, say Ag_t, is calculated by Ag_s based on its previous experience with Ag_t[5]. Ag_s compiles its experience with Ag_t in a table as shown in Table 1. In Table 1, Z denotes the number of possible ratings, and N is the total number of items co-rated by Ag_s and Ag_t. Each cell n_{ij} records the number of co-rated items on which Ag_t's opinions are j while Ag_s's opinions (after browsing the items) are i. Each cell is initiated with dummy experience number as $1/Z$. After Ag_t shares opinions as j for the first time, the dummy experience in all the cells of column j are cleared first, then cells in column j are updated based on real experience. The dummy experience is introduced to eliminate the possible appearance of the undefined $0/0$ when calculating the trustworthiness.

$R_i = \sum_{j=1}^{Z} n_{ij}$, i.e. the number of co-rated items on which Ag_s's opinions are i; $C_j = \sum_{i=1}^{Z} n_{ij}$, i.e. the number of co-rated items on which Ag_t's opinions are j. $\sum_i R_i = \sum_j C_j = N$. After compiling the experience with Ag_t, agent Ag_s calculates Ag_t's *trustworthiness* $Tr_{s,t}$ as:

$$Tr_{s,t} = \frac{(1-\sum_i (R_i/N)^2) - (1 - \frac{1}{N}\sum_i \sum_j (n_{ij}^2/C_j))}{1-\sum_i (R_i/N)^2} \quad (1)$$

$$= \frac{N \sum_i \sum_j \frac{n_{ij}^2}{C_j} - \sum_i R_i^2}{N^2 - \sum_i R_i^2} \quad (2)$$

[5] Ag_s has experience with Ag_t means Ag_t's opinions have ever been collected by Ag_s to make predictions.

As discussed before, $Tr_{s,t}$ is interpreted as Ag_s's expectation of Ag_t's competence in providing opinions to reduce its uncertainty in predicting new items' ratings. The reduction of uncertainty can be measured as the reduction of the incorrect predictions given Ag_t's opinions. In the right hand side of Eq. (1), the first and second term in the numerator are the proportions of the incorrect predictions made without Ag_t's opinions and with Ag_t's opinions respectively. Thus, Eq. (1) quantifies agent Ag_t's trustworthiness by measuring the reduction of incorrect prediction given Ag_t's opinions. Eq. (1) is further simplified to Eq. (2).

$Tr_{s,t}$ takes values in $[0, 1]$. $Tr_{s,t} = 0$ implies that Ag_t does not reduce Ag_s's uncertainty at all, whereas $Tr_{s,t} = 1$ implies Ag_s's perfect predictability of the new items' ratings given Ag_t's opinions. Every time after a new prediction has been made with Ag_t's opinions, Ag_s updates its evaluation of Ag_t's trustworthiness.

2.2 Opinions Collection

Ag_s maintains a set of *direct neighbors*, whom Ag_s contacts directly for opinions when it encounters a new item. Each direct neighbor, when contacted by Ag_s, shares its opinion if it has rating on the target item. Moreover, each direct neighbor returns all its direct neighbors as well as their trustworthiness as *referrals* to Ag_s. Instead of contacting all the referrals, Ag_s applies a probabilistic strategy in determining whether to contact a particular referral at the next step. Suppose Ag_d returns a number of referrals. Ag_s will contact a particular referral Ag_m at the next step with a probability $Tr_{d,m}$, and will not contact Ag_m with a probability $1 - Tr_{d,m}$. $Tr_{d,m}$ is Ag_d's evaluation of Ag_m's trustworthiness. Also, Ag_s will not contact an agent if it has been contacted before for the same item. Then each contacted agent carries out the similar actions as Ag_s's direct neighbors do. The only difference is that it returns referrals only when it has no opinions to share.

A path starting from agent Ag_s connecting all the contacted agents (including the direct neighbors) and ending at the agent who has opinion on the target item is called a *referral chain*. An upper limit (U) is applied on the length of a referral chain to avoid endless opinion collection.

Opinions collection usually discovers more than one agent that can share opinion on a target item. Ag_s can use the proposed trust metric to determine those agents' trustworthiness if it has previous experience with them. Trust propagation is necessary to help Ag_s reason about the trustworthiness of the agents who share opinions but Ag_s has no previous experience with. The trust propagation mechanism proposed in [4] is employed in this work. Suppose in a given referral chain starting from Ag_s, Ag_m is one of Ag_d's referrals to Ag_s. Ag_s derives Ag_m's trustworthiness through *trust propagation* as:

$$Tr_{s,m} = Tr_{s,d} * Tr_{d,m} + (1 - Tr_{s,d}) * (1 - Tr_{d,m}) \quad (3)$$

where $Tr_{s,d}$ is Ag_s's evaluation of Ag_d's trustworthiness, and $Tr_{d,m}$ is Ag_d's evaluation of Ag_m's trustworthiness. Then (3) is computed recursively by Ag_s over all the agents along the referral chain to derive the trustworthiness of the agent at the end of the referral chain.

2.3 Rating Prediction

The new items' ratings are basically derived as weighted sum of the collected opinions, with each opinion-sharing agent's trustworthiness as weight. The collected opinions are adjusted before being used to make predictions if Ag_s has previous experience with the corresponding opinion-sharing

agents. Suppose agent Ag_x shared opinion on the item O_n as $r_{x,n} = v$ and Ag_s has previous experience with Ag_x, then Ag_x's opinion $r_{x,n} = v$ is adjusted to $r'_{x,n} = i$ with a probability n_{iv}/C_v. If Ag_s has no previous experience with Ag_x, Ag_x's opinion is used directly without adjustment.

It is possible that process of opinion collection does not collect any opinion. In this case, Ag_s selects a *pseudo-opinion* as $r'_{x,n} = i$ from each direct neighbor Ag_x with a probability R_i/N (R_i and N are based on Ag_s's experience with each direct neighbor Ag_x).

Ag_s then predicts the new item O_n's rating $Pr_{s,n}$ as:

$$Pr_{s,n} = \frac{\sum_{Ag_x \in \mathcal{A}_{s,n}} Tr_{s,x} * r'_{x,n}}{\sum_{Ag_x \in \mathcal{A}_{s,n}} Tr_{s,x}} \quad (4)$$

Here $\mathcal{A}_{s,n}$ is the set of opinion-sharing agents (including those share pseudo-opinions). $r'_{x,n}$ is the adjusted opinion or pseudo-opinion shared by agent Ag_x. Each agent in $\mathcal{A}_{s,n}$ is assigned a weight which equals to its trustworthiness $Tr_{s,x}$.

3. EXPERIMENTAL RESULTS

A trust-based movie recommendation community has been simulated based on the MovieLens dataset[6]. A similarity-based community based on same dateset has also been setup to study the improvement introduced by the trust-based community. The Pearson correlation efficient is employed as the similarity metric. Agents with negative similarity are ignored when making prediction. Opinion collection with "similarity propagation" was also implemented for the similarity-based community.

The first experiment studied the improvement in terms of coverage without the presence of noisy ratings. Coverage was measured as the percentage of the dataset that the agents were able to predict rating for. The trust-based community manages to achieve a coverage very close to 100%, whereas the maximum coverage achievable with similarity-based community is less than 80%.

The second experiment studied the improvement in terms of prediction accuracy without the presence of noisy ratings. Prediction accuracy was measured as Mean Absolute Error (MAE). MAE is derived by calculating each agent's mean prediction error between the predicted ratings and real opinions, and then averaging all agents' mean errors. The values of U (limit of the length of the referral chains) and D (number of direct neighbors) are tuned to be: $U \in [3, 8]$, and $D \in \{2, 3, 4, 5, 6, 7, 8, 9, 10, 20, 30, 40, 50, 60, 70, 80\}$. Figure 1 compares the MAE achieved by the trust-based and the similarity-based community respectively when $U = 3$. It is observed that the trust-based community generally achieves higher prediction accuracy (i.e. lower MAE) than its similarity-based counterpart with different settings of D. The same trends are observable with other values of U. Due to the space limitation, comparisons of the MAE with other values of U are omitted here.

The third experiment was to study the community's robustness in the presence of noisy ratings. $D = 10$ and $U = 3$ in the third experiment. The robustness was measured in terms of *power of attack* (POA). Let O_t be the targeted item of the noisy ratings, and Ω be the set of agents who are predicting the item O_t's rating. The POA for a particular type of noisy rating ATK is given by:

$$POA(\Omega, O_t, ATK) = \frac{\sum_{a \in \Omega}(|r_{target} - r_{a,t}| - |r_{target} - r''_{a,t}|)}{|\Omega|}.$$

[6]MovieLens dataset is publicly available at http://www.cs.umn.edu/research/GroupLens/data/.

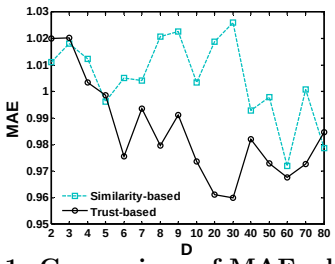

Figure 1: Comparison of MAE when $U = 3$

where $r''_{a,t}$ and $r_{a,t}$ are predictions made with and without the presence of noisy ratings respectively. r_{target} is the target rating, e.g $r_{target} = 5$, or 1 for *push* and *nuke* respectively. A positive value of POA means that the predictions have been forced toward the target rating. Otherwise, POA gives a negative value. Robustness in the presence of different ratios of noisy ratings is shown in Table 2. It is observed that the trust-based community manages to achieve smaller POA than its similarity-based counterpart. It is thus shown that the trust-based community is more robust to the presence of noisy ratings than similarity-based community.

Noisy rating ratios	POA (Push)		POA (Nuke)	
	Trust-based	Similarity-based	Trust-based	Similarity-based
25%	0.0688	0.0410	0.0722	0.0238
50%	0.1105	0.1880	0.1430	0.2145
75%	0.1375	0.2020	0.5305	0.6408
100%	0.1788	0.2211	0.6730	0.7617

Table 2: POA w.r.t. different malicious noisy ratios

4. CONCLUSIONS AND FUTURE WORK

In this paper, we have proposed a trust-based recommendation community, in which a trust metric has been designed to quantify the degrees of trust an agent should place on others, and a new prediction method has also been proposed.

Work has been reported to introduce trust into the domain of item recommendation to overcome the limitations listed in Section 1, e.g. [3, 5]. However, all of these in existing work do not make clear how an agent can determine the degrees of trust it should place on others. This paper goes beyond existing work in that it proposes a trust metric, with which an agent can practically quantify the degrees of trust it places on others.

Currently, direct neighbors maintained by an agent are not changed during its whole life cycle. It is possible that some direct neighbors become less trustworthy. In this case, those less trustworthy direct neighbors should be replaced by some indirect neighbors that are more trustworthy. The performance of the trust-based community with neighbor replacement will be further investigated.

ABSTRACT

Learning to converge to an efficient, i.e., Pareto-optimal Nash equilibrium of the repeated game is an open problem in multiagent learning. Our goal is to facilitate the learning of efficient outcomes in repeated plays of incomplete information games when only opponent's actions but not its payoffs are observable. We use a two-stage protocol that allows a player to unilaterally commit to an action, allowing the other player to choose an action knowing the action chosen by the committed player. The motivation behind commitment is to promote trust between the players and prevent them from mutually harmful choices made to preclude worst-case outcomes. Our agents learn whether commitment is beneficial or not. Interestingly, the decision to commit can be thought of as expanding the action space and our proposed protocol can be incorporated by any learning strategies used for playing repeated games. We show the improvement of the outcome efficiency of standard learning algorithms when using our proposed commitment protocol. We propose convergence to pareto optimal Nash equilibrium of repeated games as desirable learning outcomes. The performance evaluation in this paper uses a similarly motivated metric that measures the percentage of Nash equilibria for repated games that dominate the observed outcome.

1. INTRODUCTION

A rational agent, playing in iterated stage games, should maximize long-term utility. In a two-player, general-sum game, this means that the players need to systematically explore the joint action space before settling on an action combination. Reinforcement learning schemes, and in particular, Q-learning [6], have been widely used in single-agent learning situations. In the context of multi-player games, if one agent plays a stationary strategy, the stochastic game becomes an MDP and techniques like Q-learning can be used to learn to play an optimal response against such a static opponent. When two agents learn to play concurrently, however, the stationary assumption does not hold any longer, and Q-learning is not guaranteed to converge in self play. In such cases, researchers have focused on convergence to Nash equilibrium (NE) in self-play, where each player is playing a best response to the opponent strategy and does not have any incentive to deviate from his strategy.

Convergence is a desirable property in multiagent systems, but converging just to any NE is not the preferred outcome since NE is not guaranteed to be Pareto optimal (an outcome is Pareto optimal if no agent can improve its payoff without decreasing its opponent's payoff). For example, the widely studied Prisoner's Dilemma game (PD) has a single pure strategy NE that is defect-defect, which is dominated by the cooperate-cooperate outcome. A Pareto Optimal outcome may not be appealing to players if that outcome is also not a NE, i.e., there might be incentives for one agent to deviate and obtain higher payoff. For example, each agent has the incentive to deviate from the cooperate-cooperate Pareto optima in PD.

In repeated games, folk theorems[3] ensure that, when players are "patient enough", any payoff dominating a reservation payoff can be sustained by a NE. Hence, in repeated games, there are Pareto Optimal outcomes that are also NE outcomes. It is evident that the primary goal of a rational agent, learning or otherwise, is to maximize utility. Though we, as system designers, want convergence and corresponding system stability, those considerations are necessarily secondary for a rational agent. The question then is what kind of outcomes are preferable for agents engaged in repeated interactions with an uncertain horizon, i.e., without knowledge of how many future interactions will happen. We believe that the goal of learning agents in repeated self-play with an uncertain horizon should be to reach a Pareto-optimal Nash equilibria (PONE).

We are interested in developing mechanisms by which agents can produce PONE outcomes. [4] provides a solution under complete knowledge. This assumption is unrealistic in most cases: opponent valuation is in general intrinsic and private. Moreover, payoff communication opens the door for deceptive behavior. Hence, we believe that not observing the opponent payoff is a more realistic assumption. We are interested in two-person, general-sum games where each agent only gets to observe its own payoff and the action played by the opponent, but opponent's payoff is unknown. Under

these conditions, it may be difficult to guarantee convergence to a PONE. In order to compare the performance of different algorithms that are trying to converge to a PONE, we introduce a new metric: given an outcome of the game, the metric relates to the relative number of states dominating the current outcome.

2. COMMITMENT

We now present our proposed commitment protocol that can be added onto any stage game playing algorithm. The motivation behind the protocol is for agents to improve payoffs by building trust via up-front commitment to "cooperating" moves that can be mutually beneficial, e.g., a cooperate move in PD. If the opponent myopically chooses an exploitative action, e.g., a defect move in PD, the initiating agent would be less likely to repeat such cooperation commitments, leading to outcomes that are less desirable to both parties than mutual cooperation. But if the opponent resists the temptation to exploit and responds cooperatively, then such mutually beneficial cooperation can be sustained.

We build on the simultaneous revelation protocol [5]. Agents repeatedly play an $n \times n$ bimatrix game. At each iteration of the game, each player first announces whether or not it wants to commit to an action. If both players want to commit at the same time, one is chosen randomly. If no player decides to commit, then both players simultaneously announce their action, as in the traditional simultaneous play protocol. When one player commits to an action, the other can choose any action given its opponent's action. Each agent can observe which agent actually revealed, and which action the opponent played. In this paper, agents play best response action to opponent's committed action.

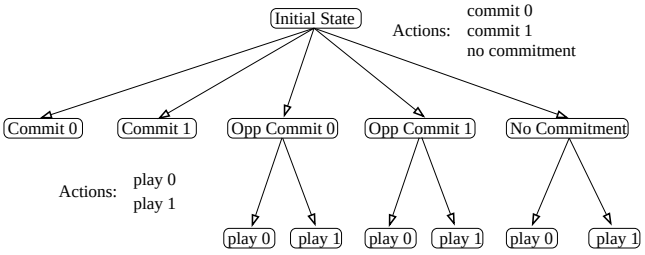

Figure 1: Game tree for a two-action game.

Such games can be represented by game trees, e.g., Figure 1 presents the tree for a two-action game. In the initial state, the agents have $n+1$ actions: it can plan to commit to any of the n actions of the game, or decide not to commit. The transition from the root of the tree depends on the decision of the opponent. The *commit* states are reached when the player commits and the opponent does not, or when both players are willing to commit, but the player wins the toss. From the *commit* state, no further decision is needed, and the payoff received depends on the play of the opponent. When the player decides not to commit, the transition can lead to any one of the n states where the opponent commits or to the state where no players is willing to commit. In both cases, the player has n actions available. From the *opp commit* states, the transition depends only on the current players' decision. From the state where there is no commitment, the transition also depends on the opponent decision. Any multiagent learning algorithm can be used to estimate the utility of different actions, including the commitment actions, from repeated play against an opponent.

Compared to NE outcome of a traditional protocol, the NE outcome with the commit protocol may differ. We hypothesize that, under rational play, the outcome of a game played with the commit protocol is not strictly dominated by the outcome of the game played with the traditional protocol. Assume that players are in a NE of the stage game and are provided the opportunity to commit. A player i commits only when it is beneficial, hence getting a higher payoff. If the other player j is improving due to the commitment, both players improve their respective payoffs. Else, j's payoffs is worse. In this case, j may improve by committing, which might decrease i's payoff. If on average both players' payoffs decrease, the players will ultimately learn not to reveal. When i commits and j cannot improve its payoff by committing, e.g. committing to any action yields a lesser payoff, the players reached a different equilibrium (i improves and j is worse off but there is no dominance). In any case, players should only benefit from the commit protocol.

3. RESULTS

We compared the use of the commit protocol with the traditional protocol of simultaneous play on various set of matrices. Any traditional algorithm for game playing can be used in combination with the commit protocol. We chose to use WoLF-PHC[1] (Win or Learn Fast - policy hill climbing) [1] as the learning algorithm. The algorithm learns mixed strategy and is guaranteed to converge to a NE in a 2-person, 2-actions repeated game.

3.1 Metric

To compare the equilibrium outcomes, we can use the concept of dominance. However, when there is no dominance between the outcomes, additional metrics are needed. Investigating the sum of the payoff of the player (a measure of the social welfare), or the product of the payoff (a measure of fairness) provides insight to the equilibrium properties of the learning algorithms. Another approach is to consider the number of equilibria that dominate the current equilibrium: the fewer outcomes that dominate the current outcome, the closer this outcome is to a Pareto Optimum. The folk theorems [3] ensure that when an outcome dominates the minimax outcome, it can be sustained by a NE of the repeated game. For an outcome x, let $d(x)$ denotes the area containing all points that dominates x in the payoff space. If $d(x) = 0$ and x dominates the minimax outcome, then x is a PONE.

Definition 1. Performance metric of an equilibrium outcome x: $\delta(x) = \frac{d(x)}{d(x_{mm})}$ where x_{mm} is the minimax outcome.

$\delta(x)$ represents the proportion of NE outcomes of the repeated games that dominates x. The smaller $\delta(x)$, the better the outcome x is with respect to convergence to a PONE. When one outcome x dominates an outcome y, $\delta(x) < \delta(y)$. The opposite is not true: when there is no dominance between x and y, $\delta(x)$ may be less, equal, or greater than $\delta(y)$.

3.2 Testbed of 2x2 conflicted games

We first use a neutral but extensive testbed of games introduced by Brams in [2]: the testbed is composed of all possible conflicting situations that can occur in a two-action two-player game with a total preference order over the four outcomes of the game. This testbed represents a wide variety of situations, including often-studied games like PD, the chicken game, battle of the sexes, etc. There is no game where agents can simultaneously obtain their most preferred outcome, which implies that each game represents a

[1]WoLF-PHC settings: $\alpha(t) = \frac{1}{10+\frac{t}{100}}$, $\delta_W = \frac{1}{10+t}$, $\delta_L = 4\delta_W$. The games were played over 10,000 iterations, and results were averaged over 40 runs.

conflicting situation. There are 57 structurally different 2x2 conflict games (no two games are identical by renaming the actions or the players). In five games, the equilibrium reached by WoLF(commit) strictly dominates the equilibrium reached with WoLF. Three of them are games where the NE is dominated. The remaining two are the games where the NE is a mixed strategy NE dominated by a pure strategy. In nine other games, the outcome obtained by WoLF(commit) is different than the outcome of the NE of the stage game played with the traditional protocol, but there is no dominance (one player gains and the other looses). We found that the use of the commit protocol fails to produce a Pareto optimal solution in only two games, one of which is the prisoner's dilemma game.

3.3 Results on randomly generated matrices

As shown in the previous experiments, the structure of some games can be exploited by the commit protocol to improve the payoff of both players. To evaluate the effectiveness of the protocol on a more general set of matrices, we ran experiments on randomly generated matrices as in [5]. We generated 1000 matrices of sizes 3x3, 5x5 and 7x7. Each matrix entry is sampled from a uniform distribution in $[0, 1]$. We compare the outcome of WoLF(commit) and WoLF. In the top plot of Figure 2, we plot different areas: the average area containing all the outcome of NE (i.e. dominating the minimax outcome), the area that dominates the outcome of the traditional and the commitment protocol. We first observe that the minimax outcome is dominated by more outcomes for larger games, i.e. the space of NE is larger. When we compare with the area that dominates the outcome found by WoLF we find that the outcome with the protocol with commitment is dominated by less outcomes, and the difference increases with the game size. In the bottom plot of Figure 2, we plot our δ metric that provides the percentage of sustainable NE of the repeated game that dominates the outcome of the algorithm. The chart indicates that the outcome obtained with protocol with commitment is dominated by at most 10% of the possible NE, when the outcome of the traditional simultaneous game is dominated by 3 times more NE. This suggests that the commitment protocol produces more efficient equilibrium than the traditional simultaneous game protocol.

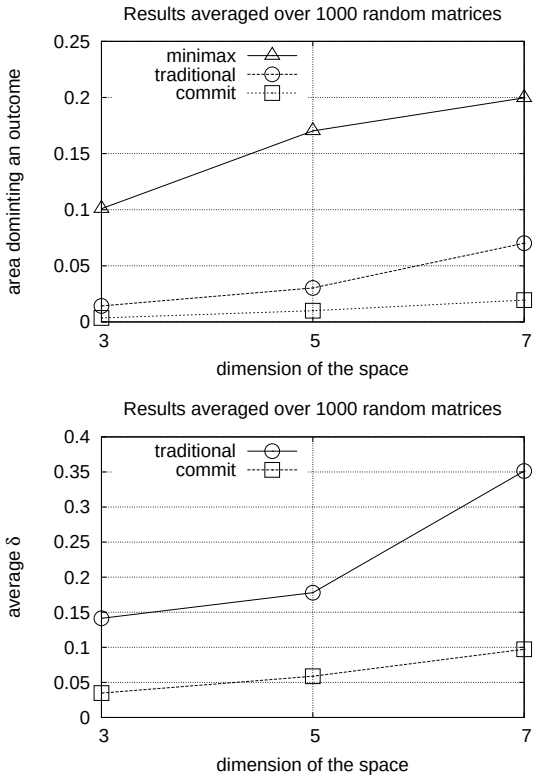

Figure 2: Results over randomly generated matrices.

4. CONCLUSION AND FUTURE WORK

In this paper, we built on a previous algorithm from [5] with the goal of producing PONE outcomes in repeated single-stage games. We propose a metric that can be used to measure the quality of an outcome: it represents the relative number of Nash equilibria of the repeated game that dominate the outcome reached. Under the assumption that the opponent payoff matrix is unknown, it might be difficult to ensure convergence to a PONE. Our proposed metric is helpful in comparing the relative efficiency of different outcomes.

We experiment with two-player two-action general-sum conflict games where both agents have the opportunity to commit to an action and allow the other agent to respond to it. The opportunity of revealing its action should not be seen as making a concession to the opponent, but rather as a means to explore the possibility of mutually beneficial outcomes. Any learning algorithm can be augmented to incorporate the commit protocol, which improves the payoffs in most cases: we empirically show that our protocol improve the payoffs obtained by WoLF-PHC in a variety of games. The experiments also show shortcomings of the current commitment protocol in that it fails to reach PONE outcomes: the primary reason for this is that a player responds to a commitment with a myopic best response.

We assume that a player does not know the payoff matrix of the opponent, which makes it difficult to estimate whether the equilibrium reached is acceptable for both players. In particular, there are situations where not playing a best response to a committed action can be beneficial for both players. To find a non-myopic equilibrium, an agent should not be too greedy! Currently, the agents are learning only their own payoff, and learn to play a best response to a committed action. We are working on learning action-utility estimates that incorporates an estimate of the preference of the opponent in the game tree presented in Figure 1. We expect that the agents will be able to more consistently discover states beneficial for both learners, and thereby converge to PONE outcomes.

ABSTRACT

We study the problem of agents attempting to find quality service providers in a distributed environment. While referrals from other agents can be used to locate high-quality providers, referrers may be malicious and provide incorrect referrals to reduce traffic to their preferred service providers. Whereas apparently it would seem that such deceptive referrals can disrupt system stability, we observe that homogeneous groups of deceptive referrals converge faster to stable agent distributions over service providers compared to homogeneous groups of truthful referrers. We conjecture that deceptive referrers can unwittingly reduce the entropy, a measure of volatility, of the system as the recipient of a bad referral may not be inclined to move even if it is not satisfied with its current service providers. Additionally, we observe that mixed groups of truthful and deceptive referrers converge faster to stable distributions compared to homogeneous group of truthful referrers. These results highlight the unexpected positive effect of deceptive agents in stabilizing a population.

Referral system, deceptive referral, satisficing distribution

1. INTRODUCTION

We investigate the usefulness of referrals from other agents in locating service providers with satisfactory performance where provider performance depends on its workload. In particular, we are interested in quick convergence of such systems to stable agent distributions over the providers where each agent is satisfied with the performance of the provider it is currently using. In previous work, we determined that truthful referral helps to increase the speed of convergence as opposed to systems without referrals. But agents may also deliberately provide misleading referrals to, among other reasons, prevent "crowding" at their favorite providers. This paper aims at determining the effect such deception would have on the system convergence and stability.

While ideally speaking agents may aspire for optimal satisfaction levels from service providers selected for performing an assigned task, dynamic, partially known, and open environments can render the realization of this ideal behavior improbable. Possible sources of inefficiencies include noisy, variable feedback about provider performance as the environment is at best partially observable, e.g. all factors affecting performance are not directly observable. Besides, an agent is unable to accurately assess the impact of its own decisions, including choice of service providers and making referrals, on its environment. In this paper, we evaluate the effects of deceptive referrals and if it can, counter-intuitively, mitigate the lack of accurate information available to agents and can maintain or even improve convergence rates to stable configurations.

2. EXPERIMENTAL FRAMEWORK

Our environment is formally defined as follows:
$\mathcal{E} =< \mathcal{A}, \mathcal{R}, perf, L, S, \Gamma >$ where:

- $\mathcal{A} = \{a_k\}_{k=1..K}$ is the set of agents
- $\mathcal{R} = \{r_n\}_{n=1..N}$ is the set of providers.
- $f: \mathcal{R} \times \mathbb{R}_+ \rightarrow [0,\ 1]$, intrinsic performance function of a provider given total load.
- $L : \mathcal{A} \rightarrow \mathbb{R}_+$, load function for the agents.
- $S: \mathcal{A} \times [0, 1] \rightarrow [0,\ 1]$, satisfaction function of agents.
- $\Gamma = \{\gamma_1, \ \ldots, \ \gamma_K\}$, the set of satisfaction thresholds of agents.

On each day, agent a_k is assigned a load $L(a_k)$. Initially, each agents know the set of service providers that can handle their tasks but not the intrinsic capabilities, $f(r_n, \cdot)$, of any provider r_n or their respective load capacity. The above formulation is consistent with our previous work on referrals [1].

Our primary objective is for every agent in the system to obtain a satisfaction above its satisfaction threshold, thereby ensuring a stable system. With no incentive to move, the system no longer oscillates and we attain an equilibrium state in finite time. Such a distribution is formally characterized as follows:

DEFINITION 1 (Γ-ACCEPTABLE DISTRIBUTION). *A distribution $D = \{\mathcal{A}_n\}_{n=1..N}$ is said to be* **Γ-acceptable distribution** *iff*

$$\forall n,\, a_k \in \mathcal{A}_n \Longrightarrow S\left(a_k,\, f\left(r_n,\, \sum_{a \in \mathcal{A}_n} L(a)\right)\right) \geq \gamma_k$$

3. INFLUENCE OF INERTIA ON CONVERGENCE SPEED

In uncontrolled systems, agents receive highly variable satisfactions. A system at a distribution close to Γ-acceptable distribution will have the tendency to evolve to a worse distribution and vice versa. Intuitively, a distribution where almost everyone is satisfied contains very few under-used or over-used providers and the rest are occupied by the right number of agents. Those under-used providers, $\mathcal{R}_u$, are very attractive. Consequently, agents will be inclined to move to them, which leads the system to a distribution where providers in $\mathcal{R}_u$ will be overcrowded. Indeed, the performance of the system oscillates between desirable values and highly undesirable ones. We believe this problematic effect can be mitigated by increasing the inertia in the system, where the inertia of an agent is its inclination to persist with a service provider it is not satisfied with and is globally measurable by an inverse function of the number of agents moving at any given time, K_{move}.

The work by Candale and Sen [1] showed that when a high number of agents switch resources simultaneously the performance of the system cannot stabilize and varies between high and low values. As a result, agents receive variable feedback from the environment leading to inaccurate learning. They also showed that when the number of agents moving simultaneously remains low, the system stabilizes quickly. We experiment with the following set of agent types:

AgentTRnD: While deciding on which service provider to use an agent can use its past experience and referrals from selected agents. A referral consists of a name of a provider and an estimation of its quality. While picking an agent to ask for referral it selects an agent, with a probability proportional to the quality of past referrals from that agent, from a set of agents whose expected quality of referral is greater than its satisfaction threshold. When an agent, a_k, fails to get an acceptable referral from other agents or from its knowledge of providers, it resorts to systematic exploration of providers with an exploration probability, α_k. The consequence of excessive exploration is a reduction in the inertia of the system and can lead to system instability.

AgentTRwD: This agent is identical to the previous one except the fact that agents always deceive. They refer the same provider as *AgentTRnD*, but alter the true estimation, *es*. More precisely, if *es* is greater than their satisfaction threshold then they report a lower estimate, and otherwise report a higher estimate.

4. EXPERIMENTAL RESULTS

The environment is setup with the exact number of service providers needed to satisfy all the agents in it.We ran experiments with environments having a population of 100 agents each and results averaged over 50 runs. The environments comprised of purely homogeneous agents, truthful and deceptive, and a mixed population of both agents in equal ratio. Agents have identical properties such as coefficient of exploration, satisfaction threshold, and the load function.

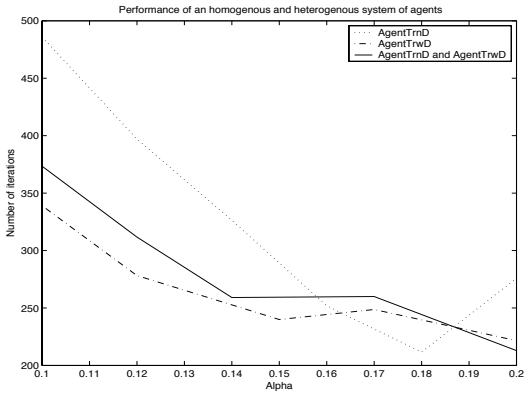

Figure 1: Speed of convergence with varying α: 100 Agents, 50 providers and $\gamma_k = 0.7$.

4.1 Influence of alpha (α)

We observe the speed of convergence of our system by varying coefficient of exploration, α (see Figure 1). We present the following observations:

1. For all agent populations the speed of convergence improves when α increases. For small values of α system convergence is delayed by a slow resource discovery process [1]. For $\alpha > 0.2$, however, exploratory actions become too frequent and increase convergence times. The effect of referrals is more pronounced for smaller values of α. With infrequent exploration, agents have to depend more on referrals to find satisfactory resources.

2. A significant, counter-intuitive result is that the presence of deceptive agents in the population (homogeneous or mixed) leads to better speed of convergence than in homogeneous population of truthful agents. Truthful referrals affect agents using the referred providers, as they will see their satisfactions decrease and then be encouraged to switch resources, which leads to system instability as illustrated in Figure 2. Deception, however, helps an agent maintain the load of its favorite provider at a low level by discouraging probable newcomers. Another key reason is that with deceptive referrals from other agents, it is more likely that an unsatisfied agent may be temporarily led to believe that it will not receive better satisfaction at

other resources. Thus it may choose to not change its provider, thereby decreasing system volatility and ultimately facilitating convergence. Unsatisfied agents, however, will not be persuaded not to change for long, and the system converges steadily.

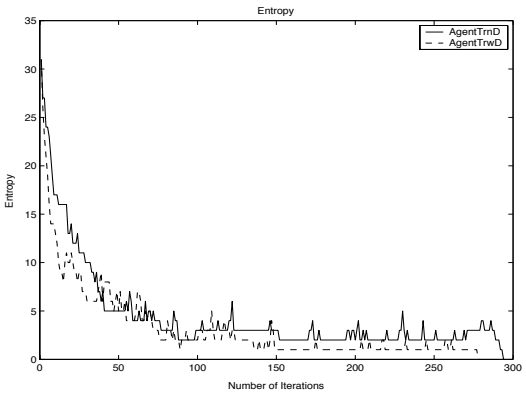

Figure 2: Entropy of truthful and deceptive agents: 100 agents, 50 resources.

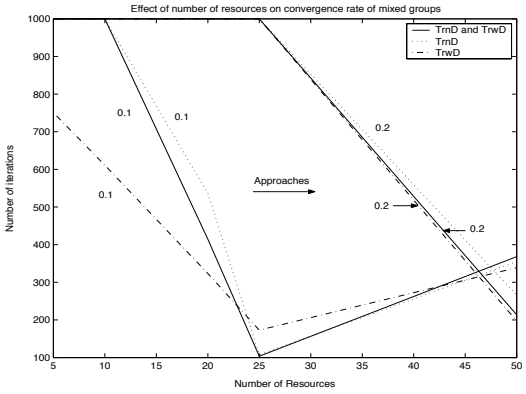

Figure 3: Speed of convergence with varying resources: 100 Agents, $\gamma_k = 0.7,\ \alpha = 0.1,\ , 0.2$.

4.2 Influence of the number of resources

We also investigated the speed of convergence by varying the number of resources (see Figure 3). We observe that deception has a positive effect on the speed of convergence when the numbers of resources is small. With smaller number of resources, it is more likely that agents are dissatisfied with their service providers, leading to greater K_{move}. Deceptive referrals help reduce that for reasons cited above.

5. RELATED WORK

Our domain was inspired by Yu and Singh [4] and Sen,Arora and Roychowdhury [3]. In both work they showed the short term cost of processing referral request and that information can negatively impact agent coordination to find a balanced distribution among resources respectively.

We believe that a more comprehensive understanding of system behavior can be obtained by studying the number of simultaneously moving agents, K_{move}. Our approach provides more detailed characterization of the system, but is consistent with general conclusions from Rustogi & Singh's [2] study as inertia can be used as a mechanism for controlling K_{move}. Rustogi & Singh [2] also claim that performance is remarkably improved when accepting imprecision.

6. CONCLUSION AND FUTURE WORK

We investigated the effect of the presence of deceptive agents in a population of referrer agents trying to coordinate their selection of service providers. Surprisingly, deception does not harm the system but, in general, helps to enhance the speed of convergence. Agents, by the use of deception, can keep the load of the provider they are currently using at a reasonable level. Besides, deception promotes system stability as it can discourage even unsatisfied agents from moving for some time.

In our future work, we plan on investigating if deceptive agent can still improve system convergence of a truthful referral system with differing satisfaction level and load function. We hope to find ways to achieve an improved convergence in such systems.

ABSTRACT

Modularization is widely recognized as a central issue in software engineering. In this paper we address the issue of modularization in cognitive agent programming languages. We discuss existing approaches to modularity in cognitive agent programming. Then, we propose a new kind of modularity, i.e., goal-oriented modularity, which takes the goals of an agent as the basis for modularization. Further, we present a formal semantics of goal-oriented modularity in the context of the 3APL agent programming language.

1. INTRODUCTION

Modularization is widely recognized as a central issue in software engineering [11, 9, 2]. A system which is composed of modules, i.e., relatively independent units of functionality, is called modular. A programming language which adheres to this principle of modularization supports the decomposition of a system into modules. The principle lies, e.g., at the basis of procedural programming and object-oriented programming, in which respectively (libraries of) procedures and classes form the modules.

An important advantage of modularity in a programming language is that it can increase the *understandability* of the programs written in the language. The reason is that modules can be separately understood, i.e., the programmer does not have to oversee the entire workings of the system when considering a certain module. Further, modularization enables *reuse* of software, since modules can potentially be used in different programs or parts of a single program. Finally, we mention an important principle which any kind of modularity should stick to, namely the principle of *information hiding*. This means that information about a module should be private to the module, i.e., not accessible from outside, unless it is specifically declared as public. The amount of information declared public should typically be relatively small. The idea behind information hiding is that a module can be changed (or at least the non-public part of a module), without affecting other modules.

In this paper we address the issue of modularization in *cognitive agent programming languages*. Cognitive agents are agents endowed with high-level mental attitudes such as beliefs, goals, plans, etc. Several programming languages and platforms have been introduced to program these agents, such as 3APL [10, 6], AgentSpeak(L) [14, 3], JACK™ [20], Jadex [13], etc. Some of these languages incorporate support for modularization, which we discuss in some detail in section 2.1.

Our contribution is the proposal of a new kind of modularity, i.e., *goal-oriented modularity*, which is, as we will argue, particularly suited for agent programming languages (section 2). Further, we present a *formalization* of goal-oriented modularity in the context of the 3APL programming language (section 3). We conclude the paper with directions for future research in section 4.

2. GOAL-ORIENTED MODULARITY

In this section, we explain the general idea of goal-oriented modularity. First, we discuss which kinds of modularity are present in today's cognitive agent programming languages and platforms (section 2.1). Then, we explain the general idea of goal-oriented modularity (section 2.2).

As for programming in general, modularization is also an important issue for agent programming. One could argue that the agent paradigm provides inherent support for modularity, since a complex problem can be broken down and solved by a team of autonomous agents. Constructing a team of agents to solve a problem rather than creating a single more complex agent, might however not always be the appropriate approach. The team approach will likely gener-

ate significant communication overhead, and having several independent agents can make it difficult to handle problems that require global reasoning [5, 4]. Following [5, 4], we thus argue that modularization is important also at the level of individual agents.

2.1 Related Work

With regard to cognitive agent programming languages such as 3APL and AgentSpeak(L), one could argue that these languages support modularization: an agent is typically composed of a number of components such as a belief base, a plan or intention base, a plan library, a goal or event base, etc. These components however do not provide the appropriate modularization, since their workings are closely intertwined and therefore they cannot be considered as relatively independent units of functionality. Cognitive agent programming languages thus need more support for structuring the internals of an agent, in order for them to deserve the predicate "modular".

One possible approach to addressing this issue of modularity of cognitive agent programming languages has been proposed by Busetta et al. in [5]. In that paper, the notion of *capability* was introduced and its implementation in the JACK cognitive agent programming language was described.

JACK extends the Java™ programming language in several ways, such as by introducing constructs for declaring cognitive agent notions like beliefs, events, plans, etc. Events are used to model messages being received, new goals being adopted, and information being received from the environment. Plans are used to handle events, i.e., if an event is posted, the reasoning engine tries to find an appropriate plan which has this event as its so-called triggering condition.

A capability in JACK is a cluster of components of a cognitive agent, i.e., it encapsulates beliefs, events (either posted or handled by the capability), and plans. Examples of capabilities given in [5] are a buyer and seller capability, clustering functionality for buyer and seller agents, respectively. A capability can import another capability, in which case the latter becomes a sub-capability of the former. Using the importation mechanism for capabilities, the beliefs of a capability can also be used by its super-capability, that is, if they are explicitly imported by the latter. Also, the beliefs of a capability can be used by its sub-capabilities if they are explicitly declared as exported (and if they are also imported by the sub-capabilities). For events, a similar mechanism exists, by means of which events posted from one capability can also be handled by plans of its sub- and possibly super-capabilities.

The notion of capability as used in JACK has been extended in the context of the Jadex platform [4]. Jadex is a cognitive reasoning engine which is built on top of the Jade [1] agent platform. A Jadex agent has beliefs, goals, plans, and events. Like capabilities in JACK, a Jadex capability clusters a set of beliefs, goals, plans, and events. Its most important difference with the notion of capability as used in JACK, is the fact that a general import/export mechanism is introduced for all kinds of elements of a capability, i.e., the mechanism is the same for beliefs, events, etc.

Another approach which could be viewed as addressing the issue of modularity in cognitive agent programming languages, has been proposed in the context of 3APL in [7]. In that paper, a formalization of the notion of a role is given. Similar to capabilities, a role clusters beliefs, goals, plans, and reasoning rules. The usage of roles at run-time however differs from that of capabilities. In the cited paper, a role can be enacted and deacted at run-time, which is specified at the level of the 3APL reasoning engine or deliberation cycle. If a role is enacted, the agent pursues the goals of the role, using the plans and reasoning rules of the role.[1] Further, the agent has a single belief base, and if a role is enacted, the beliefs associated with the role are added to the agent's beliefs. This is in contrast with JACK and Jadex where beliefs are distributed over capabilities, and can only be used in other capabilities if explicitly imported and exported. Also, only one role at the time can be active. This is in contrast with the way capabilities are used, since a JACK or Jadex agent can in principle use any of its capabilities at all times.

2.2 Our Proposal

While the approaches to modularization as described in section 2.1 are interesting in their own right, we propose an alternative which we argue to be particularly suited for cognitive agent programming languages. As the name suggests, goal-oriented modularity takes the goals of an agent as the basis for modularization. The idea is, that *modules encapsulate the information on how to achieve a goal*, or a set of (related) goals. That is, modules contain information about the plans that can be used to achieve a (set of) goal(s). At run-time, the agent can then dispatch a goal to a module, which, broadly speaking, tries to achieve the dispatched goal using the information about plans contained in the module.

This mechanism of dispatching a goal to a module can be used for an agent's top-level goals[2], but also for the *subgoals* as occurring in the plans of an agent. Plans are often built from actions which can be executed directly, and subgoals which represent a state that is to be achieved before the agent can continue the execution of the rest of the plan. An agent can for example have the plan to take the bus into town, to achieve the goal of having bought a birthday cake, and then to eat the cake.[3] This goal of buying a birthday cake will have to be fulfilled by executing in turn an appropriate plan of for example which shops to go to, paying for the cake, etc., before the agent can execute the action of eating the cake.

Before continuing, we remark that goals and subgoals in this paper are *declarative* goals, which means that they describe a state that is to be reached. This is in contrast with procedural goals, which are directly linked to courses of action. We refer to [21] for a discussion on declarative and procedural goals in general, and to [19, 16] for more background on declarative goals. Further, [17] explores semantics of subgoals, and relates declarative and procedural interpretations of subgoals.

Returning to our treatment of goal-oriented modularity, the idea is thus that agents try to achieve subgoals of a plan by dispatching the subgoal to an appropriate module, i.e., by *calling* a module. The module should then define the plans that can be used for achieving the (sub)goal. If a module is

[1]We simplify somewhat, since the details are not relevant for the purpose of this paper.

[2]Top-level goals are goals that the agent, e.g., has from start-up, or that it for example has adopted because of requests from other agents, etc.

[3]Assuming that both taking the bus into town and eating cake are actions that can be executed directly.

called for a goal, these plans are tried one by one until either the goal is achieved, or all plans have been tried. Control then returns to the plan from which the module was called. Depending on whether the subgoal is achieved or not upon returning from the module, the plan respectively continues execution, or fails. If the plan fails, another plan is selected (if it exists), for achieving the goal for which the failed plan was selected, etc.

2.3 Discussion

An advantage of our proposal is the *flexible* agent behavior with respect to handling plan failure, which comes with the usage of declarative goals. As argued in [21, 16], the usage of declarative goals facilitates a decoupling of plan execution and goal achievement. If a plan fails, the goal that was to be achieved by the plan remains a goal of the agent, and the agent can select a different plan to try to achieve the goal. While these ideas regarding declarative goals are not new, we contribute by proposing to use modules to *encapsulate* this mechanism for achieving goals by trying different plans. We thus exploit the advantages of declarative goals for obtaining modularization. Since in our view goals, proactiveness and flexible behavior are at the heart of (cognitive) agenthood, we argue that goal-oriented modularity, which builds on these notions, is a kind of modularity *fitting* for cognitive agents.

Comparing goal-oriented modularity with capabilities, we point out two major differences. Firstly, in the case of capabilities, there is no notion of *calling* a capability for a subgoal, thereby passing control to another capability. An event (or subgoal) posted from the plan of one capability, will be handled by the plans of this capability itself. That is, unless the capability imports other capabilities, in which case the plans of these other capabilities are *added* to the set of plans considered for handling the posted event (given appropriate import and export declarations of events). This is thus in contrast with goal-oriented modularity, where, in case of calling a module, *only* the plans of the called module are considered. These plans are not added to, e.g., some other set of plans, thereby preventing possibly unforeseen interactions between these plans. One could thus consider the idea of goal-oriented modularity to provide a higher degree of modularity or encapsulation of behavior at run-time, compared with the way in which capabilities are used. As we will explain in section 3, this is especially advantageous in the case of 3APL.

Secondly, modules in goal-oriented modularity contain only information about the plans which can be used to achieve certain goals. This is in contrast with capabilities, which can also contain beliefs. The idea for goal-oriented modularity is that the agent has one global belief base, rather than defining beliefs inside modules. When using capabilities, beliefs can by contrast be distributed over these capabilities, and only the beliefs of a certain capability can be accessed from this capability.

While from a software engineering perspective it might be convenient to be able to define beliefs inside capabilities (or modules), it can be considered less intuitive from a conceptual point of view. When testing, e.g., from within a plan whether the agent believes something, one could argue that the agent would have to consider *all* of its beliefs, rather than just the ones available in the capability. Also, if logical reasoning is involved as in the case of 3APL, it is more intuitive to let an agent have just one belief base. Consider for example that the formula p is in the belief base of one module, and that $p \rightarrow q$ is in the belief base of another. When testing whether q holds from the latter module, one would probably want the test to succeed.

Nevertheless, in JACK and Jadex, beliefs can be used in other capabilities if they are imported and exported in appropriate ways. Also, beliefs (or beliefsets) in those languages are effectively databases which store elements representing the beliefs of the agent. The definition of beliefs inside a capability could thus be viewed as the specification of a *part* of the larger database (or set of databases) comprising the total set of beliefs of the agent. From within a capability, an agent can then only refer to the part of its beliefs defined in this capability. It is then up to the programmer to make sure that the beliefs of a capability are the only ones relevant for the plans of this capability. The possibility of storing beliefs inside modules in a way which is somewhere inbetween the current proposal and the way it is done for capabilities, is discussed in section 4.

Comparing goal-oriented modularity with the notion of roles as used in [7], we remark the following. As in the case of capabilities, roles can, in contrast with modules, not call each other. Also, beliefs can be part of the definition of a role. However, a role does not have its own beliefs once it is enacted at run-time. If a role is enacted, its beliefs are added to the global belief base of the agent. This is more in line with goal-oriented modularity, but it is in contrast with the way capabilities are used. Further, contrary to roles, modules do not have goals. That is, a goal can be dispatched to a module, but goals are not part of the definition of a module.

3. GOAL-ORIENTED MODULARITY IN 3APL

In this section, we make the idea of goal-oriented modularity as presented in section 2 precise. In particular, we present a formalization in the context of 3APL. Nevertheless, we stress that we consider the general idea of goal-oriented modularity to be suited for cognitive agent programming languages in general, rather than for 3APL only.

3.1 Syntax

We build on a single agent and propositional version of 3APL, which comes closest to the one presented in [19]. We refer to [6, 8] for first order, multi-agent, and otherwise extended versions. This simplified version of 3APL is sufficient to present the ideas of the formalization of goal-oriented modularity. We conjecture that extending the formalization to a richer version of 3APL will not give rise to fundamental difficulties.

A 3APL agent in [19] has beliefs, a plan, and goals. Beliefs represent the current state of the world and information internal to the agent. Goals represent the desired state of the world, and plans are the means to achieve the goals. Further, a 3APL agent has rules for selecting a plan to achieve a certain goal given a certain belief, and it has rules for revising its plan during execution. We use these ingredients for our formalization of goal-oriented modularity.

Throughout this paper, we assume a language of propositional logic $\mathcal{L}$ with negation and conjunction. The symbol $\models$ will be used to denote the standard entailment relation for

$\mathcal{L}$. Further, we assume a belief query language $\mathcal{L}_\mathsf{B}$ with typical element β. A belief query can be used to test whether the agent has a certain belief. We assume an entailment relation on belief bases and belief query formulas, denoted by $\models_{\mathcal{L}_\mathsf{B}}$.[4]

Below, we define the language of plans Plan. A plan is a sequence of basic actions and module calls. Informally, basic actions can change the beliefs of an agent if executed. A module call is of the form $m(\phi)$, where m is the name of a module (to be defined in definition 4), and ϕ is a propositional formula representing the goal which is dispatched to module m.

Further, we define an auxiliary set of plans Plan′ with the additional construct $m(\phi)\downarrow$. This construct is used in the semantic definitions for recording whether module m has already been called for goal ϕ (see section 3.2 for further explanation). It should not be used by the agent programmer for programming plans, which is why we define two different plan languages.

Definition 1. *(plan) Let* BasicAction *with typical element* a *be the set of basic actions, let* ModName *with typical element* m *be a set of module names, and let* $\phi \in \mathcal{L}$. *The set of plans* Plan *with typical element* π *is then defined as follows.*

$$\pi ::= a \mid m(\phi) \mid \pi_1; \pi_2$$

We use ϵ *to denote the empty plan and identify* $\epsilon;\pi$ *and* $\pi;\epsilon$ *with* π. *The set* Plan′ *is defined as follows.*

$$\pi ::= a \mid m(\phi) \mid m(\phi)\downarrow \mid \pi_1; \pi_2$$

This simple language of plans could be extended with, e.g., if-then-else and while constructs as was done in [19], but the language as given here suffices for the purpose of this paper.

3APL uses so-called plan generation rules for selecting an appropriate plan for a certain goal. A plan generation rule is of the form $\phi \mid \beta \Rightarrow \pi$. This rule represents that it is appropriate to select plan π for goal ϕ, if the agent believes β.[5]

Definition 2. *(plan generation rule) The set of plan generation rules* $\mathcal{R}_\mathsf{PG}$ *is defined as follows:* $\mathcal{R}_\mathsf{PG} = \{\phi \mid \beta \Rightarrow \pi \ : \ \phi \in \mathcal{L},\ \beta \in \mathcal{L}_\mathsf{B},\ \pi \in \mathsf{Plan}\}$.[6]

The other type of rule which comes with 3APL, is the rule for plan revision. Plan revision rules are used to revise an agent's plan during execution. A plan revision rule $\pi_h \mid \beta \rightsquigarrow \pi_b$ represents that in case the agent believes β, it can replace the plan π_h by the plan π_b.

Definition 3. *(plan revision rule) The set of plan revision rules* $\mathcal{R}_\mathsf{PR}$ *is defined as follows:* $\mathcal{R}_\mathsf{PR} = \{\pi_h \mid \beta \rightsquigarrow \pi_b \ : \ \beta \in \mathcal{L}_\mathsf{B},\ \pi_h, \pi_b \in \mathsf{Plan}\}$.

[4]See, e.g., [19] for an example of a belief query language, in which one can express queries such as $\mathbf{B}(p)$ and $\neg\mathbf{B}(p \wedge q)$ for testing whether the agent believes p or does not believe $p \wedge q$, respectively.

[5]Note that it is up to the programmer to specify appropriate plans for a certain goal. 3APL agents can thus be viewed as a kind of reactive planning agents.

[6]We use the notation $\{\ldots \ : \ \ldots\}$ instead of $\{\ldots \mid \ldots\}$ to define sets, to prevent confusing usage of the symbol $\mid$ in this definition and definition 3.

Plan generation rules capture the information about which plan can be selected for which goal, and plan revision rules can be used during the execution of a plan. These rules thus specify the information on how to achieve goals, and therefore we propose to have these rules make up a module, as specified below. It is important to remark that non-modular versions of 3APL have one set of plan generation rules, and one set of plan revision rules, rather than an encapsulation of these into modules.

Definition 4. *(module) A module is a tuple* $\langle m, \mathsf{PG}, \mathsf{PR}\rangle$, *consisting of a module name* m, *a finite set of plan generation rules* $\mathsf{PG} \subseteq \mathcal{R}_\mathsf{PG}$, *and a finite set of plan revision rules* $\mathsf{PR} \subseteq \mathcal{R}_\mathsf{PR}$.

The mechanism of calling a module is formalized using the notion of a stack. This stack can be compared with the stack resulting from procedure calls in procedural programming, or method calls in object-oriented programming. During execution of the agent, a single stack is built (see definition 7). Each element of the stack represents, broadly speaking, a module call.

To be more specific, each element of the stack is of the form $(\phi, \pi, \mathsf{PG}, \mathsf{PR})$, where ϕ is the goal for which the module was called, π is the plan currently being executed in order to achieve ϕ, and PG and PR correspond with the plan generation and plan revision rules of the module which was called for achieving ϕ. Rather than using the name of the module to refer to the relevant plan generation and plan revision rules, we copy these rules into the stack element. The reason is that we want to remove plan generation rules if they are tried once. This will be explained further in section 3.2.

Definition 5. *(stack) The set of stacks* Stack *with typical element* S *to denote arbitrary stacks, and* s *to denote single elements of a stack, is defined as follows, where* $\phi \in \mathcal{L}$, $\pi \in \mathsf{Plan}'$, $\mathsf{PG} \subseteq \mathcal{R}_\mathsf{PG}$, *and* $\mathsf{PR} \subseteq \mathcal{R}_\mathsf{PR}$.

$$\begin{array}{lcl} \mathrm{s} & ::= & (\phi, \pi, \mathsf{PG}, \mathsf{PR}) \\ \mathrm{S} & ::= & \mathrm{s} \mid \mathrm{s}.\mathrm{S} \end{array}$$

E is used to denote the empty stack (or the empty stack element), and $E.\mathrm{S}$ *is identified with* S.

Note that the plan π of a stack element is from the extended set of plans Plan′, since a stack is a run-time construct which is not specified by the programmer when programming an agent (see definition 6). The plan π might thus, in contrast with the plans of plan generation and plan revision rules, contain a construct of the form $m(\phi)\downarrow$. The empty stack E is introduced for technical convenience when defining the semantics in section 3.2. Stacks as used here differ from intention stacks of AgentSpeak(L), as the elements comprising the stacks are essentially different: stack elements in this paper correspond with module calls, whereas in AgentSpeak(L) they represent (parts of) plans or intentions. Like non-modular 3APL, AgentSpeak(L) has one large set of plans (corresponding with the rules of 3APL).

An agent, as defined below, consists of a belief base, a goal base, a set of modules, and a function which specifies how beliefs are updated if actions are executed. As in non-modular 3APL, the belief base σ is a consistent set of propositional formulas. The goal base γ is essentially also a set of propositional formulas, and forms the top-level goals

of the agent. In contrast with non-modular 3APL however, each goal is associated with a module which should be called for achieving the goal, i.e., goals are of the form $m(\phi)$. The set of modules Mod form the modules which can be called to achieve (sub)goals. Defining how beliefs are updated through action execution by assuming a function $\mathcal{T}$, is standard for the way 3APL's semantics is usually defined. This function is used for technical convenience. We assume that $\mathcal{T}$ maintains consistency of the belief base.

DEFINITION 6. *(agent)* *Let* $\Sigma = \{\sigma \mid \sigma \subseteq \mathcal{L},\ \sigma \not\models \bot\}$ *be the set of belief bases. An agent is a tuple* $\langle \sigma, \gamma, \mathsf{Mod}, \mathcal{T}\rangle$ *where* $\sigma \in \Sigma$ *is the belief base,* $\gamma \subseteq \{m(\phi) \mid m \in \mathsf{ModName}, \phi \in \mathcal{L}\}$ *is the initial goal base, and* Mod *is a set of modules such that each module in this set has a distinct name.* $\mathcal{T}$ *is a partial function of type* $(\mathsf{BasicAction} \times \Sigma) \rightarrow \Sigma$ *and specifies the belief update resulting from the execution of basic actions.*

The notion of a configuration, as defined below, is used to represent the state of an agent at each point during computation. It consists of the elements which may change during execution of the agent, i.e., it consists of a belief base, a goal base, and a stack. Note that an agent initially has an empty stack.

DEFINITION 7. *(configuration)* *A configuration is a tuple* $\langle \sigma, \gamma, \mathrm{S}\rangle$ *where* $\sigma \in \Sigma$, $\gamma \subseteq \{m(\phi) \mid m \in \mathsf{ModName},\ \phi \in \mathcal{L}\}$, *and* $\mathrm{S} \in \mathsf{Stack}$. *If* $\langle \sigma, \gamma, \mathsf{Mod}, \mathcal{T}\rangle$ *is an agent, then* $\langle \sigma, \gamma, E\rangle$ *is the initial configuration of the agent.*

3.2 Semantics

The semantics of modular 3APL agents is defined by means of a transition system [12]. A transition system for a programming language consists of a set of axioms and transition rules for deriving transitions for this language. A transition is a transformation of one configuration into another and it corresponds to a single computation step. In the transition rules below, we assume an agent with a set of modules Mod, and a belief update function $\mathcal{T}$.

The first transition rule specifies how a transition for a composed stack can be derived, given a transition for a single stack element. It specifies that only the top element of a stack can be transformed or executed.[7]

DEFINITION 8. *(stack execution)* *Let* $s \neq E$.

$$\frac{\langle \sigma, \gamma, \mathrm{s}\rangle \rightarrow \langle \sigma', \gamma', \mathrm{S}'\rangle}{\langle \sigma, \gamma, \mathrm{s}.\mathrm{S}\rangle \rightarrow \langle \sigma', \gamma', \mathrm{S}'.\mathrm{S}\rangle}$$

In the transition rule for stack execution, we specify that s cannot be the empty stack. The reason is related to the transition rule for stack initialization of definition 9 below. In that rule, we want to specify that a stack initialization transition can only be derived if the current stack is empty. We however do not want to use that rule in combination with the rule for stack execution, since that would result in the possibility of deriving an "initialization" transition, even if the current stack is not empty.

An initialization transition can thus only be derived if the current stack is empty. The idea of initialization is that a (top-level) goal $m(\phi)$ from the goal base is (randomly) selected, and then the module m is called with the goal ϕ. The resulting stack is then of the form $(\phi, \epsilon, \mathsf{PG}, \mathsf{PR})$, where PG and PR are the plan generation and plan revision rules of m. Note that the plan of the resulting stack element is empty. The idea is that the plan generation rules of the module should now be used to generate an appropriate plan.

DEFINITION 9. *(initialization of stack)*

$$\frac{m(\phi) \in \gamma \qquad \langle m, \mathsf{PG}, \mathsf{PR}\rangle \in \mathsf{Mod}}{\langle \sigma, \gamma, E\rangle \rightarrow \langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle}$$

Note that a consequence of this way of defining the goal base is that multiple goals from the goal base cannot be dispatched to the same module in one initialization. Thinking about alternative ways to define the goal base which might allow this, is left for future research.

The following transition rule is the rule for plan generation, defining when a plan generation rule can be applied. A prerequisite for applying a plan generation rule is that the plan of the relevant stack element is empty. A rule $\phi' \mid \beta \Rightarrow \pi$ from PG can then be applied if β is true, ϕ' follows from ϕ (i.e., the goal for which the module was called), and ϕ' is not believed to be achieved. Further, for a plan generation rule to be applicable, the goal ϕ' should not already be achieved, since there is no need to generate a plan for such a goal. Note that since ϕ' follows from ϕ, it is the case that ϕ is also not reached, if ϕ' is not reached. With respect to the second condition for plan generation rule application, we remark that a plan generation rule with goal antecedent p (i.e., $\phi' = p$) can thus be applied if the agent has, e.g., a goal $p \wedge q$ (i.e., $\phi = p \wedge q$). This interpretation of plan generation rules is standard for 3APL. It is convenient when programming, since plan generation rules can be specified for parts of a composed goal.

If a plan generation rule is applied, the plan π in its consequent becomes the plan of the resulting stack element. Further, the applied plan generation rule is removed from the set of plan generation rules of the stack element.

DEFINITION 10. *(plan generation)*

$$\frac{\phi' \mid \beta \Rightarrow \pi \in \mathsf{PG} \qquad \sigma \models_{\mathcal{L}_\mathrm{B}} \beta \qquad \phi \models \phi' \qquad \sigma \not\models \phi'}{\langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \pi, \mathsf{PG}', \mathsf{PR})\rangle}$$

where $\mathsf{PG}' = \mathsf{PG} \setminus \{\phi' \mid \beta \Rightarrow \pi\}$

The reason for removing plan generation rules is that we do not want the agent to try the same plan generation rule twice, to achieve a certain goal. Otherwise, the agent could get stuck "inside" a module trying to achieve a subgoal, if all its plans keep failing to reach the goal. The idea is that modules contain various plans for achieving a certain goal. If the agent cannot reach a certain subgoal of a plan with the designated module, the agent should thus at a certain point give up trying to reach the subgoal. It should just try another plan with possibly different subgoals. Wanting to remove plan generation rules of a stack element is the reason that we copy the rules into stack elements, rather than just referring to the rules of a module using the name of the module. If we would extend this semantics to a first order version, we would have to record which instances of a plan generation rule are tried, rather than just removing the rule. This mechanism is comparable to the mechanism

[7]For technical convenience, we overload the "." operator in definition 8. We use it to "push" a stack onto a stack, rather than to push a single stack element onto a stack, as it was, strictly speaking, defined in definition 5.

for selecting plans for subgoals in JACK. In JACK it is also the case that the same plan is not tried for the same subgoal twice.

The following two transition rules are standard for 3APL, and define how a plan is executed. The only difference is that the plan is now inside a stack element. A basic action a at the head of a plan can be executed if the function $\mathcal{T}$ is defined for a and the belief base σ in the configuration. The execution results in a change of belief base as specified through $\mathcal{T}$, and the action is removed from the plan. Further, goals from the goal base which are reached, are removed. Note that actions, which are executed from within a module, operate on the global belief base of the agent.

DEFINITION 11. *(action execution)*

$$\frac{\mathcal{T}(a,\sigma) = \sigma'}{\langle \sigma, \gamma, (\phi, a; \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma', \gamma', (\phi, \pi, \mathsf{PG}, \mathsf{PR})\rangle}$$

where $\gamma' = \gamma \setminus \{m(\phi) \mid \sigma \models \phi\}$.

The transition below specifies the application of a plan revision rule of the form $\pi_h \mid \beta \Rightarrow \pi_b$ to a plan of the form $\pi_h; \pi$. The rule can be applied if β holds. If the rule is applied, the plan π_h is replaced by the body of the rule, yielding the plan $\pi_b; \pi$.

DEFINITION 12. *(plan revision)*

$$\frac{\pi_h \mid \beta \rightsquigarrow \pi_b \in \mathsf{PR} \qquad \sigma \models_{\mathcal{L}_\mathsf{B}} \beta}{\langle \sigma, \gamma, (\phi, \pi_h; \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \pi_b; \pi, \mathsf{PG}, \mathsf{PR})\rangle}$$

We now revisit the point made in section 2.3, that the encapsulation provided by modules at run-time is especially advantageous in the case of 3APL. The reason is that modules encapsulate not only plan generation rules, but also plan revision rules. These plan revision rules provide very flexible ways for revising a plan during execution, but a large number of rules can interact in possibly unforeseen ways. This has to do with the semantics of plans not being compositional in case of plan revision, as explained in [18]. Being able to cluster plan revision rules into modules thus reduces the chances of unforeseen interactions with other rules: the number of plan revision rules in a module will be small compared with the global set of plan revision rules of a non-modular 3APL agent.

The next two transition rules specify the cases in which a stack element can be popped from the stack. Both transition rules specify that an element can be popped if its plan has finished execution, i.e., if the plan is empty. The idea is, that an agent should always finish the execution of an adopted plan, even though, e.g., the goal for which it was selected might already be reached. This is standard for 3APL, and the reason is that the programmer might have specified some necessary "clean-up" actions. Consider as an example the case where an agent still has to pay after refueling, even though the goal of having gas is already reached.

The first transition rule for popping a stack element specifies that the element can be popped if the goal ϕ of the stack element is reached.

DEFINITION 13. *(goal of stack element reached)*

$$\frac{\sigma \models \phi}{\langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, E\rangle}$$

The second transition rule for popping a stack element specifies that the element can be popped if there are no more applicable plan generation rules (regardless of whether the goal is reached).

DEFINITION 14. *(no applicable plan generation rules)*

$$\frac{\neg\exists(\phi' \mid \beta \Rightarrow \pi) \in \mathsf{PG} :\ (\sigma \models_{\mathcal{L}_\mathsf{B}} \beta \text{ and } \phi \models \phi' \text{ and } \sigma \not\models \phi')}{\langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, E\rangle}$$

The next three definitions specify the semantics of the construct $m(\phi')$ for calling a module. If this construct is encountered in a plan, and it is not annotated with the symbol $\downarrow$, the module m should be called for the goal ϕ'. That is, only if ϕ' is not yet reached. If a module with the name m exists,[8] a new element with goal ϕ', an empty plan, and the rules of m, is pushed onto the stack. Further, the construct $m(\phi')$ is annotated with $\downarrow$ to indicate that a module has been called for this subgoal. This is important, since we do not want to call module m again upon returning from m.

DEFINITION 15. *(calling a module)*

$$\frac{\langle m, \mathsf{PG}', \mathsf{PR}'\rangle \in \mathsf{Mod} \qquad \sigma \not\models \phi'}{\begin{array}{l}\langle \sigma, \gamma, (\phi, m(\phi'); \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \\ \quad \langle \sigma, \gamma, (\phi', \epsilon, \mathsf{PG}', \mathsf{PR}').(\phi, m(\phi')\downarrow; \pi, \mathsf{PG}, \mathsf{PR})\rangle\end{array}}$$

The transition rules of the next definition specify that the agent can continue the execution of the rest of its plan, if the subgoal ϕ' occurring at the head of the plan is reached. The agent should continue if it has already called the module m for the subgoal, i.e., if the construct is of the form $m(\phi')\downarrow$, or if the module has not yet been called, i.e., if the construct is of the form $m(\phi')$. The latter case is however probably less likely to occur.

DEFINITION 16. *(subgoal reached)*

$$\frac{\sigma \models \phi'}{\langle \sigma, \gamma, (\phi, m(\phi')\downarrow; \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \pi, \mathsf{PG}, \mathsf{PR})\rangle}$$

$$\frac{\sigma \models \phi'}{\langle \sigma, \gamma, (\phi, m(\phi'); \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \pi, \mathsf{PG}, \mathsf{PR})\rangle}$$

The next transition rule specifies that if a module has been called for a subgoal, i.e., if a construct of the form $m(\phi')\downarrow$ is at the head of the plan of a stack element, and the subgoal ϕ' has not been reached, the plan fails. That is, the plan is replaced by an empty plan. If there are any applicable plan generation rules left, another plan can then be selected to try to achieve the goal ϕ of the stack element.

DEFINITION 17. *(subgoal dispatched and not reached)*

$$\frac{\sigma \not\models \phi'}{\langle \sigma, \gamma, (\phi, m(\phi')\downarrow; \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle}$$

In this version of modular 3APL, a plan can fail to reach a goal only in case the programmer has specified the "wrong" actions in the plans. Since all actions (as is usually the case for 3APL's formal semantics) operate on the belief base and there is no notion of an external environment, there is no notion of the environment preventing an action from being

[8] And it should if the programmer has done a good job.

executed, thereby possibly causing a plan to fail. One could thus argue that it is not necessary to have a mechanism for selecting a different plan upon plan failure, since it is the job of the programmer to make sure that the plans do not fail and reach the goals. Any practical implementation of these ideas however would involve actions being executed in the environment, and it is thus important to incorporate a mechanism for handling plan failure..

The final transition rule below is very similar to the previous, in the sense that it specifies another reason for plan failure. In particular, it specifies that a plan fails if the action at its head cannot be executed, i.e., if the function $\mathcal{T}$ is undefined for the action and the belief base of the stack element.

DEFINITION 18. *(failure of action execution)*

$$\frac{\mathcal{T}(a,\sigma) \text{ is undefined}}{\langle \sigma, \gamma, (\phi, a; \pi, \mathsf{PG}, \mathsf{PR})\rangle \rightarrow \langle \sigma, \gamma, (\phi, \epsilon, \mathsf{PG}, \mathsf{PR})\rangle}$$

3.3 Example

For illustration, we present a simple example of a modular 3APL agent. The agent has to bring a rock from the location where the rocks are $loc(rock)$[9], to its base location $loc(base)$. It has three modules, i.e., *collectRock* for the general goal of collecting the rock, and *goTo* and *pickUp* for going to a location and picking up a rock, respectively. Initially, the agent believes that it is at the base location, and that it does not have a rock, i.e., $\neg have(rock)$. Further, it has the goal $collectRock(have(rock) \wedge loc(base))$, i.e., it wants to achieve the goal $have(rock) \wedge loc(base)$ using module *collectRock*.

Below, we define the initial belief base σ and goal base γ of the rock collecting agent.

$$\begin{array}{lcl} \sigma & = & \{loc(base), \neg have(rock)\} \\ \gamma & = & \{collectRock(have(rock) \wedge loc(base))\} \end{array}$$

The plan generation rules PG_{cr} of the module *collectRock* are defined as below. The set of plan revision rules is empty.

$$\begin{array}{lcl} \mathsf{PG}_{cr} & = & \{have(rock) \wedge loc(base) \mid \top \Rightarrow \\ & & goTo(loc(rock)); pickUp(have(rock)); \\ & & goTo(loc(base))\} \end{array}$$

There is one plan generation rule which can be used for the goal $have(rock) \wedge loc(base)$, i.e., the initial goal of the agent. The plan of the rule consists entirely of calls to other modules. Note that the *goTo* module is called with two different goals. The rule does not specify a condition on beliefs (other than $\top$). In particular, there is no need to specify that the agent should, e.g., believe that it is at the base location, rather than at the rock location. If the agent would already be at the rock location, the first module call of the plan, i.e., $goTo(loc(rock))$, would be skipped, since the subgoal $loc(rock)$ is already reached (see definition 16).

The plan generation rules PG_{gt} and plan revision rules PR_{gt} of the module *goTo* are defined as follows.

$$\begin{array}{lcll} \mathsf{PG}_{gt} & = & \{loc(rock) & \mid \mathbf{B}(loc(base)) \Rightarrow toRock \\ & & loc(base) & \mid \mathbf{B}(loc(rock)) \Rightarrow toBase\} \\ \mathsf{PR}_{gt} & = & \{toRock & \mid \mathbf{B}(loc(rock)) \rightsquigarrow skip \\ & & toRock & \mid \neg\mathbf{B}(loc(rock)) \rightsquigarrow east; toRock \\ & & toBase & \mid \mathbf{B}(loc(base)) \rightsquigarrow skip \\ & & toBase & \mid \neg\mathbf{B}(loc(base)) \rightsquigarrow west; toBase\} \end{array}$$

[9]Note that all formulas are propositional, although we use brackets for presentation purposes.

This module has two plan generation rules: one for selecting a plan to get from the base location to the rock location, and one for the other way around. The plans *toRock* and *toBase* in the bodies of the plan generation rules are non-executable basic actions, which are used as procedure variables.[10] Assuming that the rock is located east from the base location, we specify plan revision rules for moving east until the rock location is reached, and moving west until the base location is reached. The action *skip* is a special action which does nothing if executed.

In this simple example, we specify separate plan revision rules for moving east and west respectively. The plans for moving to the rock location and to the base location thus use different plan revision rules. We could therefore have created two separate modules, i.e., one for going to the rock, and one for going to the base. In a more realistic setting however, one could imagine to have *one* set of plan revision rules for moving to any given location. In that case, it would be advantageous to specify these rules only in one module.

The plan generation rules PG_{pu} of the module *pickUp* are defined as below, and the set of plan revision rules is empty.

$$\begin{array}{lcl} \mathsf{PG}_{pu} & = & \{have(rock) \mid \mathbf{B}(loc(rock)) \Rightarrow pickUp1 \\ & & have(rock) \mid \mathbf{B}(loc(rock)) \Rightarrow pickUp2\} \end{array}$$

The plan generation rules of this module can be applied if the agent believes it is at the rock location. Note that the call $pickUp(have(rock))$ to this module from the *collectRock* module, can only be executed if the subgoal of the previous module call, i.e., $goTo(loc(rock))$, has been achieved. If $pickUp(have(rock))$ is executed, we thus know for sure that the agent believes to be at the rock location. The module *pickUp* illustrates that the agent may have multiple plans, i.e., $pickUp1$ and $pickUp2$ in this case, for achieving the same goal. If, e.g., $pickUp1$ fails, the agent can try $pickUp2$.

4. FUTURE RESEARCH

As directions of future research, we mention the following. In the current proposal there is no notion of importing a module into another module. Some notion of importation could be added in a straightforward way, but it will have to be investigated what exactly the semantics of importation should be. Should the rules of the imported module just be "added" to the other module, or should there be some kind of prioritization among rules of the module itself and the imported module?

Further, goal-oriented modularity as presented here provides a high degree of information hiding. That is, when calling a module, only the name of the module has to be known. In principle, any part of a module can be adapted without having to adapt the call to the module. We thus have no notion of an interface of a module, i.e., those parts of the module which are known outside the module. Nevertheless, it might be worthwile to investigate whether the framework can be extended with some notion of interface, such as the goals for which a module can be called, etc. This might be a useful tool to help a programmer.

Also, we envisage that a mechanism similar to the mechanism of dispatching a goal to a module, could be used in a multi-agent team work setting (see, e.g., [22]) to delegate a goal to an agent. Using a uniform mechanism both for

[10]Non-executable basic actions are often termed *abstract plans* in the 3APL literature.

calling modules and delegating goals to agents could potentially yield more transparent systems. In case of delegation, a plan would have to contain a request message to an agent, rather than a call to a module. A way of "returning" from the request, just as one can return from a module, would have to be defined. An agent would for example have to report back to the requesting agent, either with a message expressing that the goal has been achieved, or that he has failed and stopped trying. Moreover, it can be interesting to investigate a construct for calling modules in parallel. This can also be interesting in the case of multi-agent teamwork as also discussed in [22], since an agent could then dispatch several goals to different agents in parallel.

Finally, we remark that it could be useful to be able to store information during execution within a module, which would not need to be kept after returning from the module. This could be realized by adding actions to the specification of a module, which would then update the module's internal information store, rather than the global belief base. This could be considered as a compromise between the way beliefs are handled in capabilities, and the way we handle beliefs in the presented framework.

Concluding, we have presented the idea of goal-oriented modularity, which takes the goals of an agent as the basis for modularization. Since we view goals as being an essential ingredient of cognitive agents, we argue that this approach to modularity is suited for cognitive agent programming languages. Further, we have shown how goal-oriented modularity might be incorporated in a cognitive agent programming language, by presenting a formalization of goal-oriented modularity in 3APL.

ABSTRACT

This paper presents an implementation of (a simplified version of) the cognitive agent programming language 3APL in the Maude term rewriting language. We argue that Maude is very well suited for prototyping agent programming languages such as 3APL.

1. INTRODUCTION

An important line of research in the agent systems field is research on agent programming languages [2]. This type of research is concerned with an investigation of what kind of programming constructs an agent programming language should contain, and what exactly the meaning of these constructs should be. In order to test whether these constructs indeed facilitate the programming of agents in an effective way, the programming language has to be implemented.

This can be done using Java, which was for example used for implementing the agent programming language 3APL [13]. Java has several advantages, such as its platform independence, its support for building graphical user interfaces, and the extensive standard Java libraries. A disadvantage is however that the translation of the formal semantics of an agent programming language such as 3APL into Java is not very direct. It can therefore be difficult to ascertain that such an implementation is a faithful implementation of the semantics of the agent programming language, and experimenting with different language constructs and semantics can be quite cumbersome.

As an alternative to the use of Java, we discuss in this abstract[1] the usage of the Maude term rewriting language [6] for prototyping 3APL. Maude is based on the mathematical theory of rewriting logic. The language has been shown to be suitable both as a *logical* framework in which many other logics can be represented, and as a *semantic* framework, through which programming languages with an operational semantics can be implemented in a rigorous way [17]. We argue that, since agent programming languages such as 3APL have both a logical and a semantic component, Maude is very well suited for prototyping such languages. Further, it turns out that, since Maude is reflective, 3APL's meta-level reasoning cycle or deliberation cycle can be implemented very naturally in Maude.

An important advantage of Maude is that it can be used for verification as it comes with an LTL model checker [12]. This abstract does not further address model checking 3APL using Maude, since the usage of Maude's model checker is relatively easy, given the implementation of 3APL in Maude. The fact that Maude provides these verification facilities however, is an important, and in fact, our original, motivation for our effort of implementing 3APL in Maude.

2. IMPLEMENTATION OF 3APL IN MAUDE

3APL, which was first introduced by Hindriks [13], is a cognitive agent programming language. This means that it has explicit constructs for representing the high-level mental attitudes of an agent. The version of 3APL that we have implemented in Maude comes closest to the one presented in [25]. It is single-agent and builds on propositional logic. In this version, a 3APL agent has beliefs, a plan, and goals. Beliefs represent the current state of the world and information internal to the agent. Goals represent the desired state of the world, and plans are the means to achieve the goals. Further, a 3APL agent has rules for selecting a plan to achieve a certain goal given a certain belief, and it has rules for revising its plan during execution. Together, these elements may form the state or configuration of a 3APL

agent. In order to be able to refer to an agent's beliefs and goals, 3APL incorporates logical languages (belief and goal query languages) with corresponding semantics. The formal operational semantics of 3APL is defined by means of a transition system [21].

"Maude is a formal declarative programming language based on the mathematical theory of rewriting logic [18]. Maude and rewriting logic were both developed by José Meseguer. Maude is a state-of-the-art formal method in the fields of algebraic specification [27] and modeling of concurrent systems. The Maude language specifies rewriting logic theories. Data types are defined algebraically by equations and the dynamic behavior of a system is defined by rewrite rules which describe how a part of the state can change in one step." [20]

The general idea of the implementation of 3APL in Maude, is that 3APL configurations are represented as terms in Maude, and the transition rules of 3APL are mapped onto rewrite rules of Maude. This idea is taken from [26], in which, among others, implementations in Maude of the operational semantics of a simple functional language and an imperative language are discussed. Further, the logical languages of 3APL and their corresponding semantics can be represented in Maude as equational theories. Finally, the meta-level reasoning cycle or deliberation cycle of 3APL [13, 8, 24] can also be modelled very naturally in Maude, since rewriting logic is *reflective* [7]. "Informally, a reflective logic is a logic in which important aspects of its metatheory can be represented at the object level in a consistent way, so that the object level representation correctly simulates the relevant metatheoretic aspects. " [6, Chapter 10]

3. ADVANTAGES OF MAUDE

Based on our experience with the implementation of 3APL in Maude, we argue that Maude is well suited as a prototyping and analysis tool for logic-based cognitive agent programming languages. We observe that cognitive agent programming languages such as 3APL have a logical *as well as* a semantic component: the logical part consists of the belief and goal query languages, and the semantic part consists of the transition system. Since Maude supports both the logical and the semantic component, the implementation of languages like 3APL in Maude is very natural, and the integration of the two components is seamless.

We observe that the direct mapping of transition rules of 3APL into rewrite rules of Maude ensures a *faithful* implementation of the operational semantics of 3APL in Maude. This direct mapping is a big advantage compared with the implementation of a 3APL interpreter in a general purpose language such as Java, in which the implementation is less direct. In particular, in Java one needs to program a mechanism for applying the specified transition rules in appropriate ways, whereas in the case of Maude the term rewriting engine takes care of this. As another approach of implementing a cognitive agent programming language in Java, one might consider to implement the plans of the agent as methods in Java, which is for example done in the Jadex framework [22]. Since Java does not have support for revision of programs, implementing 3APL plans as methods in Java is not possible. We refer to [24] for a theoretical treatment of the issues with respect to semantics of plan revision.

A faithful implementation of 3APL's semantics in Maude is very important with regard to our main original motivation for this work, i.e., to use the Maude LTL model checker to do formal verification for 3APL. The natural and transparent way in which the operational semantics of 3APL can be mapped to Maude, is a big advantage compared with the use of, e.g., the PROMELA language [14] in combination with the SPIN model checker [15].

SPIN is a generic verification system which supports the design and verification of asynchronous process systems. SPIN verification models are focused on proving the correctness of process interactions, and they attempt to abstract as much as possible from internal sequential computations. The language PROMELA is a high level language for specifying abstractions of distributed systems which can be used by SPIN, and it's main data structure is the message channel. In [3], an implementation of the cognitive agent programming language AgentSpeak(F) - the finite state version of AgentSpeak(L) [4] - in PROMELA is described, for usage with SPIN. Most of the effort is devoted to translating AgentSpeak(F) into the PROMELA data structures. It is shown how to translate the data structures of AgentSpeak(F) into PROMELA channels. It is however not shown that this translation is correct, i.e., that the obtained PROMELA program correctly simulates the AgentSpeak(F) semantics. In contrast with the correctness of the implementation of 3APL in Maude, the correctness of the AgentSpeak(F) implementation in PROMELA is not obvious, because of the big gap between AgentSpeak(F) data structures and semantics, and PROMELA data structures and semantics. In [12], it is shown that the performance of the Maude model checker is comparable with that of SPIN.

A further important advantage of Maude is that deliberation cycles can be programmed very naturally as strategies, using reflection. A related advantage is that a clear separation of the object-level and meta-level semantics can be maintained in Maude. A 3APL program can be executed without making use of a deliberation cycle, while it can equally easily be executed *with* a deliberation cycle.

While we have implemented a simplified version of 3APL in Maude, we argue that the features of Maude are very well suited to support the implementation of various extensions of this version of 3APL. Implementing these extensions is left for future research.

In particular, an extension of a single-agent to a *multi-agent* version will be naturally implementable, since, from a computational point of view, rewriting logic is intrinsically concurrent [17]. It was in fact the search for a general concurrency model that would help unify the heterogenity of existing models, that provided the original impetus for the first investigations on rewriting logic [18].

Further, a more practically useful implementation will have to be *first-order*, rather than propositional. Although the implementation of a first-order version will be more involved, it can essentially be implemented in the same way as the current version, i.e., by mapping transition rules to rewrite rules. In [9], the transition rules for a first-order version of 3APL are presented. Configurations in this setting have an extra substitution component, which records the assignment of values to variables. An implementation of this version in Maude will involve extending the notion of a configuration with such a substitution component, as specified in the cited paper.

Finally, we aim to extend the *logical part* in various ways.

Regarding this propositional version, one could think of extending the belief base and goal base to arbitrary sets of propositional formulas, rather than just sets of atoms as we have used in the current implementation. Also, the belief and goal query languages could be extended to query arbitrary propositional formulas. The satisfaction relations for queries could then be implemented using, e.g., tableau methods as suggested in [17]. Further, when considering a first-order version of 3APL, the belief base can be implemented as a set of Horn clauses, or even as a Prolog program. Implementing the belief base as a Prolog program is possible in the current Java implementation of 3APL. How to define standard Prolog in rewriting logic has been described in [16]. Finally, we aim to experiment with the implementation of more sophisticated specifications of the goals and their accompanying satisfaction relations, as proposed in [23].

ABSTRACT

This paper presents a new multi-agent system platform that takes advantage of XMPP. Among the new message transport protocols that have been recently developed, Jabber (XMPP) is a protocol that is based on Instant Messaging networks that use real-time messaging between applications. This platform is fully FIPA compliant and provides a simple interface to create agents using this new communication concept.

1. INTRODUCTION

In this paper we introduce a new multiagent-system platform (called SPADE) that takes advantages of a new communication model and that provides a simple interface to create agents using this new communication concept. This communication model is based on Instant Messaging protocols that use real-time messaging between applications. Agent communication is improved by using this protocol due to its new features, such as the Contact List management for agents, the ability to receive a notification whenever any other known agent (included in its Contact List) comes online or the possibility of engaging a simultaneous multi-conference with many agents.

This new platform is fully FIPA compliant to allow interoperability with other platforms. Its main objective is to provide good performance while retaining strong scalability options and to provide an open design that allows the implementation of platform components in several high-level programming languages.

Our proposal provides a human-like framework to communicate agents. It allows them to have a conversation (with all the meta-information required in a real conversation included) with any other 'entity'. This platform is described in depth in the following section.

2. SPADE

SPADE (a Smart Python multi-Agent Development Environment) is a new platform aimed at solving the drawbacks of the communication models from other platforms. The multi-agent system platform SPADE is built around a new communication framework (Jabber[1]) which provides new and powerful capabilities to the communication layer. The platform core is designed over this layer, which communicates the platform elements with one another.

2.1 The Communication Model

Communications in SPADE are handled by means of the Jabber protocol. Jabber is the Internet standard protocol for instant messaging and presence communication[1, 2]. Its base technology is the Extensible Messaging and Presence Protocol (XMPP) standard, a set of streaming XML protocols and technologies that enable any two entities on the Internet to exchange messages, presence, and other structured information in close to real-time.

Presence notification is one of the most useful Jabber features that SPADE provides. It is a system by which an entity involved in a Jabber communication can know at any time what the current status of any of the other entities involved is. Jabber entities can declare what their current status is and all other entities who share a bond with them will automatically be notified. An entity status usually indicates its availability and readiness to engage in a communication (e.g. *'Available', 'Busy', 'Don't disturb', ...*), but it is not closed to a short predefined list. Entities can define their own status and their meanings. Two or more Jabber entities can be bonded (or *subscribed*) to each other. Entities that share a bond may make use of presence notification as described above.

Another interesting SPADE feature is **Multi-user Conference** (MUC). MUC features can be used to create forums for agents to connect to when performing a multi-agent activity. For instance, in a virtual auction scenario performed by agents, an agent playing the role of the auctioneer can create a password-protected channel and give the password only to previously certified agents. Then, in the channel, the auctioner can give the right to speak only to agents who are going to play the bidder role, leaving the rest of the agents in spectator mode. Once the auction starts, every time a bidder wants to place a bid, the agent only needs to *'speak'* in the channel, and all the other bidders and the auctioneer

will know the bid at the same time. MUC channels can also be used for broadcasting announcements, public platform information, selected distribution lists, etc.

2.2 The Platform Model

The SPADE platform is modeled according to the FIPA standard proposal for a multi-agent platform [3]. It features standard basic services (such as an Agent Management System and a Directory Facilitator) that are designed as Jabber server components (or add-ins). Although the core communication system relies on the Jabber technology, other message transport protocols, such as the *HTTP* protocol[4], are also supported.

A brief schema of the SPADE Platform can be viewed in Figure 1.

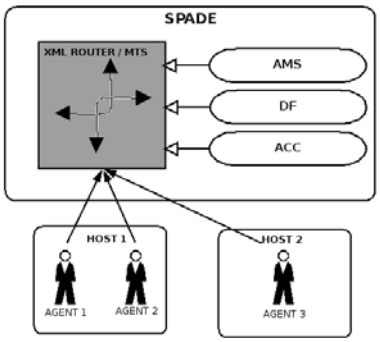

Figure 1: Platform Model

The main platform element is the **XML Router**, which the rest of the platform components and agents are connected to. It is a standard XMPP server[1] that routes all the messages from its sender to the specified receiver with no user intervention. This XML Router acts as the Message Transport System (MTS) and is the only 'third-party' component of the platform. One of this components connected to the router is the **SPADE Agent Communication Channel** (ACC), which manages all the communication within the platform. It receives the FIPA-ACL[1][5] messages that arrive to the platform and it redirects them to the correct destination element. This destination can be either an agent or another component.

2.2.1 Security Concerns

The SPADE framework provides some built-in security mechanisms that help to maintain the system's integrity. These mechanisms are developed in different security levels:

- Logging to the XML Router requires a **username and a password**. This mechanism prevents an unauthorized connection to the platform if it is not approved by the platform administrator.
- A connection to the XML Router can be encoded with a symmetric cryptographic algorithm using SSL (Secure Socket Layer). SSL provides data **cyphering**, server **authentication**, message **integrity** and, optionally, client authentication for TCP-IP connections.

[1]FIPA Agent Communication Language

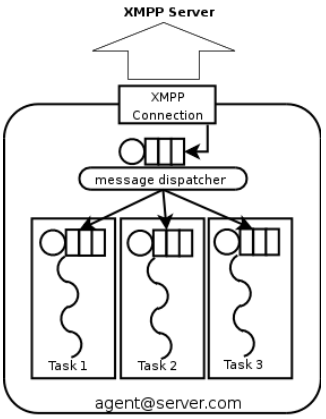

Figure 2: SPADE Agent Model

- To ensure the authentication of a message, the XML Router provides another mechanism to avoid identity theft. The platform prevents identity spoofing by overriding a '*from*' field that does not match the sender's.

2.2.2 Platform Inter-operability

The Message Transport System can manage as many MTPs as there are plugged to the platform. If the protocol is XMPP (Jabber protocol), the MTS delivers the message directly to the receiver agent. This feature allows SPADE to communicate with any kind of FIPA compliant platform that supports the XMPP Message Transport Protocol.

We have also developed a new JADE plug-in that provides a MTP implementing the XMPP protocol. This plug-in has been accepted by the JADE Team and is published in [6]. Thanks to this new MTP, a SPADE platform and a JADE platform can communicate with each other using the Jabber protocol. Actually, two JADE platforms can use this new XMPP plug-in to communicate their agents and take advantage of this new proposed Transport Protocol.

2.3 The Agent Model

Every component inside the platform is built as an agent. SPADE agents are elements that are connected to the MTS that can send messages to each other and to other platforms.

The Agent Model is basically composed of a connection mechanism to the platform, a message dispatcher, and a set of different tasks that the dispatcher gives the messages to (–see Figure 2). Every agent needs an identifier called Jabber ID (JID) and a valid password to establish a connection with the platform. If the platform registration process is disabled, then the platform administrator should define the registration policies. An agent can run serveral tasks simultaneously. A **task** is a process that an agent can execute using repeating patterns. SPADE provides some predefined task types: Cyclic, One-Shot, Periodic, Time-Out, and Finite State Machine Task. Those task types help to implement different the tasks that an agent can perform. Every agent can have as many tasks as desired. When a message arrives to the agent, the message dispatcher redirects it to the correct task queue (–see Figure 2).

2.4 The Main Features

The main features of SPADE are the following:

1. The SPADE platform has already covered the FIPA standard. AMS and DF ontology is supported.
2. SPADE supports two Message Transport Protocols: HTTP and XMPP. This feature allows different platforms to communicate using this new communication model or even older platforms that make use of the wide-spread HTTP protocol.
3. SPADE supports two different content languages: **FIPA-SL** and **RDF**, which are the two main options for content language used in today's agent communication.
4. Another feature defined by FIPA that SPADE supports is agent **mobility**. A SPADE agent can move from one platform to another authorized platform and continue it's execution in the new target.
5. As we stated in Section 2.3, SPADE agents do reach their goals by running one or more tasks.
6. SPADE has a special agent to provide a user-friendly view of the platform. This GUI provides a mechanism to load and unload agents in the platform. It allows the user to search for agents and services and send messages to any agent.
7. SPADE was developed in Python. This allows the execution of the platform in several architectures and operating systems such as Windows, Linux, MacOS, Windows Mobile, PalmOS, SymbianOS for mobile phones, etc. Python also allows using some performance characteristics lile *stackless* threads or the *psyco* module to massively speed up the execution.
8. One of the new and powerful feature of SPADE is the possibility to use **Presence Notification** between components. This allows the system to determine the current state of the components that are connected to the platform in real-time.
9. Managing a conversation with more than one agent is possible thanks to a Jabber mechanism. This mechanism (called **multi-user conference**) is based on chat rooms where an agent can join and share messages with a group of agents.
10. The Protocol used to send messages is a distributed client-server protocol. The servers that route the Jabber messages are designed to support a very large number of users and messages. This feature helps to improve the SPADE performance and scalability.
11. The platform provides a user and password authentication to improve security as well as a cyphered connection to the platform to perform confidentiality.

3. CONCLUSIONS AND FUTURE WORK

One of the main drawback on multi-agent platforms is the use of an inappropiate message transport protocol to communicate agents. To solve this, we have presented a new communication model using the Jabber Instant Messaging Protocol and we have developed a new agent platform using this technology. The new platform, called SPADE, is a fully FIPA compliant platform that supports all the required features. It has been developed in a modern language that increases the productivity of the programmer. The main characteristic of SPADE is the support of the new communication protocol between agents. This protocol, which is based on Instant Messaging systems, uses a distributed network to route messages from one agent to another. It also provides new mechanisms that improve the communicative acts, such as Presence Notification or Multi-User Conference. These characteristics, which are not present in any other agent platform, provide new communication capabilities between agents, which make agents more versatile. SPADE also has some security properties which provide confidentiality and authentication systems to the platform.

SPADE is released under the General Public License (GPL) and can be downloaded and tested at [7]. The plug-in for the JADE multi-agent platform that enables communication through XMPP is also available for download at [7] and [6].

ABSTRACT

This paper discusses three types of declarative goals and motivates their integration in logic-based agent-oriented programming languages. These goal types are perform goals, achieve goals, and maintain goals. A goal type is considered as a specific agent attitude towards goals. The semantics for each goal type is explained from an operational perspective. It is argued that the suggested semantics of the goal types ensure some desirable and expected properties.

1. INTRODUCTION

An essential characteristic of autonomous agents is their pro-active behaviour [9]. Such agents are assumed to have goals (or objectives) based on which they decide and perform actions. According to this view, an agent's goal denotes a state that the agent desires to realize by means of actions available to it. Different logics have been proposed to characterize goals, to represent and reason about them, and to specify their relations to other agent concepts such as beliefs and actions [2, 3, 6, 5]. These logics, which are mainly used to specify the behavior of autonomous agents, allow the specification of agents that have a certain attitude towards their goals. These attitudes, which are specified as logical axioms, are also known as agent types [3, 6, 4]. For example, an agent can be specified either to hold its goal until it has achieved it (blindly-committed agent type), or to drop the goal if it believes that it can *never* achieve it (single-minded agent type). It is important to note that the specification of many interesting agent types involves temporal aspects, such as in the case of the single-minded agent type, which involves the belief of an agent that it can *never* achieve some goal.

Motivated by these logics, many agent-oriented programming languages have been proposed to implement agents that can represent and reason about goals and are capable of generating plans for their goals [1]. One problem related to the implementation of agent types in agent programming languages is the implementation of the agent types that involve temporal aspects. Some agent types, such as the single-minded agent type, require that the agent is able to reason about its future execution steps to conclude that it believes the goals can *never* be achieved. Defining a programming construct that enables agents to perform such a reasoning task is, however, not an easy task, if not impossible. Moreover, the idea of implementing an agent with *one* specific attitude towards its goals is not attractive, especially when agents can have more than one goal. A more general agent-oriented programming language should therefore allow the implementation of agents that can have different attitudes towards different goals.

In order to implement goal-related agent types and to allow agents to have different attitudes towards different goals, existing programming languages have introduced the notion of goal types. For example, JACK [1] provides programming constructs to implement, among others, test, achieve, insist, and maintain goals, Jason [1] allows the implementation of achieve and test goals, and Jadex [1] provides programming constructs for achieve, query, perform and maintain goals. It is important to note that goal types with the same name captured by these agent-oriented programming languages may have a different meaning across these languages. Moreover, goals in Jadex are represented in XML using a label as the name of the goal, and a number of other parameters. In Jason and JACK, goals are created by generating a particular type of event. Such a notion of goal does not support

(logical) reasoning and therefore does not allow the derivation of subgoals. As we will explain, the derivation of goals is important in the context of agent-oriented programming. Finally, neither JACK nor Jadex provides the formal semantics of their goal types. This is in contrast with our proposal, as we aim at providing a formal semantics for the goal types. Below, we will explain our idea of these goal types and we will briefly address differences and similarities with comparable goal types from other agent-oriented programming languages. A detailed comparison between the goal types of the various languages is beyond the scope of this paper.

In this paper, we discuss three types of goals: perform goals, achieve goals, and maintain goals. In contrast to some other approaches, goals are here assumed to be represented as logical formulas with declarative semantics. This supports reasoning about goals which facilitates the generation of plans for subgoals. Moreover, we explain the *type* of a goal as an agent's attitude towards the goal. We do this with the aim of integrating them in logic-based agent-oriented programming languages. Therefore, the semantics of a goal type will be explained from an operational perspective. Note that the operational semantics perspective can directly be used to design a programming language that allows the implementation of the goal types. Unfortunately, the space limitation does not allow us to present the formal operational semantics of the goal types. Finally, we will discuss some properties of the goal types and show that they have certain desirable and expected properties.

The basic idea in this paper is that agents can have a set of goals based on which planning rules can be selected and applied to generate plans for the goals. In our framework, a planning rule indicates that a specific plan can achieve a certain goal. The application of a planning rule will add the plan of the planning rule to the plan base. Although it is possible to use a specific kind of planning rule for each goal type, we take a different approach and assume *one* kind of planning rule for every goal type. The advantage of such an approach is that it can reduce the number of rules which a programmer has to specify; a planning rule for a certain goal might be used in case this goal is an achieve goal or a maintain goal. As noted, the goals we consider in this paper are declarative goals, i.e., a goal can be represented as a logical formula denoting a desired state. An important advantage of declarative goals is that they allow reasoning, facilitating the generation of subgoals. This is especially advantageous in the context of the planning rules.

Consider, for example, "`FC and CC`" as the goal of an agent, where `FC` stands for having-fuel-in-car and `CC` for having-clean-car. We consider logical consequences of this goal as its subgoals, i.e., "`FC`" and "`CC`" are in this case the subgoals. The idea is, that for this complex goal "`FC and CC`", an agent programmer can implement either one single planning rule or two planning rules, i.e., one for each subgoal. The latter is however more generic, as the two rules can also be applied if the agent has, e.g., the goal `CC`, rather than the complex goal. The mechanism of deriving subgoals of a complex goal can be realized through logical inference mechanisms [7].

2. PERFORM GOALS

The idea of the perform goal is to allow the generation of a set of plans without demanding that the plans must reach the states denoted by the goals. The attitude of an agent toward a perform goal is thus to generate plans after which the goal will be dropped. For example, consider "`FC and CC`" as a perform goal of an agent that can generate the plan to refuel at the gas station `gs1` and the plan to clean the car in the car wash `cw1`. In this case, the agent will generate both plans after which it drops the goal entirely, regardless of the effect of those plans. However, if the agent does not have a planning rule to clean the car and can only generate the plan to refuel, then it will only generate the refuel plan after which the entire goal is dropped. This idea to drop a goal when plans are generated is practical, and similar ideas have been implemented in most agent-oriented programming languages, although sometimes under different names. For example, in JACK and Jason this type of goal is known as achieve goal.

As noted, in our approach the perform goals are represented as logical formulas. If the logical and declarative nature of the perform goals is not essential, then the question arises why we should not use *labels* instead of *logical formulas* to generate a set of plans. The reason to use logical formulas is to allow reasoning about the goals to decide which planning rule to apply. In our approach, the planning rules, which can be applied for all goal types, can be applied only if they are relevant, i.e., if the goal in their heads is logically entailed by an agent's goal. Using labels to represent perform goals requires different types of planning rules and a different procedure for rule application. Moreover, using logical formulas to represent a goal, in general, allows us to design planning rules for atomic or simple goals such that plans for more complex goals can be generated by means of plans for subgoals.

The perform goal can be enriched with a *redo* flag which may be true or false, as is also proposed in Jadex [1]. If the flag is false, then the perform goal will be removed after examining and applying all relevant planning rules. The removal of the perform goals is therefore independent of whether they are achieved or not. However, if the flag is true, then the perform goal remains in the goal base such that the applicable planning rules can be applied once again. This ensures that the plans associated with the perform goal will be generated and performed again. For example, consider a vacuum cleaner that has to clean a number of rooms repeatedly without the ability to check if a room is clean. The perform goal with a true flag can be used to model this type of behaviour. A consequence of this view is that an agent with a perform goal to which a false redo flag is assigned, can drop the goal if the relevant planning rules have tautologies as belief conditions. This is because in our framework a planning rule has a belief condition. A planning rule can only be applied if its belief condition holds.

3. ACHIEVE GOALS

The idea of an achieve goal is to reach the state denoted by it. The emphasis here is that the goal will not be dropped until the state denoted by it is achieved. This is in contrast with perform goals, which can be dropped once the plans generated for it have been executed, regardless of whether the perform goal was achieved. As for perform goals, an agent with an achieve goal will apply relevant planning rules to generate and execute plans. If the achieve goal is not reached after the execution of these plans however, it applies the planning rules again, hopefully generating different

plans, since the circumstances might have changed. Once the achieve goal is reached, it will stop generating and executing plans for this goal. For example, consider an agent with the achieve goal `FC` and two planning rules to generate either the plan to refuel at the gas station `gs1` or the plan to refuel at the gas station `gs2`. This agent will apply one rule and execute the plan to refuel at `gs1`. If the agent succeeds to refuel, the achieve goal will be dropped. Otherwise, it will apply the second rule to generate the plan to refuel at `gs2`. If both plans do not achieve the goal, then it will apply the rules again.

As suggested in [8] and implemented in Jadex, we assign a failure condition to each achieve goal to indicate when the agent should stop trying to achieve the goal and thus drop the goal. For example, `no-fuel-at-gs1-and-gs2` can be the failure condition of the achieve goal `FC`. A similar kind of goal type is introduced in Jadex and in JACK, though in JACK under the name *insist* goal. An achieve goal can thus be dropped under two circumstances: either if its failure condition becomes true, or if the state denoted by it is reached. In both cases, besides the removal of the achieve goal, the plans associated with it will be removed. A planning rule can be applied if the goal in the head of the rule is not achieved yet, if there is no plan for the same subgoal in the plan base, and if the failure condition does not hold.

Following this view, a goal with an achieve type and an impossible failure condition will not be removed from the goal base unless the state denoted by the goal is reached. Moreover, a goal with an achieve type such that the state denoted by the goal cannot be reached and its failure condition never becomes true can be replaced by the same goal with the perform type and a true redo flag. In both cases, relevant planning rules will be applied repeatedly.

4. MAINTAIN GOALS

The idea of a maintain goal is to ensure that a state holds and continues to hold. Plans should be generated and executed if the state denoted by the maintain goal is *threatened* not to hold, rather than waiting and taking action once the state does not hold. The condition under which the maintain goal is threatened not to hold will be called the maintain condition. The agent starts to generate and execute plans when the maintain condition becomes true. This triggering condition can be considered as an alarm to act in order to ensure the maintenance of the state denoted by the maintain goal. It should be noted that there might be no logical relation between the maintain goals and their triggering conditions. This relation depends usually on the application domain. However, we assume that in all agent configurations, if the triggering condition does not hold, then the maintain goal holds. Note that a maintain goal cannot be removed from the goal base.

For example, consider an agent with `FC` as a maintain goal. This means that the agent wants to maintain having a fueled car. In such a case, the maintain condition is the illuminated lamp warning of a shortage of fuel. The agent should in this case generate and execute a refuel plan. If the maintain condition continues to hold after the execution of the plan, because for example the tank station had no fuel, the agent may try to generate and execute another plan, e.g., to go to another tank station to refuel. If all plans are generated and the maintain condition still holds, then there are two options. The agent can either stop generating and executing plans since it has tried all plans, or it can continue to apply the planning rules once again, hopefully generating new plans this time. In order to allow both options, we add a *retry* flag, like in Jadex [1], to the maintain goals. If the flag is true, the agent will try to re-apply planning rules, otherwise it does not. Note that if the maintain condition holds, the state denoted by the maintain goal can either hold or not. A similar idea of maintain goals is implemented in Jadex and JACK, although in JACK the idea is that the maintain condition should hold during the execution of its related task. As a consequence, a goal with the maintain type for which the maintain condition is a tautology and the retry flag is set to false can be replaced by the same goal with the perform type having a false flag. In both cases, the relevant planning rules will be applied once.

5. CONCLUSION

In this paper, we have discussed three types of declarative goals for which we argued that they should be integrated in logic-based agent-oriented programming languages. We have already designed a simple agent-oriented programming language that allows the implementation of these goal types. This language uses a propositional language to represent the agent's goals and beliefs. The formal semantics of the programming language, and thus of the goal types, are defined and it is shown that this semantics has the properties as we have discussed in this paper. Unfortunately, because of the space limitation we could not present the details in this paper.

We plan to extend the logic-based agent-oriented programming language using a (computational) subset of the first-order predicate language instead of using a propositional language. In this way, declarative goals become more expressive. We also have a plan to start implementing an interpreter for an extended version of the programming language which we hope to be available soon.

ABSTRACT

The AgentSpeak agent-oriented programming language has recently been extended with a number of new features, such as speech-act based communication, internal belief additions, and support for ontological reasoning, which imply a need for belief revision within an AgentSpeak agent. In this paper, we show how a polynomial-time belief-revision algorithm can be incorporated into the ***Jason*** AgentSpeak interpreter. To the best of our knowledge, this is the first attempt to include belief revision within an interpreter for a practical agent programming language.

1. INTRODUCTION

Agents can be viewed as rational entities characterised in terms of their beliefs, desires and intentions and the relationships between them, and the *Belief*, *Desire* and *Intention* (BDI) approach has emerged as perhaps the dominant paradigm in agent research and development [9, 11, 6]. A key problem for BDI agents is the dynamics of beliefs (and consequently of desires and intentions). Agents are continuously presented with a stream of new information (e.g., from their sensors or other agents) requiring changes in their beliefs. In simple cases, the problem of how the agent's beliefs should be updated is straightforward: for example, if an agent's battery sensor reports that the agent's battery is 50% charged, then the agent's existing beliefs about its battery level (and any derived beliefs regarding how far it can travel before recharging) can be simply overwritten with the appropriate new belief(s). However for agents with multiple sources of information and/or more complex belief states a simple 'overwriting' strategy is inadequate. *Belief revision* is necessary when the agent receives conflicting information from different sources, or information which is contradictory in the context of the agent's own beliefs. For example, an agent may be told by Alice that the next group meeting will be held on Wednesday and by Bob that the meeting is on Thursday. If the agent's ontology contains a rule stating that each meeting has a unique date, then, from the agent's point of view, this information is contradictory. In such cases the problem of how the agent's beliefs should be revised to restore consistency is non-trivial.

Current agent-oriented programming languages typically leave belief update up to the programmer [3] and provide no support for belief revision. However as agent's belief states and the inferences performed on them become richer and more complex, such ad-hoc approaches push an ever-greater burden onto the agent programmer. In this paper, we show how to integrate correct and efficient (polynomial-time) belief revision into the architecture of a BDI agent. We focus on the well-known AgentSpeak agent-oriented programming language. However our approach and algorithms are equally applicable to other BDI agent implementations where agent's beliefs can be represented in the form of ground literals and Horn clauses (e.g., rules, or plans in case of AgentSpeak). While there has been some initial work on belief revision in abstract programming languages [10], to the best of our knowledge, the work presented here is the first attempt to include belief-revision within an interpreter for a *practical* agent-oriented programming language.

2. AgentSpeak AND *Jason*

The AgentSpeak(L) programming language was introduced in [8]. It is based on logic programming and provides an elegant abstract framework for programming BDI agents.

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. An AgentSpeak agent is defined by a set of *beliefs* (ground literals) which constitute the agent's *belief base*, and a set of plans which form its *plan library*. An AgentSpeak plan has a *head* which consists of a triggering event (the event(s) for which that plan is *relevant*), and a conjunction of belief literals representing a *context*. The conjunction of literals in the context must be a logical consequence of the agent's current beliefs for the plan to be considered *applicable* when triggered. A plan also has a *body*, which is a sequence of basic actions (i.e., atomic operations the agent can perform so as to change the environment), (sub)goals that the agent has to achieve (or test) when the plan is executed, and belief changes that can serve as "mental notes". Plans are triggered by the addition or deletion of beliefs due to communication or perception of the environment, or due to the addition or deletion of goals as a result the execution of plans triggered by previous events.

The ***Jason*** interpreter implements the operational semantics of AgentSpeak as given in, e.g., [5]. ***Jason*** in written in Java, and its IDE supports the development and execution of distributed multi-agent systems [4].Recent work has made important additions to AgentSpeak, which have also been (or are in the process of being) implemented in ***Jason***. Some of these new features, such as speech-act based communication, internal belief additions, and support for reasoning with ontological knowledge, presuppose a *belief revision* capability as part of agents' reasoning cycle. For example, in [7], an extension of AgentSpeak was proposed which incorporates ontological reasoning within the AgentSpeak interpreter. In the extended language, called AgentSpeak-DL, queries to the belief base are more expressive as their results do not depend only on the agent's explicit knowledge but also on what can be inferred from the ontology; the search for a relevant plan for a particular event is more flexible as this is not based solely on unification, but also on the subsumption relation between concepts; and agents may share knowledge by using web ontology languages such as OWL. These new capabilities can result in inconsistencies in an agent's belief base which cannot be eliminated by a simple 'overwriting' strategy.

The current implementation of ***Jason*** provides a basic belief update capability. This deletes any perceptual beliefs which are no longer perceived from the belief base and adds any new percepts as new perceptual beliefs. Belief additions executed within a plan as well as any information communicated by trusted sources is simply added to the belief base (without checking for consistency). While this approach ensures that the agent's perceptual beliefs remain consistent, it is incapable of handling derived inconsistencies, e.g., if a property is asserted of an individual which is inconsistent with the corresponding concept description. The elimination of such inconsistencies remains the responsibility of the agent developer and must be coded anew for each agent application. Our aim is to extend the ***Jason*** implementation with a belief revision capability which automatically restores belief base consistency in the face of derived inconsistencies.

3. THE BELIEF REVISION ALGORITHM

We have two main objectives when introducing belief revision in AgentSpeak. First the algorithm should be theoretically well motivated, in the sense of producing revisions which conform to a generally accepted set of postulates characterising rational belief revision. Second, we want the resulting language to be practical, which means that the belief revision algorithm must be efficient.

In the belief revision literature, these two goals have traditionally been seen as incompatible. Our approach draws on recent work [2] on efficient (polynomial-time) belief revision algorithms for rule-based agents which satisfy the well-known Alchourrón, Makinson and Gärdenfors (AGM) postulates [1] characterising rational belief revision and contraction. In this section we briefly describe the linear-time belief contraction algorithm introduced in [2]. We then explain how belief revision can be defined in terms of contraction.

We distinguish two kinds of contraction operation. AGM (or coherence) contraction of the agent's belief base K by a belief literal A is defined as the removal of A and sufficient literals from K such that A is no longer derivable using the set of plan instances executed to date. Reason-maintenance contraction additionally removes any beliefs for which A is (recursively) the sole support. To facilitate both AGM and reason-maintenance contraction, the inferential relationships between the beliefs comprising the agent's belief base are represented as a directed graph, where the nodes are beliefs and *justifications*. A justification consists of a belief and a *support list* containing the context (and possibly the triggering event) of the plan used to derive this belief: for example, the assertion of a belief A by a plan with context B triggered by a belief addition event C (or derived by an ontology rule $B, C \rightarrow A$) would have a justification $(A, [B, C])$. Foundational beliefs which were not derived, have a justification of the form $(D, [])$. In the graph, each justification has one outgoing edge to the belief it is a justification for, and an incoming edge from each belief in its support list. We assume that each support list s has a designated *least preferred* member $w(s)$. Intuitively, this is a belief which is not preferred to any other belief in the support list, and which we would be prepared to discard first, if we have to give up one of the beliefs in the list. We assume that we have constant time access to $w(s)$.

The algorithm for AGM contraction by A is then:

```
for each of A's outgoing edges
   to a justification (C, s),
   remove (C,s) from the graph
for each of A's incoming edges
   from a justification (A, s),
   if s is empty, remove (A, s);
   else contract by w(s);
remove A.
```

To implement reason-maintenance type contraction, we also remove beliefs which have no incoming edges.

In [2], it was shown that the contraction operator defined by the algorithm satisfies the AGM postulates for contraction (K-1)–(K-4) and (K-6) [1] (the recovery postulate, (K-5), is not satisfied). Closure under consequence in classical logic is replaced with closure in a weaker logic W which has a single inference rule of generalised modus ponens.

The algorithm runs in time $O(kr + n)$, where r is the number of plans, k the maximal number of beliefs in any support list, and n the number of literals in the belief base. Indeed, the upper bound on the number of steps required to remove justifications corresponding to plan instances is $r(k + 1)$ (one constant time operation for each belief in a context of the plan and one for the belief asserted by the plan). Removing all justifications corresponding to foundational beliefs costs n steps. The last step in the contraction algorithm (removing a belief) is executed at most n times.

The AGM (resp. reason-maintenance) revision of the set of literals in the agent's belief base K can then be defined as: add A, close under consequence and AGM (resp. reason-maintenance) contract by all contradictions. Note that for agents which reason using ground literals and Horn clauses, closure under consequence can be computed in polynomial time.

4. BELIEF REVISION IN *Jason*

Future releases of ***Jason*** will incorporate an implementation of the belief revision algorithm presented above as a user-selectable

option. The new implementation clearly distinguishes between *belief update*, i.e., the addition and deletion of perceptual beliefs following perception, and *belief revision* proper, i.e., the elimination of inconsistencies following belief additions by plans or ontological reasoning. A belief addition may be discarded (as at present) or may result in the deletion of some other belief(s) in order to allow the new belief to be consistently added to the belief base. Which beliefs are deleted is determined by a user-specified preference order (see below). Here, we assume that the agent's plans contain no explicit belief deletions, and that deletion of beliefs only occurs as a result of belief update and revision.

Each belief literal added to the belief base has an associated "dependencies list" (the literals that allowed the derivation of the literal in question), and a "justifies list" (the literals which the literal in question justifies, that is, it appears in their dependencies list). For example, if the plan that generated the belief change, say $+bl$, has the form "`@p` te: l_1 `&` ... `&` l_n `<-` bd", where te is a triggering event and bd a plan body, the support list of the corresponding justification is simply the ground literals from the plan context, "[l_1,...,l_n]". Note that if the triggering event, te, is itself a belief addition, the literal in te is included together with the context literals in the support list. Further, for each literal $l_1, \ldots, l_n$ we include the newly added belief in the literal's "justifies" list. We also record the time at which the belief was added as part of the justification. When deleting perceptual beliefs during belief update, we remove any justification which has the deleted perceptual belief in its support list, and mark the justified beliefs as self supporting (foundational) beliefs. This additional bookkeeping reflects the special status of perceptual beliefs: perceptual beliefs can trigger or justify the addition of other beliefs, but their deletion is not in itself a reason for removing a derived belief.

The belief revision algorithm also requires the definition of a partial order expressing the preference, or entrenchment, of each belief. To allow for user customisation, this is defined as a separate method that can also be overridden. The default method gives preference to perceived information over communicated information (as also happens in [10]), and in case of information from the same source, it gives preference to newer information over older information.

The implementation described above is conservative in revising only the agent's belief state. The agent's plans are considered part of the agent's program and are not revised (though revising, e.g., plans received from other agents would be an interesting extension). Similarly, when revising beliefs derived using ontological rules, we assume the ontology used by the agent to be immutable and consistent, and that it is consistent with every other ontology it references.

5. CONCLUSIONS AND FUTURE WORK

Experience has shown that correct and efficient implementations of agent-oriented programming languages are key in the widespread adoption of agent technology. As agent programming languages become richer, it becomes harder for the agent programmer to ensure that the belief states of agents developed using these languages are consistent. In this paper we briefly summarised the rationale for including automatic belief revision in a BDI agent programming language, and described the integration of an efficient (polynomial-time) belief-revision algorithm into the ***Jason*** AgentSpeak interpreter. Our approach is theoretically well motivated in the sense of producing revisions which conform to a generally accepted set of postulates characterising rational belief revision. We believe that other BDI agent-oriented programming languages and their platforms [3] which leave the problem of maintaining a consistent belief state entirely to agent programmer, can also benefit from our approach.

In future work, we plan to further investigate the implications of integrating belief revision into the AgentSpeak execution cycle (e.g., allowing belief deletions in plans, ontological reasoning). On the more practical side, we plan to develop large-scale agent applications to assess the performance of ***Jason*** with belief revision.

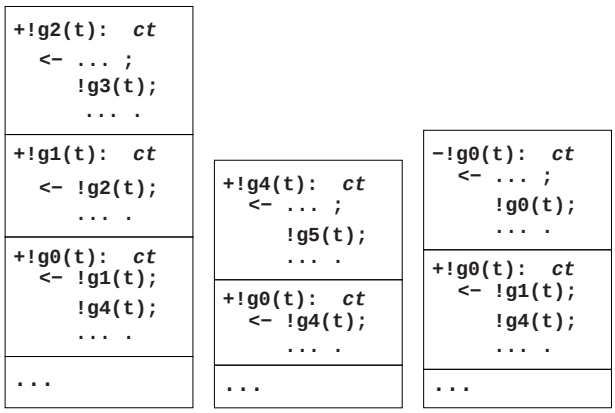
1. INTRODUCTION



In this paper, we consider the use of *declarative goals* in the AgentSpeak programming language, originally introduced in [6]. By a declarative goal, we mean a goal that *explicitly* represents a state of affairs to be achieved, in the sense that, if an agent has a goal $p(t_1, \ldots, t_n)$ then it expects to eventually believe $p(t_1, \ldots, t_n)$, and only then can the goal be considered achieved. Currently, although goals form a central component of AgentSpeak programming, they are only *implicit* in the plans defined by the agent programmer. For example, there is no explicit way of expressing that a goal should be maintained until a certain condition holds; such temporal goal structures are hidden within the plan structures themselves. While one possibility would be to extend the language to introduce an explicit construct for declarative goals and a goal base, we show that this is unnecessary. We introduce a number of *plan patterns*, corresponding to common types of explicit temporal/conditional (declarative) goal structures, and show how these can be mapped into AgentSpeak code. Thus, a programmer or designer can conceive of a goal at the declarative level, and this goal will be "translated" via these patterns into standard AgentSpeak code.

2. PLAN FAILURE

In order to present plan patterns for declarative goals, the *plan failure* handling mechanism implemented in ***Jason*** [2], and some specific *internal actions* used for dropping goals need to be presented.

We identify three cases of plan failure. The first cause of failure is a *lack of relevant or applicable plans*, which can be understood as the agent "not knowing how to do something". The second is where a test goal fails; that is, where the agent "expected" to believe something about the world, but that did not hold as expected. The third is when an action within a plan fails. Regardless of the reason for a plan failing, the interpreter generates a goal deletion event (represented by `-!`g) if the achievement of the goal g has failed. This event may be handled by a plan written to deal with such failure; e.g., the plan "`-!`g `: true <- !`g`.`" will attempt the achieve goal g again when a plan to achieve g has failed.

(a) Initial Intention (b) After .dropGoal(g1(t),true) (c) After .dropGoal(g1(t),false)

Figure 1: Internal Actions for Dropping Goals

In the next section, we also make use of the following predefined internal actions. The first, `.dropGoal(`g`,true)`, terminates g successfully, as if g were somehow achieved, while `.dropGoal(`g`,false)` terminates g with failure, meaning that g was impossible to achieve (in this case, a failure event for the plan that generated goal g is generated). It is perhaps easier to understand how these actions work with reference to Figure 1. The figure shows the consequence of each of these internal actions being executed (the plan where the internal action appeared is not shown; it is likely to be within another intention). Note that the state of the intention affected by the execution of one of these internal actions, as shown in the figure, is not the immediate resulting state (at the end of the reasoning cycle where the internal action was executed) but the most significant next state of the changed intention.

3. DECLARATIVE GOAL PATTERNS

Although goals form a central component of the AgentSpeak conceptual framework, the language itself does not provide any explicit constructs for handling goals with complex temporal structures. For example, a system designer and programmer will often think in terms of goals such as "maintain P until Q becomes true", or "prevent P from becoming true". Creating AgentSpeak code to realise such complex goals has, to date, been largely an ad hoc process, dependent upon the experience of the programmer. Below, we define a number of *plan patterns* for declarative goals — that is, complex combinations of plan structures which frequently occur in

actual scenarios — and to show how these can be realised in terms of AgentSpeak code. As we shall see, such patterns can be used to implement, in a systematic way, certain types of declarative goals and the types of commitments they represent, as discussed e.g. by Cohen and Levesque [4].

As an initial motivational example for declarative goals, consider a robot agent with the goal of being at some location (represented by the predicate `l(`X`,`Y`)`) and the following plan to achieve this goal, provided the battery charge is greater than 20% (the predicate `bc/1` stands for "battery charge", and `go` identifies an action that the robot is able to perform in the environment):

```
+!l(X,Y) : bc(B) & B > 0.2 <- go(X,Y).
```

Sometimes, using an AgentSpeak plan as a procedure can be a quite useful programming tool. Thus, in a way, it is important that the AgentSpeak interpreter does not enforce any declarative semantics to its only (syntactically defined) goal construct. However, in the plan above, `l(`X`,`Y`)` is clearly meant as a *declarative goal*; that is, the programmer expects the robot to believe `l(`X`,`Y`)` (by perceiving the environment), if the plan executes to completion. If this does not happen because, e.g., the environment is dynamic or non-deterministic, the goal cannot be considered achieved.

This is where our plan patterns for declarative goals help to express this type of situation without adding new syntactic/semantic constructs to AgentSpeak. We can easily transform the above procedural goal into a declarative goal by adding a corresponding *test goal* at the end of the plan's body, as follows:

```
+!l(X,Y) : bc(B) & B > 0.2
   <- go(X,Y);
      ?l(X,Y).
```

This plan only succeeds if the goal is actually achieved; if the given (procedural) plan executes to completion (without failing) but the goal happens not to be achieved, the test goal at the end will fail.

This solution forms a *plan pattern*, and other patterns can be applied to solve other similar problems. Our approach to the inclusion of declarative goals in the AgentSpeak programming language is inspired by the successful adoption of design patterns in object-oriented design. To represent such patterns for AgentSpeak, we will define skeleton programs with meta variables. For example, the pattern for a simple declarative goal, as the one used in the robot's location goal, is defined by the following AgentSpeak plan:

```
+!g : c <- p; ?g.
```

Here, g is a meta variable that represents the declarative goal, c is a meta variable that represents the context expression stating in which circumstances the plan is applicable, and p represents the procedural part of the plan body (i.e., a course of actions to achieve g). Note that, with the introduction of the final test goal, this plan to achieve g finishes successfully only if the agent believes g after the execution of plan body p.

To simplify the use of the patterns, we introduce *pattern rules*, which rewrite a set of AgentSpeak plans into a new AgentSpeak program according to a given pattern. The following pattern rule, called **DG** (Declarative Goal), shows how procedural goals are transformed into declarative goals. The pattern rule name is followed by the parameters which need to be provided by the programmer, besides the actual code (i.e., sequence of plans) on which the pattern will be applied.

```
+!g : c1 <- p1.
+!g : c2 <- p2.
...
+!g : cn <- pn.
```
DG$_g$ $(n \geq 1)$

```
+!g : g <- true.
+!g : c1 <- p1; ?g.
+!g : c2 <- p2; ?g.
...
+!g : cn <- pn; ?g.
+g : true <- .dropGoal(g, true).
```

Essentially, this rule adds `?`g to the end of every plan in the plan library that has `+!`g as triggering event, and creates two extra plans. The first additional plan checks whether goal g has already been achieved — in such case, there is nothing else to do. The second additional plan is triggered when the agent perceives that g has been achieved while it is executing any of the courses of action p_i $(1 \leq i \leq n)$ which aim at achieving g; if that occurs, the plan being executed in order to achieve g can be immediately terminated (with success). The internal action `.dropGoal(`g`, true)` can be used for this.

In this pattern, when one of the plans to achieve g fails, the agent gives up achieving the goal altogether. However, it could be the case that for such a goal, the agent should try another plan to achieve it, similarly to the "backtracking" plan selection mechanism available in platforms such as JACK [9] and 3APL [5]. The *Backtracking Declarative Goal* rule (**BDG**), defines this pattern based on a set of AgentSpeak plans $\mathcal{P}$ transformed by the **DG** pattern (each plan in $\mathcal{P}$ is of the form `+!`g `:` c `<-` p):

$\mathcal{P}$

BDG$_g$

DG$_g(\mathcal{P})$

```
-!g : true <- !g.
```

The last plan of the pattern catches a failure event, caused when a plan from $\mathcal{P}$ fails, and then tries to achieve that same goal g again. Notice that it is possible that the same (failed) plan is selected again, causing a loop if the plan contexts have not been carefully programmed (and the environment does not change).

In the pattern above, despite the various alternative plans, the agent can still end up dropping the intention with the goal g unachieved if none of those plans happen to be applicable. Conversely, with a *blind commitment goal*, the agent can drop the goal only when it is achieved:

$\mathcal{P}$

BCG$_g$

BDG$(\mathcal{P})$

```
+!g : true <- !g.
```

The **BCG** pattern is based on the **BDG** pattern and extends it by adding a plan that ensures that the agent will still pursue goal g even when all known plans to achieve g are not applicable.

For most applications, **BCG**-style fanatical commitment is too strong. For example, if a robot has the goal to be at some location, it is reasonable that it can drop this goal in case its battery charge is getting very low; in other words, the agent has realised that it has become impossible to achieve the goal, so it is useless to keep trying. This is very similar to the idea of a persistent goal in the work of Cohen and Levesque: a persistent goal is a goal that is maintained as long as it is believed not achieved, but still believed possible [4]. The drop condition f (e.g., "low battery charge") is

used in the Single-Minded Commitment (**SMC**) pattern to allow the agent to drop a goal if it becomes impossible:

$$\frac{\mathcal{P}}{\mathbf{BCG}_{g,BDG}(\mathcal{P})}\ \mathbf{SMC}_{g,f}$$

```
+f : true <- .dropGoal(g, false).
```

This pattern extends the **BCG** pattern by adding the drop condition represented by the literal f in the last plan. If the agent comes to believe f, it can drop goal g, signalling failure. This effectively means that the plan which generated goal g must itself fail (as g is now impossible to achieve). However, there might be an alternative for that plan which does not depend on g, so failure handling for that plan may take care of such situation.

As we have a failure drop condition for a goal, we can also have a success drop condition, e.g., because the motivation to achieve the goal has ceased to exist. Suppose a robot has the goal of going to the fridge because its owner has asked it to fetch a beer; if the robot realises that its owner does not want a beer anymore, it should drop the goal [4]. The belief "my owner wants a beer" is the *motivation* m for the goal.

Of course we can combine the drop condition and motivation to create a goal which can be dropped if it has been achieved, has become impossible to achieve, or the motivation to achieve the goal no longer exists. This *Open-Minded Commitment* (**OMC**) pattern is defined as follows:

$$\frac{\mathcal{P}}{\mathbf{BCG}_{g,BDG}(\mathcal{P})}\ \mathbf{OMC}_{g,f,m}$$

```
+f : true <- .dropGoal(g, false).
-m : true <- .dropGoal(g, true).
```

For example, a drop condition could be "no beer at location (X,Y)" (denoted below by `~b(X,Y)`), and the motivational condition could be "my owner wants a beer" (denoted below by `wb`). Consider the initial plan below, which is intended to achieve goal `l(X,Y)`:

```
+!l(X,Y) : bc(B) & B > 0.2 <- go(X,Y).
```

When the pattern $\mathbf{OMC}_{l(X,Y),\sim b(X,Y),wb}$ is applied to the plan above, we get the following program:

```
+!l(X,Y) : l(X,Y) <- true.
+!l(X,Y): bc(B) & B > 0.2
   ← go(X,Y); ?l(X,Y).
+!l(X,Y) : true <- !l(X,Y).
-!l(X,Y) : true <- !l(X,Y).
+~b(X,Y) : true <- .dropGoal(l(X,Y), false).
-wb : true <- .dropGoal(l(X,Y), true).
```

The approach of defining goals with complex temporal structures by means of patterns can also be used to specify more complex declarative goals, such as, for example, maintenance goals (the agent needs to ensure that the state of the world will always be such that g holds) and sequenced goals (i.e., when various instances of a goal should not be adopted concurrently).

4. CONCLUSIONS

In this paper we have showed that sophisticated types of goal structures can be implemented in the AgentSpeak language, with only the extensions (and extensibility mechanisms) available in ***Jason***. This is done by combining certain types of AgentSpeak plans, forming certain patterns for each type of goal and commitment towards goals that agents might have. Our approach is to take advantage of the simplicity of the AgentSpeak language, using only its well-known support for procedural goals plus the idea of patterns to support the use of declarative goals in AgentSpeak programming.

Despite the use of pre-defined internal actions such as `.dropGoal` (which had already been conceived for use with procedural goals in ***Jason***), our approach requires neither syntactical nor semantical changes in the language (as done, for example, in [10, 3]), nor the usual addition of a goal base (see e.g. [7]). Van Riemsdijk *et al.* [8] also pointed out that it is possible to build declarative goals using the procedural goals available in 3APL. Their idea correspond to our **BDG** pattern. In this paper, we have defined various other types of declarative goals and represented them as *patterns* of AgentSpeak plans. Another advantage of our approach is that, as complex types of goals are mapped down to plain AgentSpeak code using patterns, programmers can change the patterns to suit their needs, or indeed create new patterns easily.

ABSTRACT

In this paper we present Mob, a service-oriented scripting language for programming mobile agents in distributed systems. The main feature of the language is the integration of the service-oriented and the mobile agent paradigms. Mob is encoded onto a process calculus with a well studied semantics which provides us with a tool to prove the soundness of the language relative to the underlying calculus.

Keywords

Mobile Agents, Service-Oriented, Programming Language

1. INTRODUCTION AND MOTIVATION

Service-Oriented programming departs from the object-oriented paradigm by de-coupling data and processing. Services are provided in a transparent way for clients, requiring only knowledge of the contract (the service's interface). One of the main advantages of service-oriented programming is that it provides a framework on which to develop component-based systems. These have recently received a lot of attention for distributed systems, namely with the .NET [14], Jini [19] and Openwings [9] platforms.

Another major technology for Web applications is that of *mobile agents*. Mobile agents are computations that have the ability to travel through a network, by halting their execution, saving their state and then restoring it in a new host. In this paradigm, mobile agents move towards the resources (e.g., data, servers) and interact locally, unlike the usual communication paradigms (e.g., client-server), that require costly remote sessions to be maintained.

Programming languages for mobile agents come in two flavors: those *designed by hand* and those based on formal systems. In the first set we have systems such as Aglets [7], Mole [16] and Voyager [4] that mostly extend Java classes to define an agent's behavior, and scripting languages such as D'Agents [5] or Ara [13]. Providing a demonstrably sound semantics for these systems is rather difficult given the gap between the implementation and an adequate formal model.

Copyright 2006 ACM 1-59593-303-4/06/0005 ...$5.00.

Languages in the second set are based on formal systems, mostly some form or extension of the π-calculus [6, 8]. This allows researchers to build solid specifications for these programming languages and prove the languages correct *by design* by providing adequate encodings onto a base calculus. Examples of such languages have been implemented in recent years, namely, JoCaml [3], TyCO [18], X-Klaim [2], Nomadic Pict [20], Acute [10] and Alice [15].

In [12] we first introduced Mob, a programming language for developing applications based on mobile agents. Here we extend Mob with another main abstraction, *services*, thus uniting two major abstractions for Web applications. The main novelties introduced in this paper, in particular relative to [12], are as follows: a) services, described as interfaces implemented by agents, and (mobile) agents are the main abstractions of the language. Agents provide and require services and are bound to these dynamically as they move through the network; b) the Mob language has been encoded in TyCO a form of the π-calculus extended with distribution and mobility of resources and with a well-studied semantics [1,18]. This provides a tool to prove the soundness of the operational semantics of the language, thus providing a form of language security not readily available in the other languages discussed; c) the encoding onto the process calculus provided a full specification of the front-end of the compiler for Mob and allowed us to use the TyCO run-time system to run compiled Mob programs.

2. THE LANGUAGE

One of the main abstractions of Mob is the **agent**. Agents may be viewed as special objects, with a run-time associated, that provide/require services to/from the network (other agents). Agents are handled in Mob programs much like objects are handled in object-oriented languages.

The **service** is another main abstraction. An agent **implements** services and, simultaneously, **requires** services provided by other agents. There is absolutely no distinction between clients and servers. To access a service, a programmer must get a binding for an agent that provides it. The binding is obtained dynamically through the primitive **bind** that asks a network name service for an agent that provides the service. When the binding is received, interaction through method invocation can happen.

Agents may move through the network and this is controlled explicitly, at high-level, by the programmer using a primitive **go**. The movement of an agent involves moving an entire virtual machine and its state to the target host in the network. The execution resumes on arrival at the target

\end{array}
$$

Figure 1: Syntax of the Mob programming language.

host, without intervention from other agents.

Agents are multi-threaded. Thread creation and synchronization is supported through the **fork** and **join** primitives. Another form of synchronization, on data-structures, is provided by the instructions **lock** and **unlock** that support a simple form of mutual exclusion in data access.

Interaction with external services is supported with **exec** which is used to implement extensions to the core Mob language to support external functionality. These external services may be implemented in other languages, such as Java, or access network services, such as WWW queries.

The remainder of the language constructs provide fairly standard support for control flow, expressions and external calls. Due to space constraints we will briefly describe the syntax and semantics of the language. The full definition of the language and its operational semantics may be found in [11]. The syntax for a Mob program is presented in figure 1. The language defines a set reserved words identified in bold-face. The main syntactic categories are: constants (booleans, integers and strings) ranged over by c; variables, ranged over by x; agent and class identifiers, ranged over by X; service identifiers, ranged over by S; method names and method collections, ranged over by m and M, respectively; expressions, ranged over by e; commands, ranged over by C; arrays and maps, ranged over by $\{\tilde{e} : \tilde{e}\}$ and $[\tilde{e}]$, respectively, and; instructions, ranged over by P. A sequence of elements of a given grammatical category α is denoted by $\tilde{\alpha}$. The concrete syntax of Mob imposes some syntactic restrictions to the above.

We exemplify the syntax with a small example of a server and a mobile client for a simplified Time service. The server provides the service Time with a single method getTime(). Note that the **main** method may be empty since Mob agents run as daemons and some external action is required to terminate their execution.

```
service Time { getTime }
agent TimeServer() implements Time {
   main () { }
   getTime() { return exec ("getTimeApplication");}
}
new TimeServer();
```

The client requires this service and when run, it takes a sequence of hosts, and performs a cycle in which it moves to each of them, setting their time accordingly with the central time from the TimeServer.

```
agent TimeClient(hostList) requires Time {
   main () {
      timeServer = bind (Time);
      for (h in hostList) {
         go (h);
         exec ("setTimeApplication", "" ^ timeServer.getTime());
      }
}
new TimeClient([host1,...,hostn]);
```

The semantics for the Mob core language is provided in the form of an abstract machine that describes state transitions between network configurations. Each network configuration is composed of a set of agents running concurrently plus a name service for binding services to agents. Each agent has its own heap, code, a set of threads running concurrently and a set of threads suspended on resources. Besides their own local environment, threads share the agent's heap and use it to synchronize their access to resources.

For a complete formal specification of the semantics of the language we refer the reader to [11].

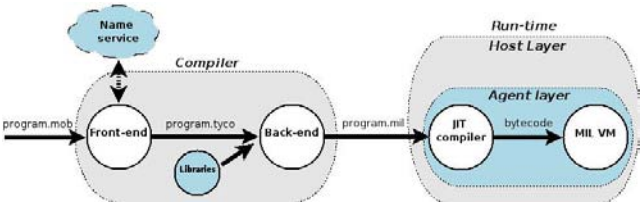

Figure 2: Compiling and running a Mob program.

3. THE COMPILER AND RUN-TIME

The compiler is divided in two main stages (figure 2). First, the *front-end* of the compiler takes the Mob source code and outputs the corresponding code in the TyCO language, as specified by the encoding of Mob in TyCO. The front-end of the compiler performs type inference on the Mob source code and in particular finds the types for both the implemented and the required services for agents. At this point the name service is contacted and a type-check is performed. The types inferred by the compiler are matched with those assumed for the service in the network. If the agent implements a service yet not registered, the interface provided becomes the *de facto* interface for that service. If type-checking succeeds, the source Mob program is transformed into a program written in the TyCO language.

The *back-end* of the Mob compiler is just the compiler for the TyCO language. It takes the TyCO code generated by the front-end and produces code written in an intermediate language called MIL (Multi-threaded Intermediate Language [17]), which is compiled *just-in-time* by the run-time system before being executed. This scheme allows the run-time to check type information in the MIL code before running it.

The run-time system is divided into two layers (figure 2). The top layer is the *host layer* and is implemented as a service that must run on every Mob-enabled host in a network. This layer is responsible for managing agents within a host and supporting their mobility. More specifically, it provides the means to create, execute, marshall, send, unmarshall and receive agents. The second layer is the *agent layer* and implements agents and the name service (also an agent). All are executed with the TyCO run-time system. Each agent is implemented with two concurrent threads: the first is an instance of the MIL virtual machine that runs the MIL code for the agent; the second handles network communication for the MIL virtual machine.

4. RELATED WORK

Of the languages more closely related to Mob none adheres to the service-oriented paradigm.

JoCaml [3] is a programming language based on the Join-calculus that provides support for distributed and mobile agent based applications. The language uses a custom vir-

tual machine and supports the migration of trees of computations (an agent and its tree of sub-agents) between hosts in a network. Just as in Mob, type-checking is mostly done at compile time except for interaction with other modules which is done dynamically. The required type information is annotated in the source program.

The X-Klaim [2] language is an implementation of the Klaim model with ad-hoc extensions to incorporate higher-order constructs, asynchronous reading of tuple-spaces and hierarchical structured networks. Programs in X-Klaim are compiled into Java classes that resort to a package, Klava, to run. Mobile agents in X-Klaim are processes with a single execution flow, rather than the multi-threaded agents found in Mob. This makes the migration of multi-threaded agents a complex and user aware operation.

Nomadic Pict [20] is perhaps the closest to ours in that it grows from another process calculus based language, Pict, and adding primitives for programming mobile computations such as agent creation, agent migration and asynchronous communication between agents. Nomadic Pict also focuses on verification and a proof of correctness for an instance of the infrastructure has been achieved. Despite the similarities our aim is to provide a scripting language that abstracts away from network location dependent information. In this respect we feel that Mob, even in its core language is higher level than Nomadic-Pict.

Acute [10] is a programming language for mobile agents built on top of Objective Caml. The language provides type-safety through a partially static/dynamic type checking scheme. Moving computations is achieved through an atomic operation that captures a collection of threads in a structure (a *thunk*) that can afterwards be marshalled and moved across the network. This contrasts to Mob where marshalling of objects or agents is transparent to the programmer. The Mob service on that node will be responsible for unmarshalling the agent and restart it. In this respect Acute provides a finer, lower level, control over migration and marshalling than Mob.

Alice is a programming language based on Oz and its implementation, Mozart [15] (itself based on Standard ML). The functionality provided by Alice is similar to that of Acute. The front-end of the Alice compiler produces Oz intermediate code so that the Oz run-time, Mozart, is used to run Alice applications. The approach is similar to the one we use since the front-end of the Mob compiler produces TyCO code that is then executed with TyCO's run-time system.

5. CONCLUSIONS

We have produced an implementation of the Mob language compiler and its run-time system. Currently we are working to prove the soundness of the Mob language. In other words, given an encoding map $[\![\cdot]\!]$, from Mob abstract-machine states into TyCO programs, we wish to prove the following conjecture:

Conjecture (Soundness) Let N and N' be network configurations in the Mob abstract-machine. If $N \rightarrow N'$ (*reduces to* in Mob) then, $[\![N]\!] \equiv [\![N']\!]$ (*is congruent to* in TyCO) or $[\![N]\!] \rightarrow [\![N']\!]$ (*reduces to* in TyCO).

ABSTRACT

We present *actorNet*, a mobile agent platform for wireless sensor networks (WSNs). WSNs are well-suited to multi-agent systems: agent autonomy reduces the need for communication, saving precious energy. Mobile agents are also an intuitive technique for remotely reprogramming sensors deployed in the field. However, implementing agent programs directly on a WSN is complicated by the many limitations of sensor nodes, including limited memory, slow processors, low bandwidth and finite energy. *ActorNet* eases development by providing an abstract environment for lightweight concurrent object-oriented mobile code on WSNs. As such, it enables a wide range of new dynamic applications, including fully customizable queries and aggregation functions, in-network interactive debugging and high-level concurrent programming on the inherently parallel sensor network platform. Moreover, *actorNet* cleanly integrates all of these features into a fine-tuned, multi-threaded embedded Scheme interpreter that supports compact, maintainable programs—a significant advantage over primitive stack-based virtual machines.

1. INTRODUCTION

A wireless sensor network is a system of autonomous sensor nodes which interact via wireless communication channels. Canonical WSN applications include environment monitoring, target tracking and structural health monitoring [9, 3, 2]. These applications are enabled by the unique features of WSNs: independent energy sources, wireless communication and large-scale deployment of inexpensive devices. Unfortunately, these features also impose severe constraints on WSNs, including limited energy and network bandwidth, small memory sizes and low processing power.

Agent systems are one promising solution to such problems. For example, an autonomous agent can make intelligent decisions on the spot without consulting a central base station, saving energy and bandwidth. Indeed, existing WSN applications such as real-time target tracking already use an agent-based approach [8]. Several challenges become apparent when building agent programs for WSN platforms. Some wireless sensor nodes have only 4KB of SRAM—a severe constraint for even moderately complex applications. Furthermore, sensor node operating systems typically support only non-blocking I/O for performance reasons, complicating application development. The tight coupling between applications and the operating system makes cross-platform interoperability and code migration difficult. In addition, WSN in-network storage services [10], while similar to agent coordination services such as tuple spaces [4], cannot meet their full potential without a supporting agent platform.

ActorNet is an agent platform that addresses these issues, making the development of agent-based solutions to sensing problems significantly easier. Specifically, *actorNet* provides services such as virtual memory, context switching and multi-tasking to support a highly-expressive yet efficient agent language for WSNs. Several agent primitives can be implemented on top of *actorNet*. For example, *actorNet* supports coordination among agents in the asynchronous communication model, typically employed in WSNs due to the gap between communication and computation speeds. Synchronization between concurrent agents in an asynchronous setting can be performed via synchronizers or join continuations, which have previously been defined in an Actor language similar to *actorNet* [1].

2. ACTOR LANGUAGE

The top layer of the *actorNet* platform is an actor language interpreter. The actor language uses the well-known S-expression syntax. Notable primitive operators include `par`, `send`, `msgq` and `callcc`, which are used extensively in this paper.

The *actorNet* language is based on the syntax and semantics of Scheme, with extensions specific to actor computation. The `par`, `send` and `msgq` operators are not found in Scheme. `Par` creates separate actors to evaluate each argument expression in parallel and returns a list of the created actors' identifiers. While these actors remain on the same *actorNet* platform, they share parts of their environments, allowing them to communicate efficiently. If an actor migrate to another platform, it can communicate back via message passing. The `send` operator provides a simple, abstract mechanism to send messages to an actor. A deep copy is made of the message data to prevent any dependence on

the source host. For example, `(send (list 100 x))` sends all data reachable from variable `x` to an actor with id 100. An actor can access its message queue by calling the `msgq` operator, which returns the list of messages the actor has received.

The `callcc` operator accesses the *current continuation* (CC)—an abstraction of the rest of the program remaining to execute. For example, the CC of the expression `(add 1 (mul 2 ↓ 3))` at the ↓ mark can be regarded as a single-parameter function `c1`: `(lambda (x) (c2 (mul 2 x)))`, where `c2` is an another single-parameter function `(lambda (x) (add 1 x))`. In general, the CC can be regarded as a stack of single-parameter functions. The operand of `callcc` is a single-parameter function: when `callcc` is called the CC is passed to the operand function.

In *actorNet*, the CC and the value that will be passed to it form the state of an actor. Because an actor can read its current continuation, it can duplicate itself or migrate to another platform voluntarily by sending its continuation–value pair to another actor. The other actor simply evaluates the continuation on the value to duplicate the sender's behavior. Using these primitives we can easily and intuitively define the agent migration function of Section 3.

```
 1 (rec (move path temp) ;;return path, max temp
 2    (seq
 3       ;;broadcast measure actors to neighbors
 4       (send (list 0 measure (id)))
 5       (delay 100) ;;wait for 10 sec
 6       (  (lambda (maxt)
 7             (par
 8                ;;if it arrives at an maximal point
 9                (cond (le (car maxt) temp)
10                ;;then return the temp along the path
11                   (return migrate path temp)
12                ;;else move to the highest temp. node
13                   (move
14                      (cond (equal path nil)
15                         (cons launch path)
16                         (cons (io 0) path))
17                      (migrate
18                         (cadr maxt)   ;;node id
19                         (car maxt)))) ;;temp
20                (setcdr (msgq) nil)))) ;;reset msgq
21          ;;find the max temp. and the node
22          (max (cdr (msgq)) (list 0 0)))))
```

Figure 1: An example actor program that migrates to a point of maximal temperature in a WSN and returns the temperature back to the base station

3. EXAMPLE

ActorNet is an implementation of the actor model of distributed computing [1] for wireless sensor networks. We present an example application that demonstrates the utility of mobile agents in a sensor network setting. *actorNet*'s support for coordination amongst mobile agents. Our example consists of an actor migrating through the WSN, in search of a local maximal temperature when the temperature is assumed to be continuously changing in space—a typical environment monitoring task. The actor in this example autonomously selects it migration path based on environmental information and reports the final result to a base station.An outline of the application follows.

1. An actor A broadcasts to its neighbors a small actor that measures the temperature at a node and sends back the result.

2. Actor A determines the local maximum temperature and migrates itself to the corresponding node. When it migrates to another node, A records its point of origin so that it can forward the maximum temperature reading back along the path it followed.

3. When it arrives at a point of maximal temperature, A migrates back to the base station. Upon arrival at the base station it prints out the temperature value.

Note that in this example we do not need any support for message routing. An actor locally broadcasts and moves itself to its neighbor with the greatest temperature, and the return path is constructed as it migrates from node to node.

Let us first construct a `migrate` function that makes an actor migrate to another node and continue its execution. The state of an actor can be considered as a pair of a continuation and a value to be passed to the continuation. Using this explicit representation, an actor can easily migrate itself to a neighboring node by sending its current continuation as obtained via `callcc`. Each *actorNet* platform hosts a `launcher` actor which regards messages sent to it as programs and evaluates them. More precisely, `migrate` can be defined as follows:

```
1  (lambda (adrs val) ;; migrate
2     (callcc
3        (lambda (cc)
4           (send (list adrs cc (list quote val))))))
```

Figure 1 shows the code for our temperature-search example. The program first broadcasts a `measure` actor that reads a temperature at a remote node and sends back the reading. The sender then waits for 10 seconds and subsequently checks its message queue, `msgq`, for the measurement. No other work is needed for synchronization. The `measure` actor can be encoded simply as

```
1     (lambda (ret) ;;measure
2        (send (list ret (io 1) (io 0)))).
```

The `(io 1)` call returns a temperature reading and the call `(io 0)` returns the node identifier. The `launcher` actor of a remote platform will evaluate this function with the return address, which is the `id` function call of the 4th line of Figure 1. Although the `measure` actor in this application is simple, it could potentially be any arbitrarily complex function. That is, one can easily distribute complex subprocesses to other nodes and later collect the results in the form of messages. This simple example demonstrates how *actorNet* facilitates multi-agent computation in sensor networks.

Returning to Figure 1, the `move` function takes as arguments a return path and the current maximum temperature reading. Migration occurs after evaluating the second parameter. Line 13 shows how the actor migrates to another node: it first appends its node id—`(io 0)`—to the return path and then migrates to the node where the greatest temperature was read. When it arrives at a point of maximal temperature, it returns the temperature value using the `return` function, listed below.

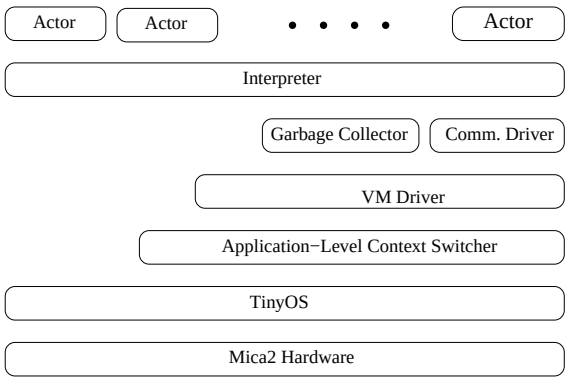

Figure 2: Architecture of the actorNet platform (Mica2 node)

```
1  (rec (return migrate path temp)
2     (cond (equal path nil)
3        (print temp)
4        (return migrate (cdr path)
5                    (migrate (car path) temp))))
```

The `return` function is similar to `move`: it migrates across the nodes along the return path. Incidentally, the `move` and `return` operations can be used to implement a variety of ant-based routing algorithms [6].

4. ACTORNET PLATFORM DESIGN

An *actorNet* is a collection of *actorNet platforms* running on sensor nodes or PCs. Platforms are networked via local wireless channels and the Internet. Each platform hosts several computing elements, called actors, which are able to interact with each other both locally and over the network. Like other virtual machines, the *actorNet* platform provides a uniform computing environment for all actors, regardless of hardware or operating system differences.

Figure 2 depicts the layered architecture of a sensor node *actorNet* platform. Actors only use the interpreter module directly; thus implementation details are hidden from actor programs. Lower-level services are necessary to reconcile the desired properties of simplicity and platform-independence in the high-level language with the specifics of the wireless sensor network environment. The layered architecture alleviates some of the complexity of application development for sensor networks, which currently involves a significant amount of low-level programming due to the tight coupling between the application and the operating system. *ActorNet* aims to provide a stricter decoupling of applications from the operating system, enabling a sensor node to safely load and execute multiple agents, while at the same time simplifying application development. In the same vein, *actorNet*'s support for application-level multitasking makes available such intuitive techniques as blocking I/O, which are usually sacrificed for the sake of efficiency by low-level WSN operating systems such as TinyOS. *ActorNet* maintains this efficiency by introducing threads which are preempted when blocking on I/O.

Several other limitations of present-generation WSN platforms are significant when designing a high-level agent language in this setting, particularly limited memory sizes. We examine representative hardware and software WSN platforms and develop services needed to overcome these limitations.

4.1 WSN Environment

Currently, the sensor node *actorNet* platform is specifically designed for Mica2 hardware. The Mica2 has an 8 MHz 8-bit ATmega 128L CPU with 4 KB of SRAM, 128 KB of program flash memory and 512 KB of serial flash [5]. The 4 KB SRAM space is shared by the stack, heap, and all TinyOS components' static variables. Limited memory heavily constrains applications requiring several coordination services. Application code, large constant tables and logged data are loaded in the flash memory units. ActorNet uses the serial flash as a virtual memory space. Flash read operations are fast, but writes are slow—it takes ∼15ms to write a 128-byte page.

TinyOS is a lightweight operating system for sensor nodes written primarily in NesC [7]. The system is structured as a collection of modules which are statically linked together based on a component specification. Modules consist of statically-allocated variables and three kinds of program blocks: `command`s, `event`s, and `task`s. Service requests are typically split-phase: a caller invokes a command, which returns quickly; once the request is satisfied, the service notifies a corresponding event procedure in the caller. This technique enables higher application throughput as compared to single-threaded blocking I/O. Long-running procedures are explicitly executed as *tasks*, which are scheduled in series and run to completion. Since only interrupts can preempt tasks or lower-priority interrupt handlers, processes must be segmented into sequences of tasks if they are to run concurrently.

4.2 Platform Services

In response to the challenges presented by the WSN environment, we have designed platform services allowing efficient memory management and blocking I/O operations.

Virtual Memory. Since the 4 KB SRAM space on the Mica2 is insufficient for many applications, *actorNet* provides a *virtual memory* (VM) subsystem. We build a page structure on the serial flash area of the Mica2 and use an inverted page table to access pages stored in an LRU cache in SRAM. The current implementation of the VM driver does not perform memory compaction, because the *actorNet* platform does not frequently allocate large chunks of memory; the primary data types are small: bytes, integers, single precision floating point numbers, and pairs of 16-bit addresses (cons cells).

Application-Level Context Switching. The non-blocking command-event I/O model employed by TinyOS is infeasible to support directly in *actorNet*, since every virtual memory access potentially involves split-phase flash memory I/O. For example, let us consider the code in Figure 3. The code on the left assumes blocking I/O: `bar` calls `foo` and `foo` calls `read`, which performs I/O. Without blocking I/O, we must resort to something like the right hand side of Figure 3: the `read` and its callers must be divided into two parts. The problem is that every time `read` is called, the functions along the call chain must be divided into two parts. Furthermore, one cannot use *automatic local variables*: all data must now be declared as static variables outside of the function def-

```
foo() {
   int a;
   ...
   read();
   ...
}
bar() {
   int a;
   ...
   foo();
   ...
}
```

```
int foo_a;
int bar_a;
prefoo() {
   ...
   preread();
}
postfoo() {
   postread();
   ...
}
```

```
prebar() {
   ...
   prefoo();
}
postbar() {
   postfoo();
   ...
}
```

Figure 3: Example program with blocking I/O (left) and without (right)

inition. This makes programs unnecessarily complicated, and also results in inefficient memory usage: local variables must be exclusively allocated as static data rather than as temporary values on a shared stack.

We have devised an application-level context switching mechanism that allows efficient blocking I/O. To explore the utility of the context switching mechanism, consider the following NesC program for `read()`. Note that there is a spin-loop in the `read()` function waiting for `isFlashReadDone` to become true.

```
read() {
   ...
   while(!isFlashReadDone)
      yield();
   return flashData;
}
```

```
task loop() {
   resume();
   post loop();
}
```

With our context switching mechanism, the `yield()` call in `read()` causes control to exit from the `resume()` call of the `loop` task. Thus, TinyOS can schedule other tasks and process pending events. Later, when the `loop` task is scheduled again and `resume()` is called, control continues following the `yield()` call in `read()` as if it had just returned from `yield()`. Note that we do not need to divide the application program into two phases as in Figure 3. Hence the yield–resume mechanism eases development of maintainable applications. To preserve portability and modularity, the context switching mechanism is implemented purely as an application-level service; we do not modify the TinyOS scheduler.

Multi-Phase Garbage Collector. The *actorNet* platform provides a *mark and sweep garbage collection* (GC) mechanism. System-level support for garbage collection has many benefits: it eases application development, eliminates the chance of memory leaks, protects other applications from misbehaving actors, and reduces the actor code size. However, for embedded applications it also has one serious drawback: GC may not always occur at the most opportune moment. This problem becomes especially severe for the *actorNet* platform, because it takes a significant amount of time to write pages to the flash memory. When virtual memory is lightly loaded, the marking step can be done quickly. However, the sweep step must check and restore all pages. In order to solve this problem, we divide the sweep step into many short phases. Combined with the context switching functionality, this greatly reduces the impact of garbage collection on application performance.

5. CONCLUSIONS

We have developed *actorNet*, a mobile agent platform for WSNs. *ActorNet* provides high-level abstractions for coordination in distributed systems, and a set of essential features to develop agent systems on WSNs. Though the current implementation is fully functional, it still has some limitations. One of the biggest remaining challenges is fault tolerence: as message transmission in WSNs is via local broadcast, using a simple message acknowledgement mechanism is infeasible since it requires that each node knows all its neighbor ids'. We are currently investigating techniques to implement a negative-acknowledgement-based rebroadcast mechanism while maintaining as much performance as possible. The virtual memory and multi-tasking environments provided by *actorNet* open the possibility for more advanced coordination mechanisms such as tuple spaces, which can be built on top of existing distributed storage services for sensor networks. Despite the current limitations, *actorNet* provides powerful, efficient high-level services for developing agent systems on WSNs.

Agent-oriented engineering and methodologies

Integrating Agent-Oriented Methodologies with UML-AT

ABSTRACT

There are many methodological approaches for Agent-Oriented Software Engineering, each one focusing on some features of multi-agent systems, but leaving others underdefined. For this reason, it would be interesting to have the possibility of applying different methods, according to their suitability to each particular problem domain and system view. Here, a key issue is how to integrate the information resulting from different methods in a common specification. We propose the use of an intermediate language called UML-AT, which would enable bidirectional transformations between models in different languages. These transformations allow representing views of those models in the language of choice at every moment. UML-AT is a UML profile based on the Activity Theory (AT) framework, which includes the concepts to describe societies of actors that are both autonomous and intentional. The translation with UML-AT mappings makes the integration process independent of any given methodology. At the same time, these mappings can be a basis to study missing features in design languages, according to what is needed in the study of the intentional and social aspects in multi-agent systems and human organizations following AT. This integration architecture by means of UML-AT mappings is illustrated with a case study about a legacy tourism application. It uses a support tool that automates the translation.

1. INTRODUCTION

Multi-Agent Systems (MAS) are used in heterogeneous application domains. Generally, a MAS is considered as a group of intentional autonomous entities (agents) that interact to satisfy some goals. Despite of this, distinct needs generate differences in methodologies about what the relevant features of MAS are and how to analyze them. Agent-Oriented Software Engineering (AOSE) includes methodologies that, for instance, focus on goals (e.g. KAOS [4]), the mental state of agents (e.g. AAII/BDI [9]), expert systems (e.g. MAS-CommonKADS [8]), recursive interconnected tasks (e.g. DESIRE [2]) or interactions (e.g. INGENIAS [15]). This specificity makes sense to explore concrete aspects of MAS. However, the development of real systems needs to gather information about several of these aspects and, frequently, from different points of view (e.g. customers, managers, analysts, or deployers). Agent-oriented methodologies facilitate the study of some features on which they are focused, whereas they give little support in the analysis of other features that they consider as less relevant.

In the absence of a general modelling language for MAS, developers can cope with the previous problem using models from different methodologies. For every view of their MAS, they could choose the languages, methodologies, and tools that are best-suited, according to their own requirements and experience. This approach has the problem of how to integrate the information from different sources: the information of a view is gathered with some models, but it influences/appears on other views, which may be specified using different models. For instance, developers can use KAOS [4] to elicit the goals and models from DESIRE [2] to specify the task decomposition; in this setting, goals from KAOS should be available in DESIRE models, without duplicating information or extra specifying effort. This idea is analogous to the method engineering approach (as in [1]), which defines a generic metamodel that is a representational infrastructure to unify existing methodologies into a single specification. Although in [1] the authors illustrate its application with two agent models, this is done in an informal way and no tool exists yet to work with it automatically. We similarly consider the definition of such a generic language, which is UML-AT. Nevertheless, instead of deriving it conceptually, our proposal is the result of experience in its use for validation of intentional and social properties of MAS [5]. Moreover, we offer tool support with the *INGENIAS Development Kit* (IDK) [15], which serves to facilitate its application and to validate the specification of UML-AT.

UML-AT [5] is defined as an UML profile that includes the concepts of the Activity Theory (AT) [16]. AT provides a

conceptual and analytical framework to understand motivations, individual-society relationships, and networks of interacting activity systems embedded in organizations. Considering AT as the foundation for this intermediate language comes from the fact that it shares with the agent-oriented approach the view of systems as organizations of intentional entities. Besides, there are precedents of its application to AOSE, for instance, in requirements engineering [7], the analysis of contradictions [5], and the design of agent communication infrastructure [14]. These features of AT are shared with other theories from Social Sciences that has been used in agent-oriented research. Some relevant examples are the Reciprocal Role Taking by G. H. Mead, the Actor-Network Theory by Callon & Latour, the foundation of the BDI by M. E. Bratman, or the Biological Theory of Knowledge by H. Maturana (see [11] for an overview of theories from Social Sciences in Distributed Artificial Intelligence). The main difference is that AT is a whole trend of social research, which has a holistic approach covering from the social movements to the individual cognition in the frame of historical development. This allows the study of MAS and their human context from different points of view using an integrating theoretical foundation.

The use of UML-AT as a *lingua franca* for the translation has several advantages in AOSE. First, the translation process becomes independent of any specific methodology. The process remains unchanged and UML-AT evolves to satisfy the map requirements of the agent-oriented methodologies. Second, it reduces the number of mappings required for a methodology to those from and to UML-AT. The set of underlying AT concepts is rich enough to support most of the intentional and social concepts considered in AOSE. In fact, AT analysis of these features in human groups is usually more sophisticated than the current studies in agent-oriented methodologies. So, the third advantage is that UML-AT is a test-bed to detect missing concepts for these features in design languages, given that human organizations are a natural metaphor for MAS. This kind of studies improves the methodologies and also helps to choose the proper modelling language for specific views of a MAS, as these studies evaluate its expressive power.

The rest of this paper is organized as follows. Section 2 briefly introduces AT and the UML-AT language. Section 3 describes the mappings and the process to specify them. Section 4 shows the translation process that uses those mappings while Section 5 describes the support tool that implements them. This process and tools are applied to a case study about the use of Tropos and INGENIAS methodologies for the development of a MAS for cultural information, in Section 6. Finally, Section 7 discusses some final issues about the integration framework.

2. THE ACTIVITY THEORY

Activity Theory (AT) [16] is an analytical framework from Social Sciences intended to study human groups through their contextualised practices. AT considers people embedded in a context that is temporal, cultural, and social. People's practices and their context reciprocally influence each other and this interaction is called *activity*.

The *activity* is the fundamental unit of analysis in AT. An *activity* is a transformation process driven by people's needs. The *activity* satisfies these needs with the *outcome* obtained from the transmutation of an *object*. The active agent that carries out the *activity* is known as the *subject*. Those *subjects* who share an *object* constitute a *community*.

The principle of mediation plays a central role in the AT. An *activity* always contains various artefacts (e.g. instruments, signs, procedures, machines, materials, laws, forms of work, or organisations). These artefacts have a mediating role: relations between elements of an *activity* are not directed, but mediated. *Tools* shape the way human beings interact with their context. A *tool* can be anything used in the transformation process of the *object*, including both material tools and tools for thinking. The relationship between *subject* and *community* is mediated by *rules* (e.g. laws, social conventions, or norms), and the relationship between *object* and *community* is mediated by the *division of labour*, which establishes how the *activity* is distributed among the members of the *community*. The *division of labour* considers the role each individual in the *community* plays in the *activity*, the power each wields, and the tasks each is held responsible for.

These concepts constitute the common core of the vocabulary for AT as agreed in its research community. To complete the vocabulary of the AT for MAS, some other entities (e.g. *activity systems*, *artifacts*, or *roles*) and relationships (e.g. mediations, contributions, or decompositions) were made explicit (since they already appear in some AT studies) or added to the previous core. An *activity system* is the context of an *activity*, and includes all the elements that appear in the AT core. An *artifact* is a generalization that can represent any concept of an *activity system*.

The set of AT concepts for MAS were translated into UML using profiles [13] to facilitate its use in AOSE processes. The resulting language is called UML-AT. The representation of an *activity system* in UML-AT, plus the *artifact* concept and mediation relationships, appears in Figure 1. The full specification of UML-AT can be found at http://grasia.fdi.ucm.es/at/uml-at.

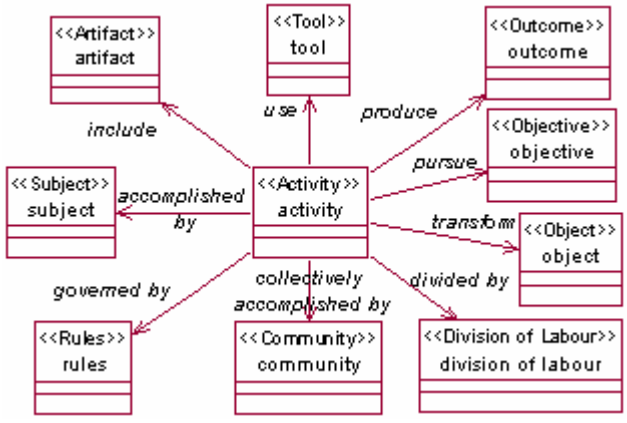

Figure 1. *Activity system* with UML-AT.

In its current version, UML-AT supports the most widespread concepts used in AOSE to describe intentional and social features of MAS. This allows representing the concepts of a given agent-oriented methodology as UML-AT diagrams and,

thus, translating MAS specifications obtained with that methodology to UML-AT. In the case of concepts from agent-oriented methods that cannot be mapped as UML-AT patterns, they will lead to the addition of new AT concepts to UML-AT.

3. MAPPINGS WITH UML-AT

Mappings contain the information required to transform the specifications of a MAS between UML-AT and the language of an agent-oriented method. A mapping is a correspondence from structures in a source language to structures in a target language, where both patterns can contain constant and variable values. These structures exchange information through shared variables. The following discussion about mappings is illustrated with the example in Figure 2. It shows a mapping from a relationship defined with the INGENIAS methodology [15] to UML-AT. This is an excerpt of the XML files for mappings that use the tool that is later introduced in Section 5.

Figure 2 shows the main elements required to define mappings. The tags *language_source* and *language_target* indicate the languages of the source specifications (e.g. INGENIAS) and the translated ones (e.g. UML-AT). A *match* describes a correspondence, in a given translation level, between two structures: the *source pattern*, which is enclosed within the *source* tags, and the *target pattern*, which is surrounded by the *target* tags. The translation level gives a sorting for the application of the mappings, as the Section 4 explains. The first translation cycle use the mappings of level 0; every subsequent cycle increases the level by 1. Both INGENIAS and UML-AT work with information represented as graphs. Their languages are specified with a meta-modelling language called GOPRR. GOPRR [10] describes *graphs* in terms of *relationships*, whose extremes are *roles* that connect with *entities*. All of these elements can have related *properties*. The elements within *source* and *target* tags reflect these primitives. A *relationship GTFailsource* in an INGENIAS view is translated to a *relationship AT_Contribute* in an UML-AT diagram, which has the same name as the *GTFailsource* (shared variable "*v2*") and a value *Avoided* of the attribute *contribution*.

Figure 2 Excerpt of mapping from INGENIAS to UML-AT.

The example in Figure 2 corresponds to a simple correspondence. Real mappings usually relate graphs. The reason for that is that the meaning of the elements in the specifications strongly depends on their relationships with others. Very simple mappings can generate translations that are not completely accurate and introduce mistakes in the resulting specifications.

The main difficulty when developing these mappings is to determine what the correct correspondence is for a given *source pattern*. This task demands a deep knowledge of the concepts involved in UML-AT and the agent-oriented methodology, but it has only to be done once for a given methodology. There are some available heuristics to carry out this process. These are based on the description of AT concepts from the point of view of the agent paradigm that Table 1 summarizes.

Table 1. AT concepts for the agent paradigm.

AT concepts	Definition with the agent paradigm
Activity System	Set of modelling elements representing a total or partial view of the MAS.
Activity	Task that pursues some relevant objective for an agent or group of agents in the MAS.
Subject	Agent, role, or organization. In general, whatever active element that behaves according to the Rationality Principle[1] can be modelled as a *subject*.
Object	An element transformed by a task and that can be considered as the reason/origin for that task. It is a prerequisite for the task.
Outcome	The product of a task that satisfies the goal of that task or is an evidence to evaluate that goal.
Objective	Need satisfied by a task.
Tool	A resource used in a task that is neither the *object* nor the *outcome* of that task. It is a prerequisite for the task.
Community	Set of *subjects* that interact in the workflows of a MAS.
Rules	Set of norms that affect the behaviour of the MAS and do not belong to the *division of labour*.
Division of Labour	Organization of the *subjects* to carry out the workflows of the system. It includes the capabilities of the involved agents, the resources that they control, and their power relationships, among others.
Artifact	Whatever element use to model a MAS.

The definitions of Table 1 give some hints to develop mappings in agent-oriented methodologies. The concepts of *activity*, *subject*, and *objective* have restrictive definitions that can be fulfilled by few concepts in a MAS. So, these concepts are a good starting point to identify the elements of an *activity system*. A *community* can only be constituted by those *subjects* that participate in a common workflow. On the contrary, the concepts of *object*, *outcome*, and *tool* are difficult to identify in a MAS. Their definitions are precise but almost any element used to model a MAS can be them depending on the context. Besides, in the case of the *object* and the *tool*, it could be necessary to know the semantic of the involved *activity* to distinguish what element is transformed into the *outcome*, i.e. the *object*, and what supports the transformation, i.e. the *tool*. The *rules* and the *division of labour* define behavioural patterns for the MAS. Many methodologies define these behaviours assigning roles. The differences between both groups of patterns emerge from the *object*. The *division of labour* determines the organization of the *community* to transform the *object*, while *rules* are more generic. Finally, an *activity system* can be constituted by multiple interconnected *activities* described with different levels of detail. This abstraction must be mainly considered as a useful way of grouping concepts that are not relevant for the analysis in the current level of detail.

4. TRANSLATION PROCESS

The translation process can be seen in Figure 3. This process consists of two main activities: the management of the translation levels and the application of individual mappings.

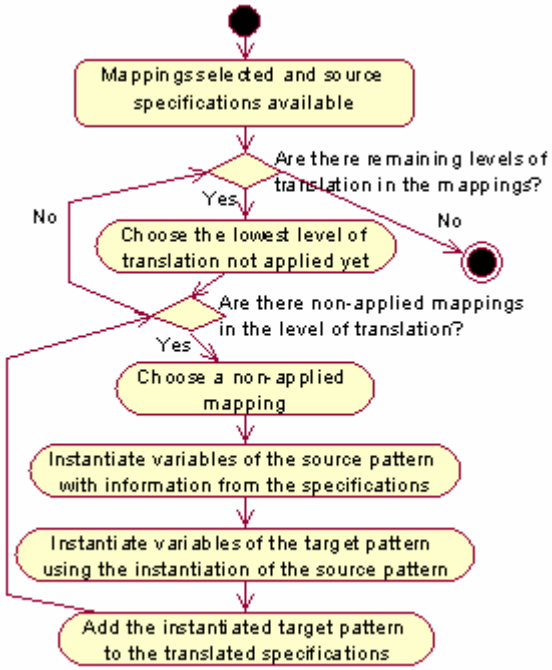

Figure 3. Translation process with mappings.

A translation level groups a set of mappings and has a sorting number. Translation levels are applied according to their sorting number from lowest to highest. Mappings in a translation level are applied sequentially, without any particular order, and can use all the concepts previously translated by other levels. These prerequisites of other concepts for the translation determine the sorting of the levels.

[1] The Rationality Principle states that "Every action taken by an agent aims at achieving one of its goals" [12]

The translation process with the mappings in a specific level consists basically of three steps:

1. Identify the pattern of the source language, i.e. the *match pattern*, over the specifications and instantiate its variables with that information. The process begins looking for groups of elements with the same structure of the *match pattern* in the specifications. When identification happens, the process has to check that the values of the properties in both the pattern and the specification are compatible. If they are compatible, the identification creates a substitution function from the variables in the *match pattern* to the corresponding elements in the specifications.
2. Instantiate the pattern of the target language, i.e. the *target pattern*, with the substitution function obtained from the identification of the *match pattern*.
3. Add the instantiated *target pattern* to the translated specifications. This is the translation of the part of the original specifications that corresponds with the *source pattern* of the mapping.

A remark has to be done about the translation process. Translations between groups of concepts are not always one to one. A given group in the source language may have several corresponding groups in the target language. These groups can correspond to several views (i.e. instances of models) of the original information in the target language; but sometimes they are different possible interpretations of the same information. This ambiguity is inherent to the fact that the modelling primitives and their meaning are different in the source and target languages. However, the negative effects of this potential multiplicity of translations are minimized for the singularity of the original information. That is to say that the multiple interpretations are only information to work in the tool, but they do not exist as part of the specifications, where only the origin of the translation exists.

5. TRANSLATION TOOL

The application of the translation process in a development is automated by a tool called the *Activity Theory Assistant* (ATA). The general purpose of the ATA is to help MAS developers with AT-based techniques. Part of this support is the translation process presented in this paper. Other techniques implemented by the ATA include the support to elicit requirements [7] or to detect AT contradictions in the specifications [5]. The modules required for the translation can be seen in Figure 4.

The knowledge of the assistant about the languages and the correspondences involved in translations comes from XML files, as those seen in Section 3. The information concerning the languages allows the ATA to validate the specifications, checking that their contents are according to the definition of the language. Correspondences specify the translations themselves.

The *graph* package gives an implementation of the primitives of GOPRR [10]. Its components are instantiated for the internal representation of information in the ATA about languages, correspondences, and MAS specifications.

The *wrappers* package provides uniform APIs for the sources of MAS specifications. The *targets* package includes wrappers for the resources related to the input/output about the translation.

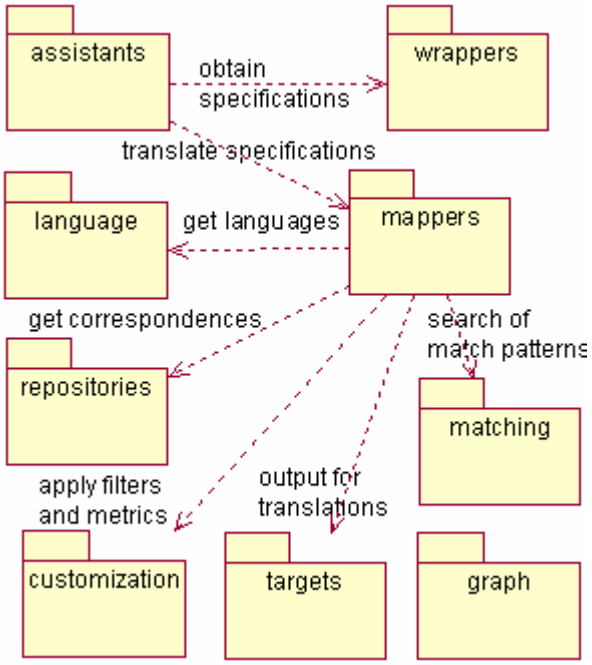

Figure 4. ATA architecture for translation.

Language gives the functionality to deal with the definition of the vocabularies, while the *repositories* package does it for the correspondences. They transform the XML descriptions to the internal structures of the ATA defined by *graph*.

Matching deals with the identification of *source patterns* in the specifications. Its results are used by the *mappers* package to translate specifications according to correspondences.

The *customization* package includes functionality to evaluate the tool. It generates statistics about the use of mappings, generated translations, or elements that the ATA could not translate.

The *assistants* module implements the functionality to coordinate all the previous packages. The core of the ATA belongs to this package.

The integration of the ATA in a specific agent-oriented development environment requires writing the corresponding components for the modules *wrappers* and *targets*. The component for *targets* is optional, since the ATA has default resources for output. As a proof of concept, the ATA is currently embedded as a plug-in of the *INGENIAS Development Kit* (IDK) (http://ingenias.sourceforge.net), which is the modelling and development tool of the INGENIAS methodology [15].

6. CASE STUDY: *eCULTURE*

To illustrate the integration architecture, this section shows a case study based on the *eCulture* system [3]. *eCulture* is a web-based broker of cultural information developed with the Tropos methodology. Tropos [3] describes a whole development process, from early requirements to implementation. This process does not fully address some issues, like the transition from the detailed design to the implementation. This transition is largely a manual process depending on developers' skills to map

concepts from Tropos specifications to the target platform. Even worse, as the process is manual, modifications in the original specifications have to be traced and updated to the final code, with the consequent negative impact on the maintainability.

Given the previous situation for Tropos, developers would prefer using the INGENIAS approach for this transition. INGENIAS [15] mainly bases the coding on templates and the IDK. The templates contain code for the target platform with variables that have to be filled with elements from the specifications. The IDK processes the templates according to the specifications and generates the code for the target platform. Of course, developers have to refine the resulting code, as there is information that neither the specifications nor the templates contain. However, most of the work caused by changes in the specifications is performed by the IDK.

The problem for the previous approach is that the languages of Tropos and INGENIAS are different. Despite the availability of support tools (OME for Tropos and IDK for INGENIAS), none of them can interoperate with the other. A possible solution is the interconnection through the ATA. In order to perform the integration, the ATA needs two mappings: from Tropos to UML-AT and from UML-AT to INGENIAS. The mappings for INGENIAS and Tropos can be found at [6]. A summary of some mappings with INGENIAS appears in Table II. There is a discussion about how to build some of these mappings in the next paragraphs. To keep the explanation simple, this argumentation only considers correspondences from concept to concept, instead of correspondences between graphs, which are more precise semantically (see Section 3 for an explanation about this topic).

The development of the mappings begins with those concepts of the AT that are more restricted. These concepts are *subject*, *activity*, and *objective*.

A *subject* is any element of a MAS that behaves according to the Rationality Principle [12]. INGENIAS has two abstractions that satisfy this definition, *agent* and *role*. Both of them have related goals and tasks to accomplish them.

An *activity* is a practice that satisfies some goal for a *subject*. The concept of *task* in INGENIAS satisfies this definition.

Another possible *activity* in INGENIAS is the *workflow*, which comprehends a set of *tasks* and their related elements like *facts* and *applications*. A *workflow* does not have a satisfaction relationship with goals, but it has a consumption relationship with them. This consumption has to be interpreted as a relation of the *workflows* with the goals that they globally pursue. The reason is that INGENIAS allows including *tasks* without goals. If these *tasks* did not share the goals of their *workflows*, they would not satisfy any purpose, which is impossible according to the Rationality Principle. Given this interpretation, *workflows* are another kind of *activities*. An *interaction* is also an *activity*. It is defined as a sorted set of *tasks* that is executed pursuing a goal, either individual for the participants or global for a group.

An AT *objective* represents a state of the world that agents want to be true. INGENIAS has its own concept of *objective* for these states. Besides, they can also be graphically represented as *mental states* of agents. So, *mental states* are AT *objectives* too.

The concept of *community* is explicitly supported in INGENIAS with *groups* and *organizations*. These *communities* include *agents* and *roles*, which share resources, and the *goals* that they pursue. These *agents* and *roles* usually participate in the same *workflows*. INGENIAS also has implicit *communities*, which are composed by *subjects* participating in the same *workflow* but that do not belong to a common *group* or *organization*.

Table II. Mappings between AT and INGENIAS.

AT	INGENIAS
Activity System	Task, Workflow, Interaction
Activity	
Subject	Agent, Role
Object	Resource, Application, Interaction, Interaction Unit, Fact, Belief, Mental State, Autonomous Entity Query
Outcome	
Objective	Objective, Mental State
Tool	Resource, Application, Task, Workflow, Interaction, Interaction Unit, Fact, Belief, Event, Mental State, Autonomous Entity Query
Community	Group, Organization
Rules	Mental State, Autonomous Entity Query, Interaction, Group, Fact, Belief
Division of Labour	
subject 1 → [decompose] → subject 2	- Organization Model group(subject 1) → [OHasMember] → agent(subject 2)
activity → [accomplished by] → subject	- Agent Model agent(subject) → [WFResponsible] → task(activity)
activity→[transform] → object	- Tasks and Goals Model task(activity)→[GTAffects]→fact(object)
object → [contribute positively] → subject	- Agent Model agent(subject)→ [GTPursues] → *goal 1*[2] agent(subject) → [WFResponsible] → *task 1*
	- Tasks and Goals Model *task 1* → [GTSatisfies] → *goal 1* *task 1* → [GTAffects] → fact(object)

The concepts of *object*, *outcome*, and *tool* are conceptually very close. Any element used by an *activity* is a *tool*. According to the previous translations for *activity*, a *tool* from INGENIAS can be a *resource*, *application*, *task*, *workflow*, *interaction*, *interaction unit*, *fact*, *belief*, *event*, *mental state*, and *autonomous entity query*. *Objects* and *products* can be translated to almost the same concepts as a *tool*. The exceptions are *task*, *workflow*, *interaction*, *interaction unit*, and *event*, as they cannot be transformed or generated by an *activity*.

The *rules* and the *division of labour* can be specified in INGENIAS with *mental states*, *autonomous entity queries*, *interactions*, *groups*, *facts*, and *beliefs*. All of them describe

[2] Elements in italics are new ones introduced by the mappings.

behavioural patterns for the agents and are therefore suitable to establish the norms of the system.

Finally, an *activity system* is a description of one or several *activities* and its context. It can be modelled in INGENIAS with *tasks*, *workflows*, and *interactions*. As it happens with the *communities*, the translation can consider implicit *activity systems* as arbitrary groups of elements in a MAS specification.

This discussion is just an example of the kind of reasoning needed to develop the mappings. More complex patterns (as those about relationships in Table II) would improve the semantic accuracy of the resulting translations.

Once having the mappings, the ATA can perform the translation. For this case study, the actor of Tropos in Figure 5 is translated to INGENIAS. The translation from UML-AT to INGENIAS is going to be discussed with more details; for Tropos, Figure 6 shows the translation to UML-AT using the mappings in [6].

The translation of Figure 6 to UML-AT is, according to mappings for relationships in Table II, as follows. The *match pattern* (i.e. the one on the left column of Table II) is searched over the specifications. For the *decompose* relationship, three matches are found, those corresponding to *Info Broker* with *Results Synthesizer*, *Info Searcher*, and *Area Classifier*. The *solution pattern* (i.e. the one on the right column of Table II) proposes to insert as translations for the *decompose* relations new *OHasMember* relations in the Organization Model. These relations connect the *Info Broker* as a *group* with the other *subjects* as INGENIAS *agents*.

The translation of the relations *accomplished by* and *transform* in Figure 6 is very similar to the one for *decompose*. It uses the second mapping for relationships in Table II.

The mapping for *contribute positively* deserves some remarks. Source and target languages of mappings usually have different semantics. For this reason, it is not always possible to find a direct translation between concepts of both languages. In the case of the *contribute* relations in AT, they can connect *artifacts* (i.e. whatever modelling element of AT), what cannot be represented in INGENIAS. A similar semantic can be obtained with the introduction of two new entities (i.e. *task 1* and *goal 1*) in the solution pattern. These entities are not saved in the specifications; they are just temporarily introduced for the modelling activity.

The result of the application of these three mappings for relationships over the specifications from Figure 6 can be seen in Figure 7. The result is split in different models of an INGENIAS specification.

7. CONCLUSIONS AND FUTURE WORK

This paper presents a framework for the integration of different agent-oriented methods in MAS development. It allows the use of the best-suited method to specify every aspect of a MAS.

The integration is based on a translation process with mappings. A mapping indicates how a structure in a source language can be represented by a structure in another language with the same meaning, or at least a close one. Mappings use as an intermediate language UML-AT. This language grounded in AT is rich enough to support most intentional and social concepts present in agent-oriented modelling languages.

The main advantages of the proposed integration architecture over others are: 1) it is independent of any agent-oriented methodology, as it is based on the neutral language UML-AT; 2) the pattern matching process gives simple explanations about the correspondences applied in the translation; 3) the addition of new methodologies just requires the specification of their mappings; 4) mappings with UML-AT are a suitable resource to discover and analyze missing features in agent-oriented languages; 5) the architecture has automated support tools.

The specification of the mappings is the hardest task of those related with the application of the architecture. It demands a deep analysis of the semantics of the involved concepts. Besides, the possibility of introducing new elements in the *solution pattern* deserves a careful consideration as it should avoid the appearance of unnecessary additional information.

Future work includes two main lines of research. The first one is the creation of mappings for new methodologies, which will enrich UML-AT with new concepts. The second one is the study of agent-oriented methodologies from the AT perspective. This study aims to improve these methods and their integrated use for development, and to get a better understanding of the foundations of the agent paradigm in Social Sciences.

ABSTRACT

We outline meta-encoding schemas for compiling nonmonotonic logic theories into Verilog HDL (Hardware Description Language) descriptions. These descriptions can be synthesized into gate level specifications for direct fabrication of silicon chips[1]. The method is applied for designing agent chips incorporating similar features found in the BDI (Belief, Desire, and Intention) and Brooks' subsumption architectures.

1. INTRODUCTION

We develop a formal declarative specification language called Layered Non-monotonic Logic (LNL) and meta-encoding schemas to generate two types of executable specifications (general logic programs and synthesizable Verilog descriptions). The reasoning mechanism of each layer is an argumentation system and lower layers are subsumed by higher layers. The semantics of the language is based on the ambiguity blocking Dung-like argumentation system [2]. The language can represent relative certainties among the components of a system and provides behavior based decomposition of a system similarly to the subsumption architecture [1]. The subsumption architecture decomposes a system into (possibly prioritized) parallel behaviors rather than the standard functional decomposition. Benefits of this approach in designing control systems are discussed in [1]. For instance, a typical functional decomposition of a cleaning robot might resemble the sequence:

perception→planning→task selection→motor control.

The decomposition of the same system in terms of behaviors would yield the following set of parallel behaviors:

1:avoid objects < 2:avoid water < 3:clean < 4:wander

where the numbers denote the layers and < denotes increasing levels of competence (i.e., more specific tasks). However, the layers of LNL represent relative confidences between layers such that layer-n is more confident than layer-$(n+1)$. Thus, each behavior will be represented by one or more layers of LNL as shown in Figure 1. The figure also shows that less competent behaviors tend to be related with more confident LNL layers. The reason is because less competent behaviors are usually more reactive or urgent behaviors. LNL supports the behavior based decomposition and conceptual decomposition by *conclusion subsumption* and *rule-subsumption* which will be noted when we give the formal definition of LNL.

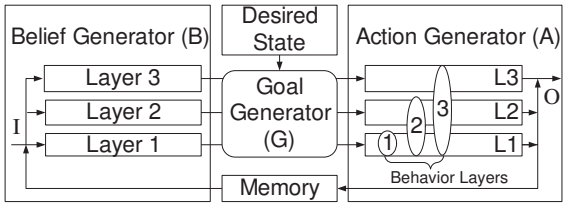

Figure 1: Conceptual view of an agent block.

2. AGENT BLOCK

We briefly discuss an agent architecture called *Agent Block* to which the specification language has been applied. Each agent block is an autonomous system that performs actions in order to achieve a certain desired state. As we can see in Figure 1, an agent block receives signals from its input (I), and reasons about the current state of the world with its background knowledge in the belief generator (B). The background knowledge is decomposed into several layers. The goal generator (G) in the figure then decides what goals to be achieved in order to make the world conform to the desired state. The set of goals then instantiates a particular behavioral specification from a set of plans in the action gen-

erator (A) and produces appropriate actions for the output (O).

Given a desired state (or a set of desired states), the goal generator can be automatically created from the plans in A and the background knowledge in B. In a very simple case, to maintain a desired state d, whenever d is not true, we can activate a set of goals defined in A that are known to be related to achieving d. Suppose the relations between each goal of A and d are described in the background knowledge B. Then, in this case G consists of rules ($\neg d \Rightarrow s$) for each goal $s \in S$ where S is the minimal subset of goals defined in A such that $S \cup B$ entails d.

An agent block specification consists of descriptions of its input, output, memory, desired state, belief generator, goal generator, and action generator. In addition, connection details between these components need to be given for a complete specification of an agent block. However, in this paper, we only outline how to specify and compile the three main parts of an agent block: belief generator, goal generator, and action generator.

Example 1. Let us consider an example specification for the part that controls a vacuum cleaning unit of the cleaning robot. Suppose that the robot performs vacuuming action ($aVac$) if it detects (on sensor sA) that the area is dirty, but it stops the action if it detects some water on sensor sB. That is, we have two parallel behaviors: avoiding water and cleaning. However, avoiding water has higher priority than cleaning. This specification can be represented as a set of defeasible rules decomposed in to two layers as follows (each number of a rule denotes the confidence level of the rule):

B={$sA \Rightarrow_1 dirty$, $sB \Rightarrow_1 wet$}
G={$wet \Rightarrow_1 \neg gclean$, $dirty \Rightarrow_2 gclean$}
A={$gclean \Rightarrow_2 aVac$}

B, G, and A represent the belief, goal, and action generator specifications, respectively. The arrows represent defeasible inferences. For instance, $sA \Rightarrow_1 dirty$ is read as 'if sA is true, then it is usually dirty'. The numbers represent relative confidences between layers such that layer-n conclusions are more confident than layer-$(n+1)$ conclusions. Then, if an area is both dirty and wet, the vacuuming unit will be turned off: $aVac$ is not true. The reason is that since wet is a layer-1 conclusion in B, $\neg gclean$ is a layer-1 conclusion in G. As layer-1 conclusions are more confident than layer-2 conclusions, $\neg gclean$ is also a layer-2 conclusion overriding $gclean$ in G. Thus, in A we cannot conclude $aVac$.

3. LAYERED NON-MONOTONIC LOGIC

We now give a formal definition of the language and its proof theory. From now on, we use *level-n* to mean the degree of confidence of layer-n. A rule r consists of its antecedent (or body) $A(r)$ which is a finite set of literals, an arrow $\Rightarrow_n$ (n is a positive integer denoting a level-n rule), and its consequence (or head) $C(r)$ which is a literal. Level-n rules are more confident than level-$(n+1)$ rules. If l is a literal, $\sim l$ is its complement. An LNL theory is a tuple $T = (R, N)$ where $R = R_1 \cup ... \cup R_n \cup ... \cup R_N$ is a finite set of rules where R_n is a set of level-n rules and N is the number of layers. Then, $\mathbb{R}_n = R_1 \cup ... \cup R_n$ is the set of layer-n rules. That is, layer-n subsumes (includes) layer-$(n-1)$ rules: *rule-subsumption*.

We obtain the meta-program representation of an LNL theory from the meta-program formalization of Defeasible Logic (DL) given in [3] by removing defeaters, strict rules, priority relations, and converting the relationship between strict rules and defeasible rules in DL in to the relationship between layer-$(n-1)$ and layer-n in LNL. Thus, it is also an ambiguity blocking Dung-like argumentation system [2]. The details of the meta-program representation of an LNL theory $T = (R, N)$ and its layers are now described. First, we obtain the *conclusion-meta-program* $\Pi_C(T)$ consisting of the following general logic programs of each layer-n where $1 \leq n \leq N$:

C1. $\mathsf{conclusion}_n(\mathsf{x})$:- $\mathsf{conclusion}_{n-1}(\mathsf{x})$.

C2. $\mathsf{conclusion}_n(\mathsf{x})$:- $\mathsf{supported}_n(\mathsf{x})$, not $\mathsf{supported}(\sim\mathsf{x})$, not $\mathsf{conclusion}_{n-1}(\sim\mathsf{x})$.

where not denotes the negation as failure, $\sim$ maps a literal x to its complement, and $\mathsf{conclusion}_n(\mathsf{q})$ means that q is a layer-n conclusion. C1 represents *conclusion subsumption* because layer-n includes layer-$(n-1)$ conclusions. Next, we obtain the *rule-meta-program* $\Pi_R(T)$ consisting of the following general logic programs for each rule $(q_1, ..., q_m \Rightarrow_i p) \in \mathbb{R}_n$ of each layer-n:

R1. $\mathsf{supported}_n(p)$:- $\mathsf{conclusion}_n(q_1)$,...,$\mathsf{conclusion}_n(q_m)$.

Then, the corresponding general logic program of T is

$$\Pi(T) = \Pi_C(T) \cup \Pi_R(T).$$

The meta-program counter part of the action generator of Example 1 is shown below:

$\mathsf{conclusion}_2(\mathsf{x})$:- $\mathsf{conclusion}_1(\mathsf{x})$.
$\mathsf{conclusion}_1(\mathsf{x})$:- $\mathsf{supported}_1(\mathsf{x})$, not $\mathsf{supported}_1(\sim\mathsf{x})$.
$\mathsf{conclusion}_2(\mathsf{x})$:- $\mathsf{supported}_2(\mathsf{x})$, not $\mathsf{supported}_2(\sim\mathsf{x})$, not $\mathsf{conclusion}_1(\sim\mathsf{x})$.
$\mathsf{supported}_2(aVac)$:- $\mathsf{conclusion}_2(gclean)$.

4. LOGIC PROGRAM REPRESENTATION

We now formally define the meta-encoding schema that translates LNL theories into compact propositional general logic programs. First, we define two literal encoding functions that encode literals in an LNL theory to previously unused positive literals. Let q be a literal and n a positive integer. Then, these functions are defined below:

$$Supp(q,n) = \begin{cases} p_n^{+s} & \text{if } q \text{ is a positive literal } p. \\ p_n^{-s} & \text{if } q \text{ is a negative literal } \neg p. \end{cases}$$

$$Con(q,n) = \begin{cases} p_n^{+} & \text{if } q \text{ is a positive literal } p. \\ p_n^{-} & \text{if } q \text{ is a negative literal } \neg p. \end{cases}$$

$Supp(q,n)$ denotes a support of q at layer-n and $Con(q,n)$ denotes a conclusion q at layer-n: $Supp(q,n)$ corresponds to $\mathsf{supported}_n(\mathsf{q})$; $Con(q,n)$ corresponds to $\mathsf{conclusion}_n(\mathsf{q})$. Let $ConA(A,n)$ be a set of new positive literals obtained from a set A of literals by replacing each literal $q \in A$ by $Con(q,n)$: $ConA(A,n) = \{Con(q,n) | q \in A\}$. With these functions, we now define the meta-encoding schema.

Let $T = (R, N)$ be an LNL theory and $\Pi(T)$ the corresponding meta-program. Let H_T be the Herbrand universe of $\Pi(T)$ which is the set of all possible grounded terms in $\Pi(T)$. Then, the Herbrand base $H_T(T)$ of $\Pi(T)$ is obtained by applying all possible consistent substitutions of

ground terms in H_T with variables in $\Pi(T)$. Thus, the meta-encoded Herbrand base (denoted as $P(T)$) of $\Pi(T)$ is obtained according to the following guidelines for each layer-n $(1 \leq n \leq N)$:

P1: For each $q \in H_T$, add $Con(q,n) \leftarrow Con(q,n-1)$.

P2: For each $q \in H_T$, add

$Con(q,n) \leftarrow Supp(q,n), not\ Supp(\sim q,n), not\ Con(\sim q,n-1)$

P3: For each $r \in \mathbb{R}_n$, add $Supp(C(r),n) \leftarrow ConA(A(r),n)$.

For most of LNL theories, this direct translation of T results in a lot of redundant rules that will be never used for generating conclusions. For instance, we can safely remove the rules produced by P2 that will be never supported. Thus, we replace 'For each $q \in H_T$' with 'For each $q \in SL_n$' in P2 where SL_n is the set of all layer-n literals that might be supported in $P(T)$. SL_n can be obtained as follows:

$$SL_n = \{C(r) | r \in \mathbb{R}_n\}$$

Let $P2(T)$ be the set of rules introduced by P2 in $P(T)$. Then, we can also reduce the number rules in P1 by replacing 'For each $q \in H_T$' with 'For each $q \in CL_n$' where CL_n is the set of all conclusion literals in layer-n of T. This is obtained as follows:

$$CL_0 = \emptyset$$
$$CL_n = CL_{n-1} \cup \{q | Con(q,n-1) \in P2(T)\}$$

Let us consider an LAS theory $T = (R,N)$ containing x unique rules in each layer. The total number of rules is $X = xN$. Then, the number of rules and facts created by the guidelines is bounded by the following equation:

$$|P(T)| \leq X(0.5 + 1.5N)$$

That is, the size of $P(T)$ is linear to the size of T. Particulary, if $N = 1$, $|P(T)| \leq 2|T|$.

The general logic program corresponding to the action generator of Example 1 is shown below:

$aVac_2^+$:- $aVac_2^{+s}, not\ aVac_2^{-s}, not\ aVac_1^-$.
$aVac_2^{+s}$:- $gclean_2^+$.

5. VERILOG HDL DESCRIPTION

Verilog is one of widely used HDL languages. An HDL is a language for formal description of electronic circuits. Most of VLSI (Very-large-scale integrated) circuit design tools can import Verilog files to generate a netlist which can be directly used to fabricate ICs. A netlist is a list of logic gates and their interconnections which make up a circuit.

The meta-encoding of an LNL theory into a Verilog module is similar to the definition of $P(T)$ which is given in the previous section. The differences are that all the used literals (referred as 'signals' in Verilog) in rules must be declared separately and signals have binary values: 1 and 0. We use value 1 to represent that a literal (a signal) is 'true' and 0 to represent 'unknown'. All defined signals are assumed to have value 0 by default but can be changed to value 1 if it is derived by a logic gate with the output value of 1. The exact implementation of this property is device specific, and thus it will be ignored in this paper.

Let $T = (R,N)$ be an LNL theory. The corresponding Verilog description $V(T)$ is obtained from T by adding the Verilog statements according to the following guidelines for each layer-n $(1 \leq n \leq N)$:

V1: For each $q \in CL_n$, add
wor $Con(q,n)$;
assign $Con(q,n) = Con(q,n-1)$;

V2: For each $q \in SL_n$, add
wor $Supp(q,n), Supp(\sim q,n), Con(q,n)$;
assign $Con(q,n) = Supp(q,n) \wedge \sim Supp(\sim q,n) \wedge \sim Con(\sim q,n-1)$;

V3: For each $r \in \mathbb{R}_n$, add
wor $Supp(C(r),n), Supp(\sim C(r),n), Con(C(r),n)$;
assign $Supp(C(r),n) = \bigwedge_{q \in A(r)} Con(C(r),n)$;

The Verilog module description of the action generator of Example 1 is shown below:

```
module A (input gclean2+, output aVac2+);
    wor aVac2+, aVac2+s, aVac2-s, aVac1-, gclean2+;
    assign aVac2+ = aVac2+s & ~aVac2-s & ~aVac1-;
    assign aVac2+s = gclean2+;
end module
```

In addition to the above description, we also need to add some device specific codes to set the default values (0) of the signals and port mapping codes between the components (B, A, G, and the memory) of the agent block. The generated Verilog descriptions can be directly compiled to a netlist using a freely available HDL synthesizer Xilinx^{TM} ISE Webpack. In the module definition, both $aVac_2^{-s}$ and $aVac_1^-$ are not necessary as they will never be true. Moreover, in practice many of subsumed rules are redundant because only few of the literals in layer-$(n-1)$ are referred in layer-n. Thus, if such redundant codes are removed, the actual size of a Verilog description of an LNL theory can be made close to the size of the original theory independent of the number of layers.

6. CONCLUSION

We have devised a formal translation method which compiles high level (non-monotonic logic based) specifications of an agent into synthesizable Verilog HDL descriptions. In contrast to current agent systems, an agent chip is realized as a concurrent computational structure on a silicon chip. This makes agent chips very robust and reactive. Since the specification language is a consistent instantiation of an argumentation system, it also has a well defined semantics which is critical for system verification and maintenance. Thus, agent chips can be readily used for mission critical applications such as distributed plant controllers, mobile robots, and patient caring systems.

ABSTRACT

The trend in agent-oriented software engineering is to consider multiagent systems (MASs) as a *radically new* way of engineering software. This position isolates agent-oriented software engineering from mainstream software engineering and could be one important reason why MASs are not widely adopted in industry yet.

In this paper, we present another perspective on software engineering with MASs. We put forward MASs as *software architecture*. We give an overview of a reference architecture for situated MAS. This reference architecture extracts and generalizes common functions and structures from various applications we have studied and built. The reference architecture provides a blueprint for architectural design of MAS applications that share the come base of the systems it is derived from. Considering MASs essentially as software architecture paves the way to integration with mainstream software engineering.

Design

1. INTRODUCTION

Researchers and practitioners in agent-oriented software engineering generally consider MASs as a *radically new* way of engineering software. Here is a list of recent quotes from literature:

- There is a fundamental mismatch between the concepts used by mainstream software engineering and the agent-oriented view. Existing software development techniques are unsuitable to realize the potential of agents as a software engineering paradigm. [15]
- Whether agent-oriented approaches catch on as a software engineering paradigm [will depend on] the degree to which agents represent a radical departure from current software engineering thinking. [5]
- We are on the edge of a revolutionary shift of paradigm, pioneered by the multiagent systems community, and likely to change our very attitudes in software modelling and engineering. [17]
- Agent-based computing can be considered as a new general-purpose paradigm for software development, which tends to radically influence the way a software system is conceived. [16]

Copyright 2006 ACM 1-59593-303-4/06/0005 ...$5.00.

This vision has led to the development of numerous MAS methodologies. Some of the proposed methodologies adopt techniques and practices from mainstream software engineering such as object-oriented techniques, e.g. Prometheus [6]; the Rational Unified Process, e.g. Mase [14]; or the Unified Modeling Language, e.g. Adelfe [3]. However, nearly all of these methodologies start from the idea that MAS provides a new way to engineer software systems. The position of being a radically new paradigm for software development isolates agent-oriented software engineering from mainstream software engineering. This could well be one important reason why MASs are not widely adopted in industry yet.

This paper presents another perspective on software engineering with MASs. We put forward MASs as *software architecture*. Considering MASs as software architecture gives MAS a clear position in the software development process, and paves the way to integration with mainstream software engineering.

Overview. Section 2 explains our perspective of MAS as software architecture. In section 3, we give a brief overview of architectural design that provides a context to apply MAS as software architecture in software engineering. Section 4 gives an overview of a reference architecture for situated MAS that architects can use for the design of concrete software architectures. Finally, we conclude in section 5.

2. MULTIAGENT SYSTEMS AS SOFTWARE ARCHITECTURE

Instead of considering MASs as a radically new approach for software development, we aim to give MASs a position in a general software engineering process. Our perspective on the essential purpose of MASs is as follows:

Multiagent systems provide an approach to solve a software problem by decomposing the system into a number of autonomous entities embedded in an environment in order to achieve the functional and quality requirements of the system.

This perspective states that MASs are an approach to *solve* a software problem. In particular, a MAS is a specific *decomposition of interacting elements* of the system intended to achieve the *requirements* of the system. This is exactly what *software architecture* is about. [1] defines software architecture as: "the structure or structures of the system, which comprise software elements, the externally visible properties of those elements, and the relationships among them." Software elements provide the functionality of the system, while the required quality attributes are primarily achieved through the structures of the software architecture. As such, MASs are in essence a family—yet a large family—of software architectures. The elements of a MAS software architecture are agents, resources, services, environment, etc. Relationships among the elements are very diverse, ranging from indirect interaction through virtual pheromone trails to complex negotiation protocols. In short, MASs are a very rich family of architectural approaches with specific characteristics, useful for a diversity of chal-

lenging application domains. Based on the problem analysis that yields the functional and quality attribute requirements of the system, the architect may or may not choose for a MAS-based solution. Quality attribute requirements such as robustness, flexibility or openness may be arguments to choose for a MAS software architecture. As such, we consider MASs as one valuable family of approaches to solve software problems in a large spectrum of possible ways to solve problems.

3. ARCHITECTURAL DESIGN

We now give a brief overview of architectural design that provides a context to apply MASs as software architecture. In the software development life cycle, architectural design iterates with requirements analysis on the one hand, and with the detailed design and development of the system on the other hand. Architectural design includes the design, the documentation, and the evaluation of the software architecture.

Design. Architectural design requires a systematic approach to develop a software architecture that meets the system requirements. In our research, we use techniques from the Attribute Driven Design (ADD [2]) method to design the architecture for a software system. The ADD method is a recursive decomposition method that is based on understanding how to achieve quality goals through proven architectural approaches. One common architectural approach are architectural patters [7]. An architectural pattern is a description of architectural elements and their relationships that has proven to be useful for achieving particular qualities. Examples of architectural patterns are pipe–and–filter or blackboard. We have developed a reference architecture for situated multiagent systems as a reusable architectural approach. This reference architecture integrates a set of architectural patterns that have proven their value in various MAS applications we have studied and built. The reference architecture provides an asset base the architect can draw from to select suitable architectural solutions.

Documentation. A software architecture is described by *views* [1]. A view describes the architecture of a software system from a particular perspective. The main views are: the module view that documents a system's principal units of implementation; the component-and-connector view that documents the system's units of execution; and the deployment view that documents the relationships between a system's software and its development and execution environment. Documenting a software architecture comes down to documenting the relevant views of the software architecture for the application at hand.

Evaluation. A software architecture is the foundation of a software system, it represents a system's earliest set of design decisions. Due to its large impact on the development of the system, it is important to verify the architecture as soon as possible. Modifications in early stages of the design are cheap and easy to carry out. In our research, we use the Architectural Tradeoff Analysis Method (ATAM [8]). The ATAM incites the stakeholders to articulate and prioritize specific quality goals; it forces the architect to provide a clear explanation and documentation of the software architecture; and especially it uncovers problems with the architecture that can be used to improve the quality of the software architecture in an early stage of the development cycle.

4. REFERENCE ARCHITECTURE FOR SITUATED MULTIAGENT SYSTEMS

The reference architecture we present in this section generalizes and extracts common functions and structures from various applications we have studied and built, including the Packet-World, a P2P file sharing system, a number of basic robot applications, and an simulator for Automatic Guided Vehicle systems. Besides these basic applications, the reference architecture considerably draws from experiences with an industrial logistic transportation system for warehouses [11]. The reference architecture provides a blueprint for architectural design of MAS applications that share the come base of the systems it is derived from.

Fig. 1 shows an overview of the reference architecture. The architecture integrates two primary abstractions: *agents* and the *environment*.

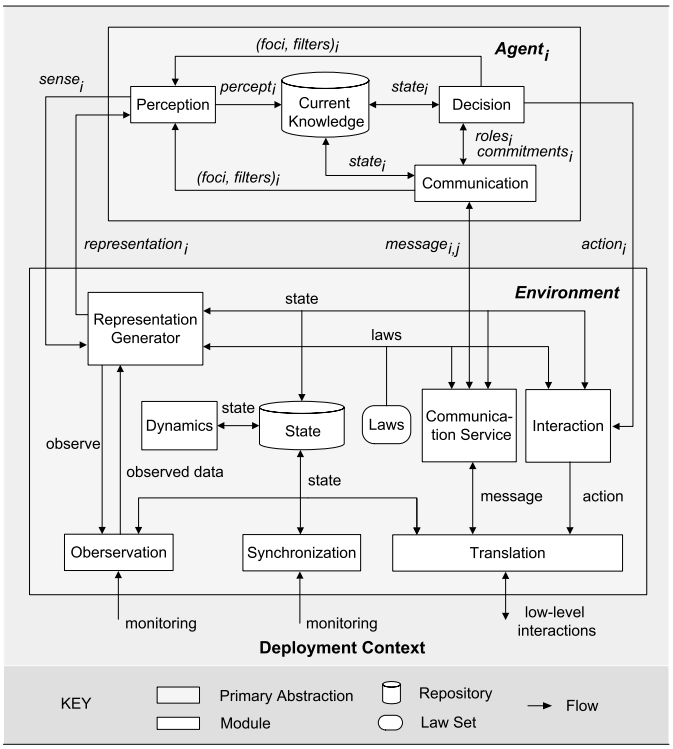

Figure 1: High-level overview of the reference architecture for situated multiagent systems

Agents. The agent architecture models perception, decision making and communication as separate modules of the agent. The *Perception* module maps a local representation of the state of the environment to a percept for the agent. We developed a model for *selective perception* that enables an agent to direct its perception at the most relevant aspects in the environment according to its current task. To sense its environment, the agent selects a set of *foci*. Foci allows the agent to sense the environment only for specific types of information. Sensing results in a representation of the agent's surrounding that can be interpret by the agent producing a percept. Finally, the percept is filtered by a set of selected *filters*, restricting the perceived data according to context relevant selection criteria. [13] zooms in on the perception module and discusses the different submodules in detail. The *Current Knowledge* module integrates percepts to update the knowledge of the agent.

The *Decision* module is responsible for action selection. We developed the decision module as a free-flow architecture, for details, we refer to [9]. Since existing free-flow architectures lack explicit support for social behavior, we introduced the concepts of a *role* and a *situated commitment*. A role covers a logical functionality of the agent, while a situated commitment allows an agent to adjust its behavior towards the role in its commitment. An agent can commit to itself, e.g. when it has to fulfill a vital task. However, in a collaboration, agents commit to one another via communication. Roles and situated commitments are building blocks for explicit collective behavior. The action selected by the decision module is passed to the environment for execution.

Communication enables agents to exchange information, and set up collaborations reflected in mutual situated commitments. We developed a communication module that processes incoming messages and produces outgoing messages according to well-defined communication protocols. The communication module (1) interprets messages and reacts to them according to the applicable protocol, and (2) initiates and

continues conversations when the conditions imposed by the applicable protocol are satisfied. Messages are passed to the message delivering system of the environment. The communication module is discussed in detail in [12].

Environment. The environment offers functionality to the agents for perception, communication and action, and it provides an interface to the *deployment context*. With deployment context, we refer to the given hardware and software and external resources with which the MAS interacts such as sensors and actuators, a printer, a network, a database, or a webservice. We now explain the different modules of the environment, for a detailed discussion of the environment model see [10].

The *State* repository represents the actual state of the environment. The environment state typically includes an abstraction of the deployment context possibly extended with other state related to the MAS environment. An example of state related to the deployment context is an abstract representation of a network topology. An example of additional state is the representation of digital pheromones that overlays the network.

The *Synchronization* module monitors specific parts of the deployment context and keeps the corresponding representation in the state repository up to date. An example is a synchronization module that monitors the topology of a dynamic network and maintains the representation of the network structure in the state repository.

The *Dynamics* module maintains dynamics in the environment that happens independent of the agents or the deployment context. A typical example is the the evaporation of a digital pheromone.

Laws represent application-specific constraints on agents' perception, interactions, and communication. We discuss examples of different types of laws below.

The *Percept Generator* generates percepts for the agents. In general, agents can perceive state of the environment, or observe elements in the deployment context. In this latter case, the percept generator requests the *Observation* module to retrieve the required data form the deployment context. Perception is subject to laws that provide a means to constrain perception. For example, for reasons of efficiency a designer can introduce default limits for perception in order to restrain the amount of information that has to be processed, or to limit the occupied bandwidth. [13] discusses the perception generator in detail.

The *Interaction* module deals with agents' actions. Actions can be divided in two classes: actions that may result in a modification of state of the environment, and actions that may result in the modification of elements of the deployment context. An example of the former is an agent that drops a digital pheromone in the environment. An example of the latter is an agent that writes data in an external data base. Actions are subject to interaction laws. For example, when several agents aim to access an external resource, an interaction law may impose a policy on the access of that resource. Actions related to the deployment context are passed to the *Translation* module that converts the high-level actions of agents into low-level interactions in the deployment context.

The *Communication Service* module collects messages and delivers messages to the appropriate agents. Message delivering can be subject to communication laws. Communication laws can just regulate the message stream, or they can impose application-specific regulations on exchanged messages. An example of this latter are a set of laws that impose agents to follow the prescribed steps of a particular protocol. The translation module converts the high-level message descriptions into low-level communication primitives of the deployment context.

Industrial Application. We have used the reference architecture for situated MASs for the architectural design of an industrial system for logistics services in a tobacco warehouse. This real-world application uses automatic guided vehicles to transport loads in the warehouse [11]. For the documentation of the software architecture of this application and a detailed report of the ATAM evaluation we refer to [4].

5. CONCLUSION

In this paper, we presented another perspective on software engineering with MASs. We put forward MASs as software architecture. Looking upon MASs as software architecture does not dilute MAS as a software engineering paradigm, on the contrary, it gives MAS a clear and prominent role in the software development process, paving the way to integration with mainstream software engineering.

We gave an overview of a reference architecture for situated MASs. The reference architecture integrates a set of patterns that architects can use during architectural design of concrete MAS applications.

Intensive experience with applying the reference architecture in a complex industrial application has convinced us that the MAS community would benefit a great deal from allocating a correct place for MAS in mainstream software engineering.

ABSTRACT
Comprehending and analyzing agent behavior is an arduous task due to complexities in agent systems and sophistication of agent behaviors, in addition to the common difficulties with any complex software system. This paper presents an integrated approach for the analysis and verification of behaviors of agent-based systems. The approach is a result of collaboration between the Tracer Tool and the TTL Checker, which together automate the analysis and verification of agents in an implemented agent system with the aim of aiding the user in redesigning, debugging, and maintaining the software system. The Tracer Tool ensures that the user's comprehension of the system behavior is accurate and provides explanations of anomalous behavior, which can be detected as a failed behavioral property by the TTL Checker. The integrated approach has been applied successfully in a case study in the domain of Unmanned Aerial Vehicles.

1. INTRODUCTION
Software comprehension is critical in debugging and maintaining complex software systems, though it has lacked appropriate attention in agent software systems. Most existing tools aimed at comprehending agent-based software can be classified either as reverse engineering tools or as model checking tools. According to [2], *reverse engineering* is "the process of analyzing a subject system to create representations of the system at a higher level of abstraction". Following this definition, a number of reverse engineering tools have been developed to assist the designer in analyzing and perusing the source code of a software system, e.g., [5]. In addition, various tools have been developed to perform *model checking* (i.e., to prove that the formal specification of a system satisfies certain behavioral properties) [3]. Nevertheless, despite the above tools to aid the user in understanding software behaviors, software comprehension has remained a time-consuming and mostly manual process. The obstacles faced by designers, developers, and end-users (who will be referred to simply as 'users') during software comprehension include (1) software complexity and sophistication, (2) the translation gap between low-level implementation structures and high-level design concepts, and (3) the large amount of time and effort demanded to gather a comprehensive picture of the software.

This paper demonstrates the Tracing Framework, which is supported by the Tracer Tool by [7] and the TTL Checker by [1], to reduce the effort in comprehending agent-based software systems. The approach to contend with the difficulties of software comprehension is to automate as many of the tasks involved in software comprehension as possible by presenting a visualization of what the agents are doing in terms of high-level agent concepts (e.g., beliefs, intentions, actions, and events) based on logs of system execution and comparing the visualization to the user's comprehension of the implemented agent system. The user's comprehension is explicitly modeled in order for the Tracer Tool to provide feedback as to the accuracy of the user's comprehension.

Additionally, the TTL Checker provides automated checking of agent or system behavioral properties against logs of system executions. This approach is similar to model-checking, except the input is a set of observations from the systems execution, rather than a formal model of the system. This is in accordance with Edmonds' emphasis on the need for empirical analysis of agent behavior, such as scenario-based analysis and field testing [4]. A user can discover behavioral anomalies from Tracer's graphical interface or be alerted by the TTL Checker. To aid the user in tracking down a problem, Tracer can generate explanations that reveal, for example, why an agent performed a certain action.

2. TRACER TOOL AND TTL CHECKER
Motivated by the difficulty of comprehending complex agent systems, the objective of the Tracing Framework [7] is to aid the

user in understanding what is happening in the agent system and why such things are happening in terms of high-level agent concepts that are familiar to software designers, developers, and end-users. The Tracing Framework is established by the ***Tracer Tool***, which provides automation to some of the arduous, manual tasks involved for comprehension (see [7] for details):

Building Background Knowledge. In order to help the user build and maintain a comprehension of the system, the Tracer Tool requires a model of what the user understands. This model is called the background knowledge and is represented as a relational graph, where each node represents an agent concept and an edge represents a relation (e.g., causal or temporal relation) between two agent concepts. Given an empty or incomplete background knowledge, the Tracer Tool can offer suggestions about possible relations between agent concepts based on observations from the system's execution, thus building up the background knowledge.

Logging. Agent concepts (i.e., beliefs, goals, intentions, action, events, and communication messages) are captured as run-time observations using a logging mechanism.

Interpretation. The observations are a manifestation of agent behavior; actual agent behavior must be interpreted with respect to the user's knowledge of expected behavior. The Tracer Tool can create an interpretation of the observations using the modeled background knowledge. The interpretation is visualized as a relational graph, similar to the background knowledge.

Explanation. When the behavior of the implementation changes due to maintenance or redesign activities, the Tracer Tool provides suggestions to update the background knowledge. Since the user must review and accept all modifications to the background knowledge, the user's comprehension is also kept updated with respect to the current implementation. To help the user decide whether a suggestion is valid or to further clarify causal factors of a particular observation, explanations can be generated by the Tracer Tool.

Verification. Given the interpretation of a system execution, patterns of agent behavior can be readily discovered. As a result, anomalous behavior can also be detected as any observation that does not conform to a behavior pattern. Currently, anomaly detection is a manual task that involves discovering behavioral patterns in the interpretation, a task at which humans are extremely good. The Tracer Tool provides a capability to verify the expected behavior (represented as causal graphs) against the actual behavior of the implemented system.

For more complex behavioral properties, the ***TTL Checker*** by [1] provides automated verification of such properties using the observations collected by the Tracer Tool. The TTL Checker is a tool that enables the automated verification of complex dynamic properties against traces. It is based on the predicate logical Temporal Trace Language (TTL) [1]. In this language, to describe dynamic properties of complex agent systems, explicit reference is made to *states*, *time points* and *traces*. Dynamic properties can be formulated that relate a state at one point in time to a state at another point in time. A simple example is the following informally stated dynamic property for belief creation:

> if the agent observes at t1 that it is raining,
> then the agent will believe that it is raining

In formalized (TTL) form this property looks as follows:

$$\forall t1 \ [\ state(\gamma, t1) \models observes(A, itsraining) \Rightarrow$$
$$\exists t2 \geq t1 \ \ state(\gamma, t2) \models belief(A, itsraining)\ ]$$

To enable the automated verification of dynamic properties specified in TTL against formal traces (or logs), the TTL Checker takes a dynamic property and one or more formal traces as input, and checks whether the dynamic property holds for the traces.

3. INTEGRATED ANALYSIS APPROACH

Combining the advantages of the Tracer Tool and TTL Checker, an integrated approach is presented for the analysis and comprehension of agent-based software. This section describes the constituent steps in this approach.

1. ***Create a number of traces (or logs) of executions of a real agent system, in terms of agent concepts such as beliefs, desires, and actions***. This step is done using the Tracer Tool (in particular, using the logging mechanism mentioned in Section 2). Normally, the logs are represented in XML format. To facilitate user understanding of the logs, a translation program has been written that translates the logs to traces in TTL format. As a result, the traces can also be loaded into a specific TTL visualization tool.

2. ***Formalize a number of relevant dynamic properties in TTL***. This step is done using a graphical editor for TTL (see [1] for details). Two types of dynamic properties can be distinguished: *generic* dynamic properties and *domain-specific* dynamic properties. Generic dynamic properties are those that are independent of the domain. A simple example is 'Communication Correctness', i.e., "all messages sent from agent a1 to agent a2 are received by agent a2". In TTL, this property looks as follows:

$$\forall \gamma 1{:}TRACES \ \forall t{:}TIME \ \forall a1,a2{:}AGENT \ \forall m{:}MESSAGE$$
$$[\ [\ state(\gamma 1,t) \models sending\_message\_to(a1, a2, m) \wedge a1 \neq a2\ ]$$
$$\Rightarrow \exists \gamma 2{:}TRACES \ \ [\ state(\gamma 2,t) \models receiving\_message\_from(a2, a1, m)\ ]\ ]$$

The TTL checker contains a library of such generic dynamic properties, which can be re-used in any domain. Domain-specific dynamic properties have to be specified by hand for every new domain. Due to the expressiveness of the TTL language, complex behavioral properties can be specified, e.g., relating events at many different time points and different traces to each other.

3. ***Automatically check the dynamic properties created in step 2 against the logs created in step 1***. This step is done using the TTL Checker (see [1]). As a result of this step, the user knows exactly which properties hold and which do not hold for the traces. Moreover, in case a property does not hold, the checker can provide detailed information about the position in the trace where the property fails. Usually this information has the form of a counter example. For example, if the aforementioned property 'Communication Correctness' fails, then the TTL Checker shows an example of a message that is sent from agent a1 to a2, but it is not received by a2.

4. ***Explain failed properties***. This step is done using the Tracer Tool (in particular, the explanation mechanism described in Section 2). Given a counter example from the TTL Checker due to a failed property, the user can examine the exact observations and its relation to other observations in the Tracer Tool's visualization. Observation details provide further evidence to track down the source of the problem, such as the type of communication message, who sent it, and why it was sent.

4. SUMMARY

Software comprehension is an essential issue during the development, maintenance, and debugging of complex agent systems. Nevertheless, existing techniques (such as reverse engineering [2] and model-checking [3]) face a number of difficulties, in particular (1) the high complexity and sophistication of the software, (2) the translation gap between low-level implementation structures and high-level design concepts, and (3) the large amount of time and effort demanded to gather a comprehensive picture of the software.

To deal with these problems, this paper presents a novel approach to analyze the behavior of agent systems. The approach is the result of the collaboration between the Tracer Tool for comprehension of agent software [7] and the TTL Checker for automated checking of dynamic properties of agent systems [1]. The integrated approach comprises four important elements, i.e. (1) logging of agent system executions in terms of high-level design concepts, (2) formalization of desired dynamic properties, (3) automated verification of dynamic properties against logs, and (4) computer-aided explanation of unexpected properties.

To test the proposed approach, it has been applied in the domain of Unmanned Aerial Vehicles (UAV), see [8]. First, using the Tracer Tool, a number of logs of the UAV system were generated in terms of agent concepts. Next, generic and domain-specific dynamic properties were specified in TTL, and checked against the generated logs. Finally, several of the unexpected properties were explained using the Tracer Tool. Using this approach, the software developers succeeded in locating some undesired behavior, which subsequently allowed them to investigate the causes for such behavior. Thus, the approach turned out useful in the comprehension and analysis of agent software.

Concerning related work, existing research addresses the different elements of the presented approach separately. For example, in [6] several tools are suggested for the collection of trace files (consisting of events and corresponding time parameters) in a distributed system. To examine the collected traces, techniques for querying distributed databases are proposed. This approach is similar to our approach in the sense that both make use of logging and analyzing real executions of an implemented system. A difference is that our approach automates reasoning further by leveraging agent concepts of agent-based systems. Furthermore, various papers, such as [10], describe tools for the visualization of agent-based system behavior based on the presumption that visualization is essential to facilitate efficient debugging of agent-based systems. This approach is also adopted in this paper to aid rapid comprehension of agent behavior in the implemented system. In addition, a variety of analysis tools can process constructs in the visualization to further help automate agent software comprehension, as shown in this paper.

Obviously, in an ideal situation the verification of dynamic properties is done exhaustively (i.e., against all theoretically possible traces instead of a practically given set of traces). However, due to the expressiveness of the TTL language, this process is highly complex. Currently, the possibilities are investigated to combine recent model-checking techniques for real-time systems (such as [9]) with the presented approach.

ABSTRACT
Research on multi-agent systems often involves experiments, also in situations where humans interact with agents. Consequently, the field of experimental (human) sciences becomes more and more relevant. This paper clarifies how things can and often *do* go wrong in distributed AI experiments. We show the flaws in methodological design in existing papers (both with and without humans) and work out an example involving human test-subjects to introduce the fundamental issues of experimental design. Furthermore, we provide researchers with an approach to improve their experimental design. We wish to stimulate researchers to conduct better experiments – which will benefit us all.

1. INTRODUCTION
In general, computer systems are built to perform on behalf of human users. Even autonomous software agents depend on human interaction for critical actions, because they are not (yet) seen as legal entities. Validation of human-agent interaction through experimentation is getting more attention lately in AI and computer science. Research in multi-agent systems more often involves humans as full-fledged participants in mixed-initiative interaction, for example in negotiation (e.g. where humans can set orders), decision support, workflow systems, etc. Actual empirical (human) research is conducted – which is an interesting and valuable trend – but needs to produce useful results.

Papers presenting experiments are seen more frequently as beneficial to our whole research community. At the same time, this community does not have a tradition in experimental design, especially not with humans. Valid and objective results are not easily gathered. Experiments need to be set up in such a way that peculiarities in human nature do not interfere with the experiment at hand. Psychology as a discipline has invested much time and effort into human experimenting – sound experimental methodology thus is available. It would be wise to apply this knowledge to experimentation in distributed AI.

Empirical research on human subjects is time consuming. It involves going through several necessary steps; Explicitation of the research question, or *hypothesis* formulation. Choice of testing method, or design. Decisions about *how* and *what type* of data will be gathered. What are the units of observation, and how many of them? Choice of data analysis methods. These issues are all crucial for choosing an *experimental design*, which refers to the formal structure of the experiment. The design *must* have at least the following properties: a) comparison of the observations under different levels of the independent variable should lead to non-ambiguous conclusions, and b) the comparison should be significantly testable.

Due to restrictions on the length of this paper we omitted the section on a brief overview of good experimental design. Instead we refer to [1], wikipedia.org, or any other good book on experimental design and statistics. Also unknown terms mentioned without explanation can be considered to be easily looked-up in such experimental handbooks. The important lesson to take home is that designing good experiments, best suited to your research question, is an art in itself. Invest time in it or you might end up with a meaningless experiment and a lot of time wasted. A final point we would like to make is that experiments should be reported in such a way that others can replicate the study.

In this paper, a number of erroneous experimental designs found in the latest AAMAS 2005 proceedings are used to illustrate common experimentation errors. We do not cite these researchers in detail, but appropriately name them 'Study 1, 2, etc'. Our aim is merely to use them as examples of well-intended, but wrongly applied efforts. Using a fictitious case, we show how proper experimentation methodology has to be applied and explain how to avoid some common pitfalls.

2. ERRORS in HUMAN EXPERIMENTS
We now focus on flawed human experiments to point out possible improvements. We confined ourselves to the papers of AAMAS

2005, to show the relevancy of this subject. As we do not want to discredit researchers who are doing interesting research, we anonymously refer to the studies, which are numbered randomly.

People are adaptive systems who are constantly reacting to their environment and thus are prone to all kinds of influences – also the ones we do not want to measure. If a comparison is made between conditions (e.g. different interfaces) in terms of quality (e.g. people can work better with a certain kind of display), the different conditions cannot be presented in one specific order to all subjects. People are known to react differently in the beginning of an experiment than near the end. Numerous different factors play a role, such as practice effects, tiring effects, enthusiasm, time-of-day effects, etc. Therefore, the absolute basics of experimental design include a proper ordering of conditions. Unfortunately though, there are experimental studies that lack even this essential basic property [10]. Sometimes there seems to be a design, but it is not made explicit enough [6, 9].

Subjects need to be *randomly* assigned to the conditions. People differ from each other in many ways; these differences need to be averaged out by appointing people to different conditions in a random manner. Also important is what psychologists call 'external validity': The type of subjects used determines whether the findings can be extrapolated to other populations. It is a common mistake to use colleagues for experimentation [8]. Also the number of subjects is important. It is not useful to compare different conditions while using only two or three subjects. This may seem obvious, but experimental populations of this size are not uncommon at all [10].

Obviously, the period before actually conducting research entails the important basics of testing. But things can also go wrong in later stages. The description of procedures in papers is often vague and lacks important details. Methods and procedures are often not orderly described. However, standardization of method formats is common in many research areas. A clear format is the following: *Participants*, *Design & procedure*, *Material and stimulus presentation*, *Results (Statistical analysis*), *Discussion*.

Statistics are related to the aspect of subject amount. If only two or three subjects are tested, results can never be statistically significant. Unfortunately, in distributed AI research the specific type of statistical analysis used is often not stated [9]; sometimes no statistical analysis is done at all [10, 8].

3. STUDYING HUMANS PROPERLY

We here give an example. The data reported are fictitious, but realistic (see e.g. [3]). Let's assume that, for a Dutch auction (in which the price of the goods decreases over time), recommending trade agents have been implemented. These trade agents support the human buyer by indicating when it is the best time to buy. Legislation requires the human still to 'push the button', as indication of an actual order to buy; software agents do not have the (legal) authority to make a contract. However, supporting agents can be used which may indicate when to buy.

Whenever the time is ready to buy, the user should able to push the button *as fast as possible*. The researchers want to know with what type of interfacing human use the trading agents best. The clock used for the auction is shown on the user's screen. This graphical representation of the clock changes in some way, thereby showing the users the best moment to buy and push a button. An analogous clock and a digital clock are used; both count down prices. Four different conditions are compared: 1) analogous clock that changes background colour as indication to buy, 2) analogous clock that changes the clock-hand colour, 3) digital clock that changes background colour, 4) digital clock that changes the digits colours. The question is: Is there a significant difference in response time in the different conditions?

Experiment 1

Method

Participants. Eight students/… (female/male, average age) participated in this study (give background information).

Design & procedure. There were four 30-min conditions; a 10-min break followed after each condition. See Table 1 for the order of conditions. Using this type of counterbalancing, four subjects would have been enough, but probably *not* for significant results.

Table 1. Order of conditions (Balanced Latin Square design)

Subject	Order of conditions			
1, 5	1	2	4	3
2, 6	2	3	1	4
3, 7	3	4	2	1
4, 8	4	1	3	2

Material and stimulus presentation. This section should entail a description of all the materials and how stimuli were presented.

Results

A repeated measures ANOVA (Analysis of Variance) was used, with within-subject factor: Condition (the four different clock types). Usually data of one or more subjects cannot be analyzed: Equipment may fail or subjects do not finish the task. This is usually reported in order to inform researchers how many subjects may be 'lost' along the way. We assume that data of one of the subjects was 'lost'. Averaged RT data are shown in Table 2.

Table 2. Mean Reaction Times (RTs, in ms) of seven subjects to the buy-signal in the four different conditions

	Condition			
Subject	*1*	*2*	*3*	*4*
1	410	460	490	500
2	490	440	450	520
3	430	480	430	480
4	470	410	510	490
5	440	510	470	470
6	460	500	520	440
7	450	420	420	460

It is not enough to just present average results of the different conditions. Let's see what the data look like when averaged over all subjects (Figure 1). Pay attention to the distorting effect on the y-axis (that starts at 435).

Condition 1 seems to yield the fastest responses, but the ANOVA reveals no significant Condition effect ($p > 0.1$): The independent variable Condition (with four levels in this case) did not have a significant effect on RT (dependent variable).

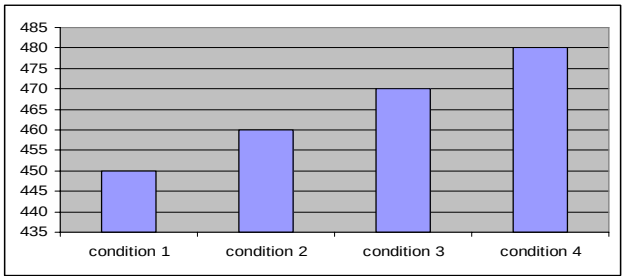

Figure 1. Performance measured in Reaction Times (ms), comparing four conditions, averaged over all seven subjects

Experiment 2: using the same example without methodology

If the four conditions were in the same order to all subjects (condition 1, 2, 3, 4.), the results would have been contaminated by fatigue effects, which have been found in the literature [4]. RTs may slow down 23% for the second and third presentation (compared to the first), and by 49% for the fourth presentation (compared to the first). If we now 'control' the data in Table 2 for these effects, the picture is totally different (see Figure 2).

The ANOVA yields a significant effect of condition; Condition 4 has the fastest response and Condition 1 the slowest [all p-values ≤ 0.01]. So now there indeed is a significant condition effect, but the effect is completely different from the picture in Figure 1. Of course, we do not know whether fatiguing effects occurred. Furthermore, there are a lot more effects that play a role [2]. All these effects are compensated for by using a proper design (see section 2).

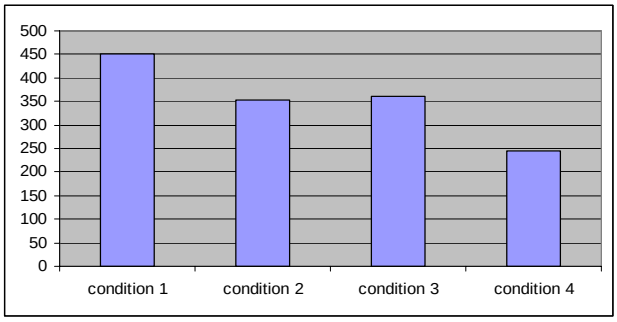

Figure 2. Performance measured in Reaction Times (ms), comparing four conditions, averaged over seven subjects (hypothetically 'controlled' for effect of fatigue, see text)

4. DISCUSSION & RECOMMENDATIONS

Experimentation is extremely useful, as it aids us to better understand strengths and weaknesses of our, models, theories and implementations. However, conducting experiments is very difficult. The difference between solid and weak methodology is the difference between valuable data and the absolute waste of time. Statistics can never make up for experimental design flaws. It is beyond the scope of this paper to provide a complete tutorial on sound experimental design. We have provided an introduction, including examples of common errors and a (fictional) case with a better experimental design. To support researchers in improving their experiments, we present a list of relevant issues and actions:

1. Think carefully about what questions you want to answer.
2. Understand that the area of experimental methodology is a specialized field; conducting experiments is very hard.
3. Accept that there are more effects out there that may harmfully influence your experimental results, therefore:
4. *Consult an expert* on methods & statistics (e.g. in the Psychology dept.). Do not try to do it all yourself.
5. Read appropriate literature on the basics of experimenting (ask the expert what would be useful in your case).
6. Let your expert analyze and comment on the design, methodology and statistical analysis you've chosen.
7. Report not only your results, but also your experimental design and procedure and chosen statistical analyses.

It is important that the distributed AI community improves its use of experimental designs. There is already research on software agents that have human-like capabilities, e.g. agents with memories, learning and adaptivity. Although agents do not get 'tired' as humans, they do live in resource-restricted environments (e.g., processing time, memory, etc.), which influence their performance. Conducting experiments with individual or groups of software agents is not an easy job, and many techniques used for human experimentation will also be necessary for experimentation with agents. This overlap in research areas is a topic we wish to explore in future publications and experiments.

5. ACKNOWLEDGMENTS

The research reported here is part of the Interactive Collaborative Information Systems (ICIS) project, supported by the Dutch Ministry of Economic Affairs, grant nr: BSIK03024 (http://www.icis.decis.nl). The authors wish to thank the participants of the 'Creating Bonds with Humanoids'-workshop at the AAMAS 2005 conference, for raising awareness on the important issue of sound experimental design.

ABSTRACT

The Agent-Community-based Peer-to-Peer Information Retrieval (ACP2P) method uses agent communities to manage and look up information of interest to users. An agent works as a delegate of its user and searches for information that the user wants by communicating with other agents. The communication between agents is carried out in a peer-to-peer computing architecture. The ACP2P is implemented using the Multi-Agent Kodama framework. This paper presents how the ACP2P method works in an agent community network and show the experimental results to illustrate the validity of this approach.

1. INTRODUCTION

Peer-to-peer (P2P) computing is an appealing approach not only to file sharing, but also to searching for information relevant to users over the large networks. Recently several studies on making use of document content information have been proposed[1][3][4]. They assume some cooperative environments where gathering all the documents from every peer in the network is possible for classifying all the peers in the network and for creating routing information between peers. However, in uncooperative environments such as business transaction environments, only the information exchanged between peers according to their transaction rules is available to them and such information is acquired only through their transaction process. In the case of Information Retrieval (IR) in such uncooperative environments, a peer can obtain other peer's documents only through their retrieval process. In other words, when a peer issues a query to other peers, the peer can receive only the documents returned by the peers. The retrieved documents a peer acquired can be re-delivered to other peers according to a handling rule of the documents. We are interested in applying agent technologies to such uncooperative environments. Considering the above things, we proposed an Agent-Community-based Peer-to-Peer information retrieval method called ACP2P method, which uses agent communities to manage and look up information related to a user query[6][5]. The agent communities can reflect the structures of human groups or societies such as laboratories, departments, institutions, research groups and so forth, where the people with the same or similar interests, objectives or aims stay together. In the prior research, we have demonstrated the method's effectiveness for reducing communication loads through several experiments[5]. However, we have not so far well discussed the accuracy performance of the method. This paper considers the ACP2P method and discusses the experimental results to illustrate the validity of this approach.

2. OVERVIEW OF THE ACP2P METHOD

The ACP2P method employs three types of agents: user interface (UI) agent, information retrieval (IR) agent and history management (HM) agent. A set of three agents (UI agent, IR agent, HM agent) is assigned to each user. An IR agent communicates with other users' IR agents not only in the community it belongs to, but also in other communities, to search for information relevant to its user's query. A pair of a Query and Retrieved Document Histories (Q/RDH) and a Query and Sender-Agent address Histories (Q/SAH) and retrieved document content files are managed by the HM agent. When receiving a query from a UI agent, an IR agent asks an HM agent to look up target agents with its histories or asks a portal agent to multicast a query to all the IR agents in its community. Where a portal agent is the representative of all IR agents in its community and can multicast a message to them. Any IR agent in a community can ask the portal agent to multicast its query with requesting the number of relevant information to be returned. After multicasting a query, the portal agent only receives the requested number of 'Yes' messages from the IR agents in the order the

messages are received and returns them to the query-sender IR agent. When receiving a query from other IR agents, an IR agent looks up the information relevant to the query from its original document and retrieved document content files, sends an answer to the query-sender IR agent, and also sends a pair of the query and the address of the query-sender IR agent to an HM agent so that it can update Q/SAH. The returned answer is either a pair of a 'Yes' message and retrieved documents or a 'No' message indicating that there is no relevant information, although retrieved documents are not returned when the query comes through a portal agent. When receiving answers with a 'Yes' message from other IR agents, the IR agent sends them to a UI agent, and sends them with a pair of a query and the addresses of answer sender IR agents to an HM agent[5].

3. EXPERIMENTS

3.1 Preliminaries

We use the Web pages of Yahoo! JAPAN, which are broadly divided into five categories: animals, sports, computers, medicine, and finance. We select 20 smaller categories from each of them in descending order of the number of Web pages recorded in a category and assign an IR agent to each selected category. A category name is used as the name of an IR agent, and the Web pages in the category are used as the original documents of the agent. To perform the experiments, we compare three methods : (1) ACP2P using the two histories (wQ/SAH for short), (2) ACP2P using the Q/RDH, not using the Q/SAH (woQ/SAH for short), and (3) a simple method always employing a 'multicast' technique (MulCst for short). In the experiments, two query sets : QL=1 and QL=2, are used. QL=1 and QL=2 consist of 10 queries, whose query length is one and two, respectively, where query length means the number of terms in a query.

3.2 Relevance Judgement and Evaluation

In a P2P network environment, gathering all documents from every peer is not always possible, that is, indexing all documents is quite difficult. Thus the first goal for IR in the P2P network environment is to achieve a result comparable with a conventional IR method using a Centralized Indexing DataBase (CIDB method for short) because distributed information retrieval systems, which an IR system in P2P networks belongs to, are not yet better than the "single collection" baseline[3] and the validity of this method is empirically shown[4]; the automatically generated queries and the "single collection" baseline are useful resources in studying federated search (distributed information retrieval) in peer-to-peer networks[4]. As the CIDB method, we employ a probabilistic IR method that applies the BM25 [7] weighting function to all the documents collected from every peer. We use the following equation:

$$\sum_{T \in Q} \log \frac{n + 0.5}{N - n + 0.5} \frac{2tf}{\frac{dl}{avdl} + tf} \quad (1)$$

Where Q is a query that contains terms T. tf is the frequency of occurrence of the term within a specific document. N and n are the number of items (documents) in the collection and the number of documents containing the term, respectively. dl and $avdl$ are respectively the document length and average document length, where the document length is the number of terms in a document, and a term is a word detected by a morphological analyzer. In order to compare the ACP2P method with the CIDB method, we used the following equation:

$$\sum_{i=1}^{N_R} \frac{1}{r(i)} / \sum_{i=1}^{N_R} \frac{1}{i}$$

Where $r(i)$ is the CIDB method's rank of the document that is ranked by the ACP2P as the ith document. For example, if a document is ranked by the ACP2P as the 2nd document and the document's rank by the CIDB method is 3, then this means that $r(2)$ returns 3. We call this measure *Reciprocal Rank Similarity* (RRS for short). We can assume that RRS's denominator $\sum_{i=1}^{N_R} \frac{1}{i}$ represents the ideal value of a given model, where it is the CIDB method in this paper. As the ACP2P approaches the given model, the RRS value becomes higher. Thus, the RRS can measure the similarity between ranks generated by the ACP2P and by the CIDB and returns a higher score the smaller $r(i)$ $(1 \leq i \leq N_R)$ is, i.e., the higher the rank. For example, if a user wants to find 3 documents relevant to his/her query and we suppose the top 3 ranked documents' rank returned by his/her agent to be 3, 5 and 1, then the RRS returns $\frac{1/3+1/5+1/1}{1/1+1/2+1/3} = 0.84$, and the top 3 ranked documents' rank to be 3, 5 and 2, then the RRS returns $\frac{1/3+1/5+1/2}{1/1+1/2+1/3} = 0.56$. In the experiment, we use the average RRS: $\frac{1}{N_a} \sum_{i}^{N_a} RRS(i)$, where N_a is the number of all IR agents and $RRS(i)$ is the RRS of the ith IR agent.

3.3 Experimental Results and Discussions

We compare the RRS values of the three methods. All 100 IR agents are assigned to a single community so that we can consider the basic performance of the ACP2P method. The results are shown in Figure 1. In the figure the vertical axis is the average RRS and the horizontal axis is the number of queries issued by each IR agent. As the value of N_R increases, the RRS value also increases and the curve of the graphs becomes flatter. We can see that the RRS value of MulCst increases as the number of queries sent increases. Considering this phenomenon, we surmise that original documents assigned to IR agents will gradually be spread over the community through the document retrieval process of each IR agent. Thus even though a portal agent selects target agents in the order their 'Yes' messages are received, the probability that higher weighted documents will be returned rises. For the same reason, since the RRS value of the MulCst increases as N_R increases, the difference of the three methods decreases. When using QL=1, the wQ/SAH almost achieves higher retrieval accuracy than the other two methods, although the RRS value is unfortunately not so high because the records stored in the content files and the two histories are originally acquired by a portal agent using the query multicasting technique and its RRS value is not so high. We think there are at least two reasons why the RRS score was not so high: 1) a portal agent selects target agents in the order their 'Yes' messages are received, and 2) the ranking results calculated by each IR agent is different from those by the CIDB method even though they use the same equation (1) in Section 3.2 because N used by each IR agent of the ACP2P and that by the CIDB method are different. The first one might be able to be settled by making the portal agent receive the 'Yes'/'No' messages of all IR agents and send them to the query-sender agent although it consumes much more time.

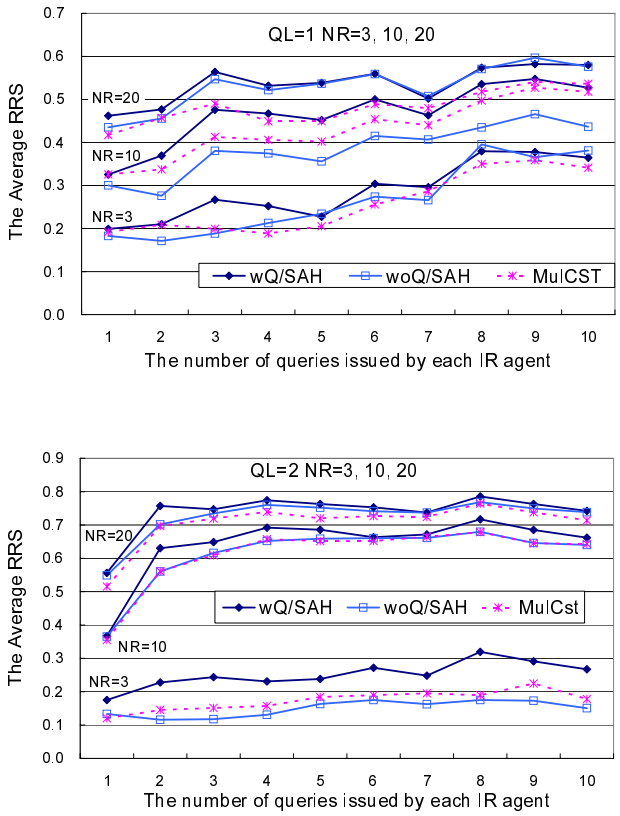

Figure 1: The comparison of average reciprocal rank similarity (RRS) of each IR agent for every query input using 3 different N_R values : N_R=3, N_R=10 and N_R=20. The query belongs to QL=1(Top) and QL=2(Bottom).

However, the second one is not so easy because N used by each IR agent will be changed through its retrieval process. Although there are several methods proposed for distributed information retrieval to estimate the number of documents in each database (DB size for short),[2], [8],[9], they assume such DB size is not varied, thus the number of documents in the network, i.e. N will not be varied either. On the other hand, we assume the DB size will be varied through the retrieval process of IR agents. Therefore a method for estimating N is necessary. In order to estimate N, we first need to estimate the total number of original documents in the network (N_{od}). As a straightforward method, we are trying to use the following simple equation. $N_{od} = \sum_{i \in YES_{IRA}} \frac{N_{QSA_o}}{n_{QSA}} * n_i + N_{QSA_o} * (N_{IRAs} - |YES_{IRA}|)$, where YES_{IRA} is the set of IR agents returning a 'Yes' message o a query issued by a query-sender IR agent. N_{QSA_o} is the number of original documents the query-sender agent has. n_{QSA} is the number of the query-sender agent's original documents relevant to the query. n_i is the number of $IR\ agent_i$'s original documents relevant to the query. N_{IRAs} is the number of IR agents in the network, where 100 in this paper. We assume that N_{IRAs} can be told by the portal agent. $|YES_{IRA}|$ is the number of IR agents in YES_{IRA}. This equation assumes that for every IR agent returning a 'Yes' message, the ratio of the number of original documents relevant to a query and the number of the original documents is the same and the number of the original documents of the IR agent returning a 'No' message is the same as the number of the query-sender agent's original documents. As well as N, we also need to estimate n and $avdl$ in equation (1). n can be estimated by letting the query-sender agent issue a query to all the IR agents returning a 'Yes' message, receive all the documents relevant to the query and count the number of original documents of the IR agents. Where every document should have the information whom it is originally owned or created by. $avdl$ can be set to the average document length of the whole documents the query-sender IR agent has. These are quite rough assumptions, but we have already received positive response from preliminary experimental results, although we need further investigation to show the detail.

4. CONCLUSIONS AND FUTURE WORK

We presented the ACP2P method and discussed the experimental results to illustrate its validity. To do the experiments, we implemented the method with Multi-Agent System Kodama. The experimental results showed that Q/SAH history help to have a higher accuracy in retrieving documents than a method without using the history. Discussing experimental results using more than one hierarchical agent community under more dynamic environments is future work.

ABSTRACT

Business process management in open environments poses special challenges. In particular, such environments are dynamic, thereby requiring frequent changes in business processes. Current business process modeling approaches handle such changes in an ad hoc manner, and lack a principled means of determining what needs to be changed and where.

This paper provides an overview of process adaptability through a novel application of business protocols, especially of protocol composition, introduced in our previous work. Through a real business scenario of auto-insurance claim processing, this paper briefly describes how a wide range of adaptations can be handled naturally and systematically via protocol composition. The illustrated adaptations have been evaluated via a prototype.

1. INTRODUCTION

Successful business process management requires supporting three key properties of open environments, namely, *autonomy*, *heterogeneity*, and *dynamism* [4, pp. 7–10]. Supporting autonomy means modeling and enacting business processes in a manner that offers maximal flexibility to the participants by only minimally constraining their behavior. Supporting heterogeneity means making as few assumptions as possible about the construction of the components for the parties, concentrating instead on characterizing the interactions among them. For open environments, interconnections among components, not the components themselves, are critical.

Dynamism has two flavors. *Membership dynamism* means that the set of components may change. Components may be added and removed at either design-time (*design-time membership dynamism*) or run-time (*runtime membership dynamism*). *Structural dynamism* means that the set of interconnections is not fixed. Dynamism reflects changes in the business requirements; modern businesses face intense pressure and must repeatedly reconfigure themselves in order to thrive, if not to survive. As changes in requirements are routine, an elegant way of handling such changes is vital. Thus, dynamism poses a difficult challenge, one that has not been adequately addressed in the literature, and is the theme of this paper. Supporting dynamism implies supporting process adaptability.

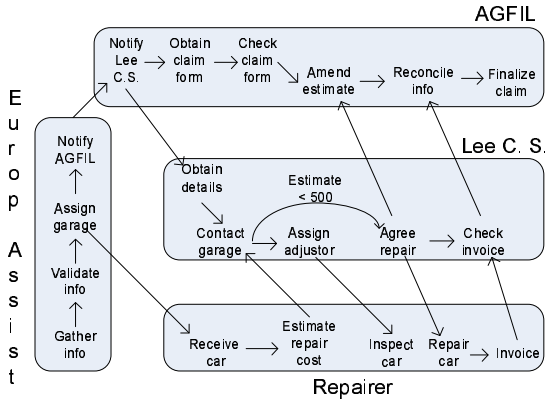

Figure 1: CrossFlow Insurance Claim Processing

Previously, Desai et al. [2] reported a methodology (named OWL-P) for developing business processes that supports autonomy and heterogeneity. The essence of OWL-P is an abstraction of business protocols. A *business protocol* is an abstract, modular, and publishable specification of rules that govern a business interaction among two or more *roles*. A protocol is abstract because it does not model the proprietary business logic of the agents enacting the roles. It is modular because it achieves a specific goal which may be a part of another bigger goal. Due to their abstract and modular nature, business protocols, each achieving a goal, can be combined to form a *composite protocol* that achieves a bigger goal. Each role's perspective of a protocol is captured in its *role skeleton*. A role skeleton, when integrated with the private business logic of an agent enacting the role, yields the agent's *local process*. A *business process* is an aggregation of the local processes of all the agents involved.

In this way, protocols partition a process in a cross-cutting manner whereas conventionally, flows are taken as partitions. For instance, peeking ahead on an example studied in great detail below, each of the boxes in Figure 1 represents a flow. Such boxes would be the modules of abstraction in conventional approaches. By contrast, OWL-P focuses on the interconnections among the boxes; such interconnections are a natural fit for the interorganizational nature of SOC environments [2]. As a striking illustration of the

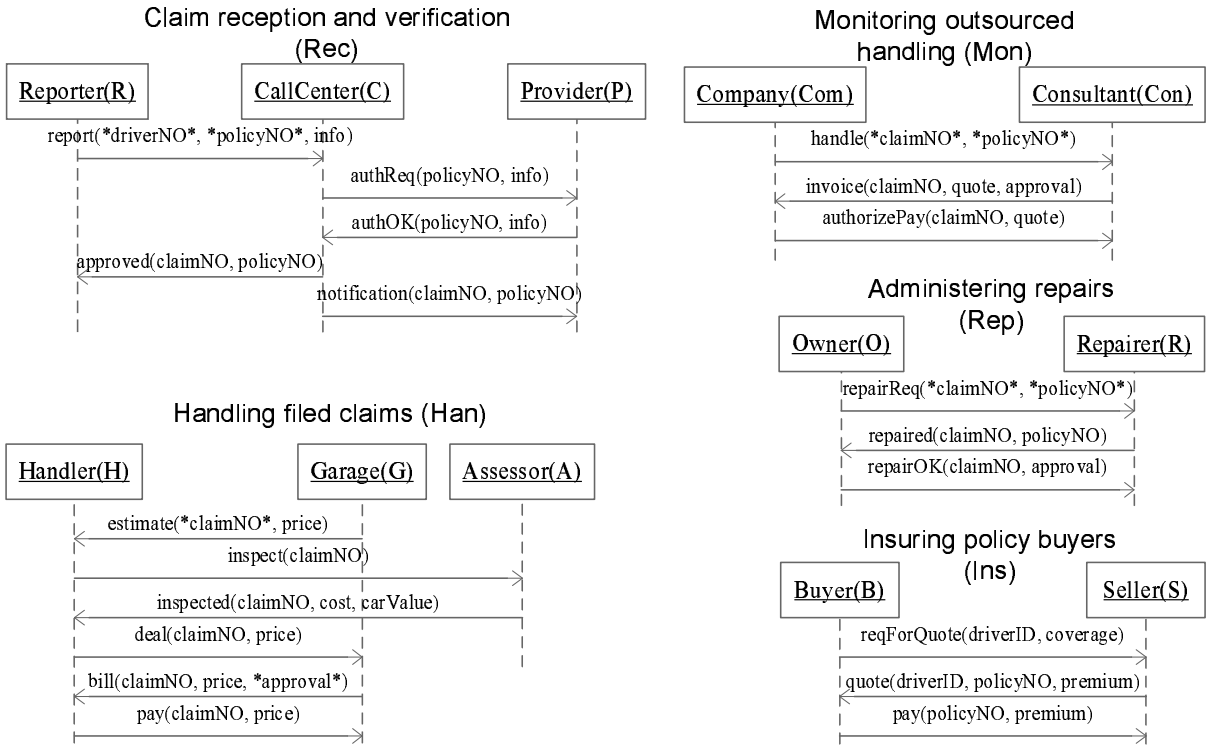

Figure 2: Scenarios from the protocols corresponding to the insurance claim process of Figure 1

importance of focusing on the interconnections, notice that the process flow (taken from [1]) in Figure 1 misses the insurance holder and its interactions altogether. Although the internal flow of the insurance holder's process (its box) may not be important to AGFIL, its external interactions with other parties (i.e., the insurance holder's interconnections) are crucial for modeling the business of AGFIL. Figure 2 shows how the above example is modeled via protocols.

Previous work on protocols provides the basic mechanisms to specify, compose, and enact them to produce software engineering benefits such as reusability and flexibility. This paper is a sketch of protocol-based treatment of dynamism in a real business scenario. Adaptability in general involves a broad variety of research challenges. Hence, this paper concentrates on three kinds of adaptations: (1) exceptions, (2) changes in business policies, and (3) changes in business models.

To illustrate the protocol-based approach, this paper considers the above insurance claim processing case studied under the CrossFlow project [1]. Being a real-life business scenario previously studied by others, this example provides an independent and significant test-case for this approach. Figure 1 shows the parties involved in the process and the process flow. AGFIL is an insurance company in Ireland. The present scenario deals with automobile insurance. AGFIL underwrites the insurance policy and covers any losses incurred. Europ Assist provides a 24-hour help-line service for receiving claims. Lee CS is a consulting firm that coordinates with AGFIL and deals with repairers to handle the claims. A network of approved repairers provide repair services. AGFIL holds ultimate control in deciding if a given claim is valid and if payment will be made to the repairer.

2. PROTOCOLS

Figure 2 shows scenarios from the protocols involved in the above insurance example. Such protocols are independently developed and stored in a repository for reuse.

Any realistic business process would involve multiple interaction protocols. For example, AGFIL would need protocols for selling insurance policies and for receiving and handling claims. Consider how protocols can be combined to form a composite protocol. Let's assume AGFIL outsources the help-line service for receiving claim reports to a call center, but handles the claims itself. The requisite process can be obtained by combining the *Ins* and *Rec* protocols in a certain way yielding a new *Bas* (Basic insurance claim processing) composite protocol.

As the ontologies of the protocols may not match, and they may have interdependencies, simply unioning the rules of the component protocols is not enough. The constraints on combining protocols are specified as a set of *composition axioms* in a composition profile. These axioms identify roles across protocols, specify data flow dependencies, event ordering constraints and ontological dependencies. Composite protocols can be treated and enacted like other protocols. The details of protocol specification and composition are discussed in our previous work [2].

Typically, the protocols are enacted with some of the roles having business relationships established via participating in some other protocol, e.g., *Ins* establishes the contract between the *buyer* and the *seller*. This business relationship is a contract represented by a set of commitments. For brevity, this presentation skips such relationship formation protocols. Figure 3 shows all such contractual commitments among the roles after all the relationships are formed and commitments delegated.

3. ADAPTING PROCESSES

Here, we describe what kinds of adaptations can be handled

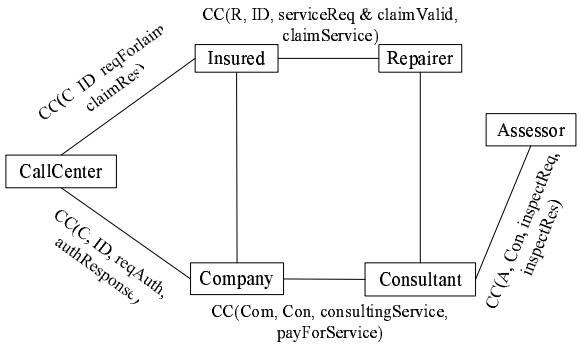

Figure 3: Commitments among parties

by applying the mechanism of protocol composition. Each of the adaptations feature varying degrees of autonomy, heterogeneity, structural dynamism, and design-time membership dynamism. The following assumes that a composite protocol *Picp* (Partial insurance claim processing) is constructed from the composition of *Bas*, *Mon*, *Han*, and *Rep* of Figure 2.

3.1 Exception Handling

Exceptions are (typically) uncommon conditions arising during a business interaction, e.g., fraudulent auto-insurance claims. Protocols facilitate incorporating the handling of an exception into an existing process.

A composite protocol *Ficp* (Fraudulent insurance claim processing) can be constructed by combining *Picp* with a protocol *Fra* (fraud detection and reporting) When AGFIL and Lee CS form their relationship, a conditional commitment CC(Com, Con, consultingService, payForService) is created meaning that AGFIL will authorize payments for handling individual claims if Lee CS provides the consulting service. In case of fraud, the *company* cancels the policy coverage of the *insured* and the *consultant* releases the *repairer* from the commitment to perform repairs. The *assessor*'s advising of a fraud should discharge CC(A, Con, inspectReq, inspectRes) and the *consultant*'s forwarding it to the *company* should mean the consulting service was provided.

The resulting interaction allows AGFIL to end the process by canceling the commitments in case of a fraud. Simply adjusting the commitments can allow greater flexibility without affecting other parties adversely. Here, the support for structural dynamism comes from the added interconnections among the existing partners to handle the exceptions. Support for autonomy comes from the ability to control the effects of foul behavior of a participant.

3.2 Changes in Business Policy

In handling claims where the value of the car is less than the estimated cost of repairs, the *company* may want to scrap the car, i.e., declare it a total loss. To settle this, it pays the *insured* a sum equal to the value of the car and takes possession of the car instead of administering repairs. Also, if the damage is minor, the *insured* may accept a cash settlement instead of having the car repaired. A protocol *Pcsc* (Pay cash and scrap car) can specify the interactions needed for such a policy.

AGFIL would have delegated its conditional commitment CC(S, B, serviceReq $\wedge$ claimValid, claimService) to Lee CS, thereby making Lee CS responsible for servicing claims, who would in turn delegate it to the *repairer*. When the *consultant* advises scrapping the car, it fulfills its commitment to provide the consulting service and the commitment to service the claim falls back to the *company* as the car is not to be repaired but to be paid for. Similarly, when the *consultant* advises a cash payment for a minor damage, and the *insured* agrees to it, it fulfills the commitment for the consulting service and the *company* becomes committed to paying the *insured*. This can be modeled by delegation. Assuming that *Picp* is the current interaction protocol among the partners, *Pcsc* can be composed with *Picp* yielding the composite protocol *Icp* (Insurance claim processing) that handles this policy change.

In *Icp*, a business policy change internal to AGFIL is accommodated across the business process. Here, support for structural dynamism comes from the modified interconnections among the existing partners to handle the policy change. Support for heterogeneity comes from the fact that a change of business logic internal to AGFIL could be accommodated.

3.3 Changes in Business Model

Quite often, enterprises change their business models to respond to changes in their business environment. Business process outsourcing (BPO) [3] has recently become a popular approach for conducting business.

The composition of *Bas* discussed in Section 2 already illustrated this type of adaptation. Let's assume AGFIL could handle claims itself. AGFIL outsourced its call center to Europ Assist to focus on its core business of selling insurance policies. Thus, the business model of AGFIL changed to have a partnership with Europ Assist.

Obviously, a change in the business model is a big shift for an enterprise; new partnerships are formed and new interconnections among the parties emerge. Thus, such a change features not only structural dynamism, but also design-time membership dynamism. Both are supported via composition with protocols having new roles.

ABSTRACT
Ubiquitous system can be considered as a system, in which many kinds of component are connected by networks and the components cooperate with each other for achieving some goals. To develop a ubiquitous system, several researches have used multi-agent models. Even thought current multi-agent models provide many benefits with ubiquitous system developments, they are not enough to develop ubiquitous systems. In this paper, we address the ubiquitous system which solves its problems with cooperative organization consisting of several heterogeneous computing components. We call such a ubiquitous system as a community computing system. In the community computing system, some goals are given to be achieved by the cooperative organization. In this paper, we propose a high-level abstraction model of multi-agent based community computing system. In addition, we propose the development process of the community computing system using MDA(Model Driven Architecture) approach.

1. INTRODUCTION
A ubiquitous system can be regarded as a multi-agent application which target support for daily-life activities. Multi-agent based ubiquitous systems are more than just an extension of multi-agent system to ubiquitous domain. General multi-agent models can not completely support specific features of ubiquitous systems. In this paper, we focused on the agent-based ubiquitous system solving the problems with mission-oriented organizations and called such ubiquitous system as the community computing system. In the community computing system, a community consists of several agents and provides ubiquitous services can not provided by individual computing component. The community computing system has features such as mission-oriented organization, role, goal, cooperation between roles or organizations, and so on. Such specific features of the community computing system can not be completely modeled using existing multi-agent models because existing models deal with general and low-level concepts. Therefore, in this paper, we propose a new high-level abstraction model using the community metaphor. In addition, we concern the development of the community computing system as well as high-level abstraction. In deed, it is hard to develop a highly complex distributed system using only a design. Therefore, we try to formulate the development process from high-level abstraction to implementation of a multi-agent based community computing system with model transformation of MDA.

The rest of the paper is organized as follows. We first introduce some related works and motivation in section 2. Then, in section 3, we propose the community computing system and its development process. Section 4 is dedicated to the conclusion and future works.

2. RELATED WORK
Gaia introduced a methodology for agent-oriented analysis and design [1]. In Gaia, a multi-agent system is regarded as a collection of computational organizations consisting of various interacting roles. Such a view of Gaia is analogous to our view of a cooperation based ubiquitous system. However, it is not adequate to apply agent-oriented methodologies including Gaia to develop a multi-agent based cooperative ubiquitous system. One reason is that they can not capture characteristics of the cooperation based ubiquitous computing. In the agent models, even in Gaia, an organization is only implicitly defined such structures within the role and interaction models. In the cooperation based ubiquitous computing systems, it is important to explicitly define organizations, because the objective of a system is realized by achieving organization's goals. Therefore, we need a high-level abstraction model to describe organization's structures and interaction behavior within and between them. To do this, we employ community metaphor. Community concept is introduced by several agent cooperation models [2]. In ubiquitous domain, PICO (Pervasive Information Community Organization) project [3] used the community concept. The community of PICO provides a framework for collaboration and coordination among

agents. The concept of community computing satisfies requirements of cooperation based ubiquitous computing such as proactive real-time collaborations for automated, continuous services providing in heterogeneous environment. Therefore, we choose the community as a metaphor describing organization's structure in a multi-agent based cooperative ubiquitous system, and then describe the interrelationships between communities. In this paper, we define that the ubiquitous system modeled by community concept as the community computing system.

Another reason is the lack of well defined and automated development process from design to implementation. Agent-oriented models only care about analysis and design of a system. This situation requires solid development process from analysis of system requirement to implementation. To define the development process of multi-agent based community computing systems, we employ MDA (Model Driven Architecture) [4]. MDA is an approach to system development, which increases the power of models in that work. Using MDA approach provides benefit to the development of community computing systems. It make the ubiquitous systems developers focus on describing the system using high-level abstraction primitives, community. Then, the high-level abstraction model is transformed to the more detailed model until a frame of source code is obtained [5].

3. COMMUNITY COMPUTING SYSTEM AND ITS DEVELOPMENT PROCESS

In this paper, we propose the high-level abstraction model and development process for multi-agent based community computing systems through the model transformation process of MDA. For applying MDA approach, we need several models representing different abstraction level and modeling languages for each model.

Before presenting each model in detail, it is worth introducing the basic concepts constructing the core of community computing.

- *Member*: it is the building blocks of a community computing system, and be implemented as an agent. It can represent a computing device, physical hardware, human, and software. At ordinary time, it performs its own action. Then, triggering a goal, it forms a community, and interact each other to achieve the goal. In this paper, we assume that all templates of member, which can be existed in a system, are predefined.
- *Community*: It is a metaphor to describe a proactive organization, and made up with agent members collaborating with others to achieve particular missions. A community has goals and protocols. A community can manage the life cycle of its own members. Offering a condition of joining into a community, a community can control entry and secession of each member. As a goal dynamically arises, a community is dynamically generated to achieve the goal. Then, the community is disorganized when the goal is attained. In this paper, we assume that community templates and the structure of each community are predefined. That is, a community, which is not predefined, is can not created in a system. As well as templates of community, goals and protocols of a community are also fixed.
- *Goal*: It is a particular condition that a community should satisfy. In short, it is the objective of a community.
- *Protocol*: It is a description of interaction between community's members to achieve a goal. It defined as a sequence of messages and member's actions. While a community performs a protocol, another goal can be issued.
- *Society*: It is a metaphor to represent U-space, the environment of a system. It is constructed by agent members and communities. At the first time, only members exist in society. After the start of the society, a community is generated if an agent recognizes a goal. When it attains its objective, a community is terminated, but the society is alive until the community computing system is exhausted.

First of all, as a most high-level abstraction model, CCM (Community Computing Model) describes the multi-agent based community computing system with community concept. Its objective is modeling the requirement and environment of a system. At runtime, a community computing system makes the space combined virtual environment and physical environment. We called this space as *U-space* (Ubiquitous space). *U-space* is a logical and physical area where ability of a ubiquitous system can influence. *U-space* can be defined as a collection of agents and communities in a CCM. To describe the CCM, we defined a modeling language, CML (Community computing Modeling Language). A CIM-PI considering implementation of Community computing system without concern about specific platforms. It shows the system in detail with computing elements and interoperation between them. A CIM-PI extends community descriptions and society descriptions of CCM in detail. In community description of CIM-PI, it is represented that mapping relationships between roles and member templates and interactions of protocols. Each role of the community is matched with certain member templates can playing the role. In addition, protocols of the community are detailed. The frame of CIM-PI (Platform Independent Community Computing Implementation Model) can be derived from CCM, and the rest should be filled by developer. To express a CIM-PI, we define CIL-PI as a modeling language. To describe implementation of a system depending on a specific platform, we also define a CIM-PS (Platform Specific Community computing Implementation Model). The skeleton of CIM-PS can be also derived from a CIM-PI, but the rest should be filled manually. A CIM-PS is represented as program codes in specific agent platform such as JAM or JADE.

Using the model transformation process from a CCM to a CIM-PS, we can obtain the frame of source code. This process allows community computing system development to be ease and systematic, because the gap between design and implementation is filled. Furthermore, we can guarantee consistency in the entire development process, because we can manage the process with coherent philosophies.

4. CONCLUSION

In this article, we proposed a high-level conceptual model using community metaphor to support dynamic management of goal-oriented organization and cooperation in multi-agent based ubiquitous systems. Then, to fill a gap between a design and implementation, we propose the entire development process through model transformation from a high-level conceptual model to an implementation model. However, there are several issues remaining for future work.

- Capability verification of community computing model
- Policy of community computing model
- Dynamic structuring of community
- Dynamic cooperation of member agents
- Test on variety platforms

ABSTRACT

The modular representation of concerns is imperative in the design modeling of multi-agent systems (MASs). However, MAS designers typically face a number of concerns that inherently affect several system agents and their respective internal elements, such as actions and goals. These crosscutting concerns encompass both internal and systemic properties, such as learning, mobility, error handling, and security. Without an explicit modeling of such MAS properties, designers can not properly communicate and reason about them and their broadly-scoped effects. The result is a multitude of agent-oriented design breakdowns: poor traceability from requirements to design models, hindering of reuse opportunities, and decreased evolvability. This paper presents an enhancement of an existing agent-oriented modeling language with aspects. We illustrate the use of our approach through some classical examples of crosscutting concerns in agent-oriented design models.

Keywords

Agent-oriented software engineering, aspect-oriented software development, modeling languages, agent-oriented design.

1. INTRODUCTION

Several systemic and internal agent properties in the design of a multi-agent system (MAS) are typically *crosscutting concerns* [1, 5, 6, 8], such as learning, code mobility, context-awareness, error handling, and security. These concerns are MAS properties that involve and affect a consistent number of goals and actions, which are scattered and tangled to each other over an agent-oriented design. For example, the learning concern is composed of a number of specific goals and actions, which crosscut the goal hierarchies and actions' descriptions associated with several agents in an application. These crosscutting concerns often are fundamental driving factors in the software development process due to their broadly-scoped influence in the MAS design. Hence software engineers need to be empowered with modular representation of these concerns in order to properly communicate and reason about them and their crosscutting design implications.

Due to the very nature of some MAS concerns, existing agent-oriented modeling languages [2, 7, 9, 11] are not able to provide explicit support for the separation of crosscutting MAS-related concerns. As a result, their crosscutting effects are inevitably spanned over the resulting agent-oriented design artifacts. These languages provide the basis to separately represent several MAS functionalities. However, they are not aimed at supporting the handling of crosscutting MAS concerns as separate "aspects". Hence these concerns cannot be modularized with the abstractions and composition mechanisms available. In fact, the need for explicitly modeling crosscutting concerns seems evident in an age where we are facing a growing number of modeling extensions with the sole purpose of coping with a specific MAS concern, such as mobility, security, and autonomy. However, each of these approaches addresses a specific concern by extending a modeling language.

In this context, this paper presents aspect-oriented enhancements of an agent-oriented modeling language, called ANote[3], in order to cope with crosscutting concerns and promote MAS designs with superior modularity. The enhancements blind aspectual abstractions [2] with fundamental agent-oriented design elements, such as agents, goals and actions. We introduce a new notation element, called *aspect*, and additional composition mechanisms to promote improved separation of MAS concerns. An aspect is a first-class, nameable entity that provides modular representation for a crosscutting concern and localizes both (a) the specification of (sets of) join points, and (b) the enhancements to be combined at the specified join points. The enhancements may add new structure and behavior to agents, goals and actions, refine or replace existing behavior.

The paper is organized as follows. Section 2 illustrates some crosscutting concerns in agent-oriented modeling in terms of an example. Section 3 presents our proposed enhancements to ANote, and presents an aspectual notation compliant to this language. Section 4 presents concluding remarks and future work.

2. CROSSCUTTING CONCERNS IN AGENT-ORIENTED MODELING

Figure 1 shows a partial design representation of a multi-agent system [4] specified with the ANote modeling language [3]. ANote defines modeling views that allow for the expression of a MAS design from different perspectives. For instance, it includes an agent view (Figure 1a), a goal view (Figure 1b), and a scenario view (Figure 1c), which are recurring perspectives in several modeling languages [1]. They support the representation of agents, actions, and goals respectively. Modeling agent systems often includes other system concerns and views, such as interaction and organizational, which have been omitted from Figure 1 due to space limitation and simplicity purposes.

The system modeled in Figure 1 is a multi-agent application that supports the management of the reviewing process for research conferences. This system will be herein referred to as Expert Committee (EC). The EC system encompasses three types of

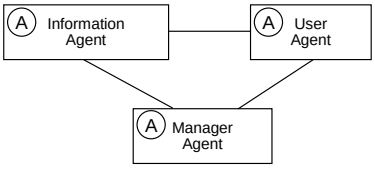
software agents (Figure 1a): (i) information agents, (ii) user agents, and (iii) the manager agent. Figures 1b and 1c illustrate some goals and actions associated with the information and user agents respectively. Information agents' goals are managing the system information that is mainly stored in a database, and providing information to the other system agents and users as requested. User agents are software assistants that represent system users in reviewing processes. Their basic functionalities are to infer and to keep information about the users' research interests and participations in scientific events.



We can notice in Figure 1 that there are some concerns which cannot be modularly represented across the design views. Learning and mobility are two examples of crosscutting concerns in the agent-oriented design of the EC system. The set of goals and actions, which are both part of and affected by these broadly-scoped concerns, are spread over the agent-oriented design. Each set of goals and actions for a specific crosscutting concern is surrounded by dotted rectangles in Figure 1. The mobility concern consists of goals that crosscut distinct goal hierarchies, and of actions intermingled with diverse scenarios.

The crosscutting manifestation leads to two major problems at the agent-oriented design level, the so-called scattering and tangling [10]. *Scattering* in agent-oriented models is the manifestation of design elements, which belong to one specific concern, over several modeling units referred to other MAS concerns. *Tangling* in agent-oriented models is the mix of multiple concerns together in the same modeling elements

Existing agent-oriented modeling abstractions and composition mechanisms are not aimed at supporting the isolate handling of crosscutting MAS concerns as exemplified in Figure 1. It brings in turn a number of substantial design pitfalls, such as: hindering of modular and compositional reasoning; replication of agent-oriented design elements; essential information loosing; and, reduced evolvability and reuse opportunities

3. AN ASPECT-ORIENTED NOTATION

This section describes our approach to support agent-oriented modeling enhanced with aspects. We show the use of our notation in the context of the ANote modeling language [3]. ANote has 7 diagrams divided into three packages. In this paper, we will focus on the structural package, which encompasses the Goal, Agent and Planning diagrams.

The goal view diagram presents the system goals, i.e. the agent goals (Figure 2). This diagram has been enhanced with an aspect-oriented notation to present how the goals of aspects influence the agent goals at well-defined join points. The extension of the goal view diagram notation has been based on and adapted from our aspect-oriented notation for object-oriented design proposed in [2]. An aspect is represented as a diamond. Some circles are attached to it. Each circle captures a way (interface) that an aspect crosscuts the agent goals.

Figure 2 shows that the Mobility aspect has an interface "IMobility" that introduces the goals "Move to Remote Host" and "Consult Remote DB" to the goals "Consult Research Agency DB" and "Consult External DB" of Information Agents. In this

case, the composition operation "introduce" (Table 1) is used to denote an aspect-agent crosscutting.

The agent view specifies the agent types that exist in a multi-agent application solution and their relationships. In ANote, an agent is the module that is able to perform actions. However, aspects also contain a number of actions that implement the crosscutting behaviors, thus becoming system modules. Figure 3 shows how the agent diagram has been enhanced with aspect-oriented notation. Here, the aspects are also represented as diamonds. The arrows represent the crosscutting relationship. We can see in Figure 3 that Information Agents and User Agents are influenced by the Learning aspect, while the Information Agent is also affected by the Mobility aspect.

The ANote dynamic package encompasses the scenario, interaction and planning diagrams that have also been enhanced with aspects, but for brevity reasons, are not presented here.

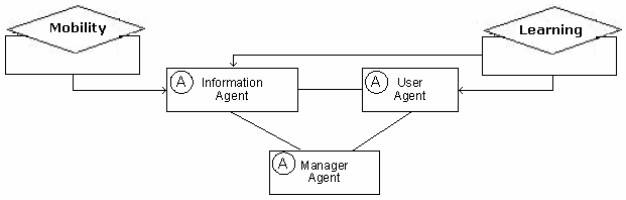

Figure 3. Aspect enhanced agent diagram.

4. CONCLUSIONS AND FUTURE WORK

This paper is a first attempt to systematically tame broadly-scoped concerns in agent-oriented design modeling. Many internal agent properties and systemic properties in the design of MAS are typically crosscutting, and they need to be handled as such. No matter what kind of decomposition and abstractions the agent-based software developers are relying on; there are always MAS concerns that crosscut the boundaries of other concerns. The lack of modularization support for crosscutting concerns generates undesirable burdens on agent-oriented design reuse and evolution.

This paper presented an aspect-oriented notation and integrated it into the ANote language. Our work is a first step towards enhancing agent-oriented models with aspects and we cannot guarantee that our set of diagrams is necessarily complete; more case studies are still necessary. Another issue is the behavioral modeling of agents, i.e. how to model crosscutting actions. We are currently working on enhancing the ANote planning view diagram to properly address other action-action composition categories.

ABSTRACT

In this paper, we identify some problems with current formalizations of conditional commitments, i.e. commitments to achieve a goal if some condition becomes true. We present a solution to these problems. We also formalize two types of communicative actions that can be used by an agent to request another agent to achieve a goal or perform an action provided that some condition becomes true. Our account is set within ECASL [9], a framework for modeling communicating agents based on the situation calculus.

1. INTRODUCTION

In recent years, the importance of agent communication in multiagent systems has been widely recognized. As a result, many researchers have developed communicative multiagent frameworks [3, 5, 7, 15, 18, 23, 25] and attempted to formalize various types of communicative actions in these frameworks. One important concept in these is the notion of *conditional commitment*. A conditional commitment is a commitment to achieve some goal if some condition becomes true (e.g. a commitment to ship some goods when payment of an agreed to amount arrives). Conditional requests are requests that seek to have the addressee acquire a conditional commitment. Any multiagent framework that deals with negotiation and cooperation ought to handle conditional commitments. Unfortunately, most definitions found in the literature (in [5, 28, 23, 1], for example) are inadequate: they either define conditional commitments as disjunctive goals, which makes the agents under-committed to the conditional goal, or define them as conjunctive goals, which renders the agent over-committed.

We will go over some examples to point out the problems associated with the disjunctive and the conjunctive accounts of conditional commitment. In these, we use the following modal operators: $\Diamond\phi$, i.e. ϕ eventually holds, Happens(α), i.e. the action α is performed next, ϕ Until ψ, i.e. eventually ψ becomes true, and as long as ψ is false, ϕ holds, and Before(ψ, ϕ), i.e. if ψ eventually becomes true, then ϕ becomes true before ψ does. The formal semantics of these operators are given in Section 2. In the following, we formulate these examples using internal/mental states semantics for communication acts, and use the terms 'intention' and 'commitment' interchangeably.

In the *disjunctive account*, a conditional commitment to achieve some goal provided that some condition holds is modeled as a commitment to achieve the goal if the condition holds, i.e. as a simple material implication. For example, consider an online marketplace domain. Suppose that there are two agents, a seller agent slr, and a buyer agent byr. If we use a disjunctive account, slr's conditional commitment to ship some goods to byr on the condition that byr pays can be modeled as follows:

$$\begin{aligned}&\text{CondInt}_{\text{dis}}(slr, GetPaid, \text{Happens}(shipGoods(slr, byr)))\\ &\doteq \text{Int}(slr, \neg\Diamond GetPaid \vee\\ &\qquad [\neg GetPaid \text{ Until}\\ &\qquad\quad (GetPaid \wedge \text{Happens}(shipGoods(slr, byr)))]).\end{aligned}$$

This says that slr's conditional commitment to ship the goods when byr pays amounts to slr having the intention that byr eventually pays and after that she ships the goods, if byr eventually pays (as mentioned earlier, the Until construct in the goal above implies that $\Diamond GetPaid$ and $\Diamond$-Happens($shipGoods(slr, byr)$)). One problem with this account of conditional intention is that there is a counter-intuitive way to satisfy the conditional intention, namely, the agent may commit to the triggering condition remaining false and deliberately perform some action that makes it remain false. Thus, in the example, to satisfy her conditional intention, slr may intentionally perform some action to stop byr from paying her, such as blocking debits from byr. In other words, there is nothing in this formalization of conditional intention that stops slr from intending not to

get paid and not to send the goods. However, this is counter-intuitive and a model of conditional commitment should not support this. Thus, with the disjunctive account of conditional commitment, the agent seems under-committed to the goal. Examples of accounts in the literature that formalize conditional commitments as disjunctive goals are [23] and [1].

In the *conjunctive account*, a conditional commitment to achieve a goal provided that a condition holds is modeled as a temporally ordered conjunctive commitment to the triggering condition and the conditional goal, where the triggering condition is achieved first. Although this model may seem appropriate in many cases, it often leads to problems. For example, suppose that *slr* has the conditional commitment to ship a replacement unit provided that *byr* reports and returns a defective good. If we use a conjunctive account, this can be modeled as follows:

$$\begin{aligned}&\text{CondInt}_{\text{con}}(slr, DefGoodRet,\\ &\qquad\qquad \text{Happens}(shipRepl(slr, byr))) \doteq\\ &\text{Int}(slr, \text{Before}(\text{Happens}(shipRepl(slr, byr)), DefGoodRet)\\ &\qquad \wedge \Diamond \text{Happens}(shipRepl(slr, byr))).\end{aligned}$$

This says that *slr*'s conditional commitment to ship a replacement unit provided that *byr* returns a defective good can be modeled as *slr*'s intention that *byr* returns a defective good before *slr* ships a replacement unit, and eventually *slr* ships a replacement unit. Note that, according to this definition, since *slr* has the intention that the defective product is returned before she ships the replacement unit, and that she eventually ships the replacement unit, it follows that *slr* has the intention that *byr* eventually returns a product, i.e. $\text{Int}(slr, \Diamond DefGoodRet)$. So *slr* may deliberately perform some action, such as shipping a defective good in the first place, to achieve this intention. Thus, the conjunctive account of conditional commitment results in over-committed agents. Both [5] and [28] formalize conditional commitments as conjunctive goals.

In this paper, we propose a solution to these problems (the *under/over-commitment problems*, henceforth). Our solution involves using an additional constraint with the disjunctive account to eliminate the under-commitment problem. We use the Extended Cognitive Agent Specification Language (ECASL) [9] as our base formalism for this. Our account is formulated for internal/mental states semantics for communication acts. Nevertheless, the same issues arise for public/social-commitment semantics (as discussed in Section 5). Once again, in this paper, we will use the terms 'intention' and 'commitment' interchangeably.

Using our definition of conditional intention, we then prove that a conditional intention becomes an ordinary intention when the associated condition is true, and that agents correctly introspect about their conditional intentions. We also formalize two types of communicative actions that can be used by an agent to request another agent to achieve a goal or perform an action provided that some confdition becomes true. Then we prove that performing such a conditional request leads to a conditional intention under the right conditions.

The paper is organized as follows: in the next section, we outline the ECASL framework. In Section 3, we present our model of conditional commitment and discuss some of its properties. In Section 4, we present some communicative acts that allow agents to make requests that result in conditional commitments. In Section 5, we compare our approach to previous work on conditional commitments. Finally in Section 6, we summarize our results and discuss possible future work.

2. ECASL

The Extended Cognitive Agent Specification Language (ECASL) [9], an extension of CASL [22, 24], is a framework for specifying and verifying complex communicating multi-agent systems that incorporates a formal model of means-ends reasoning. In this section, we outline the part of ECASL that is needed for our formalization of conditional commitment.

In ECASL, agents are viewed as entities with mental states, i.e., knowledge and goals, and the specifier can define the behavior of the agents in terms of these mental states. ECASL combines a declarative action theory defined in the situation calculus with a rich programming/process language, ConGolog [4]. Domain dynamics and agents' mental states are specified declaratively in the theory, while the agents' behavior is specified procedurally in ConGolog.

In ECASL, a dynamic domain is represented using an action theory [17] formulated in the situation calculus [12], a (mostly) first order language for representing dynamically changing worlds in which all changes are the result of named actions. ECASL uses a theory D that includes the following set of axioms:

- action precondition axioms, one per action a characterizing $Poss(a, s)$,
- successor state axioms (SSA), one per fluent, that encode both effect and frame axioms and specify exactly when the fluent changes [16],
- initial state axioms describing what is true initially including the mental states of the agents,
- axioms identifying the agent of each action,
- unique name axioms for actions, and
- domain-independent foundational axioms describing the structure of situations [10].

Within ECASL, the behavior of agents is specified using the notation of the logic programming language ConGolog [4], the concurrent version of Golog [11]. A typical ConGolog program is composed of a sequence of procedure declarations, followed by a complex action. Complex actions can be composed using constructs that include primitive actions, waiting for a condition, sequence, nondeterministic branch, nondeterministic choice of arguments, conditional branching, while loop, procedure call, nondeterministic iteration, concurrent execution with and without priorities, and interrupts. To deal with multiagent processes, primitive actions in ECASL take the agent of the action as argument.

The semantics of the ConGolog process description language is defined in terms of *transitions*, in the style of structural operational semantics [14]. The overall semantics of a program is specified by the *Do* relation:

$$Do(\delta, s, s') \doteq \exists \delta' \cdot (Trans^*(\delta, s, \delta', s') \wedge Final(\delta', s')).$$

$Do(\delta, s, s')$ holds if and only if s' can be reached by performing a sequence of transitions starting with program δ in s, and the remaining program δ' may legally terminate

in s'. Here, $Trans^*$ is the reflexive transitive closure of the transition relation $Trans$.[1]

The situation calculus underlying ECASL is a branching time temporal logic, where each situation has a linear past and a branching future. In the framework, one can write both state formulas and path formulas. A state formula $\phi(s)$ takes a single situation as argument and is evaluated with respect to that situation. On the other hand, a path formula $\psi(s_1, s_2)$ takes two situations as arguments and is evaluated with respect to the interval (finite path) $[s_1, s_2]$. A state formula ϕ may contain a placeholder constant *now* that stands for the situation in which ϕ must hold. $\phi(s)$ is the formula that results from replacing *now* by s. Similarly, a path formula ψ may contain the placeholder constants *now* and *then* that stand for the situations that are the endpoints of the interval $[now, then]$ over which ψ must hold. $\psi(s_1, s_2)$ denotes ψ with s_1 substituted for *now* and s_2 substituted for *then*. Where the intended meaning is clear, we sometimes suppress the placeholder(s).

ECASL allows the specifier to model agents in terms of their mental states by including operators to specify agents' information (i.e., their knowledge), and motivation (i.e., their goals or intentions). We use state formulas within the scope of knowledge, and path formulas within the scope of intentions. Following [13, 20], ECASL models knowledge using a possible worlds account adapted to the situation calculus. $K(agt, s', s)$ is used to denote that in situation s, *agt* thinks that she could be in situation s'. s' is called a *K-alternative situation* for *agt* in s. Using K, the knowledge or belief of an agent, $\text{Know}(agt, \phi, s)$, is defined as $\forall s'(K(agt, s', s) \supset \phi(s'))$, i.e. *agt* knows ϕ in s if ϕ holds in all of *agt*'s K-accessible situations in s. In ECASL, K is constrained to be reflexive, transitive, and Euclidean in the initial situation to capture the fact that agents' knowledge is true, and that agents have positive and negative introspection. As shown in [20], these constraints then continue to hold after any sequence of actions since they are preserved by the successor state axiom for K.

ECASL supports knowledge expansion as a result of sensing actions [20] and some *informing* communicative actions. Here, we restrict our discussion to knowledge expansion as a result of *inform* actions. The preconditions of *inform* are as follows:

$$Poss(inform(inf, agt, \phi), s) \equiv \text{Know}(inf, \phi, s) \\ \wedge \neg\text{Know}(inf, \text{Know}(agt, \phi, now), s).$$

In other words, the agent *inf* can inform *agt* that ϕ, iff *inf* knows that ϕ currently holds, and does not believe that *agt* currently knows that ϕ. The successor state axiom (SSA) for K can be defined as follows:

$$K(agt, s^*, do(a, s)) \equiv \\ \exists s'.\ K(agt, s', s) \wedge s^* = do(a, s') \wedge Poss(a, s').$$

This says that after an action happens, every agent learns that it was possible and has happened. Moreover, if the action involves someone informing *agt* that ϕ holds, then *agt* knows this afterwards. This follows from the fact that it is a precondition of $inform(inf, agt, \phi)$ that *inf* knows that ϕ, that what is known must be true (i.e. K is reflexive), and that the SSA for K requires the agent to know that $Poss(a, s)$ after a happens in s. Note that this axiom only handles knowledge expansion, not revision.

ECASL also incorporates goal expansion and a limited form of goal contraction. Goals or intentions are modeled using an accessibility relation W over possible situations. The W-accessible situations for an agent are the ones where she thinks that all her goals are satisfied. W-accessible situations may include situations that the agent thinks are impossible (i.e. that do not have a predecessor that is K-related to the current situation), unlike Cohen and Levesque's [2] G-accessible worlds. But intentions are defined in terms of the more primitive W and K relations so that the intention accessible situations are W-accessible situations that are also compatible with what the agent knows, in the sense that there is a K-accessible situation in their history. This guarantees that agents' intentions are realistic, that is, agents can only intend things that they believe are possible. Thus we have:

$$\text{Int}(agt, \psi, s) \doteq \forall s', s^*. \\ [W(agt, s^*, s) \wedge K(agt, s', s) \wedge s' \leq s^*] \supset \psi(s', s^*).$$

This means that the intentions of an agent in s are those formulas that are true for all intervals between situations s' and s^* where the situations s^* are W-accessible from s and have a K-accessible situation s' in their past. Intentions are future oriented, and any goal formula will be evaluated with respect to a finite path defined by a pair of situations, a current situation *now* and an ending situation *then*. This formalization of goals can deal with both achievement goals and maintenance goals. An achievement goal ϕ is said to be eventually satisfied if ϕ holds in some situation between *now* and *then*, i.e., if $\Diamond(\phi, now, then)$, which is defined as $\exists s'.\ (now \leq s' \leq then \wedge \phi(s'))$.[2] In [21], Shapiro showed how positive and negative introspection of intentions can be modeled by placing some constraints on K and W. To make sure that agents' wishes and intentions are consistent, W is also constrained to be serial.

ECASL provides an intention transfer communication action, *request*, which is defined in terms of *inform*. This is somewhat similar to Herzig and Longin's account [7], where a request is defined as informing about one's intentions, and the requested goals are adopted via cooperation principles. The *request* action can be used by an agent to request another agent to achieve some state of affairs. Formally, we have:

$$request(req, agt, \phi) \doteq inform(req, agt, \text{Int}(req, \phi, now)).$$

The SSA for W which handles intention change in ECASL, has the same structure as a SSA for a domain dependent fluent. In the following, $W^+(agt, a, s^*, s)$ ($W^-(agt, a, s^*, s)$, resp.) denotes the conditions under which s^* is added to (dropped from, resp.) W as a result of the action a in s:

$$W(agt, s^*, do(a, s)) \equiv W^+(agt, a, s^*, s) \vee \\ (W(agt, s^*, s) \wedge \neg W^-(agt, a, s^*, s)).$$

An agent's intentions are expanded when it is requested

[1]Since we have predicates that take programs as arguments, we need to encode programs and formulas as first-order terms as in [4]. For notational simplicity, we suppress this encoding and use formulas and programs as terms directly.

[2]We sometimes use $\Diamond$ with a path formula ψ argument, in which case, we mean that ψ holds over some interval $[s, then]$ that starts at some situation s between *now* and *then*; see Table 1 for the formal definition.

something by another agent. After the $request(req, agt, \psi)$ action, *agt* adopts the goal that ψ, unless she has a conflicting goal or is not willing to serve *req* for ψ. Therefore, this action should cause *agt* to drop any paths in W where ψ does not hold. This is handled in W^-:

$$\begin{aligned} &W^-(agt, a, s^*, s) \doteq \\ &\quad [\exists req, \psi.\ a = request(req, agt, \psi) \\ &\quad \wedge Serves(agt, req, \psi, s) \wedge \neg \mathrm{Int}(agt, \neg\psi, s) \\ &\quad \wedge \exists s'.\ K(agt, s', s) \wedge s' \leq s^* \wedge \neg\psi(do(a, s'), s^*)]. \end{aligned}$$

A limited form of intention contraction is also handled in ECASL. Agents intentions are contracted as a result of a *cancelRequest* action. ECASL also incorporates a formal model of means-ends reasoning and commitment to rational plans to achieve intentions. See [9] for the details of these.

Table 1 shows some abbreviations that will be used throughout the paper.

Table 1: Some Definitions of Temporal Operators

1. $\Diamond(\psi, now, then) \doteq \exists s'.\ now \leq s' \leq then \wedge \psi(s', then)$,
2. $\Box(\psi, now, then) \doteq \neg\Diamond(\neg\psi, now, then)$,
3. $[\phi \text{ Until } \psi](now, then) \doteq \exists s'.\ now \leq s' \leq then \wedge \psi(s', then) \wedge \forall s''.\ now \leq s'' < s' \supset \phi(s'')$,
4. $\mathrm{Before}(\psi, \phi, now, then) \doteq \exists s'.\ now \leq s' \leq then \wedge \psi(s', then) \supset \exists s''.\ now \leq s'' < s' \wedge \phi(s'')$,
5. $\mathrm{E}_\Diamond(\phi, now) \doteq \exists s.\ now \leq s \wedge \phi(s)$,
6. $\mathrm{A}_\Box(\phi, now) \doteq \neg\mathrm{E}_\Diamond(\neg\phi, now)$,
7. $\mathrm{Happens}(a, now, then) \doteq do(a, now) \leq then$,
8. $\mathrm{Happens}_G(\delta, now, then) \doteq \exists s'.\ s' \leq then \wedge Do(\delta, s', then)$.

3. CONDITIONAL COMMITMENTS

Having presented our framework, we now return to our discussion about conditional commitments. Informally, an agent *agt* has a conditional commitment or intention that ψ on the condition that ϕ if *agt* intends to achieve ψ as soon as the condition ϕ holds. In our specification, we assume that ϕ is a state formula, whereas ψ is a path formula and can represent any kind of goal (achievement, maintenance, etc.). In other words, the trigger condition ϕ of a conditional intention takes a single situation *now* as argument, unlike the goal formula ψ, which takes two situations *now* and *then* as arguments.[3] If one wishes to use an achievement goal ϕ' for ψ, one can use $\Diamond(\phi', now, then)$, i.e. eventually ϕ'.

So we now propose a formalization of conditional intentions that avoids the under/over-commitment problem:

$$\begin{aligned} &\mathrm{CondInt}(agt, \phi, \psi, s) \doteq \\ &\quad \mathrm{Int}(agt, DisjGoal(\phi, \psi, now, then) \\ &\qquad \wedge NoUnderComm(agt, \phi, now, then), s), \\ &DisjGoal(\phi, \psi, now, then) \doteq \\ &\quad [\neg\phi \text{ Until } (\phi \wedge \psi)](now, then) \vee \neg\Diamond(\phi, now, then), \\ &NoUnderComm(agt, \phi, now, then) \doteq \\ &\quad \Box([\mathrm{Int}(agt, \Box(\neg\phi, now, then), now) \supset \\ &\qquad \mathrm{Know}(agt, \mathrm{A}_\Box(\neg\phi, now), now)], now, then). \end{aligned}$$

That is, *agt* conditionally intends that ψ provided that ϕ, iff *agt* intends that the following conditions hold:

1. either (*a*) ϕ eventually holds, and ψ holds immediately from the time ϕ comes to hold, or (*b*) ϕ never holds, and
2. if in any situation *agt* intends that ϕ never comes to hold, she must also know in that situation that it can never become true.

Intuitively, this says that one way to fulfill an agent's conditional intention is to (1*a*) satisfy ψ after ϕ comes to hold, and a second way is that (1*b*) ϕ never comes to hold in the future. This part of our account is as in the disjunctive approach. However, we add to this that (2) the agent does not intend that ϕ never comes to hold unless she knows that it can never hold. Thus we require that if at some situation, *agt* intends that ϕ never comes true, it must be the case that she knows in that situation that ϕ can never become true, and she only intends this because it has become inevitable. So the additional constraint that $NoUnderComm(agt, \phi, now, then)$ ensures that *agt* will not do anything intentionally to make the triggering condition ϕ remain false. One might be tempted to define $NoUnderComm(agt, \phi, now, then)$ as $\Box(\neg\mathrm{Int}(agt, \Box(\neg\phi, now, then), now), now, then)$, i.e. *agt* never intends that ϕ never holds. However, since some event may make ϕ impossible to achieve, there is a possibility that *agt* may come to intend that ϕ always be false, if this becomes inevitable. The only case in which *agt* intends that ϕ always be false is when she knows that it can never become true.

Consider once again our online marketplace example given in Section 1 for the disjunctive account. Using this definition of conditional commitment, a seller *slr*'s intention to send the goods when a buyer *byr* pays, $\mathrm{CondInt}(slr, GetPaid(byr, slr), \mathrm{Happens}(shipGoods(slr, byr), now, then), s)$ can be formalized as follows:

$$\begin{aligned} &\mathrm{Int}(slr, DisjGoal(GetPaid(byr, slr), \\ &\qquad \mathrm{Happens}(shipGoods(slr, byr), now, then), \\ &\quad now, then) \\ &\wedge NoUnderComm(slr, GetPaid(byr, slr), now, then), s). \end{aligned}$$

slr's intention can be further expanded to:

$$\begin{aligned} &\mathrm{Int}(slr, [GetPaidAndThenSendGoods(byr, slr, now, then) \\ &\qquad \vee \neg\Diamond(GetPaid(byr, slr), now, then)] \wedge \\ &\quad [\Box((\mathrm{Int}(slr, \Box\neg GetPaid(byr, slr), now) \supset \\ &\qquad \mathrm{Know}(slr, \mathrm{A}_\Box(\neg GetPaid(byr, slr), now), now)), \\ &\quad now, then)], s), \end{aligned}$$

[3] We could also handle trigger conditions that are not state formulas. However, in these cases, since the trigger condition holds over a time interval, it is not always clear when exactly the triggering of the commitment to the conditional goal should occur. To avoid these complications, we stick to state formulas as triggers.

where,

$$GetPaidAndThenSendGoods(byr, slr, now, then) \doteq$$
$$[\neg GetPaid(byr, slr) \text{ Until}$$
$$(GetPaid(byr, slr) \wedge$$
$$\text{Happens}(shipGoods(slr, byr), now, then))]$$
$$(now, then).$$

From this, we can see that there are only two ways by which *slr* can satisfy this conditional intention: either at some future or current situation *byr* pays *slr* and then *slr* sends the goods to *byr*, or, *byr* never pays *slr*, and as long as *slr* does not know that *byr* will never pay her, she does not intend not to get paid. Since *slr* cannot intend not to get paid, she cannot deliberately perform anything (for example block payments from *byr*) to make the triggering condition remain false. If at a later situation, *slr* learns that it has become impossible for *byr* to ever pay her, *slr* will inevitably intend that *byr* never pays her, but otherwise she cannot acquire this intention. Thus, our formalization of conditional commitment does not suffer from the under-commitment problem.

Moreover, since we use the disjunctive approach, our account does not suffer from the over-commitment problem associated with the conjunctive approach. Consider the second example given in Section 1, where *slr* has the intention to ship a replacement unit when *byr* returns a defective good. Using our definition, this can be expanded to *slr*'s intention that either *byr* never returns a defective product, or *byr* returns a defective product and *slr* ships the replacement unit after that. Thus *slr* is not over-committed and will not perform something deliberately so that *byr* returns a product. The additional constraint that *slr* never intends that *byr* never return a product unless she knows that *byr* will never return a product does not lead to any over-commitment. Thus our formalization of conditional intention is also free from the over-commitment problem.

Note that our account allows the agent who has a conditional intention to intend not to know whether the condition holds. We could easily strengthen the definition to rule this out, but it is not clear that this is always appropriate.

Next, we show two simple properties of conditional intention. Assume that the domain theory D (as discussed in Section 2) includes our definition of conditional commitment given above. Then we have the following theorem that says that if an agent *agt* conditionally intends that ψ provided that ϕ in situation s, and if she knows that ϕ holds in s, then *agt* intends that ψ in s.

THEOREM 1.

$$D \models \text{CondInt}(agt, \phi, \psi, s) \wedge \text{Know}(agt, \phi, s) \supset$$
$$\text{Int}(agt, \psi, s).$$

So when the agent knows that the condition has become true, a conditional intention reduces to an ordinary intention. The second property states that agents are able to introspect their conditional intentions:

THEOREM 2.

$$D \models [\text{CondInt}(agt, \phi, \psi, s) \supset$$
$$\text{Know}(agt, \text{CondInt}(agt, \phi, \psi, now), s)] \wedge$$
$$[\neg\text{CondInt}(agt, \phi, \psi, s) \supset$$
$$\text{Know}(agt, \neg\text{CondInt}(agt, \phi, \psi, now), s)].$$

Thus, if an agent has a conditional intention (does not have a conditional intention, resp.) that ψ provided that ϕ, then she knows that she has (does not have, resp.) this conditional intention.

It would be interesting to prove additional results about conditional intentions, for instance, that a conditional intention persists as long as its condition is known to remain false and not known to have become impossible. We leave this for future work.

4. CONDITIONAL REQUESTS

We now discuss two communicative acts, *requestWhen* and *reqActWhen*, that can be used by an agent to request someone to achieve ψ or to execute a program δ respectively, on the condition that ϕ becomes true. Recall that, in ECASL the SSA for W determines whether an agent adopts a goal when requested; the requested goal is adopted by the requestee via cooperation principles encoded in the SSA for W. Thus, we model requests as informing about intentions, rather than as primitives. In the following, we use $CondIntCont(agt, \phi, \psi)$ as an abbreviation for the content of a conditional intention $DisjGoal(\phi, \psi, now, then) \wedge NoUnderComm(agt, \phi, now, then)$. Now, one simple way to model a requester *req*'s request to requestee *agt* to achieve ψ on the condition that ϕ is as follows:

$$requestWhen_{sim}(req, agt, \phi, \psi) \doteq$$
$$request(req, agt, CondIntCont(req, \phi, \psi)).$$

This says that, *req*'s conditional request to *agt* to achieve ψ provided that ϕ amounts to *req*'s request to *agt* to fulfill the content $CondIntCont(req, \phi, \psi)$ of her own conditional intention. Using the definition of *request*, this conditional request amounts to *req* informing *agt* that she currently intends to achieve ψ provided that ϕ. However, note that the content $CondIntCont(req, \phi, \psi)$ of this conditional intention includes mental attitudes that refer to *req*, rather than *agt*. Since the SSA for W does not automatically replace the agent parameters of mental state operators used in a goal formula, if we model conditional requests as above, given appropriate conditions (i.e., when *agt* agrees to serve *req* on $CondIntCont(req, \phi, \psi)$ and does not currently have the intention that $\neg CondIntCont(req, \phi, \psi)$), *agt* will adopt the intention that $CondIntCont(req, \phi, \psi)$, but not that $CondIntCont(agt, \phi, \psi)$. Thus she will not have the conditional intention to achieve ψ provided that ϕ after the conditional request is performed, and this simple definition is not quite correct.

For example, suppose that the manager agent *mgr* wants to conditionally request the seller *slr* in situation s to ship the goods when the buyer *byr* pays her. So *mgr* can do this by performing the following action in s:

$$requestWhen_{sim}(mgr, slr, GetPaid(byr, slr),$$
$$\text{Happens}(shipGoods(slr, byr), now, then)),$$

which can be expanded to:

$$request(mgr, slr,$$
$$CondIntCont(mgr, GetPaid(byr, slr),$$
$$\text{Happens}(shipGoods(slr, byr), now, then))).$$

After the request is performed, if *slr* agrees to serve *mgr* on $CondIntCont(mgr, GetPaid(byr, slr)$, Happens (*ship-*

$Goods(slr, byr), now, then))$, and does not intend that $\neg CondIntCont(mgr, GetPaid(byr, slr), \text{Happens}(shipGoods(slr, byr), now, then))$, the SSA for W will ensure that:

$$\text{Int}(slr, CondIntCont(mgr, GetPaid(byr, slr), \text{Happens}(shipGoods(slr, byr), now, then)), s_r),$$

which can be expanded to:

$$\text{Int}(slr, DisjGoal(GetPaid(byr, slr), \text{Happens}(shipGoods(slr, byr), now, then), now, then) \wedge NoUnderComm(mgr, GetPaid(byr, slr), now, then), s_r),$$

where s_r is the situation that results from performing the $requestWhen$ action in s. Now, using the definition of conditional intention, we can see that in s_r, slr does not have the conditional intention of sending the goods provided that byr pays her. The problem is with the mental state operators in the $NoUnderComm(mgr, \ldots)$ part of slr's intention: they say that mgr will not intend that the payment not occur unless she knows it can never occur. What we need is for this constraint to hold for slr.

To deal with this problem, we propose the following model of conditional requests:

$$requestWhen(req, agt, \phi, \psi) \doteq request(req, agt, CondIntCont(agt, \phi, \psi)).$$

This says that req's request to agt to conditionally achieve ψ provided that ϕ amounts to req's request to agt to fulfill the content of agt's conditional intention to achieve ψ provided that ϕ, i.e., $CondIntCont(agt, \phi, \psi)$. Using the definition of *request*, this can be further expanded to:

$$requestWhen(req, agt, \phi, \psi) \doteq inform(req, agt, \text{Int}(req, CondIntCont(agt, \phi, \psi), now)).$$

That is, req can request agt to achieve ψ on the condition that ϕ by informing agt that she intends that $CondIntCont(agt, \phi, \psi)$. Note that, the agent parameter of $CondIntCont(agt, \phi, \psi)$ is now the requestee agt, rather than the requester req. This guarantees that given that agt serves req and does not have the opposite intention, she will conditionally intend to achieve ψ provided that ϕ after req conditionally requests her this. Thus this formalization of conditional request does not suffer from the above mentioned problem.

We also define a special type of conditional request, namely, a request to perform an action when some condition holds:

$$reqActWhen(req, agt, \phi, \delta) \doteq requestWhen(req, agt, \phi, Happens_C(\delta, now, then)).$$

This states that req's conditional request to agt to execute the program δ provided that ϕ amounts to req's conditional request to agt to execute δ starting in the situation where ϕ holds.

Now consider what happens when mgr conditionally requests slr to ship the goods when byr pays her, that is, when mgr performs the $reqActWhen(mgr, slr, GetPaid(byr, slr), shipGoods(slr, byr))$ action. Given that slr agrees to serve mgr and does not have the opposite intention, the SSA for W will make slr adopt the following intention:

$$\text{Int}(slr, CondIntCont(slr, GetPaid(byr, slr), \text{Happen}_C(sendGoods(slr, byr), when, then)), s_r),$$

and thus, by the definition of conditional intention, she will conditionally intend to send the goods when byr pays her. Thus, our formalization of conditional requests allows the proper transfer of conditional intention from the requester to the requestee.

We next present a theorem that shows how agents' intentions are affected by the *requestWhen* action. Assume that the domain theory D includes our definition of these new communicative actions. We can show that:

THEOREM 3.

$$D \models [\neg\text{Int}(agt, \neg CondIntCont(agt, \phi, \psi), s) \wedge Serves(agt, req, CondIntCont(agt, \phi, \psi), s) \wedge Poss(requestWhen(req, agt, \phi, \psi), s)] \supset \text{CondInt}(agt, \phi, \psi, do(requestWhen(req, agt, \phi, \psi), s)).$$

This says that if in some situation s, an agent agt does not intend not to fulfill the content of a conditional intention to achieve ψ provided that ϕ, and if she serves another agent req on the content of this conditional commitment in s, then she will have the conditional intention to achieve ψ given that ϕ after req conditionally request her this in s, provided that the request is possible in s.

It would be useful to extend our framework with a communication act that allows a conditional commitment created as a result of a *requestWhen* to be cancelled. We believe that the existing ECASL *cancelRequest* action can be used to define such a conditional commitment cancelling act. We leave this for future work.

5. RELATED WORK

The under-commitment problem that we pointed out in Section 1 is related to another problem involving intentions discussed by Cohen and Levesque [2]. In that paper, they consider a robot who drops the intention of bringing a bottle of beer by breaking the last available bottle and thus making the intention impossible to achieve. Their solution was twofold: (1) they formalize intentions as persistent goals and (2) they assume that existing intentions act as a screen of admissibility over new intentions. In their framework, an agent's intentions persist until she knows that they have been achieved, or knows that it has become impossible to achieve them. Since the robot intends to bring a bottle of beer, she will not drop this goal until she achieves it or gets to know that it has become impossible to achieve. However, the robot can break the last available bottle to make her goal unachievable. But since an agent's current intentions provide a screen of admissibility for adopting new intentions, she cannot have these two conflicting intentions at the same time. Thus since she intends to bring a bottle, she cannot adopt the intention to break the only available bottle. Note that while this problem has similarities with the one addressed here, it does not involve conditional intentions.

In the literature, there has been some work on conditional intention. However, as mentioned earlier, all of the proposed treatments that we are aware of seem to suffer from the under- or over-commitment problems. Although it does not explictly address conditional intentions, the FIPA agent communication language specification [5] defines a type of communication act that leads to conditional intentions. In that framework, an agent can conditionally request another agent to execute an action when some condition holds. This

is modeled as follows: req's conditional request to agt to perform act when ϕ holds amounts to req informing agt that she has the intention that agt execute act and that ϕ be true just before that. Note that req's intention amounts to the conjunction that ϕ be true at some point and agt executes act right after that. Thus, this treatment of conditional intention can be viewed as a conjunctive account where the intention is to first achieve the triggering condition ϕ, and then to achieve the conditional goal. As discussed in Section 1, this leads to the over-commitment problem.

Yolum and Singh [28] present a different model of conditional commitment that relies on a social obligation-based semantics rather than a traditional one based on mental states. Their main concern was the study of communication protocols that accommodate exceptions and take advantage of opportunities. They model interaction protocols using *commitment machines* that supply a content to protocol states and actions in terms of the social commitments of the participating agents. In their formal semantics, which is only briefly described, they adopt a branching time temporal model. The semantics for commitments involves a modal accessibility relation for commitments C that relates a state of the protocol (i.e. a time-point) s, a debtor agent x, and a creditor agent y to a set of paths P. Intuitively, x is responsible to y for satisfying ϕ in state s iff ϕ holds at time-point s along all paths p that are C-accessible from (x, y, s). To model conditional commitment, they introduce a strict implication operator (denoted by $\rightsquigarrow$) that requires the consequent to hold when the antecedent holds. The strict implication is false when the antecedent is false. Their semantics says that $\phi \rightsquigarrow \phi'$ holds in a state s iff ϕ holds in s and for all s' that satisfy ϕ, every s'' that is similar to s' (i.e. $s'' \approx s'$) also satisfies ϕ'. What they mean by the similarity relation $\approx$ is not explained. Thus for them, a conditional commitment $C(x, y, \phi \rightsquigarrow \phi')$ holds in state s iff on all C-accessible paths p, ϕ holds at s, and whenever some s' satisfies ϕ, every s'' that is similar to s' satisfies ϕ'. Since they model conditional commitments using the $\rightsquigarrow$ operator, which behaves like a conjunction with some additional constraints, it appears that their formalization suffers from the over-commitment problem. It is also not clear how their formalization ensures that the goal is achieved *after* the condition along the paths.

Both [1] and [23] model conditional commitment as a disjunctive goal. In their social commitment and argument network based framework, Bentahar et al. [1] define conditional commitments as a simple implication. Their semantics of conditional commitment goes as follows: $M, s \models \text{CondInt}_{Ben}(agt_1, agt_2, \phi, \psi)$ iff $M, s \models \text{EF}^+\phi \Rightarrow M, s \models \text{ABC}(agt_1, agt_2, \psi)$, where s, E, F^+, and ABC denotes a time-point, there exists a path, sometime in the future, and absolute commitment, respectively. This says that agt_1 is committed to agt_2 to achieve ψ on the condition that ϕ means that agt_1 is unconditionally committed to agt_2 to achieve ψ if ϕ holds at some timepoint over some path in the future. Besides suffering from the under-commitment problem associated with disjunctive accounts, this seems to require commitment to the goal too early, before the condition becomes true.

In [23], Shapiro et al. describe a framework for specifying communicative multiagent systems using ConGolog [4] within the situation calculus, an early version of CASL. Since they were lacking a goal-revision mechanism at that point, they introduced a type of conditional request, the *requestUnless* action, in an attempt to avoid the need for goal-revision. $requestUnless(req, agt, \phi, \psi)$ means that req is requesting agt to adopt the goal that ψ unless ϕ is obtained. The execution of $requestUnless(req, agt, \phi, \psi)$ makes agt adopt the goal that $\phi \vee \psi$. This amounts to modeling conditional intentions as disjunctive goals, and hence the account suffers from the under-commitment problem.

6. CONCLUSION

In this paper, we identified some problems with many existing formalizations of conditional commitments. These seem to either have the agents over-committed, intending to achieve the condition under which the goal would have to be achieved, or under-committed, possibly intending that this condition remain false forever. We could not find any problem-free account in the literature. We presented a definition of conditional intentions that does not suffer from these problems. We then formalized two types of communicative actions that allow agents to make requests that lead to conditional commitments. We also proved some properties of conditional commitments and conditional requests. Finally, we discussed previous work on conditional commitments.

Note that, our framework allows an agent with a conditional intention to not intend that the trigger condition eventually becomes true. However, it does not allow her to intend that the trigger condition never comes to hold, without also knowing that it can never become true. In other words, in our framework, an agent's conditional intention that ψ provided that ϕ is not consistent with her intention that $\Box\neg\phi$, unless she already knows that this must be the case. This might be problematic in some cases. For instance, in our example where a seller has a conditional intention to ship a replacement unit when a buyer returns a defective product, we might want to say that the seller has the intention that the buyer never returns a defective good. However, it is not possible for an agent to consistently have both of these intentions in our framework. One way to overcome this limitation might be to adopt a richer semantic model of intention, where one allows different degrees of preferability, similar to the levels of plausibility in traditional belief revision frameworks such as [6]. Such semantic models and the resulting logics are more expressive, but much more complex to specify and reason in.

The theory presented here is a part of our ongoing research on the semantics of speech acts and agent communication in the situation calculus. In [8], we present an extended version of this work where we model some simple communication protocols that deal with conditional requests. Much work remains. In the future, we would like to prove other properties of conditional commitments, for example, about the persistence and revision of such commitments. We also plan to formalize complex interaction protocols, such as the Contract Net protocol [27] and the Net Bill protocol [26], using our formalization of conditional intention. It would also be interesting to try to use this formalization to implement flexible communication agents as in [19] and to develop tools to support multiagent programming.

Contextualizing Commitment Protocols*

ABSTRACT

Commitment protocols are modularized specifications of interactions understood in terms of commitments. Purchase is a classic example of a protocol. Although a typical protocol would capture the essence of the interactions desired, in practice, it should be adapted depending on the circumstances or *context* and the agents' preferences based on that context. For example, when applying purchase in different contexts, it may help to allow sending reminders for payments or returning goods to obtain a refund. We *contextualize* a protocol by adapting it via different transformations.

Our contributions are the following: (1) a protocol is transformed by composing its specification with a transformer specification; (2) contextualization is characterized operationally by relating the original and transformed protocols; and (3) contextualization is related to protocol compliance.

Categories and Subject Descriptors

I.2.11 [**Distributed Artificial Intelligence**]: Multiagent Systems

1. INTRODUCTION

This paper studies commitment protocols (for short, "protocols"), which are modularized interactions characterized in terms of the commitments among the interacting agents. Protocols are key in designing multiagent systems, such as for implementing business processes. Protocols would be composed and instantiated to realize such systems. Protocols geared for business applications are increasingly being standardized and published, although existing approaches do not offer a formal semantics.

Although protocols are modular and reusable, one size does not fit all. Consider a business example such as a purchase protocol. A basic purchase protocol would capture the essence of how agents should interact to effect a purchase. However, it might not be able to accommodate the many variations needed to handle all the different contexts in which it might be applied. The correct interactions might depend upon the *context* where it is applied: the social or trust relationships between the agents (would the seller insist on advance payment?), the goods being sold (do they need a prescription?), the geographic location (is it legal to sell Schedule C pharmaceuticals without a prescription?), legal considerations (should the seller verify the buyer's age?), and so on. Further variations of context might be inherited from the rules of an electronic marketplace (the Uniform Commercial Code in the US [8]) or a business culture, e.g., can goods be returned for a refund with no questions asked or can goods be returned if they are faulty, and so on. A merchant that knows how to participate in a basic purchase protocol would need to interact differently in each of the above cases.

Developing protocols from scratch for each of the possible contexts would be a difficult undertaking, tedious and error prone at best. This paper proposes an approach wherein protocols are generated by taking an existing protocol and transforming it. To this end, protocols and *transformers* are specified formally and declaratively. Ideally, each transformer is designed for a particular aspect of context. For example, one transformer might accommodate reminders; another might accommodate returns and refunds. In this way, the task of engineering protocols is greatly simplified.

The main contributions of this paper include the following: (1) specifying protocols and transformers formally and independently of each other, (2) formally characterizing transformations based on how they modify a protocol, and (3) determining an agent's compliance with a protocol that takes transformations into account.

This paper advances our program of research that treats interaction as a key abstraction for multiagent systems and treats protocols—as abstractions of interaction—as first-class citizens in contrast to object classes. Modeling protocols enables sophisticated management of interactions and of associated representations such as commitments. Architecturally, an emphasis on interactions is essential for open systems, because openness arises from making the end points dynamically changeable. A system being designed is guaranteed to be open when the interactions among its participants are reified, and the participants are described not as specific entities but in terms of the roles they play in those interactions.

Organization. The rest of the document is organized as follows. Section 2 presents a purchase protocol which serves as our running example. Section 3 develops a language for specifying protocols and a computational model for them. Section 4 presents contexts and transformers relevant to our running example. Section 5 semantically characterizes transformations and defines compliance. Section 6 discusses some key literature and directions.

2. RUNNING EXAMPLE

This paper uses purchase as a running example. This section

describes its "base" variant next. Figure 1 shows the base protocol in an informal graphical notation formalized later.

Commitments provide meaning to agent interaction. During the execution of a protocol, agents enter into, modify, and satisfy commitments. A commitment *C(x, y, p)* binds a debtor *x* to a creditor *y* for fulfilling the condition *p*. A conditional commitment *CC(x, y, p, q)* denotes that if condition *p* is brought about, then the commitment *C(x, y, q)* will hold. Following Singh [6], we use the following operations for the creation and manipulation of commitments: *create*, *discharge*, *cancel*, *assign*, *delegate*, and *release*. Commitment operations do not happen arbitrarily. They are typically governed by normative policies that characterize the set of circumstances under which the operations can happen.

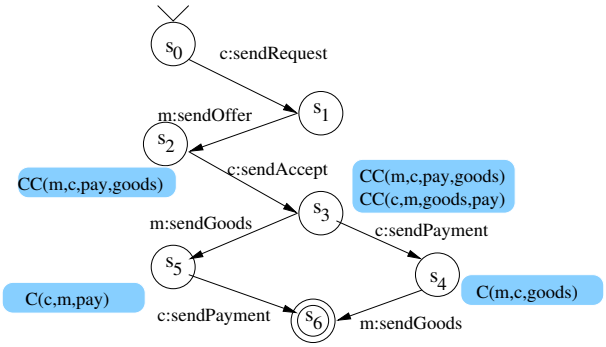

Figure 1: The base purchase protocol

The base purchase protocol has two roles: merchant and customer abbreviated m and c, respectively. For simplicity, we assume reliable, synchronous communication. Thus, sending a message is concurrent with its receipt. The protocol has the following steps. (1) The customer begins the protocol by sending a request for quotes to the merchant. (2) The merchant sends an offer in response. By sending an offer, the merchant creates the conditional commitment CC(m,c,pay,goods) meaning that if the customer pays, then the merchant will send the goods. (3) The customer accepts the offer, thereby creating another conditional commitment CC(c,m,goods,pay) meaning that if the merchant sends the goods, then the customer will pay. (4) If the customer sends a payment to the merchant, then CC(c,m,goods,pay) is discharged and CC(m,c,pay,goods) is reduced to C(m,c,goods) meaning that the merchant is now committed to sending the goods. Conversely, if the merchant sends goods to the customer, then CC(m,c, pay,goods) is discharged and CC(c,m,goods,pay) is reduced to C(c,m,pay) meaning that the customer is now committed to paying for the goods. (5) If the customer has paid in the previous step, then the merchant sends the goods, thereby discharging its commitment. Conversely, if the merchant has sent the goods in the previous step, then the customer sends the payment, thereby discharging its commitment. In either case, no commitments or conditional commitments hold in the resulting state, which is indicated as the final state of the protocol.

3. PROTOCOLS, FORMALLY

We specify protocols declaratively in $C+$ [2], an action description language based on the nonmonotonic causal logic, which captures *universal causation*—every fact that obtains must be caused.

We specify protocols in $C+$ because it supports *elaboration tolerance*. This means that a specification can be refined merely by adding to the existing specification; nothing need be removed from it even if the desired effect is that some inferences are disabled. Elaboration tolerance is a major motivation behind nonmonotonic reasoning. For protocols, elaboration tolerance means that certain interactions can be removed or modified simply by adding axioms to an existing specification. As Section 4 shows, the parts that are to be added correspond to protocol transformers.

3.1 The Action Description Language C+

A specification in $C+$ consists of a set of causal laws. The *signature* of a $C+$ specification is the set of constants that occur in it. ^{act} and ^{fl} represent the sets of actions and fluents, respectively. Each constant c is assigned a nonempty finite domain *Dom(c)* of symbols. An *interpretation* of is an assignment of values $c = v$ for each $c \in$ where $v \in$ *Dom(c)*. A parameterized constant represents a family of constants, the members of which are all its ground instances.

An action description in $C+$ describes a transition system, a graph with states as vertices and actions as edges. Here, a state s is an interpretation of ^{fl} and a transition is a triple $\langle s, e, s' \rangle$ where s and s' are states, and e is an interpretation of ^{act}.

Below, we explain informally the meanings of the kinds of laws we use. Here $a, b \ldots$ represent boolean action literals, and $f, g, \ldots$ represent boolean fluent literals (except in declarations, where they are treated as names); $A, B, \ldots$ and $F, G, \ldots$ represent formulas (combinations using $\wedge, \neg, \vee$) of actions and fluents, respectively.

SCHEMA 1. *a :: exogenousAction.*

Schema 1 declares an exogenous action a, which means that there is a default cause for a to happen or not happen. In other words, a simply happens or does not happen. We model *protocol actions* such as sendRequest and sendOffer as exogenous actions.

SCHEMA 2. *a :: action.*

Schema 2 declares an action that is not exogenous. Such actions are termed *auxiliary actions*. Auxiliary actions must be caused by protocol actions. Commitment operations are auxiliary actions.

Let P_A and A_A denote the sets of protocol and auxiliary actions, respectively. Then $P_A \cup A_A =$ ^{act}, the set of actions of an action description. All actions are atomic—they either happen or do not happen.

SCHEMA 3. *f :: inertialFluent.*

Schema 3 declares a fluent with the property that its value persists from one state to the next unless changed by some other law.

SCHEMA 4. *f :: sdFluent.*

Schema 4 declares f as a static fluent, that is, the value of f depends only on other fluents, not on actions.

SCHEMA 5. *nonexecutable a if b.*

Schema 5 ensures that a and b do not happen concurrently. We use axioms of this schema for every pair of distinct protocol actions, thereby ensuring that no two protocol actions are concurrent.

SCHEMA 6. *a causes b if F.*

Schema 6 says that in a state where F (the precondition) holds, if a happens, then b happens concurrently. If F is the formula $\top$, the law reduces to a causes b. In this case, in a state where a happens, b happens concurrently.

We restrict the usage of Schema 6 so that a and b are protocol and auxiliary actions, respectively. This makes sense if we think of protocol actions causing commitment actions. Also, it does not make sense for b to be a protocol action as we apply Schema 5 to restrict protocol actions to be nonconcurrent.

SCHEMA 7. *a causes F if G.*

Schema 7 says that in a state where G holds, if a happens, then F holds in the next state. If G is the formula $\top$, the law reduces to a causes F. In this case, in a state where a happens, F holds in the next state.

SCHEMA 8. *nonexecutable a if F.*

Schema 8 specifies that in a state where F holds, a cannot happen. Axioms of this schema help impose an ordering on the protocol actions.

SCHEMA 9. *a causes a.*

Schema 9 specifies that the action a happens by default if a is a positive literal. If a is negative literal, then a does not happen by default.

SCHEMA 10. *caused f if f.*

Schema 10 says that the fluent f holds by default if f is a positive literal. If f is a negative literal, then f does not hold by default.

SCHEMA 11. *caused f if F.*

Schema 11 says that f holds in a state where F holds.

3.2 Protocol Specification

Listing 1 specifies commitments and commitment operations in $C+$. Only partial listings are shown due to space limitations. Complete listings for all specifications in this paper are available at http://research.csc.ncsu.edu/mas/code/. Listing 1 is independent of any particular protocol, and is incorporated into each protocol. Commitments and conditional commitments are modeled as inertial fluents (Lines 10–11). Commitment operations are modeled as simple (not exogenous) actions (Lines 12–13). Causal laws of Schema 7 are used to model commitment operations (Lines 18–19). By default, all commitment actions are disabled (Line 27). These laws are required because of universal causation—they explain situations in which the commitment actions do not happen.

```
1  % The listing referred to as 'com-ops' from other listings

23  ...

25 % By default, all commitment actions are disabled;
26 % they must be caused by protocol actions.
27  -create(x,y,p) causes -create(x,y,p).
28  ...
```

Listing 1: The basic commitment operations captured in $C+$

Listing 2 specifies the purchase protocol of Figure 1. Note that it includes Listing 1. Protocol actions are declared on Lines 11–12 as exogenous actions. They correspond to the labels on the edges in Figure 1. Fluents that capture the state of the protocol are declared in Lines 15–16. Line 21–22 capture the modeling of the sendRequest action. Lines 25–28 show a part of the modeling of the sendGoods action. Lines 26–28 capture the discharging of the merchant's commitment to send goods. Other protocol actions are appropriately captured, but are not shown here. Towards the end of the listing, the initial and final states of the protocol are defined. The initial state is one where none of the fluents (except initial) hold. The final state is one where a successful exchange of goods and payment has happened. Fluents initial and final are declared to be statically determined (Line 18) as their value depends only on other fluents. Conceptually, initial and final are metafluents: they are part of the ontology for specifying protocols. The nonexecutable axioms serve to impose an ordering on actions. For instance, a sendRequest can happen only in the initial state (Line 22).

```
1  % Include basic commitment operations from Listing 1
2  :-include 'com-ops'.

4  :- objects
5    merchant, customer ::role;
6    goodsc, payc, acceptc ::condition.

35  caused initial if initial.

37 % Not in initial state if any fluent holds
38  caused -initial if request(x,y).
39  caused -initial if offer(x,y).

41 % Similar axioms relating initial and other fluents
42  ...

44 % By default, not in final state
45  caused -final if -final.

47 % In final state, if pay and goods
48  caused final if pay(customer,merchant) &
49                  goods(merchant,customer).
```

Listing 2: The base purchase protocol in $C+$

The sending of a message is captured by the occurrence of the corresponding protocol action. Receiving a message is assumed to be synchronous with its sending. The fluents describe the state of the protocol. Commitment actions give meaning to protocol actions in terms of how protocol actions affect commitments. Therefore, it makes sense to model a commitment action as happening concurrently with the protocol action that causes it.

3.3 Transition Systems

As noted earlier, an action description in $C+$ formally describes a transition system. The transition system of a protocol is based on the transition system of its $C+$ action description with the removal of redundant transitions and unreachable states.

DEFINITION 1. *The set of transitions of a protocol P specified as an action description D is $T_P = \{\langle s, e, s'\rangle \mid \langle s, e, s'\rangle \in T_D$ and $s \neq s'\}$, where T_D denotes the set of transitions of D.*

Thus the transition system of a protocol is different from its action description. In the transition system semantics of $C+$, a nonaction (i.e., the nonoccurrence of an action $a \in {}^{act}$, denoted by the interpretation $a =$ false), is also considered an action. T_D contains transitions where e is interpreted such that every $a \in {}^{act} =$ false. Effectively, no action happens in such transitions. T_D also contains transitions where e is interpreted such that some $a \in {}^{act} =$ true, but the state does not change. (Such transitions could be produced, for example, by axioms of Schema 7 when the action a happens in a state where G does not hold.) Both these types of transitions appear as self-loops around states and are computationally redundant. Definition 1 removes such transitions.

DEFINITION 2. *The set of states of a protocol P specified as an action description D is $V_P = \{s \mid s \in V_D$ and $\exists\langle s', e, s''\rangle \in T_P$ such that $s = s'$ or $s = s''\}$, where V_D denotes the set of states described by D, and T_P denotes the set of transitions of P.*

Definition 2 removes isolated vertices (states). Such vertices have no incoming or outgoing edges.

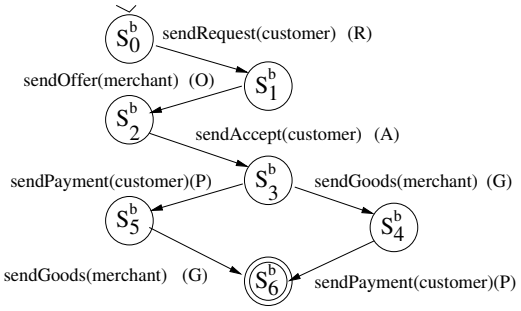

Figure 2: Transition system corresponding to Listing 2

Formally, then, a protocol P is described by $\langle T_P, V_P, V_I, V_F\rangle$, where $V_I \subseteq V_P$ such that $\forall v \in V_I : v \models$ initial, and $V_F \subseteq V_P$ such that $\forall v \in V_F : v \models$ final. Figure 2 shows the transition system corresponding to base purchase (Listing 2). Let's call this protocol P_B (B for base). Table 1 shows the interpretation of the states.

Lemma 1 shows that exactly one protocol action occurs in any transition. We will use this result later.

LEMMA 1. *In the transition system of a protocol P with protocol actions $\{p_1, \ldots, p_n\}$ and auxiliary actions $\{a_1, \ldots, a_m\}$, for every transition $\langle s, e, s'\rangle \in T_P$, exactly one $p_i =$ true $(1 \leq i \leq n)$, in interpretation e.*

Proof. The proof follows from the assumptions specified above about protocol actions and auxiliary actions. By Schema 5, no two protocol actions are concurrent. Therefore, at most one $p_i =$ true $(1 \leq i \leq n)$, in the interpretation e. If some $p_i =$ true, we are done. Else, Definition 1 removes nonaction loops, there must be auxiliary $a_j =$ true $(1 \leq j \leq m)$. However, by Schema 6, auxiliary actions are caused only by protocol actions. Thus some $p_i =$ true in e.

State	Fluents
s_0	*initial*
s_1	*request(customer, merchant)*
s_2	*request(customer, merchant), offer(merchant, customer), CC(customer, merchant, goodsc, payc)*
s_3	*request(customer, merchant), offer(merchant, customer), accept(customer, merchant), CC(customer, merchant, goodsc, payc), CC(merchant, customer, payc, goodsc)*
s_4	*request(customer, merchant), offer(merchant, customer), accept(customer, merchant), goods(merchant, customer), C(c, m, payc)*
s_5	*request(customer, merchant), offer(merchant, customer), accept(customer, merchant), pay(customer, merchant), C(m, c, goodsc)*
s_6	*request(customer, merchant), offer(merchant, customer), accept(customer, merchant), goods(merchant, customer), pay(customer, merchant), final*

Table 1: Interpretation of states in Figure 2: only fluents that obtain are shown.

4. CONTEXTS AND TRANSFORMERS

Section 3 showed how to specify protocols in $C+$, and developed a computational model for them. This section exploits the elaboration tolerance of $C+$ to support the independent specification of protocols and transformers. A protocol transformer is a $C+$ specification that encodes a generic way to handle an aspect of context. To apply a transformer to a protocol, we simply append it to the protocol specification.

A transformer specification may use *external* constants, i.e., fluents and actions that are not declared in it. External constants must be declared in a protocol to which the transformer is applied. Such constants represent part of the interface between the protocol and the transformer. Below we model a few transformers for the base purchase protocol (P_B).

4.1 The Return-Refund Transformer

EXAMPLE 1. *Sending returns and refunds: In some settings, a customer may return goods bought and obtain a refund (if a payment was made). Likewise, a merchant may refund the customer's payment unilaterally if it is unable to deliver the promised goods.* ∎

```
1  :- constants

3    sendReturn(role), sendRefund(role)::exogenousAction;
4    returned(role,role), refunded(role,role)::inertialFluent.

6  % Capturing the effects of the return action

8    sendReturn(customer) causes returned(customer,merchant)
9          & -goods(merchant,customer) if
10         goods(merchant,customer).
11   sendReturn(customer) causes create(merchant,customer,
12         goodsc) if pay(customer,merchant) &
13         goods(merchant,customer).
14   sendReturn(customer) causes cancel(customer,merchant,
15         payc) if commitment(customer,merchant,payc)
16         & goods(merchant,customer).
17   sendReturn(customer) causes ccreate(merchant,customer,
18         payc, goodsc) if commitment(customer,merchant,
19         payc) & goods(merchant,customer).
20   sendReturn(customer) causes ccreate(customer,merchant,
21         goodsc, payc) if commitment(customer,merchant,
22         payc) & goods(merchant,customer).

24 % Sending goods causes them to be not returned.
```

```
26   sendGoods(merchant) causes -returned(customer,merchant).

28 % Axioms for refunds
29   ...
```

Listing 3: Return-Refund transformer in C+

Listing 3 shows a transformer that adds refunds and returns to base purchase. The actions and fluents are declared in Lines 3–4. Lines 8–22 capture the semantics of return. sendReturn(customer) is successful only if goods have already been sent, and it undoes the effect of the sending of goods by the merchant (Lines 8–10). The remaining causal laws capture the effects of performing a return depending on whether payment has already been sent (Lines 11–13) or not (Lines 14–22). In addition, sending goods undoes the effect of returning them (Line 26). This enables cyclic behavior of sending and returning goods. Refunds (not shown in the listing) are captured similarly.

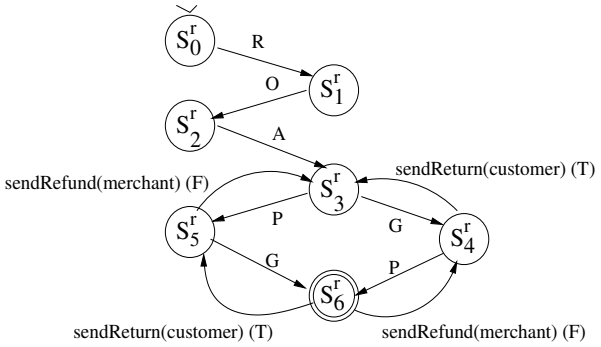

Figure 3: Transition system produced by applying the Return-Refund transformer

To apply this transformer to P_B (base purchase), we append it to the specification of P_B. We refer to the resulting protocol as P_R (for returns and refunds). Figure 3 shows the transition system of P_R. R, O, A, G, P mean the same as in Figure 2.

4.2 The Reminder Transformer

EXAMPLE 2. *Sending reminders: In some context where agents are notorious for not fulfilling their commitments on time, it would be useful for the creditor of a commitment to remind the debtor about the pending commitment. A customer can remind the merchant to send the goods and conversely, a merchant can remind the customer to send a payment.* ∎

```
1  :- constants

3    sendReminder(role) :: exogenousAction;

5  % Every protocol action must cause a transition into
6  % a new state. The num of the reminder serves to
7  % distinguish between two reminders.

9    reminder(role,role,num) :: inertialFluent;

11 % reminderNum keeps track of the number of reminders.
12 % To save space, we removed the lines that say
13 % maxReminders=6

15   reminderNum :: inertialFluent(0..maxReminders).

17 % Reminder: increment reminderNum after every reminder.
```

```
19 sendReminder(y)  causes reminder(x,y,i) & reminderNum=i+1
20         if commitment(x,y,p) & i=reminderNum where
21         i < maxReminders.
```

Listing 4: Reminder transformer in C+

Listing 4 shows a transformer that adds reminders to base purchase. Commitments are the only external constants in this transformer. Both the customer and the merchant can send reminders (limited to six maximum) depending on which commitment holds. The declaration of the fluent reminder(role, role, num) on Line 9 includes a parameter num. Recall that Definition 1 removes self-loops from the transition system. Therefore, protocol actions must be specified so that every time a protocol action happens, it causes a state change. Without the num parameter, reminders after the first reminder would not cause a state change, and would be removed by Definition 1.

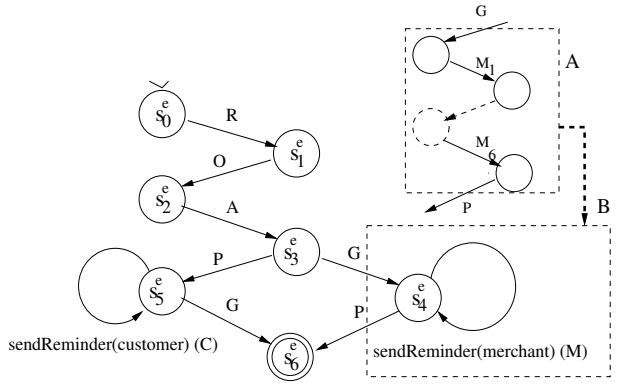

Figure 4: Transition system produced by applying the Reminder transformer

When we apply this transformer to P_B (by appending it to P_B), we obtain a protocol P_E (for reminders). Because the transition system obtained is large, Figure 4 shows the simplified transition system of P_E. Every reminder that the merchant sends transitions the protocol into a new state as shown in block A. We collapse block A into block B, thereby making it seem that reminders happen in a self-loop. We do the same for the customer's reminders. Note that such simplification is not possible in general. We make this simplification here, because we focus on commitments, and sending reminders does not change the commitments in any state.

4.3 The Pay-Before-Goods Transformer

This is an example of a transformer that *removes* some previously allowed interactions. Recall that base purchase allows sending goods and payment in any order.

EXAMPLE 3. *Pay first: In a context where customers are not trustworthy (but merchants are), merchants requires payment before delivery of goods.* ∎

```
1  % Goods sent only after payment.

3    nonexecutable sendGoods(merchant) if
4          -pay(customer,merchant).
```

Listing 5: Pay-Before-Goods transformer in C+

Listing 5 removes the path where the merchant sends goods before payment is received. When we append this transformer to P_B,

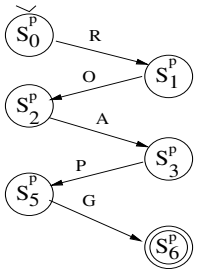

Figure 5: Transition system produced by applying the Pay-Before-Goods transformer

we obtain the protocol P_P (for pay first) as shown in Figure 5. Its transition system is similar to Figure 2, but with the goods-before-payment path removed.

4.4 The Discount Transformer

The previous transformers did not add any new commitments to base purchase; this does.

EXAMPLE 4. *As an incentive for the customer to pay and complete the transaction, the merchant promises to give a 10% discount on the customer's next purchase if the customer pays.* ▮

```
1  :- objects
2  % 10 percent discount on next purchase.

4    discountNextPurchase :: condition.

6  :- constants

8    sendDiscountOffer(role) ::exogenousAction,
9    discountOffer(role,role) ::inertialFluent.

11 % DiscountOffer

13   sendDiscountOffer(merchant) causes discountOffer(
14           merchant,customer).
15   sendDiscountOffer(merchant) causes ccreate(merchant,
16           customer,payc,discountNextPurchase).

18 % DiscountOffer only if not customer has not paid.

20   nonexecutable sendDiscountOffer(merchant) if
21           pay(customer,merchant) ++
22           -offer(merchant,customer).
```

Listing 6: Discount transformer in C+

Listing 6 shows the corresponding transformer. A new action sendDiscountOffer(merchant) is introduced which creates a conditional commitment that if the customer pays, then it receives a 10% discount on the next purchase. This action can happen only before pay, and only after offer.

Applying this transformer to P_B yields the protocol P_D (for discount). In the resulting transition system, the paths in P_B remain and new paths with sendDiscountOffer(merchant) are added. Figure 6 shows part of the resulting transition system with one such added path, between s_0 and s_8. Note that in s_8, a final state, the fluent C(merchant, customer, discountNextPurchase) holds.

5. SEMANTICS OF TRANSFORMATIONS

The base purchase protocol and its transformations described above offer differing functionality, yet are similar in that they are all purchase protocols. The notion of protocol subsumption [3] helps

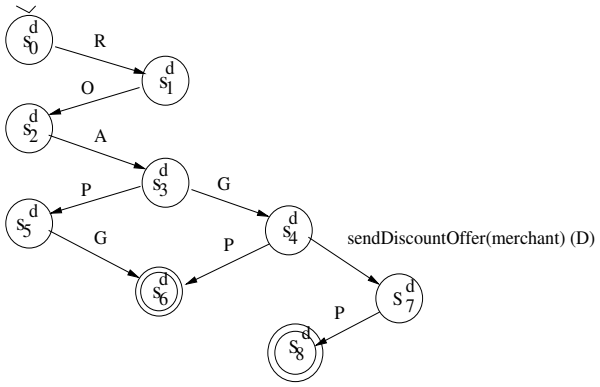

Figure 6: Transition system produced by applying the Discount transformer

characterize the relationship between a protocol and its transformations. The following reviews protocol subsumption, and applies it for understanding transformations.

5.1 Protocol Subsumption

Runs. A run represents a path in the transition system from a initial state to a final state.

DEFINITION 3. *A run of a protocol is a series of transitions* $\langle s_0, e_0, s_1\rangle$, $\langle s_1, e_1, s_2\rangle$, ...,$\langle s_{n-1}, e_{n-1}, s_n\rangle$ *such that* $s_0 \in S$, *the set of initial states, and* $s_n \in F$, *the set of final states.*

$\langle s_0, e_0, s_1, e_1, \ldots, e_{n-1}, s_n\rangle$ is an abbreviated representation of a run. Using Lemma 1, we further abbreviate a run by indicating only protocol actions instead of complete action interpretations, e.g., $\langle s_0, p_0, s_1, p_1, \ldots, p_{n-1}, s_n\rangle$ where $p_i \in P_A$, the set of protocol actions. For example, the set of runs corresponding to Figure 2 is $\{\langle s_0, R, s_1, O, s_2, A, s_3, G, s_4, P, s_6\rangle, \langle s_0, R, s_1, O, s_2, A, s_3, P, s_5, G, s_6\rangle\}$.

State Similarity. We introduce *state similarity* to compare states occurring in runs of different protocols. A state-similarity function f maps a state to a set of states, i.e., $f : \mathbf{S} \rightarrow 2^{\mathbf{S}}$. From f, we induce a binary relation $\approx_f \subseteq \mathbf{S} \times \mathbf{S}$, where $\approx_f = \{(s, f(s)) : s \in \mathbf{S}\}$. We require f to be such that $\approx_f$ is an equivalence relation. For example, commitments could be used to compare states. Two states are *commitment similar* if the same set of commitments hold in them. State-similarity forms the basis of protocol comparison.

Run Subsumption. Let $\prec_\tau$ be a temporal ordering relation on states in a run τ. $s \prec_\tau s'$ means that s occurs before s' in τ.

DEFINITION 4. *A run* τ_j *subsumes* τ_i *under a state-similarity function* f, *denoted by* $\tau_j \gg_f \tau_i$ *if for every state* s_i *that occurs in* τ_i, *there exists a state* s_j *that occurs in* τ_j *such that* $s_j \approx_f s_i$, *and for all* s'_i *that occur in* τ_i, *if* $s_i \prec_{\tau_i} s'_i$ *then there exists* s'_j *that occurs in* τ_j *such that* $s_j \prec_{\tau_j} s'_j$ *and* $s'_j \approx_f s'_i$.

For the sake of subsumption analysis, we omit the actions of a run, thus abbreviating a run $\langle s_0, p_0, s_1, p_1, \ldots, p_{n-1}, s_n\rangle$ to just $\langle s_0, s_1, \ldots, s_n\rangle$. Run subsumption is reflexive, transitive, and antisymmetric up to state similarity [3]. Longer runs subsume shorter runs, provided they have similar states in the same temporal order. For example, the run $\langle s^r_0, s^r_1, s^r_2, s^r_3, s^r_4, s^r_3, s^r_4, s^r_6\rangle$ in purchase with returns and refunds (Figure 3) subsumes under commitment similarity, the run $\langle s^b_0, s^b_1, s^b_2, s^b_3, s^b_4, s^b_6\rangle$ in base purchase (Figure 2, states with the same subscript being commitment similar). However, the run $\langle s^d_0, s^d_1, s^d_2, s^d_3, s^d_4, s^d_7, s^d_8\rangle$ in purchase with discount

(Figure 6) does not subsume under commitment similarity, any run in base purchase as state s_6^b does not have a corresponding commitment-similar state in purchase with discount.

Protocol Subsumption. Informally, a more *general* protocol allows more variations in its runs than a less general one. To help formalize this notion, we define a *span* of a protocol as a set of runs allowed by it. A transition system directly yields a span. We define the *closure* of a protocol as a span that is closed under run subsumption. That is, if a run is in the closure, then all the runs that subsume it (under some state-similarity function) are also in the closure. Closures are unique, and provide a firm basis for comparing protocols.

DEFINITION 5. *The transition-span of a protocol specification P, denoted by $[P]$, is the set of runs in its transition system.*

For example, $[P_B] = \{\langle s_0, s_1, s_2, s_3, s_4, s_6\rangle, \langle s_0, s_1, s_2, s_3, s_5, s_6\rangle\}$ is a transition-span of base purchase.

DEFINITION 6. *The closure of a protocol P under a state-similarity function f is given by $[\![P]\!]_f = \{\tau \mid \forall \tau' \in [P] : \tau \gg_f \tau'\}$.*

DEFINITION 7. *A protocol P subsumes a protocol P' under a state-similarity function f, denoted by $P[\![f]\!\rangle P'$, if $\forall \tau' \in [\![P']\!]_f$, $\exists \tau \in [\![P]\!]_f$, such that $\tau' \gg_f \tau$.*

Considering our example protocols, under commitment-similarity function f, (1) P_B (base purchase) subsumes P_R (with returns and refunds) and vice versa because $[\![P_B]\!]_f = [\![P_R]\!]_f$, (2) P_B subsumes P_E (with reminders) and vice versa because $[\![P_B]\!]_f = [\![P_E]\!]_f$, (3) P_B strictly subsumes P_P (pay-before-goods) because $[\![P_P]\!]_f \subset [\![P_B]\!]_f$, and (4) P_D (with discount) strictly subsumes P_B because $[\![P_B]\!]_f \subset [\![P_D]\!]_f$. (Comparing across Figures 2, 3, 4, 5, and 6, the states labeled with the same subscript are commitment similar.)

DEFINITION 8. *The set of induced runs of a protocol P under a state-similarity function f is $([P])_f = [\![P]\!]_f \setminus [P]$.*

In other words, the induced runs are not explicitly present in the transition system but are implicitly present in the specification.

5.2 Types of Transformations

A transformation can be viewed as a function that takes a protocol as input and produces a different protocol. In simple terms, a transformation either (1) adds, (2) removes, or (3) adds and removes runs from a protocol. The definitions below characterize transformations based on how they change the span of a protocol. The examples below use commitment similarity as the state-similarity function.

DEFINITION 9. *A transformation is closure expanding with respect to a state-similarity function f if the resulting transition-span has at least one additional run that does not belong to the closure of the original protocol.*

The transformation from P_B (Figure 2) to P_D (Figure 6) is closure expanding since it adds the run $\langle s_0^d, \ldots, s_8^d\rangle \notin [\![P_B]\!]_f$.

LEMMA 2. *A protocol resulting from a closure-expanding transformation with respect to a state-similarity function f strictly subsumes the original protocol under f.*

DEFINITION 10. *A transformation is closure preserving with respect to a state-similarity function f if the transition span of the resulting protocol is different from that of the original protocol, but their closures are identical (under f).*

No.	$[P]$		$[\![P]\!]_f$		Transformation
	Removes	Adds	Removes	Adds	
1	x	x	x	x	null
2	x	x	x	✓	Impossible
3	x	x	✓	x	Impossible
4	x	x	✓	✓	Impossible
5	x	✓	x	x	Closure preserving
6	x	✓	x	✓	Closure expanding
7	x	✓	✓	x	Impossible
8	x	✓	✓	✓	Impossible
9	✓	x	x	x	Closure preserving
10	✓	x	x	✓	Impossible
11	✓	x	✓	x	Closure contracting
12	✓	x	✓	✓	Impossible
13	✓	✓	x	x	Closure preserving
14	✓	✓	x	✓	Closure expanding
15	✓	✓	✓	x	Closure contracting
16	✓	✓	✓	✓	Not characterized

Table 2: Transformation possibilities

The transformations from P_B (Figure 2) to P_R (Figure 3) and to P_E (Figure 4) are both closure preserving since each transformation adds runs that were already present in $[\![P_B]\!]_f$. A transformation that removes runs from the transition span, but is still closure-preserving, is one that removes reminders from P_E.

LEMMA 3. *A protocol resulting from a closure-preserving transformation with respect to the state-similarity function f subsumes the original protocol under f, and vice versa.*

DEFINITION 11. *A transformation is closure contracting if the resulting transition-span is a proper subset of the transition-span of the original protocol.*

The transformation from P_B (Figure 2) to P_P (Figure 5) is closure contracting since it removes the run $\langle s_0^b, \ldots, s_4^b, s_6^b\rangle \in [P_B]$.

LEMMA 4. *A protocol subsumes a protocol resulting from a closure-contracting transformation under every f.*

Table 2 shows that the above-defined types of transformations represent an exhaustive list; there can be no other type of transformation. Each row is to be read as "a transformation that Removes (if ticked) and Adds (if ticked) from $[P]$, and at the same time Removes (if ticked) and Adds (if ticked) from $[\![P]\!]_f$ is of type Transformation". To understand the table, we present the following observations that follow from the definition of closure. (1) To change the closure, the transition span must be changed making the transformations in rows 2–4 impossible. (2) A transformation that only adds runs to the transition span cannot remove runs from the closure making transformations in rows 7–8 impossible. (3) Similarly, a transformation that only removes runs from the transition-span cannot add runs to the closure making rows 10 and 12 impossible. (4) The transformations of the type in row 16 cannot be generally characterized in terms of closures—depending on the specific transformation in consideration, the transformation may be expanding, preserving or contracting, or there may be no subset relation between the closures of the original and the resulting protocol—causing them to be labeled 'not characterized'. We lack the space to give detailed examples.

5.3 Compliance

How can we use the above characterization of transformations? One use is in determining compliance. In open systems, checking whether an agent complies with stated protocols is nontrivial. A simple approach for verifying compliance is to check an agent's enactment of a protocol against the protocol's state machine: any deviation from the state machine would be a violation. But some deviations may be necessary for variations in context. A commitment-based approach can allow flexible enactments while enabling verification of compliance [9]. Practical settings, however, often require more structure than general-purpose commitment reasoning allows. In particular, agreement among the interacting parties (expressed in a protocol) may be needed to facilitate their interactions. For example, in a certain context, the parties involved may find sending reminders appropriate, but not allowing arbitrary returns. Where do we get this structure from?

The closure of a protocol specifies which runs it allows. This is important not just for deviations but also for accommodating agents who participate in multiple protocols in a potentially interleaved manner. By changing the similarity function f, we obtain different closures. Thus, the state-similarity function leads to a configurable definition of compliance. An appropriate similarity function can be defined for each domain of interest or institution. Below, enactment refers to an agent's interactions.

DEFINITION 12. *An agent is compliant with a protocol P in a domain f as long as any enactment belongs to $[\![P]\!]_f$.*

Given Definition 12, we relate transformations to compliance as follows. Consider a domain f in which agents use protocol P. If an agent replaces P with another protocol P' and acts in a manner compliant with P', then under what conditions can we say that it is also compliant with P? To be compliant with both P and P', an agent's enactment must belong to both $[\![P]\!]_f$ and $[\![P']\!]_f$.

LEMMA 5. *An agent compliant with P' in a domain f is compliant with protocol P if P' can be obtained from P using a closure-preserving transformation with respect to f.*

In a domain with commitment-similarity, an agent that is compliant with P_R (with returns and refunds) or P_E (with reminders) is compliant with P_B (base purchase), but an agent using P_P (pay first) or P_D (with discount) is not.

6. DISCUSSION

This paper has formalized protocols and transformers, demonstrated how they work, and shown some of their useful properties. When protocols and transformers are treated as software components [7], we can think of creating libraries of them, and using them as off-the-shelf components to create the desired multiagent systems. The key requirement behind components is that they are sufficiently rigorously defined that third-party developers can compose them in ways that the original designers might not have anticipated. This requirement is met for protocols by the present approach.

Some interesting challenges remain. How do we know that a transformer does not conflict with a protocol? For example, applying a Goods-Before-Pay transformer (the inverse of the example of Listing 5) on the Pay-Before-Goods protocol of Figure 5 will result in a protocol with no runs. Clearly, we can build a transition system for the transformed protocol and observe that it allows no runs. However, a characterization based on the specification language would be more perspicuous and helpful during design. In general, what kinds of correctness guarantees can we make regarding a transformer based on the schemas used in it?

Engineering protocols, like any other artifacts, presupposes the existence of effective tools. Because, in practice, protocols would be developed in multiple ways, more than one kind of tool is needed. This paper has concentrated on supporting protocol design from existing protocols. Others have addressed this problem via a composition of existing protocols [10] or as a refinement of part of an existing protocol [4]. In specification terms, a transformer is not different from a protocol. Thus the present approach has elements of composition in a rigorous manner and shows in what cases the resulting protocols are refinements of the original protocols. An alternative approach is to support protocol design from first principles, i.e., based on requirements analysis of the desired class of applications, an approach such as Dooley graphs [5] or Tropos [1] that yields specifications from early requirements would be natural. It would be interesting to see how the approaches can be combined so that we can develop a library of protocols and transformers from first principles, and enable the development of additional protocols as needed from the components in the library.

ABSTRACT

This paper reports on the development of a utility-based mechanism for managing sensing and communication in cooperative multi-sensor networks. The specific application considered is that of GLACSWEB, a deployed system that uses battery-powered sensors to collect environmental data related to glaciers which it transmits back to a base station so that it can be made available world-wide to researchers. In this context, we first develop a sensing protocol in which each sensor locally adjusts its sensing rate based on the value of the data it believes it will observe. Then, we detail a communication protocol that finds optimal routes for relaying this data back to the base station based on the cost of communicating it (derived from the opportunity cost of using the battery power for relaying data). Finally, we empirically evaluate our protocol by examining the impact on efficiency of the network topology, the size of the network, and the degree of dynamism of the environment. In so doing, we demonstrate that the efficiency gains of our new protocol, over the currently implemented method over a 6 month period, are 470%, 250% and 300% respectively.

1. INTRODUCTION

Multi-sensor networks are being deployed in a wide variety of application areas and, in particular, they have recently been advocated for a number of environmental monitoring applications [8]. Moreover, there is an increasing interest in controlling these networks using multi-agent system techniques [7]. In this vein, we consider a particular sensor network, GLACSWEB [8], that we have deployed in the Brikdalsbreen glacier in Norway, and examine how it can be modelled as a (cooperative) multi-agent system. In this case, the two main tasks performed by the sensors (agents) are gathering data from the environment and communicating it towards a central sink node (i.e. an agent that harvests data from all other agents). In general, the agents work towards the predefined system goal of maximising data collection (hence the cooperative nature of the system). However, they are invariably constrained in at least one of the following dimensions: their available power, their communication bandwidth, their memory storage and their processing capability. Of these, power is the most important since it is required for everything else. Thus, it directly influences the life-span of the agents and, hence, that of the system as a whole. Given this, we focus on developing a communication and a sensing protocol for this network. Nevertheless, the solution we develop is also more broadly applicable to networks that have any form of limited power supply.

In more detail, the purpose of the GLACSWEB multi-sensor network is to monitor sub-glacial behaviour in order to understand climatic change. Figure 1 shows GLACSWEB's central base station that is located on top of the glacier and figure 2 shows a typical GLACSWEB node. The individual nodes each sense their own data and then communicate it directly to this sink node. As such, the system's communication protocol is energy inefficient since it lacks the energy savings that a multi-hop approach would provide [12] (i.e. one in which agents relay data for one another). Furthermore, at present, sensing in GLACSWEB is carried out at a pre-determined constant rate which is blind to the actual variations in the environment. This decoupling results in unnecessary sampling because, given the same energy expenditure, the information gained by sensing a slowly varying environment is less than what could be gained in a more dynamic situation.

Against this background, this paper develops a Utility-based Sensing and Communication protocol (called USAC). This consists of a sensing and a routing protocol that uses the cost of transmission and the value of observed data as utility metrics in the agents' decision-making process. In doing so, we advance the state of the art in the following ways :

- We develop a novel mechanism for adaptive sampling.

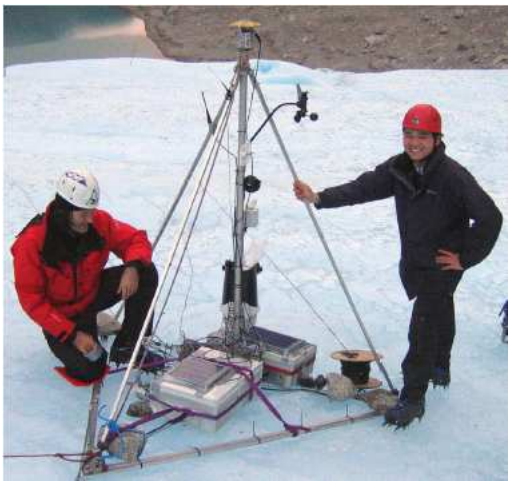

Figure 1: GLACSWEB base station

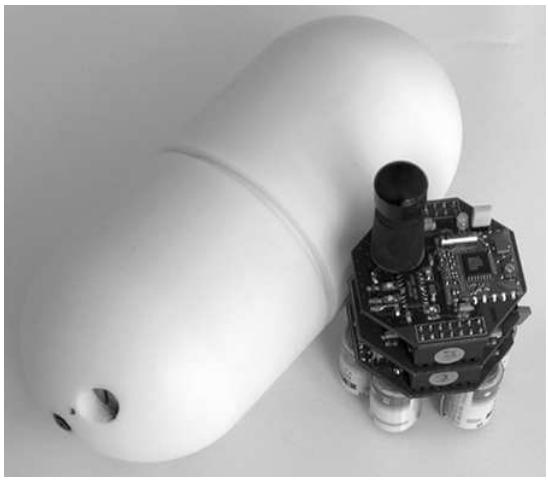

Figure 2: A GLACSWEB sensor probe

In this, each agent adjusts its rate depending on the rate of change of its observations and a valuation function (based on a sound information theoretic foundation) that the agents use for assigning a value to the data they observe.

- We devise a new routing protocol that finds the cheapest cost route from an agent to the centre. Here, the cost of a link from one agent to another is derived using the opportunity cost of the energy spent relaying the data (i.e. the value that a relay could have gained by using the energy in sensing instead of relaying).

- We empirically evaluate the USAC protocol against the current GLACSWEB protocol and show that it introduces a significantly higher gain in information, whilst reducing power consumption.

The remainder of this paper is organised as follows. Section 2 provides some basic background on GLACSWEB and a discussion about related work in the area of sensor networks modelled as multi-agent systems. We then detail the sensing protocol and the routing protocol of USAC in sections 3 and 4 respectively. The USAC protocol is then empirically evaluated in section 5 in a wide range of scenarios. We conclude in section 6.

2. BACKGROUND AND RELATED WORK

GLACSWEB is a deployed pervasive sensor network that directly monitors sub-glacial movement to determine how it is affected by climatic changes. In order to do this, it uses a network of sub-glacial probes which are placed at different locations inside the glacier as shown in figure 3.

The protocol currently followed by GLACSWEB is a simple one in which the probes sample the glacier every four hours and then transmit these readings directly to the base station located at the top of the glacier daily. At this time, there are twenty probes in the glacier with an additional batch of ten deployed every summer. However, as a result of the hostile environment (due to the low temperatures, the strain resulting from moving ice and the englacial water bodies) and the power hungry protocol, there is a high probe failure rate of around 50% per year. This provides the motivation for the research carried out in this paper.

Speaking more generally, it is widely recognised that there is a strong need for a well defined protocol stack in a sensor network that helps combine power and routing awareness, and that integrates data with the networking protocols. To this end, a number of routing protocols have been investigated in this area. In particular, flooding [4] is one of the oldest and most common routing techniques. In flooding, each agent receives an item of data and then repeats it by broadcasting unless the destination of the packet is the agent itself. This is a reactive technique and does not require costly topology maintenance or complex route discovery algorithms. However, it can easily cause data implosion and/or data overlap which results in unnecessary wastage in communication power. The SPIN [5] routing protocol adopts a publish-subscribe approach to the problem in which the agent nodes operate efficiently and conserve energy by all sending meta-data describing the sensor data instead of sending the actual data. Thus, this model is useful for those agents interested in the data advertised and is an effective protocol to minimise energy spent in consumption until the actual data is transmitted. However, it fails to place a limit on the energy consumed in wasted advertisements (i.e. for which there are no subscribers for the data). Moreover, the downside of both these models is that they involve significant amounts of communication and so consume large amounts of power which is often limiting.

To combat this, a number of researchers have focused on intelligent adaptive sensing [3]. Such work demonstrates that an active sensing approach can maximize a mobile sensor network's lifetime by sensing only during the most informative situations. However, our research differs from such approaches in that we focus on the sudden changes in the observed data rather than simply investigating regular patterns. In addition, our work reuses the utility derived from the sensing protocol in the communication protocol, thereby intertwining these two critical aspects of a sensor network. As a result, our model is sensor-centric, in contrast to the query-centric model adopted in [3].

The concept of utility has previously been used in the context of sensor networks for both cooperative [1, 6] and selfish

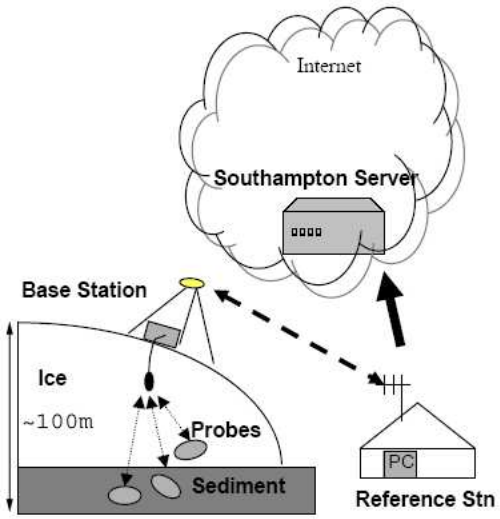

Figure 3: Architecture of the GLACSWEB network.

agents [2, 11]. In the latter case, the concept of selfishness arises mainly in those applications where agents are individually owned by different stakeholders (which is not true in our case). The focus of our work is on cooperative agents (since all nodes are owned by one stakeholder, the University of Southampton) and differs from existing research by combining the sensing and communication protocol via the utility function.

3. THE SENSING PROTOCOL

In this section, we detail the sensing protocol of USAC which provides the agents with a sensing schedule. We concentrate here only on the sensing actions of an agent (thereby ignoring the communication actions dealt with in section 4 so as to simplify the exposition). This focus results in a single agent model in which the agent has to make optimal local decisions concerned with the timing of its sensing.

In more detail, the model for the sensing protocol is as follows. From the remaining battery energy, E_i, and the energy, E_{sense}, each sensing action takes[1], agent i can calculate the maximum number of sensing actions, N_s^r, it has remaining ($N_s^r = E_i/E_{sense}$). Given this, the agent then needs to derive an optimal schedule for determining *when* to carry out these actions. In order to do this, a metric is required to determine how well a particular schedule does compared to another. The metric we use in this case is derived from *information-theory* because this enables us to have a principled means of obtaining maximum information from the environment.

3.1 The Valuation Function

An optimal sampling rate can only be derived if the agent has knowledge about the future data. However, this requirement is contradictory since in the case that the agent knows the future data, it does not need to sense the environment. As a result, an agent can only find an optimal sampling rate based on its forecast of the future data. Then, upon observing previously forecasted data, the agent gains information by reducing its uncertainty about this data to zero. Here the representation we use for the uncertainty of the data is the confidence interval of a predicted data point. Specifically, the x% confidence interval of a data point is a range of values centred around the mean of the forecast within which x% of the data is guaranteed to fall. For example, a 100% confidence interval is the range of values the data can only ever take, whereas a 10% confidence interval implies that only 10% of the forecasted data is guaranteed to fall in this interval. From this, it can be seen that a lower confidence interval is more useful since its range is smaller. Therefore, a good forecast is one that minimises the confidence interval.

The forecasting method we use here is based on a limited-window linear regression model. This is because it provides a good forecasting model for data that can be characterised as piecewise-linear functions of time with added Gaussian noise (which is the case for data collected in the GLACSWEB environment). Thus, the data can be represented by a set of equations of the form:

$$x_{T_i+\tau} = \alpha_i + \beta_i\tau + \eta \tag{1}$$

where $\{T_1, T_2, \ldots, T_I\}$ represent the times at which a phase change (i.e. a sudden variation in the data model) occurs, $\alpha_i + \beta_i\tau$ is the equation of the line after the phase change at time T_i, and η is noise.

Thus, there are three major aspects of the data which are unknown:

- The current line segment equation (i.e. $\alpha_i + \beta_i\tau$).
- The time at which a phase change occurs (i.e. $\{T_1, T_2, \ldots, T_I\}$).
- The level of noise in the environment (i.e. η).

Now, given observations $(\widehat{x}_1, \ldots, \widehat{x}_n)$ taken at time $(t_1, \ldots, t_n)$, a linear regression model of window size m would then estimate β_i as:

$$\overline{\beta}_i = \frac{\min(m,n)\sum_{i=lb}^{m}(t_i.\widehat{x}_i) - \sum_{i=lb}^{m} t_i \sum_{i=lb}^{m} \widehat{x}_i}{\min(m,n)\sum_{i=lb}^{m} t_i^2 - \left(\sum_{i=lb}^{m} t_i\right)^2} \tag{2}$$

where $lb = \max(n - m + 1, 1)$. Furthermore, using this model, we can estimate α_i as:

$$\overline{\alpha}_i = \frac{\sum_{i=lb}^{m} \widehat{x}_i - \overline{\beta}_i \sum_{i=lb}^{m} t_i}{\min(m,n)} \tag{3}$$

From this, the value at time interval ϵt after the last measurement is predicted as:

$$x_{t_n+\epsilon t} = \overline{\alpha}_i + \overline{\beta}_i(t_n + \epsilon t) \tag{4}$$

along with confidence intervals given by:

$$ci(t_n) = 2\sigma\mathcal{N}(c/2) \tag{5}$$

where σ is the standard deviation of the m samples and $\mathcal{N}(c)$ is the inverse of the positive part of the normal distribution function and c is the confidence level. Given this, we then calculate the value of a data point as:

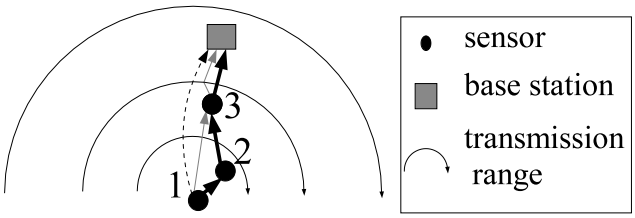
$$V(data(t_s)) = \mid ci(t_{s-1}) - ci(t_s) \mid \tag{6}$$

[1]The sensors within GLACSWEB have the same E_{sense} and take the same amount of time to carry out one observation.

ALGORITHM 1.

1. *Observe data,* $n_{sample}++$
2. *If* $n_{sample} = 1$ *then* $V(data(t_s)) = V_{max}$
3. *If* $n_{sample} = 2$ *then* $V(data(t_s)) = V_{max}$, *calculate* $ci(t_s)$
4. *If* $n_{sample} > 2$ *then calculate* $ci(t_s)$ *and* $V(data(t_s))$
   - *if* $data(t_s) \in ci(t_{s-1})$ *then* $f_{sample}(t_s) = max(\alpha f_{sample}(t_{s-1}), f_{min})$
   - *else* $f_{sample}(t_s) = f_{max}$ *and* $n_{sample} = 1$
5. *Go to Step 2*

Figure 4: The sensing protocol algorithm.



where $ci(t_{s-1})$ is the confidence interval before the data was sampled at time t_s and $ci(t_s)$ is the confidence interval at time t_s calculated using $data(t_s)$. Having defined the sensing protocol, we now turn to the algorithm to implement it.

3.2 The Algorithm

The algorithm we embed inside each agent for the sensing protocol is given in figure 4. The core concept behind this protocol is reflected in step 4. Here the reasoning is that if at time t_s the observed data falls outside the confidence interval, then the agent should set its sampling rate f_{sample} to a maximum f_{max}. This is because if the data falls outside the interval then the agent believes that there has been a phase change in the environment. Hence it starts sampling at the most frequent rate in order to better incorporate this phase change in its forecasting model. However, if data falls within the confidence interval, it implies that the agent already has a good regression model. Hence, it can afford to reduce its sampling rate (represented in step 3 by the multiplicative factor $\alpha \in [0, 1]$) until the lower bound f_{min} which has been set by the requirements of the glaciologists. Steps 2 and 3 enable the agent to obtain the two data points required to carry out a linear regression.

4. THE ROUTING PROTOCOL

Once a sensor has collected data from the environment, it needs to transmit it towards the base station. So far, in GLACSWEB this is done by direct transmission to the centre [10]. However, as discussed in section 2, this is inefficient since the power required to transmit data from one node to another is proportional to the square of the distance between the nodes (from basic radio transmission theory). As a result, the total energy spent by transmitting data directly to the centre via a single hop is more than the energy spent when the data is relayed via successive intermediaries to the centre. In order to see this effect, consider the example shown in figure 5. Here, sensor 1 could transmit data to the base station (bs) via the following three routes: $1 \rightarrow 2 \rightarrow 3 \rightarrow bs$ (bold), $1 \rightarrow 3 \rightarrow bs$ (grey) and $1 \rightarrow bs$ (broken line). The total energy consumed for the transmission of one packet of data would then be 12 $(4 + 4 + 4)$, 20 $(16 + 4)$ and 36 respectively, thereby suggesting the use of route $1 \rightarrow 2 \rightarrow 3 \rightarrow bs$.

sender \ receiver	2	3	base
1	4	16	36
2	X	4	16
3	4	X	4

Figure 5: Three possible routes via which sensor 1 can transmit its data to the base station. The concentric semi-circles show the range of sensor 1 with three power levels chosen such that the range grows linearly. The table shows the energy required for a sensor to transmit a packet directly to another.

However, an approach based solely on the transmission power is too naïve since it disregards the two following aspects:

1. **The opportunity cost of the energy used by each sensor.** If a sensor does not relay data, it could then use that energy in order to carry out additional sensing (which contributes towards the value of the network). Since each sensor is in a different local environment (due to the different placement of the sensors in the glacier), they derive different values by sensing the environment. Hence, it might be preferable for a sensor to transmit its data via a more energy-consuming route if the least energy-consuming route contains a sensor in a highly dynamic environment.
2. **The total power required to transmit along a particular route.** The transmission of data also requires the receiving node to be in a listening mode (i.e. the agent needs to switch on its antenna for receiving data which also consumes power). Thus the route $1 \rightarrow 2 \rightarrow 3 \rightarrow bs$ requires both sensor 2 and 3 to additionally spend energy receiving the data.

We tackle these two problems by developing a utility-based communication protocol. This protocol is based on the value of the data to be routed to the base station (which is derived according to section 3) and the cost of transmitting the data. We next detail how to calculate the cost of communication, before going onto the algorithm used for the communication protocol in section 4.2.

4.1 The Cost of Communication

The multisensor network is modelled as a multi-agent system consisting of a number of agents, $\mathcal{I} = \{1, \ldots, n\}$, that each have K different discrete power levels, $\{pt_i^1, \ldots, pt_i^K\}$, (with $pt_i^{k+1} > pt_i^k$) at which they can transmit. At each level, there is a set of neighbours $n_i(pt_i^k) \subseteq \mathcal{I}$ to which agent i can transmit data. Due to the nature of radio transmission, $n_i(pt_i^k) \subseteq n_i(pt_i^{k+1})$.

Thus, the direct communication of data from any agent i to another agent j, where $j \in n_i(pt_i^k)$ consumes a certain

amount of energy Et_i^j which is given by:

$$Et_i^j(data) = pt_i^{k*} \times t_i^j(data)$$

where pt_i^{k*} is the lowest power level at which $j \in n_i(pt_i^k)$ and $t_i^j(data)$ is the amount of time a data packet takes to transmit. Now, in this scenario the size of each sensed data packet and the bandwidth available to each agent is the same, so $t_i^j(data)$ is constant for all agents and sensed data packets. Therefore, by slight abuse of notation, we shall hereafter refer to $Et_i^j(data)$ as Et_i^j.

The cost of communication of an agent i to another agent j is then the opportunity cost of that decision. Now, there are two particular scenarios to consider when communicating data. If, on one hand, an agent is originating the data, then its cost of communication is given by:

$$c_i^j(originate) = \frac{Et_i^j}{Et_i^j + E_i^{sense}} \times v_i^{sense}(t_n) \quad (7)$$

where E_i^{sense} is the energy spent by i in sensing new data and $v_i^{sense}(t_n)$ is the value of the new data. On the other hand, if an agent is relaying data, then its cost of transmission is given by:

$$c_i^j(relay) = \frac{Et_i^j + E_i^{receive}}{Et_i^j + E_i^{sense}} \times v_i^{sense}(t_n) \quad (8)$$

where $E_i^{receive}$ is the energy spent by the agent receiving the data which it then relays.

Now, since it is not possible to assign $v_i^{sense}(t_n)$ before actually carrying out the observation, we need to estimate it. Due to the nature of the data (where sudden changes are possible) we estimate $v_i^{sense}(t_n)$ using a moving average with window size w. Thus at time t_n the estimated value of the data is given by:

$$\overline{v_i}^{sense}(t_n) = \frac{1}{\min(n, w)} \sum_{i=\max(n-w,0)}^{n-1} v_i^{sense}(t_i)$$

We choose such a forecasting method since it evens out the changes in value that random noise can introduce, whilst at the same time updating the value of the data fairly quickly as time progresses. However, it should be noted that this forecasting method (or for that matter any forecasting method) cannot guarantee to correctly predict the value of the data all the time. Also, the moving average only starts once the number of samples collected by the sensor $> w$. Up to that point, the estimated value is just an average.

Having thus explained how the cost of communication is calculated, we now detail the algorithm followed by each agent when communicating data.

4.2 The Algorithm

The algorithm we use for the communication protocol is given in figure 6. It consists of four main steps, namely:

1. **Initialisation.** In this phase, the network topology is discovered and each agent is made aware of the power level it must transmit at in order to reach each of its neighbours. This phase is run each time probes are deployed within the glacier.

ALGORITHM 2.

1. ***Initialisation.***

   Run a network discovery protocol that establishes $n_i(pt_i^k)\ \forall k, i$. Go to step 3.

2. ***Update transmission power.***

   At predefined intervals of time, t_{update} ($> 1/f_{min}$), the centre broadcasts a message $msg_0 = \langle P_0^{trans}, P_0^{rec} \rangle$ at the highest power level pt_0^K, where P_0^{trans} is the power at which the centre has transmitted this message and P_0^{rec} is the minimum power at which the centre can receive data. An agent can then calculate the minimum power required to transmit to the centre as:

   $$P_i^{min} = \frac{P_0^{rec} P_i^{rec}(msg_0)}{P_0^{trans}}$$

   assuming that the dissipation of power is symmetric between 0 and i. From P_i^{min}, an agent can then determine the minimum power level $pt_i^{k*}(0)$ required to transmit to the base station (since $0 \in n_i(pt_i^k)$ if $pt_i^k > P_i^{min}$). It can then determine $Et_i^0(data)$ and thus $c_i^j(originate)$.

3. ***Update cost of transmission to base.***

   Let $I(k*) \in I$ be the set of agents that require the minimum power level pt_i^{k*} to transmit to base ($I(k*) = n_0(pt_0^{k*}) - n_0(pt_0^{k*-1})$). Note that $pt_0^0 = \{0\}$. Agents $i \in I(1)$ can calculate their own cost of relaying data to the base station, $c_i^0(relay)$. Upon calculation, they broadcast the message $\langle c_i^0(relay) \rangle$ at power level pt_i^K.
   Then for $k = 2$ to K do*

   - *Agents $i \in I(k*)$ calculate the cost of relaying data $c_i^j(relay)$ to all agents $j \in I(k*-1)$.*
   - *They also update their cost of transmission, $c_i^0(originate)$, as $\min(c_i^l(originate) + c_l^0(relay))$ where $l \in \cup_{a=1}^{k*-1} I(k*-a)$*
   - *They then broadcast the message $\langle c_i^0(relay) \rangle$ at power level pt_i^K where $c_i^0(relay) = \min(c_i^l(relay) + c_l^0(relay))$.*

4. ***Transmit data.***

   Send the data packet through the lowest cost path if $V_i(data(t_s)) > c_i^0(originate)$. Update $c_i^j(originate), c_i^j(relay)$ from the value of newly sensed data.

5. ***Repeat Step.***

   ***If** time to update transmission power levels,*
   ***then** go to Step 2*
   ***else if** time to update relay and originate costs*
   ***then** go to Step 3*
   ***else** sense data and go to step 4.*

Figure 6: The routing protocol algorithm.

2. **Update energy band of agent.** This step is responsible for dividing the agents into different power level groups with respect to the base. This segmentation is then used in the next step in order to update the cost of relaying data.

3. **Update cost of transmission to base.** This step is required so as to find the minimum cost route from each agent to the centre. In order to do so, agents in each power level group successively transmit the cost of their cheapest route to the centre.

4. **Transmit data**. Having found the cheapest cost of transmission to the base, the agent then decides whether or not to transmit its observed data.

5. EMPIRICAL EVALUATION

The aim of these experiments is to determine the relative performance of USAC when compared to the currently deployed GLACSWEB protocol. Now, the performance of any protocol in this scenario is contingent on a number of factors such as the network topology, the number of agents within the network and the type of environment in which it is employed. Thus, in order to generalise our results, we benchmark the performance of USAC against GLACSWEB, whilst independently varying each of the factors mentioned above. We also calculate the *efficiency* (i.e. the value of the data gained over the energy consumed) of USAC relative to GLACSWEB in each case.

5.1 Experimental Setup

The GLACSWEB simulator lets each of the nodes take one of the following actions in a single time period: *sense*, *idle − listen* (where an agent enables its antenna so that it is ready to receive data), *transmit* a single packet, *receive* a single packet and *sleep*. With the exception of *transmit*, all actions have a set power consumption value affixed to them. The power consumption of the *transmit* action is dependent on the variable transmission power of the agent transmitter. Each such agent has five levels of transmission power to communicate with agents at different transmission ranges. The radio propagation model in the simulation was assumed to be symmetric. We decided to ignore the *processing* action of the agent due to its near negligible power consumption. Specifically table 1 shows the typical energy consumption of each action based on the values obtained from the fielded system. Furthermore, the energy capacity of the node was 77760 J and the confidence level within the sensing protocol was set to 10% (again based on our experience with the fielded system).

Table 1: Energy consumption of sensor node actions

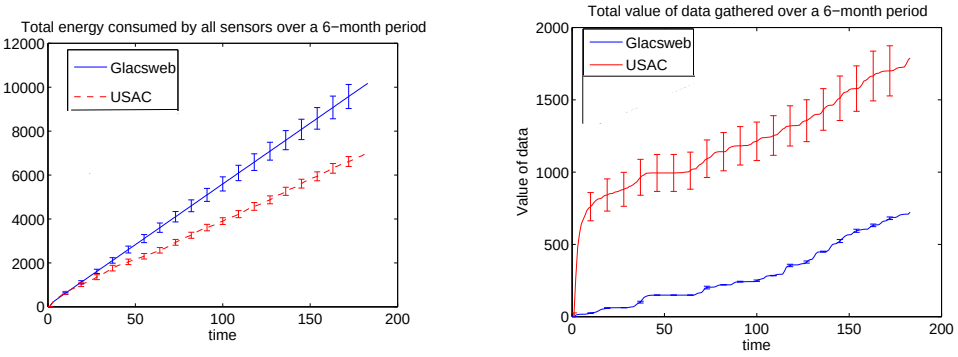
Sensor Action	Energy consumption(Joules)
Transmission per packet	0.47
Reception per packet	0.37
Idle transceiver on	0.086
Sense	0.015
Sleep per second	0.000032

We also decided to use a simple version of the IEEE 802.11 Medium Access Control [9] where RTS/CTS[2] control packets are only used before transmission of the data packets that are sent in a burst. Also there was no difference between overhearing and receiving in terms of power consumption. However, agents were programmed to ignore packets that were not destined to them and thereafter lower their power consumption by switching to the idle transceiver mode. In order to obtain statistically significant results, we report average result and standard deviations of 200 simulations in each of the experiments carried out. The data used in our experiments are derived from segments of the data collected[3] by the fielded probes over the last year.

[2]Request-To-Send/Clear-To-Send.

5.2 Network Topology

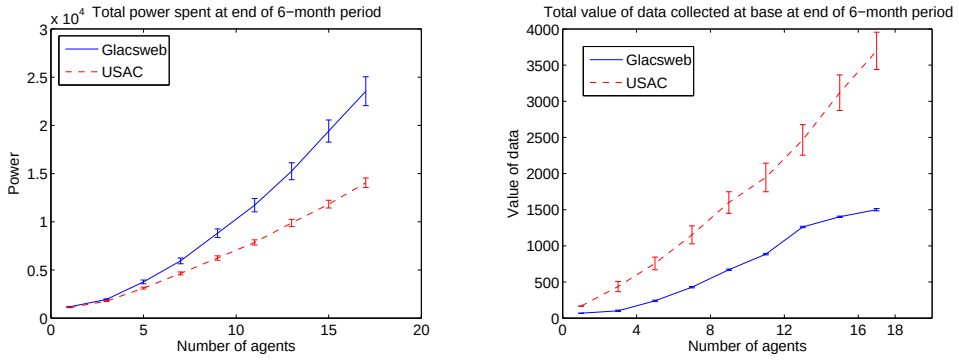
In this experiment, we simulated the two protocols for a fixed number of agents (10) randomly distributed around the centre. The sensed data model for each agent and number of agents in the networks were fixed for each instance of the simulation. The purpose of this was to analyse how the two protocols fared against each other with the changing topology of the network. The results of these simulations are shown in the two plots in Figure 7.



Both plots show the superiority of USAC over GLACSWEB. The big jump at the beginning of USAC's value graph is attributed to the maximum rate of sampling in the initial stages. Once a sufficient number of samples have been collected, the sampling rate is reduced and adjusted according to the change in observed data. The overall graphs of both protocols are linear. However, the gradient of USAC is steeper than that of GLACSWEB. This is because USAC increases its sampling whenever the observed data changes. The efficiency gain of USAC over GLACSWEB in this experiment was calculated to be 470%.

5.3 Network Size

In this experiment, we conducted simulations by varying the number of agents in the network from 1 to 20. Figure 8 illustrates the performance of USAC against GLACSWEB with varying network size. Due to the variability of the data, we concern ourselves with the average of the final total at the end of each simulation to ensure an effective comparison.



As can be seen, USAC consistently consumes less energy and still manages to collect more valued data at the sink node (even as the size of the network is increased). However, the random placement of the agent nodes results in a greater variance in the total value of data collected using USAC. This is due to the way that USAC reallocates the energy saved, when not relaying, to the task of sensing. In particular, the network topology in an instance of the experiment determines the amount of energy an agent spends on communication and therefore the amount of sensing it performs. In other words, an agent closer to the base station might relay and communicate more data since the value of the data derived might often be more than the cost of communication. On the other hand, an agent further away from the base station might be forced to communicate and relay less data because the cost of communication may now have surpassed the value of data it has sensed. The efficiency gain of USAC over GLACSWEB in this part of the experiment was calculated to be 250%.

(a) Energy Consumption (b) Value Derived

Figure 9: The total energy spent and total data value gathered at the end of a 6-month period plotted against a measure of dynamism of data.

5.4 Dynamism of the Environment

In this experiment, simulations were carried out by varying the data model of the agent nodes whilst keeping the topology and size of the network constant. The degree of dynamism in the data model is defined as the number of phase changes that occur in the piecewise linear data model of the environment used by the agent. The results of these simulations are shown in figure 9.

The results from sub-figure 9(a) show that USAC adapts its power consumption based on the dynamism of the data (in contrast to GLACSWEB where the sensing protocol is static and unaffected by the type of data it is measuring). This results in the higher total value of data collected at the sink for USAC as shown in sub-figure 9(b). The high variance observed with USAC is due to the random times at which phase changes occur. Thus, if two phase changes occur very close to each other, there is a possibility of misrepresenting the changes which leads to low power consumption and low value. This experiment showed that USAC has an efficiency gain of 300% over GLACSWEB.

6. CONCLUSIONS AND FUTURE WORK

The protocol we have developed in this paper allows agents to act in a decentralised (based on the nature of their local environment) manner, while self-organising to form a network whose performance is high in terms of minimising energy consumption and maximising the value of data gained. It makes use of the localisation ability of individual agents to determine the cheapest cost path to the sink and incorporates the value of the observed data to calculate the cheapest path. We have also shown that our protocol is superior to the currently deployed GLACSWEB protocol, even when the distribution of agents around the sink and the nature of observed environment is varied.

Whilst we have specifically considered evaluating the effectiveness of our protocol in the GLACSWEB sensor network, the challenges involved here are very similar to those that occur in the design of many other sensor networks. For example, we are currently exploring the possibility of using it in the FloodNet system (a sensor network for monitoring river levels in which the sensors are solar powered)[4]. Also, in the current work, we have considered just one particular way of calculating the value of information. In future work, we wish to investigate whether more complicated information theoretic measures, such as Kullback-Liebler divergence and Mahanalobis distance, would be a better basis for measuring information and whether these more sophisticated measures would improve the system's efficiency. It would also be interesting to introduce additional factors in the simulation such as network openness and scalability (where agents come and leave the system) and extend our protocol to accommodate this aspect of dynamism in the network.

ABSTRACT

A strength of commitment protocols is that they enable agents to act flexibly, thereby enabling them to accommodate varying local policies and respond to exceptions. A consequent weakness is that commitment protocols thus fail to distinguish between possible executions that are normal and those that may be allowed but are not ideal. This paper develops an approach for specifying *preferences* among executions that are allowed by a protocol. It captures sets of executions via an event constraint specification language and gives them a denotational characterization based on branching-time models. This paper develops algorithms for choosing the best execution path by considering the interplay between the preference specification of a protocol and local policies of agents interacting using the protocol, thereby giving the specifications a natural operational characterization. The value of the concepts developed is illustrated by its application to a recent practical framework for protocols called OWL-P. Further, the paper shows that the operational and denotational characterizations of preference specifications coincide.

I..2.11 [**Distributed Artificial Intelligence**]: Multiagent Systems

1. INTRODUCTION

Commitment protocols capture the essence of the desired interactions in high-level terms. Protocols regulate the externally observable, social behavior of agents, distinguishing what is allowed from what is not. Current approaches, however, do not make any finer distinctions about what is *normal* and what is not.

This paper is about the main consequences of taking a knowledge engineering stance toward commitment protocols.

- To accommodate the openness of the given system, protocols must apply in a wide range of contexts. That is, they must generally allow multiple execution paths. For example, a purchase protocol should allow the possibility that payment might be made before delivery of goods, in which case a refund should be made if delivery is unsuccessful.
- To accommodate agent autonomy, protocols must enable the participating agents to choose their actions and responses to the above kinds of conditions as they see fit. For example, a purchase protocol should allow the possibilities that negotiations may fail, that the payment may be made via a third party, that an agent awaiting missing goods may send a reminder for them.
- To be realistic, the protocols themselves must be based on a study of different usage scenarios, wherein not all possible executions are considered equal. For example, as a practical matter, we would all recognize that it is more normal for a purchase protocol to lead to an exchange of goods and money than for a refund to be issued or for the goods to be repossessed by the merchant because of lack of payment.

In other words, protocols should be flexible enough to accommodate exceptions, but should be described in such a manner that exceptions are distinguished from normal executions. Moreover, protocol descriptions should ideally enable the specification of a hierarchy of exceptions, some being more acute (i.e., less desirable) than others.

Protocol Preferences and Agent Policies. To capture the above motivations, we propose that protocol specifications be enhanced with modular, pluggable descriptions of the *preferences* among executions of the protocol. These preferences are the protocol designer's view of what are the most normal or most desired executions. In this sense, they have a normative force. Individual agents would have their own *policies* for how they participate in a given protocol. The policies should generally be in line with the protocol preferences. (Verifying compliance with protocol preferences, however, is nontrivial—we return to this point in Section 6.)

Protocols can be refined to yield protocols that serve the same goal but impose additional requirements. For example, payment by cash is a refinement of payment (in general). Agents contemplating interacting can negotiate about the refinement of the protocol that they will enact. For example, if a merchant accepts only cash, payment by check or charge card is ruled out and payment by cash is the only kind of payment that will work.

More interestingly, agents who are participating in a protocol may negotiate about the specific actions that each would take (from among those that are allowed by the given protocol). For exam-

ple, given that two parties agree to participate as seller and buyer in a purchase protocol, they might then negotiate about whether the seller is willing to send the goods before the buyer makes a payment. Protocol preferences thus provide a basis for argumentation among the parties.

Approach. As explained in greater detail below, in our framework, protocols are denotationally characterized using sets of runs (i.e., computations), and are operationalized via translation into executable rulesets. With the above background, the approach of this paper proceeds as follows to enable augmenting protocol specifications with preferences.

- We augment an existing protocol specification language with an ability to specify preferences among different executions of protocols. For simplicity of specification, we use a simple language based on linear temporal logic to specify expressions over protocol events to identify executions that are of interest.
- We show how preferences based on such expressions can be operationalized into executable rulesets.
- We show how the above preferences are mapped into a graph whose points are sets of runs, and characterized via branching time models.
- We show that the model-theoretic and the operational characterizations coincide.

We provide the example of a typical interaction between a merchant and a customer through this paper to illustrate our approach.

Contributions. Our main contribution is in developing a new methodology for designing commitment protocols. Our methodology can be used for the following

Modeling exceptions. In traditional process models, exceptions are modeled in an ad hoc manner, when the designer demarcates blocks of the process and assigns exception handlers to those blocks. In our approach, exceptions can be defined separately from the specification of the process or the protocol. As a result, different exception conditions can be assigned to the same protocol based on the context of the protocol execution. This is similar in spirit to aspect-oriented software development.

Selecting protocols. When multiple protocols are available for an agent to realize a certain interaction, that agent can negotiate with the other parties involved in the protocol and, based on its preferences, find out if an execution of that protocol with those participants would be acceptable to it. For example, a customer agent that does not wish to enact a hotel booking protocol in which the hotel can cancel the room and award a refund can choose which hotel to interact with if its preferences are made clear before enactment and if the hotel and the customer try and negotiate the protocol to enact based on their preferences.

Organization. Section 2 introduces commitments and commitment protocols. Section 3 describes the language used to specify sets of execution sequences and its semantics. This section also describes how preferences among sets of execution sequences are specified. Section 4 gives an algorithm for resolving preferences among execution sequence sets so that agents can choose the best course of action. Section 5 lists important patterns that arise due to the interplay between local-actions, nonlocal actions, local policies, and protocol preferences. Section 6 concludes the paper with a summary of our contributions and a survey of related literature.

2. BACKGROUND

We formalize protocols as transition systems similar in spirit to commitment machines [9], which are declarative specifications. For compatibility with this model, we use the linear temporal logic-based event ordering language proposed by Singh [7] to specify preferences between sets of executions in that transition system. Although Singh's language is given semantics based on linear models, the models are related in an incremental manner to other possibilities: thus it supports a branching interpretation. We use expressions over events in this language to specify sets of runs of a protocol over which preferences can be expressed. This section briefly introduces the semantics of commitments to lay the groundwork for preference specification and introduces the language.

2.1 Commitments

A commitment $\mathsf{C}(x, y, p)$ denotes that the agent x is obliged to the agent y for bringing about the condition p. Here x is called the *debtor*, y the *creditor*, and p the *condition* of the commitment. The condition is expressed in a suitable formal language.

Commitment Operations. Commitments are created, satisfied, and transformed in certain ways. The following operations are conventionally defined for commitments, where $c \equiv \mathsf{C}(x, y, p)$: $\text{CREATE}(x, c)$ establishes the commitment c, and can only be performed by c's debtor *x*. $\text{CANCEL}(x, c)$ cancels the commitment c, and can only be performed by c's debtor *x*. Generally, cancellation is compensated by making another commitment. $\text{RELEASE}(y, c)$ releases c's debtor *x* from commitment c, and only can be performed by the creditor *y*. $\text{ASSIGN}(y, z, c)$ replaces *y* with *z* as c's creditor. $\text{DELEGATE}(x, z, c)$ replaces *x* with *z* as the c's debtor. $\text{DISCHARGE}(x, c)$ c's debtor x fulfills the commitment.

A commitment is *active* if it has been created, but not yet been operated upon by a *discharge*, *delegate*, *assign*, *cancel*, or *release*. A commitment is *satisfied* when its condition becomes true. Commitments can also be *conditional*, denoted by $\mathsf{CC}(x, y, p, q)$, meaning that x is committed to y to bring about q if p holds. A conditional commitment such as $\mathsf{CC}(x, y, p, q)$ becomes an unconditional commitment $\mathsf{C}(x, y, q)$ when its condition p holds. A commitment is *breached* when it is not possible that the commitment will be satisfied. Realistic settings assign deadlines to commitments to detect their breach or satisfaction [5].

Commitment Protocols. Commitment protocols are interaction patterns expressed in terms of the commitments that arise between the participants of the interaction. Commitment protocols have been operationalized via commitment machines. Commitment machines generate computations or *runs*, which are sequences of *states* that a valid protocol execution goes through. Propositions represent facts about the universe of discourse of the protocol such as the actions that the protocol participants have taken, commitments that have been created and operated upon, and messages that have been sent. Each state is a snapshot of the evolving state of the system (as the given agents interact), and is labeled by *propositions* that hold true there. State changes are caused by *messages* that the participants send to each other.

This paper builds on OWL-P [1, 2], which is a practical framework and an associated language for specifying, combining, and enacting commitment protocols. OWL-P (OWL for Protocols and Processes), uses OWL (Web Ontology Language) to specify protocol and protocol composition constructs. An OWL-P specification identifies roles that participate in the protocol, the messages that are exchanged (with the meanings of the messages in terms of commitments that are created), and a set of rules that constrain the set of

runs of the protocol by specifying ordering, data flow, and other constraints.

The flexibility of commitment protocols arises because they use commitments and other propositions to assign meanings to states and thus capture the essence of an interaction. Treating commitments explicitly enables further kinds of sophisticated reasoning, such as involving delegation and other kinds of manipulation of commitments. For example, a customer in a purchase protocol can delegate to a third party (such as a bank) the payment commitment that the customer has towards the merchant.

2.2 Running Example

We illustrate our approach with an example interaction in which a merchant sends some goods to a customer in exchange for a payment. The exact protocol for this exchange involves variations because the customer could pay before the merchant ships the goods and, if not satisfied, can return the item to the merchant for a refund of the payment.

3. SPECIFYING PREFERENCES

OWL-P specifies protocols declaratively and leverages the semantics of commitments and their operations to make protocols flexible. However, OWL-P does not distinguish between the normal and abnormal executions of a protocol. For example, executions in a purchase protocol that involve returns and refunds or missing shipments are treated on par with the normal executions involving no missing shipments or delayed payments. For this reason, we extend OWL-P to capture preferences among sets of executions. We first devise a language over events to concisely specify sets of protocol executions. Next, we specify preferences among such sets using this language.

3.1 The Constraint Specification Language

We use the event-based linear temporal logic $\mathcal{I}$ as introduced by Singh [7] for specifying sets of executions. We repeat here the syntax and semantics of $\mathcal{I}$ from [7]. *I* is the start symbol of the BNF for the language of $\mathcal{I}$. In this BNF, *slant* indicates nonterminals, $\longrightarrow$ and | are meta-symbols of the BNF, /* and */ begin and end comments, respectively, and all other symbols are terminals.

L_1. *I* $\longrightarrow$ *dep* | *dep* $\wedge$ *I* /*conjunction: interleaving*/

L_2. *dep* $\longrightarrow$ *seq* | *seq* $\vee$ *dep* /* disjunction: choice*/

L_3. *seq* $\longrightarrow$ *bool* | *event* | *event* $\cdot$ *seq* /* before: ordering*/

L_4. *bool* $\longrightarrow 0 \mid \top$

Dependency. A dependency is an expression generated by I. It specifies constraints on the occurrence and ordering of events.

Event Literal Set. $\Gamma \neq \{\}$ is the set of event literals as generated by the nonterminal *event.* Each event e literal has a *complement* $\overline{e}$. Intuitively, initially, neither an event nor its complement holds; ultimately, one of them must hold. Γ_D is the set of literals mentioned in a dependency D and their complements. For example, $\Gamma_e = \{e, \overline{e}\}$. For a set of dependencies $\mathbb{D}$, we define $\Gamma_{\mathbb{D}}$ as $\Gamma_{\mathbb{D}} = \bigcup_{D \in \mathbb{D}} \Gamma_D$.

In our example, we denote the payment made by the customer by p, the sending of goods by the merchant by s, the return of the goods by ret, and a refund by ref. Using these event literals, we can specify the constraint "refund can be done only after payment has been made" as a dependency $\overline{ref} \vee p \cdot ref$.

Since state labels in OWL-P capture the history of events in the system, the event-based language (and semantics) that we use here can be applied to the state-based execution semantics of OWL-P.

The formal semantics of $\mathcal{I}$ is based on runs, i.e., sequences of events. Legal runs satisfy the following requirements:

1. Event instances and their complements are mutually exclusive.
2. An event instance occurs at most once in a computation.

Universe of Runs. $\mathbb{U}_{\mathcal{I}}$ is the universe of runs; it contains all legal runs involving event instances from Γ.

3.2 Constraint Language Semantics

For a run $\tau \in \mathbb{U}_{\mathcal{I}}$ and $I \in \mathcal{I}$, $\tau \models I$ means that I is satisfied over the run τ . This notion can be formalized as follows. Here, τ_i refers to the ith item in τ and $\tau_{[i,j]}$ refers to the subrun of τ consisting of its elements from index i to index j, both inclusive. $|\tau|$ is the last index of τ and may be ω for an infinite run. We use the following conventions in the specification of semantics below: $e, f, \overline{e}, \overline{f}$, etc. are literals; D, E, etc. are dependencies; i, j, k, etc. are temporal indices; and τ, etc. are runs. The semantics of $\mathcal{I}$ is

M_1. $\tau \models e$ iff $(\exists i : \tau_i = e)$

M_2. $\tau \models I_1 \vee I_2$ iff $\tau \models I_1$ or $\tau \models I_2$

M_3. $\tau \models I_1 \wedge I_2$ iff $\tau \models I_1$ and $\tau \models I_2$

M_4. $\tau \models I_1 \cdot I_2$ iff $(\exists i : \tau_{[0,i]} \models I_1$ and $\tau_{[i+1,|\tau|]} I_2)$

Denotation. The denotation $[\![D]\!]$ of a dependency D is the set of runs that satisfy D, i.e., $[\![D]\!] = \{\tau : \tau \models D\}$.

For example, the denotation of the dependency $\overline{ref} \vee p \cdot ref$ is the set of runs in which there is no refund ($\overline{ref}$) or, if there is a refund, a payment precedes it ($p \cdot ref$).

3.3 Residuation

The residual of a dependency D by an event e is denoted by D/e and corresponds to the largest set of runs satisfying the given dependency. Formally, $\nu \in [\![D/e]\!]$ iff $(\forall v : v \in [\![e]\!] \Rightarrow (v\nu \in \boldsymbol{U}_{\mathcal{I}} \Rightarrow v\nu \in [\![D]\!]))$

The residual represents what remains in the dependency after a certain event has occurred for the dependency to be satisfied on any run. The following are residuation rules as given by Singh:

R_1. $0/e \doteq 0$

R_2. $\top/e \doteq \top$

R_3. $(E_1 \wedge E_2)/e \doteq ((E_1/e) \wedge (E_2/e))$

R_4. $(E_1 \vee E_2)/e \doteq ((E_1/e) \vee (E_2/e))$

R_5. $(e.E)/e \doteq E$ if $e \notin \Gamma_E$

R_6. $D/e \doteq D$ if $e \notin \Gamma_D$

R_7. $(e' \cdot E)/e \doteq 0$ if $e \in \Gamma_E$ where e' is any event literal

R_8. $(\overline{e} \cdot E)/e \doteq 0$

Consider the dependency $p \cdot ret \cdot ref$, which encodes "payment followed by a return followed by a refund." The residual of this dependency with p is $ret \cdot ref$, which is what is left to be done to satisfy the dependency after p occurs. The residual of this dependency with s, however, is the dependency itself, since the dependency does not specify whether s occurs.

3.4 Preferences

The specification language $\mathcal{I}$ supports dependencies to succinctly specify sets of runs. To induce a preference structure over such sets, i.e., to specify if one set is preferred over another, we introduce the *preference relation*.

Preference Relation. Let $\mathbb{R} \subseteq 2^{\mathbb{U}_\mathcal{I}} \times 2^{\mathbb{U}_\mathcal{I}}$ be the preference relation between sets of runs. $\mathbb{R}$ is irreflexive, transitive, and antisymmetric. $(S_i, S_j) \in \mathbb{R}$ means that any run in S_i is preferred over any run in S_j. Consequently, $\mathbb{R}$ is downward closed in the sense that if $(S_i, S_j) \in \mathbb{R}$, then for all subsets S_i' and S_j' of S_i and S_j, respectively, $(S_i', S_j') \in \mathbb{R}$. For convenience, we apply $\mathbb{R}$ to dependencies, meaning that their denotations are appropriately related. $(D_i, D_j) \in \mathbb{R}$ means that any run in the denotation of D_i is preferred over any run in the denotation of D_j, i.e., $\forall \tau_i, \tau_j : \tau_i \in [\![D_i]\!]$ and $\tau_j \in [\![D_j]\!], \tau_i$ is preferred over τ_j.

A commitment protocol is associated with a set of dependencies. For a protocol P specified in terms of a set of dependencies D_P, the denotation of the protocol is the set of runs that the protocol allows, and is given by $[\![P]\!] = \bigcup_{D \in D_P} [\![D]\!]$. We encode our merchant-customer example by the following dependencies

P_1. Refund only if payment has been done: $\overline{ref} \vee p \cdot ref$.

P_2. Return only if goods have been shipped: $\overline{ret} \vee s \cdot ret$.

P_3. If payment has been made and goods have been returned, then refund: $\overline{p} \vee \overline{ret} \vee ref$.

Preference Graph. A preference graph specifies preferences among a set of dependencies. Each dependency labels one node of the graph, and a preference relation specifies preferences among these dependencies, and consequently among the nodes they label. A preference graph $L = \langle D_x, R \rangle$ specifies preferences among the elements of the set of dependencies D_x using the partial order induced by R over D_x. For the above L, we define its event literal set to be the set of all events that are mentioned in the dependencies in D_x, and their negations. $\Gamma_L = \bigcup_{D \in D_x} \Gamma_D$.

Figure 1 shows a schematic representation of an example preference graph. This graph encodes the following:

D_1. The most preferred runs are those in which payment and shipping occur, and a return or a refund do not.

D_2. Less preferred than runs in D_1 are runs in which goods are returned and payment is refunded.

D_3. Also less preferred than runs in D_1 are runs in which the payment is refunded and the goods are returned.

D_4. Less preferred than all of the above are runs in which goods are returned, but no refund occurs.

D_5. Also preferred less than D_1, D_2, and D_3 are runs in which the goods are shipped, a refund is made, but the the goods are not returned.

Preference Node Denotation. The denotation of a preference node N_D labeled by D, with respect to a protocol P and a graph $L = \langle D_P, R \rangle$, where $D \in D_P$, is the set of runs allowed by the protocol that are also allowed by D, but not by nodes in L that are preferred over N_D. The motivation for the above is that each run can occur in the denotation of at most one node in the graph. Thus if a given run is allowed by two sets of runs, one preferred over the other, the run from the less preferred set would not "get credit" for this run. On each path from the top to the bottom of the graph, a given run can occur at most once. Formally, $[\![N_D]\!] = [\![P]\!] \cap ([\![D]\!] - \bigcup_{(D_i, D) \in R} [\![D_i]\!])$.

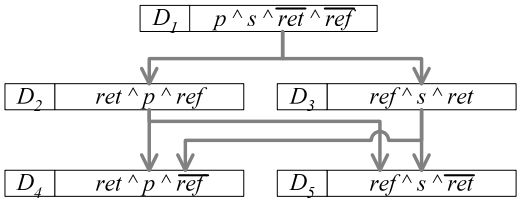

Figure 1: A preference graph for our example, $L = \langle \{D_1, D_2, D_3, D_4, D_5\}, \{(D_1, D_2), (D_1, D_3), (D_2, D_4), (D_3, D_4), (D_2, D_5), (D_3, D_5)\} \rangle$.

Consider the preference node formed from D_4. Since the protocol contains no runs in which the payment has been made, goods have been returned, and the refund does not occur, $[\![D_4]\!] = \{\}$. However, the protocol allows runs in which the payment is refunded, the goods have been shipped, but are not returned. The preference node formed from D_5 captures such runs as the least preferred runs in the protocol.

4. RESOLVING PREFERENCES

How can an agent operationalize a preference graph during protocol enactment?

4.1 Evolution of Graphs

A preference graph evolves as events occur, causing the state of the protocol to change. The evolution changes the denotation of each node of the graph because events residuate dependencies that label graph nodes. Below, we describe, and give an algorithm for, the evolution of a (preference) graph. An *evolution tree* captures the evolution of a graph. Below, $\tau + e$ concatenates event e to run τ.

Evolution Tree. An evolution tree $\mathbb{T}_L$ of a graph L represents all possible states that L can evolve through as a result of events in Γ_L. An evolution tree is a tuple, $\mathbb{T}_L = \langle \mathbb{V}, V_{\tau_0}, \mathbb{E}, L \rangle$, where $\mathbb{V}$ is a set of *evolution* nodes, V_{τ_0} is a distinguished root node, $\mathbb{E} \subseteq \mathbb{V} \times \mathbb{V}$ is a set of *evolution edges*, and L is a preference graph.

Evolution Node. An evolution node captures a state of a preference graph. An evolution node corresponds to a *path* in the evolution tree. This path is a legal run and is the sequence of the events that occurred for the evolution node to be generated, starting from the root of the evolution tree. Evolution nodes are represented as $V_\tau = \langle L, \tau \rangle$, where L is a graph (as evolved from the original preference graph) and τ is the path to V_τ from the root node of the evolution tree. The root node of an evolution tree T_L is $V_{\tau_0} = \langle L, \tau_0 \rangle$, where τ_0 is the zero-length run.

Evolution Edge. An edge labeled e that originates at V_τ ends at $V_{\tau+e}$. Thus edges are written as $\langle V_\tau, e, V_{\tau+e} \rangle$.

Given a graph L, we construct the evolution tree $\mathbb{T}_L$ for it by first creating the root evolution node $V_{\tau_0} = \langle L, \tau_0 \rangle$. From a node V_τ, we create an edge labeled e for each event e in Γ_L that does not occur in τ. For each edge e, we create a new evolution node $V_{\tau+e} = \langle L', \tau + e \rangle$. For this new node, we set $L' = \langle D', R' \rangle$, where D' is the set of nonzero dependencies obtained by residuating each dependency in L by e, and R' relates two dependencies in D' if the dependencies corresponding to them in D were related by R. That is, we preserve the preferences among the residual dependencies in the evolution nodes. Algorithm 1 generates an evolution tree of a specified finite depth.

Figure 2 shows parts of the evolution tree generated using Algorithm 1 on the graph shown in Figure 1. In this figure, end denotes a special event signaling the end of the protocol. The complements of events that have not occurred are asserted when end occurs. In the figure, for example, since ret and ref have not occurred, their complements $\overline{ret}$ and $\overline{ref}$ are asserted when end occurs.

input : A preference graph $L = \langle D_x, R \rangle$, and a limit MAX_DEPTH for the depth of the tree generated
output: An evolution tree $\mathbb{T}_L = \langle \mathbb{V}, V_{\tau_0}, \mathbb{E}, L \rangle$ of L

Create the root node $V_{\tau_0} = \langle L, \tau_0 \rangle$;
depth $\leftarrow 1$;
$V \leftarrow V_{\tau_0}$;
$\mathbb{T}_L.\mathbb{V} \leftarrow \{V\}$;
$\mathbb{T}_L.\mathbb{E} \leftarrow \{\}$;
siblings $\leftarrow \{V\}$;
while *depth* $<$ *MAX_DEPTH* && *siblings* $\neq \{\}$ **do**
  foreach *evolution node* $V \in$ *siblings* **do**
    siblings $\leftarrow$ siblings $-\{V\}$;
    foreach *event* $e \in \Gamma_L$ *such that* $e \notin V.\tau$ **do**
      $V_{V.\tau+e} \leftarrow$ `createChildNode` (V, e) ;
      $\mathbb{T}_L.\mathbb{V} \leftarrow \mathbb{T}_L.\mathbb{V} \cup \{V_{V.\tau+e}\}$;
      $\mathbb{T}_L.\mathbb{E} \leftarrow \mathbb{T}_L.\mathbb{E} \cup E$;
      if $V_{V.\tau+e}.L.D \not= \{\}$ **then**
        siblings $\leftarrow$ siblings $\cup \{V_{V.\tau+e}\}$;
  depth $\leftarrow$ depth $+1$;
return $\mathbb{T}_L$;

Procedure `createChildNode` (V, e): Create a child evolution node for the node V on event e
input : An evolution node $V = \langle L, \tau \rangle$, where $L = \langle D, R \rangle$, and an event e.
output: An evolution node that represents the state of L on event e.
$D' \leftarrow \{\}$;
$R' \leftarrow \{\}$;
foreach *dependency* $d \in V.L.D$ **do**
  if $d/e \not= 0$ **then**
    $D' \leftarrow D' \cup (d/e)$;
    foreach *preference* $(d_i, d_j) \in V.L.R$ **do**
      if $d == d_i$ ***or*** $d == d_j$ **then**
        $R' \leftarrow R' \cup (d_i, d_j)$;
$L' = \langle D', R' \rangle$;
$V_{V.\tau+e} = \langle L, V.\tau + e \rangle$;
return $V_{V.\tau+e}$

Algorithm 1: GenerateEvolutionTree(L, MAX_DEPTH): Compute the evolution tree for a graph $L = \langle D_x, R \rangle$, where MAX_DEPTH is a bound on the depth of the tree to be generated.

4.2 Choosing Between Runs

Consider an agent X operating within the preference graph specified for a protocol in which it is participating. For such an agent to determine, the action to take (there is an event corresponding to every action instance), each evolution node is a decision point. X chooses the event would that take the protocol to the most preferred preference graph node. Since preference nodes are distributed among the evolution nodes, and X cannot change the state of the protocol at a finer granularity than that of evolution nodes, X determines which evolution node is the most preferred. To determine this, a *preference graph of evolution nodes* is constructed as follows: At any evolution node, to decide the next action to take, induce a graph among the child evolution nodes using the original preference structure, i.e., the preference structure specified in the root of the evolution tree. Once this is done, induce a graph on the evolution nodes based on the following criterion. Given two evolution nodes V_1 and V_2, create an edge from V_1 to V_2 (i.e., mark that V_1 is preferred over V_2) if and only if there is a nonzero dependency D_1 in V_1 which is preferred over all nonzero dependencies in V_2, and no nonzero dependency in V_2 is preferred over D_1. Formally,

$$(V_1, V_2) \in \mathbb{O} \quad \Leftrightarrow \quad \exists D_1 \text{ in } V_1 : \forall D_2 \text{ in } V_2, \\ (D_1, D_2) \in \mathbb{R} \text{ and } (D_2, D_1) \notin \mathbb{R}$$

where $\mathbb{O}$ is the preference relation over evolution nodes. $\mathbb{O}$ is irreflexive, antisymmetric, and transitive by the above definition. Algorithm 2 shows how a preference graph can be constructed between evolution nodes. Applying this algorithm to the children of the root evolution node V_{τ_0} in Figure 2, we obtain the evolution node graph shown in Figure 3. Figure 4 shows the same graph in detail. Since V_p contains the dependency D_1/p which is preferred over all dependencies in V_{ret} and no dependency in V_{ret} is preferred over D_1/p, we create an edge from V_p to V_{ret}. Similar reasoning for all four evolution nodes yields the graph of Figure 3.

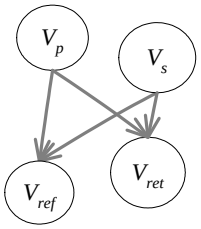

Figure 3: The preference graph for the evolution nodes V_p, V_s, V_{ret}, and V_{ref} shown in Figure 2, based on the preference graph L shown in Figure 1

Selecting the Best Path. Given the graph of preferences among the child (evolution) nodes, the best action to take (event to bring about) is the event that leads to a node in the evolution node graph over which no other node is preferred. However, the evolution node preference graph might have many such nodes. The agent can then choose any one of these. Section 5 discusses some criteria for path selection.

4.3 Types of Events

So far, we have discussed a single agent's perspective. In agent interaction, however, events are brought about by different agents during the enactment of a protocol. Choosing the best path, if one is available, is therefore not up to a single agent. We therefore recognize two types of events, *observed* and *controlled*.

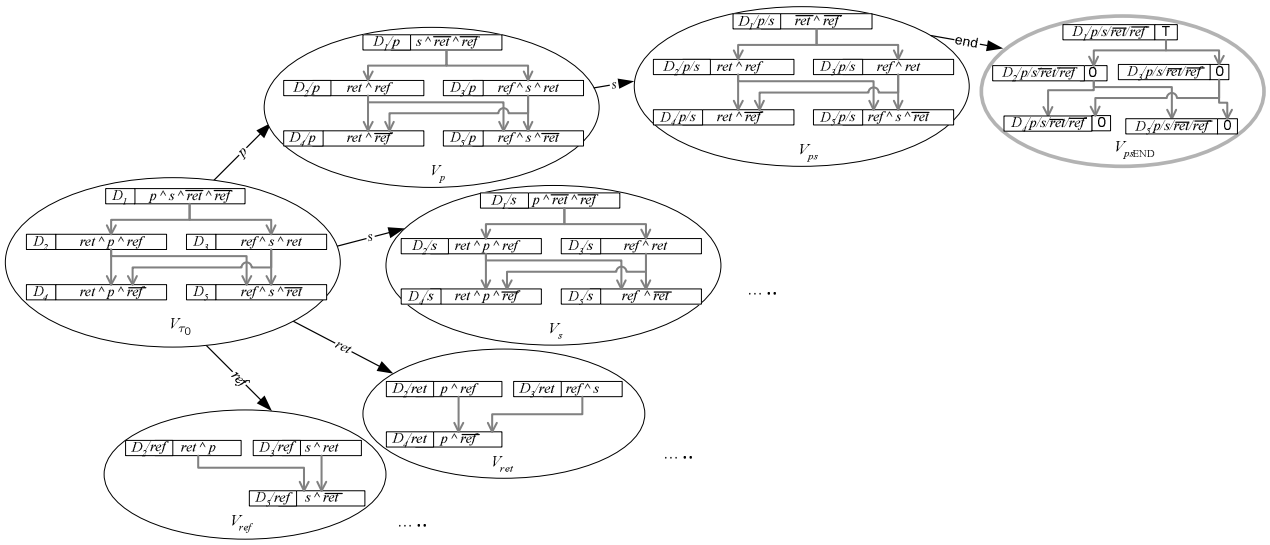

Figure 2: A partial evolution tree for the preference graph shown in Figure 1. Note that the denotations of preference nodes are not taken into consideration in this figure, so that we can illustrate the generation of the evolution nodes clearly. If denotations were taken into account, $[\![D_4]\!] = \{\}$, and this figure would have fewer dependencies. END is a special event signaling the end of the run.

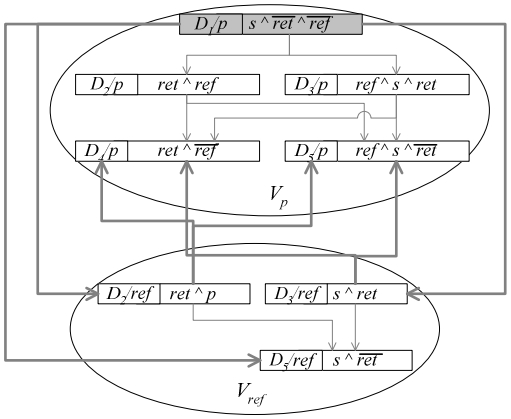

Figure 4: A detailed view of a part of the evolution node preference graph shown in Figure 3. Grey arrows indicate the preference relation. V_p is preferred over V_{ref} because of D_1/p, which is shown in a grey rectangle.

Controlled Events. For a given agent, an event that it can bring about is called a controlled event. We introduce a distinguished controlled event, Noop, which means "do nothing" (in this protocol). An agent can perform a Noop to wait.

Observed Events For a given agent X, an event which X can observe, but not bring about, is called an observed event. We distinguish two unique observed events, start and end, which are observed by agents participating in a protocol when the protocol begins and ends, respectively.

Whether an event is observed or controlled is decided when the events are described for the system being modeled. In our example, payment (p) and return (ret) are controlled events for the customer, and observed events for the merchant, whereas sending goods (s) and refund (ref) are controlled events for the merchant and observed events for the customer.

5. PATTERNS FOR PATH SELECTION

Given that an agent will make a choice at every node of the evolution tree, and that events can be controlled or observed, we identify typical patterns of decision-making that agents can adopt in common situations. Before describing these patterns, we explain rule-based protocols of the type found in the OWL-P framework.

5.1 Rule-Based Protocols

We envision the application of our algorithms in a rule-based protocol enactment framework, such as OWL-P. OWL-P enables agents to specify their *local policies* independent of the protocol specification. The general structure of rules in such protocols is the Event-Condition-Action (ECA) structure,

$$\begin{array}{c}\text{On } e\\ \text{if } \textit{localPolicy}(e, x)\\ \text{then do } a(x)\end{array}$$

Here, e is an event and $a(\cdot)$ is an action (with a corresponding event e_a), which depends on the local policy for its parameters.

As an example, consider a purchase protocol which requires that the receiver of a $\textit{rfq}(c, m, \textit{itemID})$ message (which is a request for a price quote for an item)–the merchant m–respond the the sender–the customer c–with a $\textit{quote}(m, c, \textit{itemID}, \textit{price})$ message (which is a price quote). The rule for this requirement will be

$$\begin{array}{c}\text{On } \textit{rfq}(c, m, \textit{itemID})\\ \text{if } \textit{localPolicy}(\textit{rfq}(c, m, \textit{itemID}), \textit{price})\\ \text{then do } \textit{quote}(m, c, \textit{itemID}, \textit{price})\end{array}$$

Where multiple choices of action are afforded by the protocol on the same triggering event, there will be one rule for each action, with the same event and condition. In such a case, the local policy decides which rule to enable. In case the policy enables multiple rules, the preference specification of the protocol is used to decide which action to take. Based on these principles, we describe patterns of decision-making that agents can use.

5.2 Clear Choice

If an agent has to choose between paths in an evolution tree, and exactly one most-preferred node exists in the evolution node preference graph, the agent takes the path to that node. This situation is shown in Figure 5, and is termed *Clear Choice* .

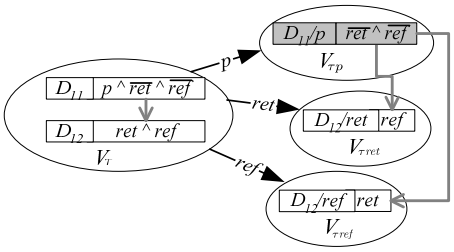

Figure 5: Clear choice: An agent can unambiguously decide which path to choose, since the evolution node preference graph has exactly one node $V_{\tau p}$, over which no other node is preferred.

Using Noop. Sometimes, even when there is a clear choice, an agent might not take any action because of its local policy. Consider the situation shown in Figure 6. This is a variant of our example in which the customer can send an rfq, which is a request for a price quote, to the merchant, to which the merchant can reply with q, which is a quote. At V_τ, the customer c can send either an *rfq* or a payment. According to the preference graph (dictated by the protocol), *rfq* is preferred over payment. However, the customer might not wish to send an *rfq*. Further, instead of performing the only other alternative, payment (p), the customer might want to wait, hoping for a quote (q), or a shipment (s) from the merchant. Since the protocol does not require that c act immediately (most realistic protocols have a notion of timeouts and deadlines), c can perform a Noop, which is do nothing, waiting till its policy allows it to perform an *rfq* or till the protocol forces c to perform p (which will also be a policy decision, if the policy has been designed to not violate the protocol).

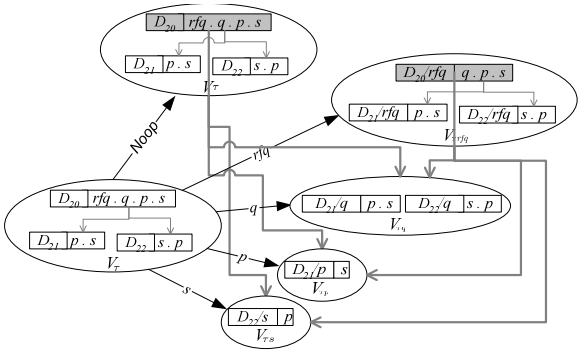

Figure 6: Using a Noop when local policy does not allow the best choice and the protocol does not impose immediate deadlines on the other choice(s). rfq is the best choice for the customer, followed by p, but the the customer chooses to wait using a Noop. This creates two most-preferred nodes, V_τ and V_{rfq}.

5.3 Unclear Choice

The choice of action to take (or event to generate) will be unique if there is exactly one evolution node over which no other node is preferred. However, this is not always the case. Although there will never be a cycle among the preference relations between the evolution nodes (straightforward proof by construction of the evolution node preference graph), it is possible that there are multiple most-preferred nodes, as in Figure 3, where both V_p and V_s are most-preferred, i.e., the customer can either pay or wait for the merchant to send the goods. Since the choice here is between a controlled and an observed event, we call this situation *Unclear Nonlocal Choice*. In such a case, the agent may choose to wait for other agents participating in the protocol to take some action.

There can also be cases in which two or more controlled events are most-preferred (*Unclear Local Choice*). An agent will rely on its local policy to make a choice when this happens. In the Noop example, if there were no preference between D_{20} and D_{21}, the customer would have to decide whether to send an *rfq* or to send a payment. In OWL-P, such local policy-based decisions drive the protocol by enabling agents choose one run from among the many runs that a protocol allows.

6. DISCUSSION

Protocols help us capture agent interactions perspicuously. The very strength of protocols, namely, their flexibility, can pose a challenge. Executions allowed so as to make a protocol flexible under exceptional conditions can begin to be selected over superior executions even when the exceptional conditions do not obtain. This paper proposes that protocols be specified generically, and preference conditions among different sets of runs be stated separately, depending on the context of usage of the protocol. Preferences serve as a rough-and-ready means to capture design goals wherein the normal executions are preferred, yet abnormal executions arising from exceptions or unexpected actions by some of the agents are allowed.

This paper identified a denotational semantics for preference conditions understood as a graph. Next, it showed how such a graph evolves as events and actions take place. It proposed a simple method by which an agent can decide upon its next action, describing an anomalous condition and giving an algorithm for identifying it.

Preferences are often understood solely in decision-theoretic terms. Decision theory is clearly important for modeling preferences and coming up with strategies for acting according to them. However, a denotational understanding of preferences can support the proper application of decision theory.

Related Literature. Yolum and Singh [10] developed one of the first operationalizations of commitments. They specified protocols by listing legal states in terms of the commitments and domain propositions that hold at that state, and using an event calculus planner to generate the set of runs that were allowed. Winikoff *et al.* [9] advance this line of research. Fornara and Colombetti have also proposed a commitment-based interaction protocol framework [3]. However, none of the above approaches specify or operationalize a notion of preferences among the various execution sequences allowed by a protocol. Our work, therefore, is a significant step in this direction. Grosof *et al.* [4] implement rule based agent interaction systems where rules are prioritized. Grosof and colleagues propose *Courteous Logic Program*s, or CLPs. In a CLP, when there is ambiguity regarding which rule to fire, i.e., a conflict arising because multiple rules can be fired at a particular state of the world, the priorities assigned to the rules are used to resolve the conflict. Our work is similar to CLPs in this respect, but different in that we propose a scheme in which preferences among *runs* are specified, independent of a protocol specification. Further, we also present a methodology for translating these preferences into rules that can be

embedded into the (rule-based) protocol specification.

Our work is based on the concept of social interaction among agents, which gives importance only to the observable behavior of agents. We describe how preferences among runs can exist. However, we do not study how agents can reason about the benefits of using one set of protocol runs over another. Pasquier and Chaib-Draa [6] introduce the cognitive dissonance theory into multiagent communication by incorporating the theory and dialogue game protocols into agent interactions. Their theory explores ways in which agents can decide when to start dialogues with other agents and what kind of dialogues to initiate, among other things. This line of research is complementary to and would strengthen the interaction framework we have presented here. Preferences among the available runs of a protocol have also been studied from the game theoretic point of view by Otterloo *et al.* [8]. They describe a logic that can be used for reasoning about a strategy to adopt in a game when the preferences of other agents in the game are known. The work differs from ours because of the use of games instead of commitment protocols. Also, preferences of agents are assumed to be known by other agents, which does not always apply in real-world applications such as the business interaction we have outlined in this paper. We plan to incorporate such reasoning among agents into our framework.

input : An evolution node V_τ, and a root preference graph $L_r = \langle D_r, R_r \rangle$
output: A graph $L_e = \langle V_e, R_e \rangle$ representing the preferences among the child nodes of V_τ.

1 $V_e \leftarrow$ All child nodes of V_τ;
2 $R_e \leftarrow \{\}$;
3 **foreach** *child node* $V_{\tau+x}$ *of* V_τ **do**
4 **foreach** *child node* $V_{\tau+y}$ *of* V_τ **do**
5 **foreach** *dependency* d_x *in* $V_{\tau+x}$ **do**
6 isPrefOverAll $\leftarrow$ true ;

ABSTRACT

In multi-agent systems, social commitments are increasingly used to capture roles, social norms, the semantics of agent communication as well as other inter-agent dependencies. Those systems rest on the assumption that agents respect their commitments. In this paper, we present an ontology of sanctions and punishment philosophies which are required ingredients of any social control mechanism susceptible to fosters agents' compliance with the commitments they create.

1. INTRODUCTION AND MOTIVATIONS

A multi-agent system (MAS) is considered an *open* MAS if the following properties hold [5]: (1) agents' behavior and interactions cannot be predicted in advance; (2) agents' internal architecture is not publicly known and (3) agents do not necessarily have common goals, desires or intentions.

The first of those properties implies that the execution of open MAS is *non-deterministic*. Open societies are usually subject to unanticipated outcomes in their interactions. The second property implies that an open MAS can have members with different internal architectures; therefore, they can be *heterogeneous*. The third property implies that the members of an open society may be non-benevolent, non-cooperative or even insincere. In addition, the agents may fail to, or choose not to, conform to some of the normative aspects of the MAS in order to achieve their individual goals. In that context, providing the means and tools for the achievement of a chosen/emergent social order in such system is a challenging issue.

Social commitment has been introduced as a public and social primitive that allows to capture all social and normative dimensions of MAS, including: social norms, roles and the semantics of communication as well as other interagent dependencies. One of the key feature of those public and social primitives is their flexibility, which allow to take into account the dynamic of the environment. Most approaches assume that the agents will respect their social commitments (thus applying regimentation). This assumption is unrealistic since unintended violation is likely to occur and unilateral cancellation as well as commitment modification are desirable.

In a perspective of knowledge transfer, this short paper presents an ontology of social control mechanisms that can be used to support the *enforcement of flexible social commitments* in open systems.

2. ONTOLOGY OF SANCTIONS AND SOCIAL CONTROL MECHANISMS

Introduced in sociology as early as the end of the 19th century, the concept of social control originally denoted the capacity of a group or society to regulate itself and to secure coherency and unity in social life [7]. Social control, in this sense, relates to how social action is coordinated toward a chosen or an emergent social order. Often seen as all-encompassing, practically representing any phenomenon leading to conformity or as a broad representation of regulated mechanisms placed upon society's members, social control can be viewed as the glue holding society together [4].

Modern theories of social control focus on the strategies and techniques that help to regulate agent behavior, and lead to conformity and compliance with the rules of society (at both the macro and the micro levels). In the remainder of this section, we detail the main elements used in the enforcement of social commitments: (1) sanctions, which are considered in their general sense of incentives (the next section presents an ontology of sanctions along their different dimensions), and (2) philosophies of punishment (Section 2.2), which result in punishment strategies determining the type of sanction (and its magnitude) to be applied, and explains how sanctions are assigned to social commitments.

2.1 Sanctions

In this paper, we only consider *individual sanctions* and, for simplicity, leave aside other types of sanctions, such as *collective sanctions* [6] (which may be associated to teams, roles or groups of agents). In the next subsections, we go through the three main dimensions of sanctions: direction, type and style.

Sanction Directions

Sanctions have a specific direction. It is usually useful to consider both:

- *positive sanctions*: positive sanctions are rewards that encourage a continuation of desired behavior. For ex-

ample, it is common in open systems that agents accept committing to a task only if the associated reward is worth pursuing.

- *negative sanctions*: on the other hand, negative sanctions are used to discourage norm violating behavior. For example, agents that cannot fulfill their commitments are expected to be punished.

In brief, positive sanctions are incentives to pursue a particular behavior while negative sanctions are incentives against its violation. For the sake of simplicity, in the rest of the paper we use the words sanction to denote negative sanctions, and reward to denote positive rewards

Sanction Types

The first sanction type is *automatic sanctions*, which arises when the violators action carries its own penalty (e.g., because it is not being coordinated with the actions of others). For example, someone who drives on the wrong side of the road has a higher than normal probability of crashing into another car. We will not consider these unintended (since no one decides that they should apply) sanctions in the scope of this paper.

Within the vast literature addressing this topic from various perspectives including economics, criminology, sociology, social psychology, AI and MAS, we encounter three broad types of non-automatic sanctions: (1) material sanctions, (2) social sanctions, and (3) psychological sanctions.

Material sanctions include physical sanctions like physical retaliation or repairing actions, as well as financial sanctions like fees. Material sanctions can be applied immediately at the time of occurrence or be delayed through time.

There are *social sanctions* as well. Trust, credibility and reputation are social values that could be affected by social sanctions. As pointed out in [9], social sanctions are usually the effects of some implicit informational disclosure where the violator's action conveys information about himself that he would rather not have others know. For example, that an agent cancels or modifies a big number of its commitments without any explicit reason might be taken into account by the other agents when evaluating his reputation and the trust they put in him.

Psychological sanction types, which may be more useful in believable agents [1] and which have been used in advanced mono-agent design in mixed communities, can be important as well. Examples of psychological sanctions are guilt (where the violator feels bad about his violation as a result of his knowledge of social norms, quite apart from external consequences), and shame (where the violator feels that his action has lowered himself either in his own eyes or in the eyes of other agents).

The time horizon of sanctions indicates whether the effects of sanctions are long-lasting or short-lived. This concept is important since some sanction types may extend through time (e.g., trust, reputation, credibility) while others may not (e.g., immediate material sanctions). Subtle and complex phenomena, like forgiveness, can require taking into account this time issue.

Sanction Styles

For the specific formal needs of MAS, we distinguish two sanctions styles: implicit and explicit. *Implicit sanctions* are "autonomously" and unilaterally decided by agents. The major difficulty associated with implicit sanctions is that they are not publicly known and agents have to discover whether or not they have been sanctioned (for example, by noticing that others do not communicate with them anymore). On the contrary, *explicit sanctions* are publicly known (at least among the interacting agents).

Another useful distinction can be made between *a priori* decided sanctions and *a posteriori* decided sanctions. In particular, a posteriori decided sanctions do not allow agents to reason about the pros and cons of respecting their commitments. That the punished agent can disagree with the sanction assigned a posteriori may lead to litigation. The complexity associated with litigation makes a posteriori sanctions less desirable than a priori sanctions in open MAS.

In the remainder of the paper, we will consider only a priori defined explicit sanctions. Among a priori known explicit sanctions, we can distinguish *static*, a priori known, explicit, sanction systems provided to all agents at design time, and *dynamically* decided, a priori, explicit sanctions, which are negotiated by the agents through their communications.

2.2 Punishment Policies

Social control mechanisms to enforce social commitments should be designed according to a philosophy of punishment. By punishment, we mean the imposition of sanctions to satisfy open system designers' desire for retribution against wrongdoers. According to social control theorists, there are five different philosophies of punishment from which all *punishment policies* can be derived [10]:

- *Deterrence*: issued from the classical school of criminology, and supported by philosophers like Beccaria [2] and Bentham [3], deterrence is a utilitarian principle stating that the aim of sanctions is to prevent future violation. For deterrence to be effective, punishment must be swift, certain and severe. Applied to the enforcement of social commitment in MAS, it means that commitments should be associated with heavy and explicit sanctions. This extreme position, i.e. using severe sanctions with a high prohibitive effect, tends to transform social commitments into strict obligations, losing part of the flexibility objective desired for commitments.

- *Retribution*: retribution considers that the violation should be repaired by a penalty as severe as the wrongful act.

- *Incapacitation*: incapacitation considers the impairment or restriction of the agent's ability to commit the violation again. In human societies: exclusion, firing, and imprisonment, are the most common methods of incapacitation. Applied to the enforcement of social commitment in MAS, this punishment philosophy may result, for example, in the exclusion of wrongdoers from the system (at least for a certain time). As in human societies, it could have a preventive effect toward others violations, but it is not sure that it could be practical for artificial agents. Although, it is a consideration that is system-dependant, incapacitation usually results in the loss of opportunity during the time of the punishment, a circumstance that could be considered as a material sanction. For example,

in e-business systems, losing activity time usually has material consequences. Since it is reducible to some material explicit sanction, we will consider incapacitation as a special case of the retribution philosophy in the rest of the paper.

- *Rehabilitation*: rehabilitation is the process of correcting from erroneous behavior and returning to a rightful course. This philosophy seems more difficult to implement in MAS since it would require policies to notify the entity responsible for wrongdoers that its decision-making mechanism must be corrected. Moreover, this philosophy would suppose pro-social learning capabilities that cannot be imposed in an heterogeneous open system.

- *Restoration*: restoration attempts to make the victim and community "whole again" through rituals. This punishment mainly occurs in less industrialized countries and will not be treated here since it requires social and cultural dimensions that are not yet considered in MAS.

Since punishment philosophies like incapacitation, rehabilitation and restoration focus on the choice of sanctions types and styles rather than on the choice of sanctions strength, we will restrict our analysis to the two remaining philosophies: deterrence and retribution. While both of them seem adequate for open MAS, we will argue that retribution is a practically better choice for open MAS.

Indeed, the last decades of work in economics and law provide two basic reasons why it is best for sanctions to equal harm[1]. Here, we reformulate these arguments toward retribution punishment policies using MAS terminology.

The first argument concerns the *level of precautions* taken by parties, where the term "precautions" is to be interpreted generally. If sanctions are less than harm, precautions will tend to be inadequate and agents will tend to not respect adopted social commitments when it is to their advantage to do so. Symmetrically, if sanctions exceed harm, precautions will be excessive and may preclude agents committing to wanted commitments (this is the case with the deterrence punishment philosophy). For example, even if sincerely wanting to, an agent will not commit to a course of action if the sanctions attached to violation (which may occur unintentionally) are prohibitive. However, it has been shown that if sanctions equal harm, agents will have socially correct incentives to take precautions [8].

The second reason why it is desirable for sanctions to equal harm involves the agents' *level of activity*, that is, the extent to which agents participate in risky activities. An agent's level of activity affects the magnitude of expected total harm, independently of the precautions taken when engaging in an activity. For example, the more commitments an agent takes (its level of activity), the greater the possible number of accidents (violations) will occur, independently of the safety features of the agent (which affect the expected harm per commitment) [8].

It is worth noticing that concluding that damages should equal harm would require making two assumptions. The first assumption is that agents are *risk neutral*. If injurers are risk averse then the optimal level of sanctions tends to be lower than harm, because it reduces the imposition of risk on injurers and because sanctions do not need to be as high to induce injurers to behave appropriately. The second assumption is that of *strict liability*, which stipulates that injurers are definitely found liable and that injurers cannot escape the corresponding sanctions.

[1]Here, harm is the violation of a particular social commitment and is at least equal to the effort that is needed to fulfill the commitment.

3. CONCLUSION

In this paper, we have raised the problem of the enforcement of flexible social commitment in open systems which has been neglected in the past. We have introduced and discussed tools for treating this problem (Section 2), namely sanctions (Section 2.1) and punishment philosophies (Section 2.2). In doing so, we have shown that supporting the enforcement of social commitments may be made through a priori defined explicit sanctions (statically specified or dynamically negotiated) under a retribution punishment philosophy. In order to gain flexibility, the regimentation usually associated with social commitments has been moved to the sanction system itself. Indeed sanctions must be respected to ensure that this solution does not lead to the meta-problem of the enforcement of sanctions.

Notice that the design of (domain dependent) punishment policies, linking objective (or subjective) actions values to material sanctions, is an open research issue that we wish to inquire in future work.

ABSTRACT

Social commitments have been increasingly used to model inter-agent dependencies and normative aspects of multi-agent systems such as the semantics of agent communication. However, current cognitive agent architecture rest on a formalization of private mental states. In this paper, we propose a modelling of the links between private mental states resulting in individual intentions and social commitments.

1. INTRODUCTION AND MOTIVATIONS

On one hand, social commitment has been introduced as a first class concept to represent socially established (and grounded) interagent dependencies and normative aspects such as roles, authority relations, social norms and the semantics of agent communication [13]. On the other hand, main current cognitive agent architectures rest on a formalization of private mental states [18]. In this paper, we propose a modelling of the links between private mental states (resulting in individual intentions) and social commitments when used in the context of agent communication.

2. SOCIAL COMMITMENTS

Social commitments are useful to model the semantics of agents' interactions. In that context, being able to cancel or modify commitments is a key feature that allows agents to reassess the consequences of past dialogues in the context of dynamic environments. This *semantical flexibility* should not be confused with the commonly considered structural flexibility of dialogues. Since [9] discusses our modelling of flexible social commitments and their enforcement through sanctions, we simply re-introduce the basic of it here.

The notion of commitment is a social one, and should not be confused with the notion of individual commitment used to emphasize individual intention persistance. Conceptually, commitments are oriented responsibilities contracted towards a partner or a group. Following [17], we distinguish *action commitments* from *propositional commitments*.

Commitments are expressed as predicates with an arity of 6. Thus, an *accepted* action commitment takes the form:

$$C(x, y, \alpha, t, s_x, s_y)$$

meaning that agent x is committed towards agent y to α since time t, under the sanctions sets s_x and s_y. An accepted propositional commitment would have propositional content p instead α. *Rejected* commitments, meaning that x is not committed toward y to α, takes the form $\neg C(x, y, \alpha, t, s_x, s_y)$. This notation allows to compose the actions or propositions involved in the commitments: $\alpha_1|\alpha_2$ classically stands for the choice, and $\alpha_1 \Rightarrow \alpha_2$ for the conditional statement that α_2 will occur in case of the occurrence of the event α_1. Finally, agents keep track of each commitment in which they are debtor or creditor in their *agendas*, which constitutes a kind of distributed "Commitment Store".

In previous work, we have proposed a dialogue games based agent communication language (DIAGAL [7]) which is sound an complete according to the creation, cancellation, modification and discharge of social commitments. In that context, social commitments allow to get ride of the main problems associated with the mentalistic semantics previously proposed. Indeed, according to the principle of *information asymmetry*, what is said does not convey anything about what is actually believed. However, what is said socially commits the locutors toward one another. Social commitments raise action expectations and the enforcement of social commitments through various social control mechanisms take place instead of the sincerity and the cooperativeness assumptions. Social commitments, when modelled with their enforcement mechanism (as in [9]), are not necessarily sincere and don't require the agents to be cooperative. From this perspective, communication serves to coordinate the agents whether or not they are cooperative and whether or not they are sincere.

These social commitment based frameworks, enhancing the social aspects of agents' communications, entail a change of paradigm: agents do not necessarily have to reason on others' intentions anymore but rather they must reason on taken and to be taken social commitments. However, social commitments were not taken into account in previous cognitive agents theory. As a first step to fill this gap, we propose to model the links between private cognitions and social commitments.

3. INDIVIDUAL INTENTIONS

According to the classic practical reasoning scheme, private cognitions end up in intentions through deliberation and we make the usual distinction between *intention to* (do something or that someone do something) and *intention that* (a proposition holds) [2]. The *intention to* relates to a particular course of action (eventually of a complex and structured type), while *intention that* refers to a propositional statement that the agent wants to became true. Intentions are either accepted ($I_A(p)$) or rejected ($\neg I_A(p)$).

In order to address the social dimension of communication, we will further distinguish between *internal individual intentions* and *social individual intentions*[1]. Internal individual intentions are intentions that the agent can try to achieve alone while social individual intentions are the intentions that relate to other agents' actions. Social individual intentions are intentions concerning goals which require other agents to be worked on. More generally, any intention that is embedded in a somewhat collective activity would be considered as a social individual intention except if it is part of an already socially accepted collective plan. Those social intentions are intentions about a (even indirectly) collective state of affairs indicating that those intentions will be part of a social activity (a problem requiring action, permission or opinion of the others: commerce, exchange, joint action, delegated actions,...). A classic example is delegation where an agent A has the social intention that an agent B achieves a particular action α, $I_A(\alpha_B)$.

Among internal individual intentions, we will also consider *failed individual intentions* which are the intentions that the agent failed to find an individual plan for or for which the available plans failed. This last type matches the case where the agent faces an individual problem he cannot solve alone or he failed to solve alone.

In our approach, failed individual intentions as well as the social individual intentions will be treated through dialogue. The phase of identifying intentions involving a social dimension appears to be crucial for integrating social commitment based approaches with existing cognitive agent architectures. In our approach, all intentions that are not achievable internal intentions will be selected as such. Filtering those failed and social intentions from the other ones is achieved by selecting the intentions for which the mean-end reasoning failed. For example, in the JACK-BDI framework [6], intentions that don't match any individual plans or for which all available individual plans have failed fall into those categories. Notice that this selection process implies that trying to achieve individual action (through execution of individual plans) is the prioritized behavior of the agent. Figure 1 sums up this intention typology.

4. LINKING INTENTIONS AND SOCIAL COMMITMENTS

In this context, we can return to the general question: what are the links between social commitments and private mental states? As a first answer, we propose linking private and public cognitions as follows. Ideally, an accepted social commitment is the socially accepted counterpart of an

[1]With the "individual" qualifier in both, we mean that we do not refer to notions of we-intention or collective intentions such as those developed by [11] or [15]. Here, intentions are classical private intentions.

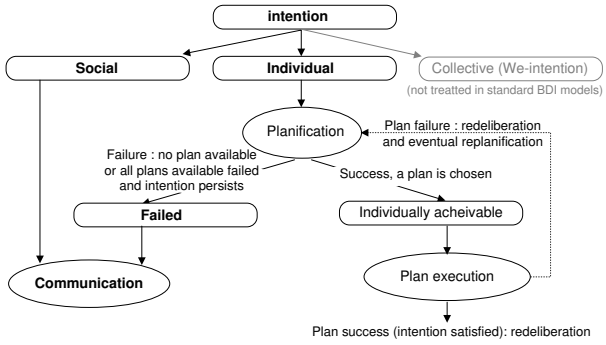

Figure 1: Operational typology of intentions.

accepted intention. Commitments in action are the counterparts of "intentions to" while propositional commitments are the counterparts of "intentions that". In our approach, those links are taken into account by positive and negative binary constraints that link the agents intentions and social commitments. Positive constraints take into account the correspondence relation introduced above while negative constraints model the incompatibility relations that hold between incompatible intentions or/and social commitments.

Let's take an example to illustrate those relations. If an agent A has the accepted individual social "intention to" that another agent B achieves an action α (noted $I_A(\alpha_B)$), our links mean that the corresponding social commitment from B toward A to achieve α_B (noted $C(B, A, \alpha_B, t, s_B, s_A)$ must be socially accepted as part of this intention satisfaction. This ideal link between those two cognitions is captured with a positive constraint. For this constraint to be satisfied, both elements (the intention and the corresponding commitment) must be accepted or rejected. However, all other possibilities are also important to consider. Furthermore, incompatibility relations are modelled with negative constraints.

5. RELATED WORK

Those relations between the private and public cognitions are not completely new since many authors have already considered individual intentions as a special kind of individual commitment [2, 16]. Our links extend this to reach the social level in the appropriate cases by saying that social individual intentions or failed individual intentions should ideally lead to the social acceptance of their social commitments counterparts through dialogue. Those links complement Singh's previous work [12], which introduces the idea of linking individual and social commitments. Comparable links have been introduced for so-called normative-deliberative cognitive agent architecture [5, 1, 3]. In particular, following [4], the following axioms have been introduced [10]:

$$S\text{-}COMM(i, j, \tau_i) \rightarrow I_j(\tau_i),^2 \text{ and}$$
$$S\text{-}COMM(i, j, \tau_i) \rightarrow I_i(\tau_i)$$

From which, one can deduce the following theorem:
$\vdash \neg S\text{-}COMM(i, j, \tau) \vee (I_i(\tau) \wedge I_j(\tau))$, which clearly states

[2] Sometimes formulated : $S\text{-}COMM(i, j, \tau_i) \rightarrow Goal_j(Does_i(\tau))$.

that either the social commitment is rejected or both i and j have the intention that i achieves the action τ. This formalization is not compatible with the semantic flexibility of social commitments described in Section 2. For example, if i decides to violate or cancel the aforementioned commitment, it is probably because he does not have the corresponding intention accepted. In that case, we have the accepted commitment $S\text{-}COMM(i, j, \tau_i)$ and the rejected intention $\neg I_i(\tau_i)$ that holds which invalidates the second of the above axioms. Symmetrically, if the agent j tries to cancel the accepted commitment $S\text{-}COMM(i, j, \tau_i)$, it can be because he does not have the corresponding intention accepted. In that case, we have $S\text{-}COMM(i, j, \tau_i)$ and $\neg I_i(\tau_i)$ which invalidates the first of the above axioms. In other words, those axioms are not flexible enough to provide a good modelling of the links that lie between intentions and flexible social commitments.

Constraints provide bidirectional and symmetric links that go behind the above mentioned axioms.[3] This is why we used constraints in order to model those links. Examples where a commitment is accepted and the corresponding intention is not or the reverse are very common and just mean that the positive constraint linking those two elements is not satisfied. As a consequence, not only those bidirectional links are more correct than the previously criticized axioms but they allow for a new question to be asked. When such a constraint is not satisfied, the agent has to decide which elements' acceptance state he will try to change in order to satisfy this positive constraint: his intention or the corresponding social commitment. This is the basic question of the attitude change process that we modelled in previous works [8].

6. CONCLUSION

While social commitments capture the social interdependencies of the agent, individual intentions make the links between the agent private cognition and its individual or social behavior. This short paper advances the state of the art by motivating and proposing a modelling of the links between individual intentions and social commitments. While this idea is not new, it is shown how the proposed links improve previous proposals.

ABSTRACT

In this paper we present the MAP^a language for expressing coordination and communication between agents in multi-agent systems. This is accomplished by defining patterns of dialogues between groups of agents, expressed as protocols. Our protocols are flexible and directly executable. Furthermore, our language allow us to specify the connection between communication and knowledge management in a way that is independent of the specific reasoning techniques used.

1. INTRODUCTION

Multi-Agent Systems (MAS) are a popular technique in Artificial Intelligence for effecting reasoning in a distributed manner. These systems are defined from collections of individual agents which are composed together into systems within an environment. Each individual agent is an autonomous and rational entity, and exhibits intelligent behaviour based on interactions with other agents in the environment. It is this intelligent behaviour that distinguishes a MAS from a conventional distributed software system.

An agent in a MAS is intended to perform in a similar way to a human agent. That is, the agent should be capable of acting on behalf of others, either humans or agents. To accomplish this, it is necessary for the agent to be able to *communicate* and *coordinate* with other agents to achieve certain tasks. This inter-operability between agents is surprisingly difficult to achieve. There are a wide range of issues that have to be addressed, including at least the following: The agent must divide the problem into tasks for which external cooperation is required, and find suitable agents to accomplish these tasks. The tasks must be communicated to the external agents, who must in-turn agree to participate. The agent should interact with these external agents to ensure the task is accomplished, and finally interpret the outcome to obtain the results. These issues may be further complicated as the external agents may use different formalisms or have a different world-view from the initiating agent. Furthermore, it is generally not possible to compel another agent to perform any particular task. Instead, it is typically necessary for agents to negotiate to reach a consensus on a given task. The provision of a solution to many of these issues is the focus of this paper.

To address the issues of communication and coordination that we have highlighted, it is useful to take our inspiration from human *social systems*, where these issues are solved in the real world. Following this approach, it is common to treat a group of agents as a *society* [3]. The agents in the society will typically share a common interest, e.g. solving a particular problem. To become a member of this society, an agent must agree to observe certain rules and conventions. In return, the agent can itself benefit from the society, e.g. the expertise of other agents. In this societal view, it becomes possible to define conventions for the agents to follow, and the incentives for agents to operate together are made clear. This in-turn makes the issues of communication and coordination more manageable.

In any society, the rules and conventions are expressed as *social norms*. These norms may often be implicit, but are necessary nonetheless. For example, at a conference talk there is an implicit norm that the speaker does the talking while the audience listens. If everyone were to talk at the same time then the conference would break down. Thus, it is these social norms that ensure the smooth running of the society. Returning to MAS, we can readily define social norms for a group of agents to follow. These rules should be defined in such a way to facilitate the successful interaction between agents. However, the rules should not be overly restrictive in that they affect the autonomy of the agents.

A popular way to express the social norms between groups of agents is by means of an explicit *protocol*. A protocol is a statement of the social norms. The protocol can be examined in-advance by an agent to inform their decision on whether to join a particular society. The protocol also acts as a guide for the agents to follow once they are operating within the society. This approach has been successfully adopted in the Conversation Policy (CP) [2] and Electronic Institutions (EI) [1, 4] formalisms, among others.

In this paper, we define a language which can express protocols. Our protocols define patterns of *dialogue* between groups of agents. If a group of agents follow a particular dialogue then they should reach a particular well-defined outcome. Nonetheless, the protocols contain decision points in which the agents can behave autonomously. The protocols that we define are *executable specifications*. That is, the formalisms that we use to specify our protocols are exactly the same as those used for enactment. This is in contrast to the more traditional means of MAS construction, where an initial specification is refined into an executable model. For example, a MAS specified in a Belief-Desire-Intention (BDI) logic, and implemented in a FIPA-compliant architecture.

Our language defines Multi-Agent Protocols, and is called MAP^a. This language is an extension of the MAP language which we previously presented in [6]. The extensions in this paper make the protocols more flexible and dynamic, but retain the lightweight nature of the previous definitions. In MAP^a, we treat protocols as first-class objects which can be passed between agents as opposed to our previous static definitions. We also permit the organisation of roles in hierarchies, structuring role definitions in a modular and reusable way. Finally, we permit the management of knowledge to be expressed in our protocols, which enables a better connection between the protocol and the agent reasoning processes at the decision points.

2. MAP^A LANGUAGE DEFINITION

MAP^a is a lightweight language-based formalism for the expression of protocols, which express social interactions between groups of agents. The key concepts in MAP^a are *scenes*, and *roles* which we now explain. A scene can be thought of as a bounded space in which a group of agents interact on a single task. We assume that a scene places barrier conditions on the agents, such that a scene cannot begin until all the agents are present, and the agents cannot leave the scene until the dialogue is complete.

The concept of an agent *role* is also central to the definition of our protocols. Agents entering a scene assume a role which they can change during the scene. For example, a hospital scene may involve agents with the roles of *doctor* and *patient*. Roles are defined as a hierarchy, where more specialised roles appear further down in the graph of roles. For example, an agent may initially assume the role *doctor* but may change to the more specialised role *surgeon* during a scene.

A protocol is defined as a sequence of definitions parameterised on the role. Thus, the protocol steps which an agent follows in a scene are directly dependent on the role, or subrole, which they assume. The role also identifies capabilities which the agent must provide. It is important to note that a protocol only contains operations which are specific to the mechanisms of communication and coordination between agents. This makes it straightforward to understand the operation of the protocol without extraneous details, and makes it possible to verify the protocols using automated means, e.g. model checking [5]. All of the other agent facilities, e.g. the reasoning processes, are encapsulated by *decision procedures* which are external to the protocol. In effect, the decision procedures provide an interface between the communicative and the rational process of the agent. We allow a decision procedures to be private to a particular agent, or shared between agents playing the same role.

Interaction between the agents in a scene is performed by the exchange of messages. Messages can be sent or received and this exchange happens in a blocking manner. Every message has an associated identifier which is used to indicate the type of the message and parameters. For convenience, we do not assign any fixed semantics to these messages. However, individual agents can agree on a semantics for a particular scene. In this way, we can readily represent FIPA-style agent communication, e.g. the contract-net protocol.

The final concept in MAP^a is the representation of knowledge management during agent interaction. The language allows us to define *knowledge*, represented as axioms, at a scene level, a role level, or the level of an individual agent. In this way, we can clearly express the exchange of knowledge between one agent and another, and the transition from private to public knowledge of certain facts during protocol execution.

Figure 1: MAP^a Language Syntax.

A BNF-style abstract syntax for MAP^a is shown in Figure 1. Superscripts are used to indicate a set, e.g $P^{(i)}$ is a set with elements P of size i. To illustrate the MAP^a language syntax we now define in Figure 2 a general negotiation protocol. We have used the following abbreviations: IS is an Information Seeker role, IP is an Information Provider role, t and newt are a negotiation topic and new negotiation topic, f and newf are a fact and new fact, a is an answer, and prot is a protocol variable.

There are four parts to the negotiation protocol, parameterised on the roles of Patient, GPDoctor, IS, and IP. The core of the dialogue is between an information seeker (IS) and an information provider (IP). The roles Patient and GPDoctor begin the dialogue. The Patient starts searching for a suitable information provider for a given topic and fact (t, f) and will then initiate a dialogue with this provider. $K^{(b)}$ and $Proc^{(a)}$ stand for Patient knowledge and Patient procedures. $K^{(b)}$ can be defined as the basic knowledge that patients have about illnesses, and $Proc^{(a)}$ can be the set of possible actions to perform in presence of some illness. GPDoctors adopt the role of providers with advanced knowledge of medicine, $K^{(d)}$, and treatments for the known diseases, $Proc^{(c)}$.

The information provider (IP) is defined in four cases separated by the choice operator. The evaluation model of the protocol is such that the protocol will backtrack and retry

agent(id$_1$, Patient, Proc$^{(a)}$, K$^{(b)}$, t, f) =
id$_2$=search_doctor(t, f) then (agent(id$_1$, IS,
Proc$^{(a)}$,K$^{(b)}$∪{answer(t,f)=null}, t, f, id$_2$)).

agent(id$_1$,GPDoctor, Proc$^{(c)}$, K$^{(d)}$)=
agent(id$_1$, IP, Proc$^{(c)}$, K$^{(d)}$).

agent(id$_1$, IP, Proc$^{(t)}$, K$^{(z)}$) =
(request(t, f) ⟸ agent(id$_2$, IS)
then agent(id$_1$, IP, ∅, ∅)) or
(a=get_answer(t, f) then
inform(t, f, a) ⟹ agent(id$_2$, IS)) or
(prot = get_protocol(t, f) then
what_to_do(t, f, prot)⟹agent(id$_2$, IS)) or
((newt, newf) = next_to_know(t, f) then
agent(id$_1$, IS, ∅,
{answer(t,f)=null,answer(newt,newf)=null},
newt, newf, id$_2$) then agent(id$_1$, IP, ∅, ∅, id$_2$)).

agent(id$_1$, IS, Proc$^{(m)}$, K$^{(s)}$, t, f, id$_2$) =
(request(t, f) ⟹ agent(id$_2$, IP) then
agent(id$_1$, IS, ∅, ∅, t, f, id$_2$)) or
(inform(t, f, a) ⟸ agent(id$_2$, IP) then
agent(id$_1$, IS, ∅, {answer(t,f)=a} , t, f, id$_2$) or
result=Newknowledge({answer(t,f)=a})) or
(what_to_do(t, f, prot) ⟸ agent(id$_2$, IP) then
prot
then agent(id$_1$, IS, ∅, {answer(t,f)=prot} ,t,f,id$_2$)
or result=Newknowledge({answer(t,f)=prot}))
or (request(newt, newf) ⟸ agent(id$_2$, IS)
then agent(id$_1$, IP, ∅, ∅)
then agent(id$_1$, IS, ∅, ∅, t, f, id$_2$)).

Figure 2: MAP^a Negotiation Protocol.

each of these cases until one of them can be satisfied. In the first case, the information provider receives a request for information (on some topic and fact) from an information seeker. The information provider will then update its state and attempt to answer the request. The appropriate answer is determined in the remaining cases. The second case is triggered when the information provider has a direct answer for the request, in which case this answer is returned to the seeker. In the third case, it is necessary for the seeker to perform additional actions before the request can be satisfied, so the provider sends a protocol to the seeker containing the appropriate actions. In the final case, more information is required, so the provider becomes a seeker for this new information. What he learned as IP is taken as private knowledge for the new role of IS (answer(t,f)=null, answer(newt,newf)=null). Upon obtaining the extra information, the agent reverts back from a seeker to a provider again.

The information seeker (IS) protocol is essentially the complement of the information provider protocol, and there are four corresponding cases. In the first case, the seeker sends a request for information to the provider. The remaining cases deal with the responses from the provider. In the second case, the requested information is received from the provider and the protocol either restarts with the new private knowledge (answer(t,f)=a) or terminates. In the third case, a protocol is received from the provider which is evaluated. Lastly, in the fourth case, a request for more information is received, and the agent assumes the role of a provider until this request is satisfied.

3. CONCLUSIONS

In this paper we have presented an overview of our MAP^a language. The purpose of this language is the specification of the communication and coordination processes between groups of agents in a multi-agent system. This is accomplished by the definition of protocols which express social behaviours between the agents. In particular, these protocols define social norms which agents must observe if they are to participate in, and benefit from, the society. The use of protocols ensures that the interactions between agents in the society happen in a controlled and predictable manner. Nonetheless, these protocols do not overly restrict the individual autonomy of the agents.

Our approach differs from previous work on multi-agent protocols, in a number of important ways. Our protocols are executable specifications, and we have constructed a meta-interpreter for our protocols in Java. This direct execution eliminates a potentially error-prone refinement task between the specification and implementation. Our protocols are defined separately from the reasoning processes of the agents. This enables our protocols to be independently examined and verified before an agent subscribes to the society. Furthermore, it permits a range of reasoning strategies to be adopted, e.g. reactive or planning systems, rather than restricting us to a single model.

With regard to future work, we plan to use MAP^a in conjunction with Web Services, to perform service composition on the Semantic Web. We also plan to use the language with eco-grammars to perform automatic agent-based grammar generation. Our future plans for extensions to the language include facilities for constraint satisfaction and the inclusion of deontic relationships between agents.

ABSTRACT

We study how decentralized agents can develop shared vocabularies without global coordination. Answering this question can help us understand the emergence of many communication systems, from bacterial communication to human languages, as well as helping to design algorithms for supporting self-organizing information systems such as social tagging or ad-word systems for the web. We introduce a formal communication model in which senders and receivers can adapt their communicative behaviors through a type of *win-stay lose-shift* adaptation strategy. We find by simulations and analysis that for a given number of meanings, there exists a threshold for the number of words below which the agents can't converge to a shared vocabulary. Our finding implies that for a communication system to emerge, agents must have the capability of inventing a minimum number of words or sentences. This result also rationalizes the necessity for syntax, as a tool for generating unlimited sentences.

Keywords

self-organizing vocabularies, win-stay lose-shift

1. INTRODUCTION

We study the question of how decentralized agents can develop a shared vocabulary without global coordination. This is a fundamental question that underpins how we understand the emergence of many communication systems arising in nature and in human society, e.g., how do different organisms develop the communication needed to coordinate their activities, how do encoding/decoding networks arise in the brain, or how did human languages emerge? The study of this question can also help us design algorithms that support self-organizing information systems such as social tagging, web ad-words, or peer-to-peer retrieval systems.

Two general frameworks, *evolutionary* and *self-organizing*, have been proposed to study the emergence of communication systems. Evolutionary frameworks assume that vocabularies of agents are inherited genetically and/or learned culturally from parents or teachers. The driving force for the emergence of shared vocabularies comes from mechanisms in which good communicators produce more offspring with similar vocabularies[2, 6, 7]. In contrast, in self-organizing frameworks decentralized agents actively develop shared vocabularies without global knowledge in a short span of time by changing their own representations via distributed learning and positive feedback loops[1, 3, 4, 8]. The work reported here can be seen as an effort in the self-organizing camp.

Most existing work on the development of shared vocabularies has been done using computer simulations and only intuitive interpretations. While this is often suggestive, to achieve a thorough understanding we need to augment simulation studies with mathematical characterizations of specific conditions and limitations under which the emergent behaviors are stable. Recent work by Baronchelli et al.[1] provides one example; they explain how a sharp transition to a shared vocabulary observed in simulations can occur as the density of certain inter-agent vocabulary hypotheses grows beyond a "tipping point."

In this paper, we focus on a formal communication model in which senders and receivers can adapt their communicative behaviors through a type of win-stay lose-shift learning strategy[5]. To simplify the characterization of the dynamics, we study a model that consists of two agents. Through simulations and analysis, we give the conditions under which the agents can develop a stable shared vocabulary.

2. WIN-STAY LOSE-SHIFT ADAPTATION MODEL

Our communication model consists of two agents, called a *sender* and a *receiver*. In our model, there are m meanings $\{x_1, \cdots, x_m\}$, and n words $\{y_1, \cdots, y_n\}$. The sender and

Figure 1: An illustration of repeated play of communication games.

receiver each have a dictionary, consisting of a list of entries. The sender's entry is of the format $<meaning, word>$ or $<x, y>$. Each entry is indexed by a meaning; it indicates that for each meaning there is one and only one entry. For each entry $<x, y>$, there is an associated number that indicates how many more times the sender has successfully communicated the meaning x via the word y than he has failed to do. Such a number is called the *wins* of the entry, and denoted by $wins_s(x)$, where the subscript $_s$ indicates the sender. We require $wins \geq 0$. When there is no win (i.e., $wins = 0$), the word y will be empty. Initially, all entries have no win.

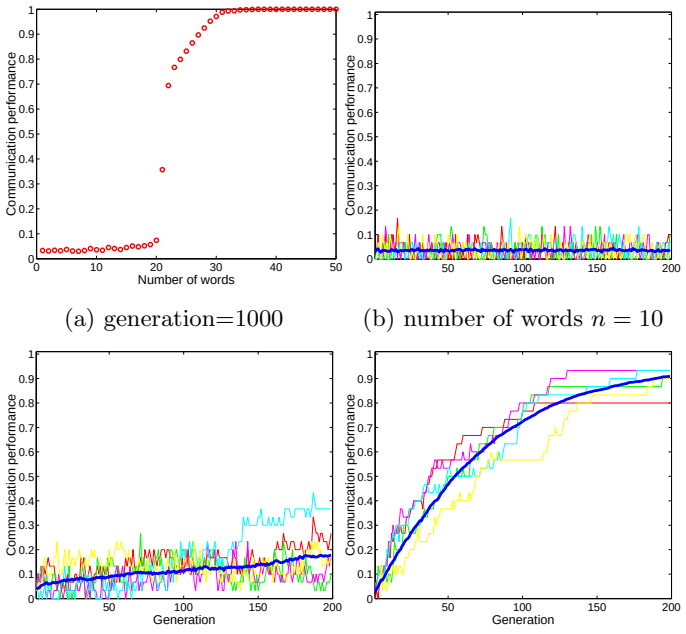
Similarly, the format $<word, meaning>$ or $<y, x>$represents the receiver's entry. Each entry is indexed by a word; it indicates that for each word there is one and only one entry. For each entry $<y, x>$, there is an associated number that indicates how many more times the receiver has successfully interpreted the word y to the meaning x than he has failed to do. Such a number is called the *wins* of the entry, and denoted by $wins_r(y)$, where the subscript $_r$ indicates the receiver. When there is no win (i.e., $wins = 0$), the meaning x will be empty. Initially, all entries have no win.

A communication event is initiated by the sender who tries to communicate a meaning to the receiver. The meaning that the sender wants to communicate is drawn according to some probability distribution. (In this short paper, we will assume it is uniform distribution.) To communicate a meaning, say, x, the sender needs to represent it as a word. The sender looks up the meaning x in his dictionary. Let the found entry be $<x, y>$. If $wins_s(x) > 0$, then the sender will use word y to represent the meaning x. If $wins_s(x) = 0$, which means the word y is empty, then the sender will randomly choose a word to represent the meaning. (This is the idea of *win-stay lose-shift*.)

When receiving a word, say, y, the receiver looks up the word in her dictionary. Let the found entry be $<y, x'>$. If $wins_r(y) > 0$, then the receiver will use the meaning x' to interpret the word y. If $wins_r(y) = 0$, which means the meaning x' is empty, then the receiver will randomly choose a meaning as the interpretation to the word.

If the interpreted meaning x' is correct (we suppose *successful task performance* can provide feedback on communicative success), i.e., $x' = x$, we say the communication is successful; otherwise, the communication is failed. When the communication succeeds, the sender will update the *wins* of the entry indexed by x according to the reward rule: $wins_s(x) \leftarrow wins_s(x) + 1$. If the word field is empty he will replace it with the word y. Similarly, the receiver will update the *wins* of the entry indexed by y according to the rule: $wins_r(y) \leftarrow wins_r(y) + 1$. If the meaning field is empty she will replace it with the meaning x.

When the communication fails, the sender will update the *wins* of the entry indexed by x according to the rule: $wins_s(x) \leftarrow wins_s(x) - 1$ if $wins_s(x) > 0$. If $wins_s(x) = 0$ he will replace the word field with empty. Similarly, the receiver will update the *wins* of the entry indexed by y according to the rule $wins_r(y) \leftarrow wins_r(y) - 1$ if $wins_r(y) > 0$. If $wins_r(y) = 0$ she will replace the meaning field with empty.



We call one communication event between the sender and receiver a *communication game*, and thus we model the vocabulary development process as repeated play of communication games (Fig. 1).

3. SIMULATIONS

In this section, we show by simulations that for a given number of meanings, there exists a threshold of the number of words below which the agents can't develop a shared vocabulary using the win-stay lose-shift adaptive communication model. In Fig. 2(a), we can see that there exists a dramatic *phase transition* when the number of words n is around a *threshold* $n^* = 21$. When n is above the threshold, the two agents can develop a communication system with converged communicative performance given by $\min\{\frac{n}{m}, 1\}$; that is, the sender and receiver can develop $\min\{n, m\}$ meaning-word agreements. However, when the number of words is below the threshold, it rapidly approaches random guess—the sender and receiver can't develop any effective communication system, or a shared vocabulary. The three graphs (c,d,e) in Fig. 2 illustrate the dynamics of communication over time for three specific settings of the number of words: $n = 10$, $n = 21$, and $n = 40$.

4. A SIMPLE ANALYSIS

In this section, we give a simple analysis aiming to understand why the above phase transition phenomenon happens. The basic idea is that soon or later the sender and receiver will form a temporary meaning-word agreement. Then, in the following rounds, this temporary agreement may be either reinforced or weakened. If the temporary agreement has a better chance to be reinforced than to be weakened, random walk theory tells us that the temporary agreement will have a positive probability of becoming a permanent agreement. We will show that the probability for a temporary agreement to become permanent depends on the relation between the number of words and the number of meanings. When the number of meanings is fixed, the more the words,

(a) generation=1000 (b) number of words $n = 10$

(c) number of words $n = 21$ (d) number of words $n = 40$

Figure 2: (a) Communication performance (success ratio) as a function of the number of words n when the number of meanings is held constant at $m = 30$. A dramatic phase transition occurs when the number of words n is around a threshold $n^* = 21$, above which the agents can develop a communication system with eventual communication performance given by $\min\{\frac{n}{m}, 1\}$. The performance numbers, marked by red circles, are obtained by averaging the results from 100 runs (after 1000 generations, where each generation contains $m = 30$ rounds of play). (b,c,d) Dynamics of adaptive communication over time (only 200 generations are shown). The thick lines in the graphs are obtained by averaging the results of 100 runs, 5 of which are shown as thin lines. All meanings are uniformly distributed.

the better the chance for a temporary agreement to become permanent. (See Fig. 1 for a better understanding of the following analysis.)

For simplicity, we will assume that all meanings are uniformly distributed. Since we have m meanings, so given a meaning the probability that it is chosen for play is $\frac{1}{m}$.

Without loss of generality, let a temporary agreement be on the meaning-word pair (x_1, y_1). With probability $\frac{1}{m}$, at the next round the sender will play game on the meaning x_1. Clearly the communication on meaning x_1 will succeed, so the *wins* value of the sender and receiver, $wins_s(x_1)$ and $wins_r(y_1)$, will increase by 1. Therefore we have a *reinforcement probability* of $\frac{1}{m}$ that the temporary agreement will be reinforced.

With probability $1 - \frac{1}{m}$, at the next round the sender will play game on a meaning other than x_1, say, x_2. If the *wins* value of x_2 in the sender's dictionary is zero, i.e., $wins_s(x_2) = 0$, then the sender will randomly choose a word from the n words to represent the meaning x_2, and so there is a probability of $\frac{1}{n}$ that word y_1 will be used to represent the meaning x_2. If this happens, the communication will fail, because the receiver will interpret word y_1 as meaning x_1. And then, the *wins* of the word y_1 in the receiver's dictionary, $wins_r(y_1)$, will decrease by 1. In summary, we have a *weakening probability* of $(1-\frac{1}{m})\frac{1}{n}$ that the temporary agreement will be weakened.

If the reinforcement probability, $\frac{1}{m}$, is larger than the weakening probability, $(1 - \frac{1}{m})\frac{1}{n}$, the temporary agreement will become stable. Therefore, by solving the following inequality

$$\frac{1}{m} > (1 - \frac{1}{m})\frac{1}{n}$$

we can see that when $n > m-1$, the sender and receiver can guarantee to establish a permanent agreement. Note that if in the above analysis we consider the case of $wins_s(x_2) > 0$, then the weakening probability will be even lower, and thus the condition $n > m-1$ can be relaxed. This partly explains why in the above simulations the threshold value is $n^* = 21$ rather than $n^* = m - 1 = 29$.

Clearly, the two agents can develop as many as $\min\{m, n\}$ stable agreements, since there are at most $\min\{m, n\}$ distinct pairs of meaning-word. And thus, the maximum converged communicative performance should be $\min\{m, n\}\frac{1}{m}$ or equivalently $\min\{\frac{n}{m}, 1\}$.

5. CONCLUSION

We have presented an adaptive communication model in which a sender and a receiver can adapt their communicative behaviors through a simple learning strategy—win-stay lose-shift. By computer simulations and mathematical analysis, we find that for a given number of meanings, there exists a threshold for the number of words below which the agents can't develop a shared vocabulary. Our finding shows that for a communication system to emerge, agents must be able to invent a minimum number of words or sentences. This result also rationalizes the necessity for syntax, as a tool for generating unlimited sentences.

Though this analysis treats just two communicating agents, we believe it can be extended to the case of multiple agents—one sender and many receivers, many senders and one receiver, or many senders and many receivers.

ABSTRACT

We study the effects of various *emergent* topologies of interaction on the rate of language convergence in a population of communicating agents. The agents generate, parse, and learn sentences from each other using recurrent neural networks. An agent chooses another agent to learn from, based on that agent's *fitness*. Fitness is defined to include a frequency-dependent term capturing the approximate number of interactions an agent has had with others—its "popularity" as a teacher. This method of frequency-dependent selection is based on our earlier *Noisy Preferential Attachment* algorithm, which has been shown to produce various network topologies, including scale-free and small-world networks. We show that convergence occurs much more quickly with this strategy than it does for uniformly random interactions. In addition, this strategy more closely represents choice preference dynamics in large natural populations, and so may be more realistic as a model for adaptive language.

1. INTRODUCTION

One of the main problems in language evolution is to get a population of agents to converge to a common language, without globally imposing some kind of hierarchy on the population. The general problem can be stated as "Given a landscape of states and possible moves between them, and a search strategy under which agents learn from encounters with others, what constraints on the agent interaction topology will ensure the most rapid convergence to some highest-fitness state?" In effect, how should agents make choices of learning partners to achieve the fastest collective convergence to the best objective state? This is the problem we study, in the context of developing a common and high-quality language.

The "fitness" of a state in this formulation is defined by both an intrinsic measure (the objective quality of the state), and by a frequency-dependent measure (the number of agents that are in that state).

A simple strategy for rapid convergence would be to designate a special agent from which each agent learns its own language. This corresponds essentially to a pre-imposed or designed language, which may or may not be of the highest objective quality. Such a centralized system is brittle in practice because a) the teacher agent has to be responsible for adapting the language to keep up with changing tasks, environments and needs of all the agents, b) communicative load on the teacher increases at least linearly with population size, reducing scalability, and c) the centralized teacher is a single failure point. Multi-agent systems are generally distributed and open, which means that there is no central control point, and agents may enter and leave the population at any time. This means that although desirable for its speed, uniformity, and certainty, a pre-imposed interaction topology with a centralized teacher is both undesirable and unrealistic for a general multi-agent system.

2. RELATED WORK

Although there has been much work on how the topology of interaction graphs affect the convergence of a population of agents, none has focused on emergent topologies.

Delgado[2], extending the model of Shoham and Tennenholtz [5], examined the emergence of social conventions in a population of agents. His key result showed that social conventions could emerge much more quickly amongst a population of agents with small-world or scale-free interac-

tion graph topologies rather than regular interaction graphs. The interaction graph topology was prespecified though, and there was no learning in the model.

Lee et. al [4] empirically studied the effect of interaction topology on the critical learning fidelity in the Komarova et. al. model [3]. Although several different interaction topologies were used, the topologies were not emergent and were prespecified by the creator of the experiments.

Our agents use simple recurrent neural networks to generate, parse, and learn languages from each other. Further, the interaction topology emerges in a distributed manner as a consequence of a specific rational agent strategy, based on our own Noisy Preferential Attachment (NPA) algorithm [6]. These two mechanisms, taken together, capture the desirable features of *agent autonomy* (learning and choice), *realism* (*emergent* global interaction patterns), and *flexibility* (continuous adaptation of the collective language space).

3. EXPERIMENTAL FRAMEWORK

Fitness: In our model, Each agent has a fitness, defined as follows:

$$f_i(t) = \alpha L_i(t) + (1 - \alpha)K_i(t). \quad (1)$$

$L_i(t)$ is the intrinsic fitness of the language used by agent i at time t, which may correspond to its expressivity or how good it is at describing a task. $K_i(t)$ is the number of times agent i has communicated a set of messages to another agent up to time-step t. $K_i(t)$ is normalized over the population. α is a constant representing a tradeoff between these two components of fitness.

Interaction topology: At each time-step, an agent chooses another agent with whom to interact, with probability proportional to the fitness of that agent. With a small probability p, however, it might switch to another agent chosen uniformly randomly. This "noise" is helpful in keeping the topology from getting too centralized.

The intuition is that if a large number of agents are listening to a particular agent, then it makes sense to pay more attention to that particular agent because its language is probably shared by many agents. The key thing here is that the central teacher agent *emerges* from the interactions between agents, rather than being prespecified.

The parameter p also models incomplete knowledge of the interaction history of the entire population. The assumption is that, since there is no central controller telling each agent the fitness of all the other agents, each agent must maintain an estimate of the fitness of the other agents. Since the agents may not be able to observe all the other agents all the time, this estimate will have some error. It turns out that we can take advantage of this error to produce scale-free topologies. In the absence of error, i.e. if $p = 0$, frequency-dependent selection would result in a pin-wheel topology. This is because initially none of the nodes in the graph have any links, and so the first node to acquire a link acquires all the links. However, when $p \neq 0$, but is small, it can be shown that the resulting topologies have power-law like or exponential degree distributions. This model for determining interactions is derived from a version of the preferential attachment algorithm [1], which we call *Noisy Preferential Attachment* (NPA), that is based on the replicator-mutator equation of biological evolution.

4. EXPERIMENTS AND RESULTS

We did an experiment with a population of 200 agents. The intrinsic fitness term for each agent, L_i, was set to zero, because in the current experiments the agents are not situated, i.e. they are not performing a particular task, nor are they receiving any external inputs except communication from other agents.

The parameter p, which is the probability of choosing a partner uniformly randomly, was set to 0.05. The maximum sentence length was set to 10. The number of agents sampled by the learner, m, was set to 1.

The set of terminals for all the languages was the same, and consisted of five symbols: `a, b, c, d, e`. Each agent's SRN had five input nodes, six hidden layer nodes, and five output nodes. The symbols were encoded using a 1-of-n encoding, and all weights were initialized uniformly randomly in the range $[-0.5, 0.5]$.

The simulation was run for 2000 time steps, and coherence of the population was evaluated every 20 time steps. Coherence is evaluated as the average error of an agent on a set of sentences sampled from the entire population. An agent only took the last 300 time steps into account when selecting an agent to interact with. The simulation was run twenty times with identical parameters, and the results are shown in figures 1 and 2.

	a	b	c	d	e	none	mean frequency	variance
Freq-dep Interaction	5	0	13	1	0	1	.7715	.008
– Cluster A	1	0	5	0	0	0	.644	.005
– Cluster B	4	0	8	1	0	0	.811	.001
Uniform Interaction	0	0	0	0	0	20	nan	nan

Table 1: The dominating language in the 20 frequency-dependent interaction runs and the 20 uniformly random interaction runs. The letter dominance threshold was set to 0.75 and the language dominance threshold was set to 0.5. Mean frequency and variance is the average and variance of the proportions of the dominating language.

A key difference between the runs is that the networks in clusters A and B are dominated by a single node, whereas the outliers both have multiple nodes with high in-degree. This difference can be objectively measured by calculating the *betweenness centrality* for the networks. Betweenness centrality is a value that measures how close a network is to a pin-wheel structure. It is a number between 0 and 1, and a low value means that the network is closer in topology to a ring or a fully-connected network. As shown in table 2, the average betweenness centrality for clusters A and B is very close to 1, whereas the value for the outliers is much smaller.

Network	Average betweenness centrality
High outlier	0.5451
Cluster A	0.9348
Cluster B	0.9016
Low outlier	0.7881

Table 2: The betweenness centrality for a network measures to what extent it is dominated by a single node.

The surprising fact here is that betweenness centrality is smaller for both the high and the low outlier. This can be explained by examining the actual languages to which the populations converge.

An agents language is dominated by the letter `a` if the frequency of the letter `a` is higher than some *letter dominance threshold*. A run is dominated by letter `a` if the proportion of agents using `a` dominated languages is higher than the *language domination threshold*. For each run of the simulation, we found the dominant language, or whether the run was not dominated.

Table 1 shows the distribution of dominating languages. In nearly all the frequency-dependent interaction runs, there was a dominating language. The average of the proportion of the dominating language is .7715. The one run that did not converge to a dominating run is the high outlier in Figure 1. In this case, the language distribution was split between an `a` language and a `b` language, which is why there is a high error for this run. This run resulted in a network with low betweenness centrality, just like the low outlier, but the difference is that in this run, the two most connected nodes in the network correspond to agents with different languages. In the low outlier, the most connected nodes all correspond to agents with the same language.

5. DISCUSSION AND FUTURE WORK

We showed that by incorporating a frequency-dependent measure in the definition of fitness for an agent, we can generate scale-free topologies, which lead to quick convergence. This definition of fitness makes intuitive sense: if many agents are talking to a particular agent, then it pays to talk to that agent more, since it probably speaks a widely-spoken and useful language.

However, the tradeoff in this case is convergence vs robustness. Networks with high betweenness centrality, as are generally observed in our simulations, are very susceptible to attack, because removing the dominant node will cause the network to fall apart. This suggests one direction for future work: how do we converge to a stable language if agents have finite lifetimes?

The other observation is that the population converges to a "simple" language, i.e. a language consisting entirely of strings of a single symbol. It may be the case that in the absence of some external pressure towards a complex language, populations always tend towards a maximally simple common language as it is the most easily learnable. This suggests another natural followup: how do we converge to a "good" language? The "goodness" of a language can be incorporated into our framework using the frequency-independent part of fitness. Thus, agents that are particularly good at solving some task and talking about it may have high frequency-independent fitness. Therefore we intend to study convergence in a situated population of agents, where the environment would provide the pressure towards a more complex language.

ABSTRACT
To integrate protocols in real organizations, we need to take into account three complementary dimensions: the protocols behavior, the structure and deontic aspects of the organization being considered and its informational model. Basic Petri Nets (PN) are known to deal suitably with the behavioral aspect while some high level extensions are intended to take into account one of the additional dimensions. This paper proposes a formalism called *Organizational Petri nets* to capture these three dimensions in a coherent framework. We give the definition of this new formalism, precise its semantics and illustrate its use through an example.

1. INTRODUCTION
Protocols are one of the basic building blocks [7] for structuring the design of Multi-Agent Systems (MAS) and coordinating their execution. In real-world applications such as Agent-Oriented Information Systems (AOIS), protocols involve three inter-dependant dimensions: the behavioral, organizational and informational ones. These three dimensions may capture by the three inter-related models described below. *The behavioral model* describes the protocol control structure, i.e. the actions (performatives sending or receiving, elementary actions) constituting the steps of a protocol, and their coordination (a pre-order relation between these interventions). *The organizational model* should refer to the logical actors able to carry out the activity of the organization, in order to define the specific contribution of each role with regard to the others and the rule applied to grant these roles to the concrete actors. This determines "what agents have permission to do within a protocol". Moreover, AOIS applications – such as e-alliance, inter-organizational workflow or e-institutions – often deal with documents conform to regulations like contracts or norms. In this case two other deontic aspects should be represented: obligation and prohibition. Finally, the *informational model* represents documents, forms and data having attributes that are handled and exchanged by the actors of the organization, possibly through the contents of communicative acts.

Although High Level Petri Nets are suitable for specifying, validating, simulating and even implementing protocols (see [1],[2],[3]), when referring to the state of the art, no Petri net dialect meets all the previous requirements. However, two works merit to be examined. The first one is due to Raskin and al. [9] who extend Petri nets by integrating deontic aspects. Unfortunately, this work is based on basic Petri nets and does not allow to represent the actors and information involved in Protocols. In other words, protocols cannot be described within their execution context. The second work, by Sibertin [5], proposes the Petri Nets with Objects (PNO) formalism which combines coherently the Petri net theory and the Object-Oriented (OO) approach. While PN are very suitable to express the dynamic behavior of protocols, the OO approach permits the modeling and structuring of its active (actors) and passive (information resources) entities. In a basic PN, tokens are atomic undistinguishable items, whereas in a PNO they are objects provided with attributes and methods. Unfortunately, PNO do not take into account the deontic aspect of Protocols. Notably, they do not give means to represent the obliged and prohibited actions.

Consequently, the aim of this paper is to provide a High Level Petri net language integrating the above three dimensions (behavioral, organizational and informational) to represent AOIS protocols. The proposed formalism is a combination of the two above-mentioned languages: Deontic Petri Nets [4] and PNO [5]. After presenting the formalism, we develop an example for the modeling of the book borrowing procedure of a library.

2. ORGANIZATIONAL PETRI NETS

2.1 Syntactic Definition of OgPN
Definition 1 (OgPN): An Organizational Petri Net (OgPN) is a n-uple (C,P,T,V, PreCd, Act, EmR, Pre, Post, Resp, Cost, CTD):

- **C** is the set of classes of the object processed by the net, **C** = **A** ∪ **D** where **A** contains the classes of active objects (the organizational actors) and **D** contains the classes of passive data or resources; any object class in *A* is assumed to have a predefined *penalty* attribute;
- **P** is the set of *places*, typed by a function ***P→ C****;

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. To copy otherwise, or republish, to post on servers or to redistribute to lists, requires prior specific permission and/or a fee.
AAMAS'06, May 8-12, 2006, Hakodate, Hokkaido, Japan.
Copyright 2006 ACM 1-59593-303-4/06/0005...$5.00.

- **T** is the set of *transitions*, **T = Id ∪Vi ∪ Re** where these sub-sets are respectively the sets of *ideal*, *violation* and *repair* transitions. Transitions in **Vi** and **Re** are the sub-ideal ones;
- **V** is the set of *variables* that label the arcs;
- **PreCd** is the set of *preconditions* that guard transitions;
- **Act** is the set of *actions* performed on transition occurrences;
- **EmR** is the set of *emission rules* that control the direction of tokens at the completion of transitions;
- **Pre** is the *forward incidence function*: $\boldsymbol{P}$ x $\boldsymbol{T} \rightarrow \boldsymbol{V}$ *;
- **Post** is the *backward incidence function*: $\boldsymbol{T}$ x $\boldsymbol{EmR}$ x $\boldsymbol{P} \rightarrow \boldsymbol{V}$*;
- **Resp** is the function that associates to each sub-ideal transition a variable corresponding to the *responsible actor*: **Vi ∪ Re → V** where the type of **Resp***(t)* belongs to *A*;
- **Cost** is the function that states the punishment or reward resulting from the occurrence of a transition *t*; if t ∈ **Id** then **Cost**(t) = 0; if t∈**Vi** then **Cost**(t)> 0; if t∈**Re** then **Cost**(t) < 0;
- **CTD ⊂ Vi x Re**, is a relation which associates each repair transition to violation transitions and thus defines the *Contrary To Duty* obligations: (t, t') ∈ **CTD** ⇔ t' repairs t.

Each sub-ideal transition must have an actor responsible for that transition, which will assume the cost of performing this transition. Accordingly, a violation or repair transition has an input variable whose type belongs to *A*, and at each occurrence of the transition, the actor linked to that variable is charged with the value of the *Cost* function. The *penalty* attribute of the object classes in *A* is intended to store the amount of each actor penalties.

2.2 Semantics of Organizational Petri Nets

The *Organizational Petri Nets* formalism is a combination of the *Deontic Petri Net* and *Petri Net with Object* formalisms, which both have a well-funded semantics extending the *basic Petri nets* semantics. In this line, the OgPN semantics includes the PNO semantics (as defined in [6]) and introduces into actor objects the DPN's computation of penalties.

A transition may occur, by a *substitution principle* [5]**,** only if it can pick tokens in its input places in such a way that each of its input variables is bound to an element of its domain of value.

Definition 2 (Transition firing): The occurrence of a transition *t* that may occur with a substitution S from a marking M yields the marking M' (noted $M \xrightarrow{t,s} M'$) by following this 5-steps process:

1. Withdraw from the input places of *t* the tokens bound to its input variables: M'(p) := M(p) \ S(***Pre***(p, t));
2. Generate new objects, if needed to instantiate the output variables of *t* that are not already input variables;
3. Perform the action $\boldsymbol{Act_t}$ of *t,* that most often consists in calling methods or updating values of attributes of the objects bound to the transition variables;
4. If the transition *t* is a violation or repair one, update the penalty of the actor responsible for the occurrence of *t*: a.penalty := a.penalty + ***Cost***(t), where a = S(***Resp***(t));
5. Evaluate emission rules $\boldsymbol{EmR_t}$ of *t* to decide the one r that is satisfied, and put tokens bound to variables into the appropriate output places: M'(p) := M(p) + S(***Post***(t, r, p)).

Steps 1 and 5 define the location of tokens into places, while steps 2 to 4 compute the value of these tokens.

The **cost** associated to the executions of a transition is a penalty of the actor responsible for that transition occurrence. Provided that its initial value is null, the penalty attribute of an actor is the sum of the costs of the transition occurrences he is responsible for. Most often, the execution of a sequence of transitions is more significant than the occurrence of a single transition in isolation. Let s = t1**.** … **.**tn ∈ T* be a sequence of transitions and M a marking. *s* is enabled from M and its occurrence yields the marking M' if substitutions S1, …, Sn and marking M1,… Mn=M' such that $M \xrightarrow{t1,s1} M1 \xrightarrow{t2,s2} \dots \xrightarrow{tn,sn} Mn$ exist.

According to the semantics of DPN, the **cost of a transition sequence** $s = t_1 \dots t_n$ is the sum of the costs associated to the transitions in *s*: $\boldsymbol{Cost}(s) = \sum_{i=1..n} \boldsymbol{Cost}(t_i)$. If an actor *a* is responsible for all the transitions of a sequence *s*, the performance of this sequence will update his penalty in the following way: a.penalty := a.penalty + ***Cost*** (s).

3. EXAMPLE

Let us first describe the protocol for borrowing books from a library. Someone, who has borrowed a book, must return it in time and without damages. If the borrower delays the book delivery he is penalized. Likewise, if he damages the book, he is first penalized but he may repair the damage. In case of repairing, his penalty is reduced.

The design of an OgPN consists in three inter-dependant stages that correspond to the production of three models: informational, organizational and behavioral models.

The *informational model* describes the structure of the information together with some integrity constraints. In an OgPN, information units are represented as object classes, using the powerful mechanisms (such as classification, inheritance, polymorphism…), that allow to describe complex data structure (forms, rules…) usually used in normative systems. These objects will flow in the OgPN and are transformed by actions performed by the actors. In our example, we only consider the attributes of the Book class (see table 1).

Table 1. The Book Class

Class Book
Attributes:
Title: string
Author: string
Reference: string
ReturnDate: date
Aspect: {Good, Damaged, Repaired}
State: {Available, Returned, Borrowed}
End

The *organizational model* structures the actors in object classes sharing the same features. A class represents a role and can comprise actors having the same capabilities or belonging to the same organizational unit. It also attributes to each actor, permission to perform actions on objects of the informational model and the responsibility of some actions that violate the rules of the organization. In our context, roles are described as objects or agent classes; the permissions are implicitly given by the declaration of method's parameters, which refer the objects classes of the informational model. The inheritance mechanism propagates permissions between roles. An actor is responsible for

all actions implemented by methods, it can perform, and its "*penalty*" attribute records its amount of penalties.

The organizational model is limited in our example to a single role described by the `Borrower` class (see table 2). This role contains attributes and methods, and has the permission to handle books since this type of object appears as a parameter of the methods. The `penalty` attribute is updated each time an agent playing the role transgresses a deontic rule expressed in the Petri net.

Table 2. The Borrower Class

Class Borrower
Attributes:
Name: string
Penalty: integer
Methods:
Borrow (B : Book) % triggered when the borrower borrows the book
Read (B : Book) % triggered when he reads the book
ReturnLate (B : Book) % triggered when he returns the book late
Return (B : Book) % triggered when he returns the book
Repair (B : Book) %triggered when he repairs the damaged book
Damage (B : Book) %triggered when he damages the book
End

Finally, the *behavioral model* describes how the protocols behave by defining the action sequences and the information and roles involved in each action. Thanks to the high expressive power of Petri nets, the designer may express a lot of control structures (parallelism, sequence, alternative…), which represent deontic constraints between two actions. The permissions granted to a role are expressed by the nature of the arc between an information place and a transition. The ideal, violation and repair actions are represented by transitions with their respective cost. Violation and repair transitions charge the actor responsible for that transition.

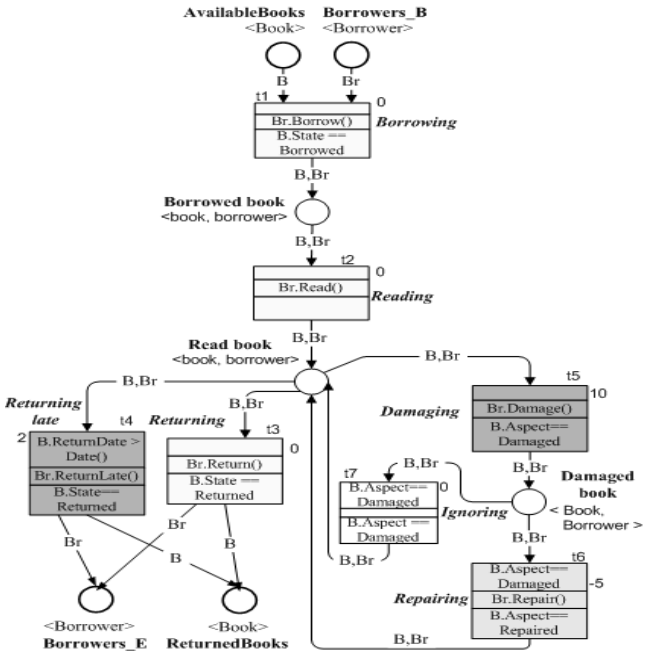

Figure 1. OgPN modeling borrower behavior

Regarding the behavioral model (see figure 1), the organizational Petri net includes seven transitions and six places typed with the two previously defined classes. The two initial places (`AvailableBooks` and `Borrowers_B`) represent a starting situation where a Borrower arrives in order to borrow an available Book. The two final places (`ReturnedBooks` and `Borrowers_E`) correspond to a situation where the Borrower has returned the Book. The transitions are grayed to distinguish more easily between ideal transitions (white: t1, t2, t3, t7), transgression transitions (dark grey: t4, t5) and repair transitions (bright grey: t6). The number associated to each transition represents its cost. For example, the transition `t6` called `Repairing` is a repair transition and its cost is "-5". Here the responsible actor is implicit because there is only one actor. However in case of ambiguity, the cost is prefixed with the responsible class name: <name>: cost. Let us explain a scenario represented by sequence s2 = t1.t2.t5.t6.t4 corresponding to the case where the Borrower borrows the Book (t1), reads it (t2), damages it (t5), repairs it (t6) and finally returns it late (t4). The penalty gained by the Borrower agent linked to the `Br` variable during an execution of this sequence is the sum of the costs of the transitions, that is 10 – 5 + 2 = 7.

Let us notice that this OgPN is an executable specification that can be used for simulation purpose. To completely control the operational functioning of a library, the code of the methods of object classes must be given.

4. CONCLUSIONS

We gave the formal semantics of the formalism called *Organizational Petri Nets* and some guidelines to produce models through an example. The advantages of this formalism are: 1) an easy integration in real world organization 2) the possibility of simulating protocols before their deployment 3) behavioral analysis capabilities 4) an operational semantics. In future work, we will investigate how this formalism can help to support the notion of protocol in existing agent-oriented methodologies like GAIA.

ABSTRACT

This work proposes an asynchronous algorithm for solving Distributed Constraint Optimization problems (DCOPs) using a new kind of nogoods, namely valued nogoods. The proposed technique is an extension of the asynchronous distributed optimization (ADOPT) where valued nogoods enable more flexible reasoning, leading to important speed-up. Valued nogoods are an extension of classic nogoods that associates each nogood with a threshold and optionally with a set of references to culprit constraints.

DCOPs have been shown to have very elegant distributed solutions, such as ADOPT, distributed asynchronous overlay (DisAO), or DPOP. These algorithms are typically tuned to minimize the longest causal chain of messages, as a measure of how the algorithms will scale for systems with remote agents (with large latency in communication). Among the mentioned techniques, DPOP performs very well for the chosen metric (requiring a number of such sequential messages linear in the number of agents), but in general has exponential space requirements. DisAO and ADOPT have the advantage of needing only polynomial space. ADOPT has the property of maintaining the initial distribution of the problem. ADOPT needs a preprocessing step consisting of computing a depth first search (DFS) tree on the agent graph. We show that valued nogoods reduce the practical importance/need of this preprocessing since independent subproblems are now dynamically detected and exploited.

1. INTRODUCTION

Distributed Constraint Optimization (DCOP) is a formalism that can model naturally distributed problems. These are problems where agents try to find assignments to a set of variables subjects to constraints. The natural distribution comes from the assumption that only a subset of the agents has knowledge of each given constraint. Nevertheless, in DCOPs it is assumed that agents try to maximize their cumulated satisfaction by the chosen solution. This is different from other related formalisms where agents try to maximize the satisfaction of the least satisfied among them [22].

Several synchronous and asynchronous distributed algorithms have been proposed for distributedly solving DCOPs. Since a DCOP can be viewed as a distributed version of the common centralized Valued Constraint Satisfaction Problems (VCSPs), it is normal that successful techniques for VCSPs were ported to DCOPs. However the effectiveness of such techniques has to be evaluated from a different perspective (and different measures) as imposed by the new requirements. Typically research has focused on techniques in which reluctance is manifested towards modifications to the distribution of the problem (modification accepted only when some reasoning infers it is unavoidable for guaranteeing to reach solutions). This criteria is largely believed valuable and adaptable for large, open, and/or dynamic distributed problems. It is also perceived as an alternative approach to privacy requirements [15, 21, 26, 17].

A synchronous algorithm, synchronous branch and bound, was the first known distributed algorithm for solving DCOPs [7]. Stochastic versions have also been proposed [27]. From the point of view of efficiency, a distributed algorithm for solving DCOPs is typically evaluated with regard to applications to agents on the Internet, namely where latency in communication is significantly higher than local computations. A measure representing this assumption well is given by the number of cycles of a simulator that lets each agent in turn process all the messages that it receives [23]. Within the mentioned assumption, this measure is equivalent for real solvers to the longest causal chain of sequential messages, as used in [18].

From the point of view of this measure, a very efficient currently existing DCOP solver is DPOP [12, 11], which is linear in the number of variables. However, in general that algorithm has message sizes and local computation costs that are exponential in the induced width of a chosen depth-first search tree of the constraint graph of the problem, clearly

[0]We thank Benjamin Pflanz, Boi Faltings, Rina Dechter, Adrian Petcu and reviewers for useful comments.

invalidating the assumptions that lead to the acceptance of the number of cycles as efficiency measure.

Two other algorithms competing as efficient solvers of DCOPs, are the asynchronous distributed optimization (ADOPT) and the distributed asynchronous overlay (DisAO). DisAO works by incrementally joining the subproblems owned by agents found in conflict. ADOPT implements a parallel version of A* [16]. While DisAO is typically criticized for its extensive abandon of the maintenance of the natural distributedness of the problem at the first conflict (and expensive local computations invalidating the above assumptions like DPOP [4, 8, 1]), ADOPT can be criticized for its strict message pattern that only provides reduced reasoning opportunities. ADOPT also works only on special orderings on agents, namely dictated by some Depth First Search tree on the constraint graph.

It is easy to construct huge problems whose constraint graphs are forests and that are easily solved by DPOP (in linear time), but unsolvable with the other known algorithms. It is also easy to construct relatively small problems whose constraint graph is full and therefore require unacceptable (exponential) space with DPOP, while being easily solvable with algorithms like ADOPT, e.g. for the trivial case where all tuples are optimal with cost zero.

In this work we address the aforementioned critiques of ADOPT showing that it is possible to define a message scheme based on a new type of nogoods, called *valued nogoods*, that not only virtually eliminates the need of precomputing a DFS tree of the constraint graph, but also leads to significant improvement in efficiency. Nogoods are at the basis of much flexibility in asynchronous algorithms. A nogood specifies a set of assignments that conflict constraints [20]. A basic version of the valued nogoods consists in associating each nogood to a threshold, namely a cost limit violated due to the assignments of the nogood. It is significant to note that the valued nogoods lead to efficiency improvements even if used in conjunction with a DFS tree, instead of the less semantically explicit cost messages of ADOPT. We find that a version of valued nogoods that is associated with a list of culprit constraints [13] produces additional important improvements. Each of these incremental concepts and improvements is described in the following sections.

2. DFS-TREES

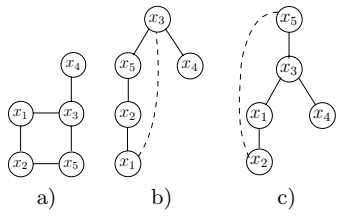

Figure 1: For a DCOP with primal graph depicted in (a), two possible DFS trees (pseudotrees) are (b) and (c). Interrupted lines show constraint graph neighboring relations not in the DFS tree.

The primal graph of a DCOP is the graph having the variables as nodes and having an arc for each pair of variables linked by a constraint [5]. A Depth First Search (DFS) tree associated to a DCOP is a spanning tree generated by the arcs used for visiting once each node during some depth first traversal of its primal graph. DFS trees were first successfully used for distributed constraint problems in [3]. The property exploited there is that separate branches of the DFS-tree are completely independent once the assignments of common ancestors are decided. Two examples of DFS trees for a DCOP primal graph are shown in Figure 1.

Nodes directly connected to a node in a primal graph are said to be its *neighbors*. In Figure 1.a, the neighbors of x_3 are $\{x_1, x_5, x_4\}$. The *ancestors* of a node are the nodes on the path between it and the root of the DFS tree, inclusively. In Figure 1.b, $\{x_5, x_3\}$ are ancestors of x_2. x_3 has no ancestors.

3. ADOPT

ADOPT [9] is an asynchronous complete DCOP solver, which is guaranteed to find an optimal solution. Here, we only show a brief description of ADOPT. Please consult [9] for the detail. First, ADOPT organizes agents into a Depth-First Search (DFS) tree, in which constraints are allowed between a variable and any of its ancestors or descendants, but not between variables in separate sub-trees.

ADOPT uses three kinds of messages: VALUE, COST, and THRESHOLD. A VALUE message communicates the assignment of a variable from ancestors to descendants who share constraints with the sender. When the algorithm starts, each agent takes a random value for its variable and sends appropriate VALUE messages. A COST message is sent from a child to its parent, which indicates the estimated lower-bound of the cost of the subtree rooted at the child. Since communication is asynchronous, a cost message contains a context, i.e., a list of the value assignments of the ancestors. The THRESHOLD message is introduced to improve the search efficiency. An agent tries to assign its value so that the estimated cost is lower than the given threshold communicated by the THRESHOLD message from its parent. Initially, the threshold is 0. When the estimated cost is higher than the given threshold, the agent opportunistically switches its value assignment to another value that has the smallest estimated cost. Initially, the estimated cost is 0. Therefore, an unexplored assignment has an estimated cost 0. A cost message also contains the information of the upper-bound of the cost of the subtree, i.e., the actual cost of the subtree. When the upper-bound and the lower-bound meet at the root agent, then a globally optimal solution has been found and the algorithm is terminated.

4. DISTRIBUTED VALUED CSPS

Constraint Satisfaction Problems (CSPs) are described by a set X of variables and a set of constraints on the possible combinations of assignments to these variables with values from their domains.

DEFINITION 1 (DCOP). *A distributed constraint optimization problem (DCOP), aka distributed valued CSP, is defined by a set of agents $A_1, A_2, ..., A_n$, a set X of variables, $x_1, x_2, ..., x_n$, and a set of functions $f_1, f_2, ...f_i, ..., f_n$, $f_i : X_i \rightarrow \mathbb{R}$, $X_i \subseteq X$, where only A_i knows f_i.*

The problem is to find $\operatorname{argmin}_x \sum_{i=1}^{n} f_i(x_{|X_i})$. *We assume that x_i can only take values from a domain $D_i = \{1, ..., d\}$.*

For simplification and without loss of generality one typically assumes that $X_i \subseteq \{x_1, ..., x_i\}$

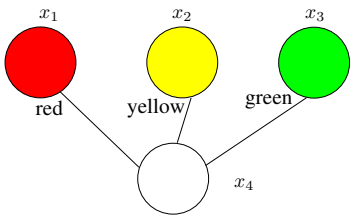

Figure 2: MIN resolution on valued global nogoods

Our idea can be easily applied to general valued CSPs.

5. COST OF NOGOODS

Previous flexible algorithms for solving distributed constraint satisfaction problems exploit the inference power of nogoods (e.g., ABT, AWC, ABTR [23, 24, 19])[1]. A nogood $\neg N$ stands for a set N of assignments that was proven impossible, by inference using constraints. If $N = (\langle x_1, v_1\rangle, ..., \langle x_t, v_t\rangle)$ where $v_i \in D_i$, then we denote by $\overline{N}$ the set of variables assigned in N, $\overline{N} = \{x_1, ...x_t\}$.

In order to apply nogood-based algorithms to DCOP, we redefine the notion of nogoods as follows. First we attach a value to each nogood obtaining a *valued global nogood*.

DEFINITION 2 (VALUED GLOBAL NOGOOD). *A valued global nogood has the form $[c, N]$, and specifies that the (global) problem has cost at least c, given the set of assignments, N, for distinct variables.*

Given a valued global nogood $[c, (\langle x_1, v_1\rangle, ..., \langle x_t, v_t\rangle)]$, one can infer a *global cost assessment (GCA)* for the value v_t from the domain of x_t given the assignments $S = \langle x_1, v_1\rangle, ..., \langle x_{t-1}, v_{t-1}\rangle$. This GCA is denoted (v_t, c, S), and is semantically equivalent to an applied global value nogood, (i.e. the inference):

$$(\langle x_1, v_1\rangle, ..., \langle x_{t-1}, v_{t-1}\rangle) \rightarrow (\langle x_t, v_t\rangle \text{ has cost } c).$$

REMARK 1. *Given a valued global nogood $[c, N]$, one can infer the GCA (v, c, N) for any value v from the domain of any variable x, where x is not assigned in N, i.e., $x \notin \overline{N}$.*

E.g., if A_3 knows the valued global nogood $[10, \{(x_1, r), (x_2, y)\}]$, then it can infer for the value r of x_3 the GCA $(r, 10, \{(x_1, r), (x_2, y)\})$.

PROPOSITION 1 (MIN-RESOLUTION). *From a set $\{(v, c_v, S_v)\}$ containing exactly one GCA for each value v in the domain of variable x_i and $\forall k, j$, assignments for $\overline{S_k} \cap \overline{S_j}$ are identical in both S_k and S_j of a minimization VCSP, one can resolve a new valued global nogood: $[\min_v c_v, \cup_v S_v]$.*

Example 5.1 *For the graph coloring problem in Figure 2 (costs are not shown), x_1 is colored red (r), x_2 yellow (y) and x_3 green (g). Assume that the following valued global nogoods are known for each of the values $\{r, y, g\}$ of x_4:*

(r): $[10, \{(x_1, r), (x_4, r)\}]$, obtaining for x_4 the GCA $(r, 10, \{(x_1, r)\})$

(y): $[8, \{(x_2, y), (x_4, y)\}]$, obtaining for x_4 the GCA $(y, 8, \{(x_2, y)\})$

(g): $[7, \{(x_3, g), (x_4, g)\}]$, obtaining for x_4 the GCA $(g, 7, \{(x_3, g)\})$

By min-resolution on these GCAs one obtains the valued global nogood $[7, \{(x_1, r), (x_2, y), (x_3, g)\}]$, meaning that given the coloring of the first 3 nodes there is no solution with (global) cost lower than 7.

Min-resolution can be applied on valued global nogoods:

COROLLARY 1.1. *Assume $\mathcal{S}$ is a set of no-goods associated to the variable x_i, such that for each $[c_v, S_v]$ in $\mathcal{S}$, $\exists\langle x_i, v\rangle \in S_v$. If $\mathcal{S}$ contains exactly one global valued nogood $[c_v, S_v]$ for each value v in the domain of variable x_i of a minimization VCSP, i.e. $\cup_v\{v\} = D_i$, one can resolve a new valued global nogood: $[\min_v c_v, \cup_v(S_v \setminus \langle x_i, v\rangle)]$.*

REMARK 2 (DFS SUBTREES). *Given two GCAs (v, c'_v, S'_v) and (v, c''_v, S''_v) for a value v in the domain of variable x_i of a minimization VCSP, if one knows that the two GCAs are inferred from different constraints then one can infer a new GCA: $\langle c'_v + c''_v, S'_v \cup S''_v\rangle$. This is similar to what ADOPT does to combine cost messages coming from disjoint problem subtrees [10, 3].*

This powerful reasoning can be applied when combining a nogood obtained from the local constraints with a valued nogood received from other agents (and obtained solely by inference on other agents' constraints). When a DFS tree of the constraint graph is used for constraining the message pattern as in ADOPT, this powerful inference applies, too.

The question is how to determine that the two GCAs are inferred from different constraints, in a more general setting. We introduce tagging of cost assessments with the identifiers of the constraints used to infer them.

DEFINITION 3 (SRC). *A set of references to constraints is a set of identifiers, each of them for a distinct constraint.*

Note that several constraints of a given problem description can be composed in one constraint (in a different description of the same problem).

REMARK 3. *For privacy, a constraint can be represented by several constraint references and several constraints of an agent can be represented by a single constraint reference.*

Now we generalize the concept of *valued global nogood* into the concept of *valued nogood*.

DEFINITION 4 (VALUED NOGOOD). *A valued nogood has the form $[SRC, c, N]$ where SRC is a set of references to constraints having cost at least c, given a set of assignments, N, for distinct variables.*

Valued nogoods are generalizations of valued global nogoods. Valued global nogoods are valued nogoods whose SRCs contain the references of all the constraints.

Once we decide that a nogood $[SRC, c, (\langle x_1, v_1\rangle, ..., \langle x_i, v_i\rangle)]$ will be applied to a certain variable x_i, we obtain a cost assessment tagged with the set of references to constraints SRC[2], denoted $(SRC, v_i, c, (\langle x_1, v_1\rangle, ..., \langle x_{i-1}, v_{i-1}\rangle))$.

[1]Other algorithms, like AAS, exploit generalized nogoods (i.e., extensions of nogoods to sets of values for a variable), and the extension of the work here for that case is pointed to in [13]

[2]This is called a *valued conflict list* in [13]

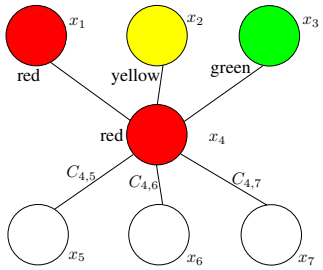

Figure 3: SUM-inference resolution on CAs

DEFINITION 5 (COST ASSESSMENT (CA)). *A cost assessment of variable x_i has the form (SRC, v, c, N) where SRC is a set of references to constraints having cost with lower bound c, given a set of assignments, N, for distinct variables, and the assignment of x_i to some value v.*

As for valued nogoods and valued global nogoods, cost assessments are generalizations of global cost assesments.

REMARK 4. *Given a valued nogood $[SRC, c, N]$, one can infer the CA $(SRC, v, c, N))$ for any value v from the domain of any variable x, where x is not assigned in N, i.e., $x \notin \overline{N}$. E.g., if A_6 knows the valued nogood $[\{C_{4,7}\}, 10, \{(x_2, y), (x_4, r)\}]$, then it can infer for the value b of x_6 the CA $(\{C_{4,7}\}, b, 10, \{(x_2, y), (x_4, r)\})$.*

We can now detect and perform the desired powerful reasoning on valued nogoods and/or CAs coming from disjoint subtrees, mentioned in Remark 2.

PROPOSITION 2 (SUM-INFERENCE). *A set of cost assessments for the value v of some variable, (SRC_i, v, c_i, N_i) where $\forall i, j : i \neq j \Rightarrow SRC_i \cap SRC_j = \emptyset$, and the assignment of any variable x_k is identical in any N_i where x_k is present, can be combined into a new cost assessment. The obtained cost assessment is (SRC, v, c, N) such that $SRC{=}\cup_i SRC_i$, $c{=}\sum_i (c_i)$, and $N{=}\cup_i N_i$.*

Example 5.2*[!th] For the graph coloring problem in Figure 3, x_1 is colored red, x_2 yellow, x_3 green, and x_4 red. Assume that the following valued nogoods are known for (x_4, r):*

- $[\{C_{4,5}\}, 5, \{(x_2, y), (x_4, r)\}]$ *obtaining CA* $(\{C_{4,5}\}, r, 5, \{(x_2, y)\})$
- $[\{C_{4,6}\}, 7, \{(x_1, r), (x_4, r)\}]$ *obtaining CA* $(\{C_{4,6}\}, r, 7, \{(x_1, r)\})$
- $[\{C_{4,7}\}, 9, \{(x_2, y), (x_4, r)\}]$ *obtaining CA* $(\{C_{4,7}\}, r, 9, \{(x_2, y)\})$

Also assume that based on x_4's constraint with x_1, one has obtained for $\langle x_4, r\rangle$ the following valued nogood:

- $[\{C_{1,4}\}, 10, \{(x_1, r), (x_4, r)\}]$ *obtaining CA* $(\{C_{1,4}\}, r, 10, \{(x_1, r)\})$

Then, by sum-inference on these CAs one obtains for x_4 the CA $[\{C_{1,4}, C_{4,5}, C_{4,6}, C_{4,7}\}, r, 31, \{(x_1, r), (x_2, y)\}]$, meaning that given the coloring of the first 2 nodes, coloring x_4 in red leads to a cost of at least 31 for the constraints $\{C_{1,4}, C_{4,5}, C_{4,6}, C_{4,7}\}$.

REMARK 5 (SUM-INFERENCE FOR VALUED NOGOODS). *Sum inference can be similarly applied to any set of valued nogoods with disjoint SRCs and compatible assignments. The result of combining nogoods $[SRC_i, c_i, S_i]$ is $[\cup_i SRC_i, \sum_i c_i, \cup_i S_i]$. This can also be extended to the case where assignments are generalized to sets [13].*

The min-resolution proposed for GCAs translates straightforwardly for CAs as follows.

PROPOSITION 3 (MIN-RESOLUTION). *A set of cost assessments for x_i, (SRC_i, v_i, c_i, N_i) where $\cup_i \{v_i\}$ covers the whole domain of x_i and $\forall k, j$, assignments for $\overline{N_k} \cap \overline{N_j}$ are identical in both N_k and N_j, can be combined into a new valued nogood. The obtained valued nogood is $[SRC, c, N]$ such that $SRC{=}\cup_i SRC_i$, $c{=}\min_i(c_i)$ and $N{=}\cup_i N_i$.*

Example 5.3 *For the graph coloring problem in Figure 2, x_1 is colored red, x_2 yellow and x_3 green. Assume that the following valued nogoods are known for the values of x_4:*

(r): $[\{C_{1,4}\}, 10, \{(x_1, r), (x_4, r)\}]$ *obtaining CA* $(\{C_{1,4}\}, r, 10, \{(x_1, r)\})$

(y): $[\{C_{2,4}\}, 8, \{(x_2, y), (x_4, y)\}]$ *obtaining CA* $(\{C_{2,4}\}, y, 8, \{(x_2, y)\})$

(g): $[\{C_{3,4}\}, 7, \{(x_3, g), (x_4, g)\}]$ *obtaining CA* $(\{C_{3,4}\}, g, 7, \{(x_3, g)\})$

By min-resolution on these CAs one obtains the valued global nogood $[\{C_{1,4}, C_{2,4}, C_{3,4}\}, 7, \{(x_1, r), (x_2, y), (x_3, g)\}]$, meaning that given the coloring of the first 3 nodes there is no solution with cost lower than 7 for the constraints $\{C_{1,4}, C_{2,4}, C_{3,4}\}$.

As with valued global nogoods, the min-resolution could be applied directly on valued nogoods:

COROLLARY 3.1 (MIN-RESOLUTION ON NOGOODS). *From a set $\{[SRC_v, c_v, S_v)] | \exists v, \langle x_i, v\rangle \in S_v\}$ containing exactly one valued nogood for each value v in the domain of variable x_i of a minimization VCSP, one can resolve a new valued nogood: $[\cup_v SRC_v, \min_v c_v, \cup_v (S_v \setminus \langle x_i, v\rangle)]$.*

6. ADOPT WITH NOGOODS

We will now present a distributed optimization algorithm using valued nogoods, to maximize the efficiency of reasoning by exploiting increased flexibility. The algorithm can be seen as an extension of both ADOPT and ABT, and will be denoted Asynchronous Distributed OPTimization with valued nogoods (ADOPT-ng).

Like in ABT, agents communicate with **ok?** messages proposing new assignments of sender's variable, **nogood** messages announcing a nogood, and **add-link** messages announcing interest in a variable. Like in ADOPT, agents can also use **threshold** messages, but their content can be included in **ok?** messages.

For simplicity we assume in this algorithm that the communication channels are FIFO. Addition of counters to proposed assignments and nogoods can help to remove this requirement with minimal additional changes (i.e., older assignments and older nogoods for the currently proposed value are discarded).

6.1 Data Structures

Each agent A_i stores its agent view (received assignments), and its outgoing links (agents of lower priority than A_i and having constraints on x_i). Instantiations may be tagged with counters. To manage nogoods and CAs, A_i uses matrices l[1..d], h[1..d], ca[1..d][i+1..n], lvn[1..i][i..n], lr[i+1..n] and lastSent[1..i-1] where d is the domain size for x_i. *crt_val* is the current value A_i proposes for x_i.

- l[k] stores a CA for $x_i = k$, that is inferred solely from the constraints between x_i and prior variables.
- ca[k][j] stores a CA for $x_i = k$, that is obtained from valued nogoods received from A_j.
- lvn[k][j] stores the last valued nogood for variables with higher and equal priority than k and that is received from A_j, j>i. lvn[k][i] stores nogoods coming via **threshold/ok?** messages.
- lr[k] stores the last valued nogood received from A_k.
- h[k] stores a CA for x_i =k that is inferred from ca[k][j], lr[t], lvn[t][j], and l[k], for all j and t. Before inference, the valued nogoods in lvn[t][j] need to be first translated into a CAs as described in Remark 4.
- lastSent[k] stores the last valued nogood sent to A_k.

6.2 ADOPT with valued nogoods

The pseudocode for ADOPT-ng is given in Algorithm 1. To extract the cost of a CA we introduce the function *cost*(), $cost((SRC, T, c, v))$ returns c. The $min\_resolution(j)$ function applies the min-resolution over all values of the current agent, but using only CAs having no assignment from agents with lower priority than A_j (e.g., not using lvn[t][k] for $t > j$). The $sum\_inference()$ function used in Algorithm 1 applies the sum-inference on its parameters whenever this is possible (detects disjoint SRCs), otherwise selects the nogood with highest threshold or whose lowest priority assignment has the highest priority (this has been previously used in [2, 19]). Function $vn2ca(vn, i)$ transforms a valued nogood vn in a cost assesment for x_i. Its inverse is function $ca2vn$. Function $target(N)$ gives the index of the lowest priority variable present in the nogood N. Like with file expansion, "*" in an index of a matrix means the set obtained for all possible values of that index (e.g., lvn[*][t] stands for $\{lvn[k][t] \mid \forall k\}$).

An agent A_i stores several nogoods (CAs) coming from the same source A_t and applicable to the same value v (namely the one at ca[v][t], all those at lvn[k][t] for any k, and lr[t] when v is *crt_val*).

REMARK 6. *The order of combining CAs matters. Notation $lr[t]_{|v}$ stands for vn2ca(lr[t]) when lr[t]'s value for x_i is v, and $\emptyset$ otherwise. To compute h[v]:*

1. *a) When maintaining DFS trees, for a value v, CAs are combined for each DFS subtree s: tmp[v][s]=sum-inference$_{t \in s}$(ca[v][t], $lr[t]_{|v}$, lvn[*][t]); b) Else, CAs coming from each agent A_t are combined: tmp[v][t]=sum-inference(ca[v][t], $lr[t]_{|v}$, lvn[*][t]);*
2. *CAs from step 1 (a or b) are combined: h[v]=sum-inference(tmp[v][*]);*
3. *Add l[v]: h[v]=sum-inference(h[v], l[v]);*
4. *Add threshold: h[v]=sum-inference(h[v], lvn[*][i])*

In ADOPT-ng agents are totally ordered, A_1 having the highest priority and A_n the lowest priority. Each agent A_i starts by calling the init() procedure, which initializes its l with valued nogoods infered from local (unary) constraints. It assigns x_i to a value with minimal local cost, *crt_val*, announcing the assignment to lower priority agents in outgoing-links. The agents answer any received message with the correponding procedure: "**when** receive **ok?**", "**when** receive **nogood**", and "**when** receive **add-link**".

When a new assignment is learned from **ok?** or **nogood** messages, valued nogoods based on older assignments for the same variables are discarded and the l vector is updated. Received nogoods are stored in matrices ca, lr and lvn. The vector h is updated on any modification of l, lvn, lr or ca. A_i always sets its *crt_val* to the index with the lowest CA threshold in vector h (preferring the previous assignment). On each change to the vector h, its values are combined by min-resolution to generate new nogoods for each higher priority agent (or ancestor, in versions using DFS trees). The generation and use of multiple nogoods at once is already shown useful for the constraint satisfaction case in [25].

The threshold valued nogood tvn delivered with **ok?** messages sets a common cost on all values of the receiver (see Remark 4), effectively setting a threshold on costs below which the receiver does not change its value. This achieves the effect of THRESHOLD messages in ADOPT.

Intuitively, the convergence of ADOPT-ng can be noticed from the fact that valued nogoods can only monotonically increase valuation for each subset of the search space, and this has to terminate since such valuations can be covered by a finite number of values. If agents A_j, j<i no longer change their assignments, valued nogoods can only monotonically increase at A_i for each value in D_i: nogoods' thresholds only increase as they only change by sum-inference.

LEMMA 1. *ADOPT-ng terminates in finite time.*

PROOF. Given the list of agents $A_1, ..., A_n$, define the suffix of length m of this list as the last m agents. Then the result follows immediately by induction for an increasingly growing suffix (increasing m), assuming the other agents reach quiescence.

The first step of the induction (for the last agent) follows from the fact that the last agent terminates in one step if the previous agents do not change their assignments.
