Assuming that the previous induction assertion is true for any suffix of k agents. Let us prove that it is also true for a suffix of k+1 agents: For each assignment of the agent A_{n-k}, the remaining k agents will reach quiescence, according to the assumption of the induction step, or the assignment's CA threshold increases. After values are proposed in turn and the smallest threshold reaches its highest estimate, agent A_{n-k} selects the best value and reaches quiescence. The other agents reach quiescence according to the induction step. □

LEMMA 2. *The last valued nogood sent by each agent additively integrates the non-zero costs of the constraints of all of its successors.*

PROOF. At quiescence, each agent A_k has received the valued nogoods describing the costs of each of its successors, in the list given by the used ordering on agents (or descendants in the DFS tree when a DFS tree is maintained).

```
procedure init do
    h[v] := l[v]:=initialize CAs from unary constraints;
    crt_val=argmin_v(cost(h[v]));
    send ok?(⟨x_i, crt_val⟩,∅) to all agents in outgoing-links;
when receive ok?(⟨x_j, v_j⟩, tvn) do
    integrate(⟨x_j, v_j⟩);
    if (tvn no-null and has no old assignment) then
        k:=target(tvn); // threshold tvn as common cost;
        lvn[k][i]:=sum-inference(tvn,lvn[k][i]);
    check-agent-view();
when receive add-link(⟨x_j, v_j⟩),A_j do
    add A_j to outgoing-links;
    if (⟨x_j, v_j⟩) is old, send new assignment to A_j;
when receive nogood(rvn, t) from A_t do
    foreach new assignment a of a linked variable x_j in
    rvn do
        integrate(a); // counters show newer assignment;
    if (an assignment in rvn is outdated) then
        if (some new assignment was integrated now) then
            check-agent-view();
        return;
    foreach assignment a of a non-linked variable x_j in
    rvn do
        send add-link(a) to A_j;
    if ((j := target(rvn)) == i) then
        vn2ca(rvn, i) → CA rca for a value v of x_i;
        ca[v][t]:=sum-inference(rca,ca[v][t]);
        lr[t]:=rca;
    else
        lvn[j][t]:=rvn;
    check-agent-view();
procedure check-agent-view() do
    for every(v ∈ D_i) update l[v] and recompute h[v];
    for every A_j with higher priority than A_i (respectively
    ancestor in the DFS tree, when one is maintained) do
        if (h has non-null cost CA for all values of D_i)
        then
            vn:=min_resolution(j);
            if (vn ≠ lastSent[j]) then
                send nogood(vn,i) to A_j;
    crt_val=argmin_v(cost(h[v]));
    if (crt_val changed) then
        send ok?(⟨x_i, crt_val⟩,
                ca2vn(sum-inference(lvn[*][k],ca[crt_val][k]))
            to each A_k in outgoing_links;
procedure integrate(⟨x_j, v_j⟩) do
    discard CAs and nogoods in ca, lvn, and lr that are
    based on other values for x_j;
    store ⟨x_j, v_j⟩ in agent view;
```

Algorithm 1: Procedures of A_i in ADOPT-ng

The lemma results by induction for an increasingly growing suffix of the list of agents (in the order used by the algorithm): It is trivial for the last agent.

Assuming that it is true for the agent A_k, it follows that it is also true for agent A_{k-1} since adding A_{k-1}'s local cost to the cost received from A_k will be higher (or equal when removing zero costs) to the result of adding A_{k-1}'s local cost to one from any successor of A_k. Respecting the order in Remark 6 guarantees this value is obtained. Therefore the sum between the local cost and the last valued nogood coming from A_k defines the last valued nogood sent by A_{k-1}. □

THEOREM 4. *ADOPT-ng returns an optimal solution.*

PROOF. We prove by induction on an increasingly growing suffix of the list of agents that this suffix converges to a solution that is optimal for their subproblem.

The induction step is immediate for the suffix composed of the agent A_n alone. Assume now that it is true for the suffix starting with A_k. Following the previous two lemmas, one can conclude that at quiescence A_{k-1} knows exactly the cumulated cost of the problems of its successors for its chosen assignment, and therefore knows that this cumulated cost cannot be better for any of its other values.

Since A_{k-1} has selected the value leading to the best sum of costs (between his own local cost and the costs of all subsequent agents), it follows that the suffix of agents starting with A_{k-1} converged to an optimal solution for their subproblem. □

The space complexity is basically the same as for ADOPT. The SRCs do not change the space complexity of the valued nogood.

6.3 Optimizing valued nogoods

Both for the version of ADOPT-ng using DFS trees, as well as for the version that does not use such trees preprocessing, if valued nogoods are used for managing cost inferences, then a lot of effort can be saved at context switching by not discarding nogoods that remain valid [6]. The amount of saved effort is higher if the nogoods are carefully selected (to minimize their dependence on changes in often switched low priority variables). Computing valued nogoods by minimizing the index of the least priority variable involved in the context is shown by our experiments to perform well in this case. This is done by computing the valued nogoods using incrementally lower priority variables, and keeping the valued nogoods with lower priority agents only if they have better thresholds. Nogoods optimized in similar manner were used in several previous DisCSP techniques [2, 19].

6.4 Exploiting DFS trees

Note that while our versions of ADOPT work better than the original DFS-tree based version, they can also create hybrids by using an existing DFS tree. We have identified two ways of exploiting such an existing structure. The first way is by having each agent send its valued nogood only to its parent in the tree (less efficient in length of longest causal chain of messages but more efficient in number of total messages), roughly equivalent to the original ADOPT. The other way is by sending valued nogood to all the ancestors. This later hybrid can be seen as a certain fulfillment of a direction of research suggested in [9], namely communication of costs to higher priority parents.

An extension proposed to this work consists in integrating consistency maintenance in nogood-based optimization. This can be done with the introduction of *valued consistency nogoods*, as described in [13, 14].

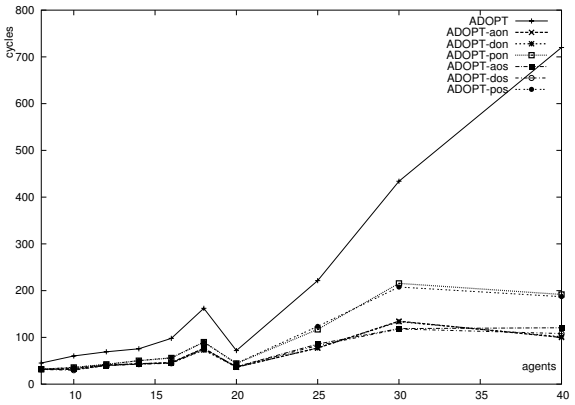

Figure 4: Longest causal chain of messages (cycles) used to solve versions of ADOPT using CAs, on problems with density .2.

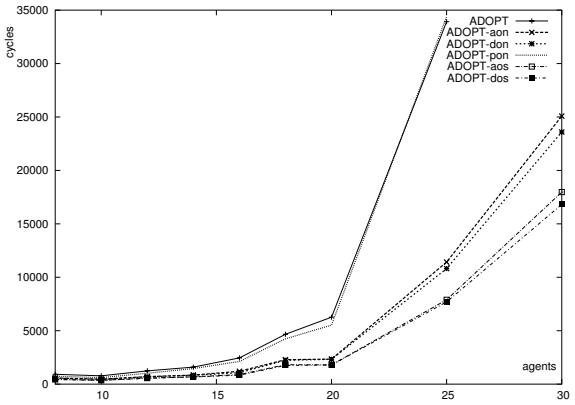

Figure 5: Longest causal chain of messages (cycles) used to solve versions of ADOPT using CAs, on problems with density .3.

7. EXPERIMENTS

We implemented several versions of ADOPT-ng, differing by how the agents picks the targets of his nogoods. In the implementation ADOPT-pon, valued global nogoods are sent only to the parent of the current agent in the DFS tree. In ADOPT-don, the valued global nogoods are sent to all the ancestors of the current agent in the DFS tree. ADOPT-aon is a version where the DFS tree is reduced to the linear list of agents (each having the predecessor as parent). ADOPT-pos, ADOPT-dos, and ADOPT-aos are the corresponding versions with valued nogoods rather than valued global nogoods. These are early versions that do not yet exploit threshold nogoods in **ok?** messages. Improvements from those techniques will be reported elsewhere.

The algorithms were compared on the set of problems posted together with ADOPT, which are the same problems that are used to report ADOPT's performance in [9]. To correctly compare our techniques with the original ADOPT we have used the same order (or DFS trees) on agents for each problem. The set of problems distributed with ADOPT and used here contain 25 problems for each problem size. It contains problems with 8, 10, 12, 14, 16, 18, 20, 25, 30, and 40 agents, and for each of these numbers of agents it contains test sets with density .2 and with density .3. The density of a (binary) constraint problem's graph with n variables is defined by the ratio between the number of binary constraints and $\frac{n(n-1)}{2}$. Results are averaged on the 25 problems with the same parameters.

The number of cycles, i.e., longest causal (sequential) chain of messages, for problems with density .2 is given in Figure 4. Results for problems with density .3 are given in Figure 5. The original ADOPT for 20 and 25 agents and density .3 required more than 2 weeks for solving one of the problems, and it was therefore evaluated using only the remaining 24 problems at those problem sizes.

We can note that the use of valued nogoods brought up to 10 times improvement on problems of density 0.2, and up to 5 times improvement on the problems of density .3.

Another interesting remark is that sending nogoods only to the parent node is significantly worse (in number of cycles), than sending nogoods to all ancestors. Versions using DFS trees require less parallel/total messages, being more network friendly, as seen in Figure 6.

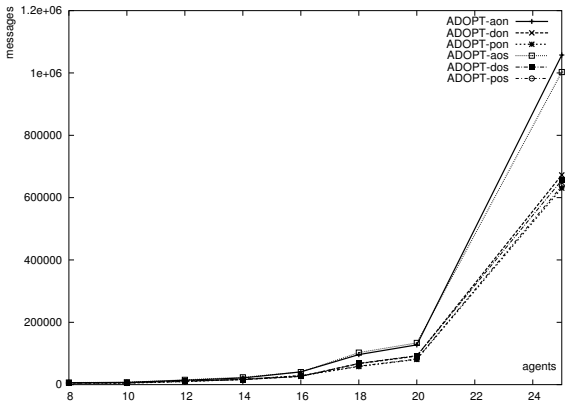

Figure 6: Total number of messages used by versions of ADOPT-ng using CAs to solve problems with density .3.

Figure 5 shows that, with respect to the number of cycles, the use of SRCs practically replaces the need of precomputing a DFS tree since ADOPT-aos is one of the best solvers, only slightly worse than ADOPT-dos. SRCs bring improvements over versions with valued global nogoods, since SRCs allow detection of dynamically obtained independences.

We do not perform any runtime comparison since our versions of ADOPT are implemented in C++, while the original ADOPT is in Java (which obviously leads to all our versions being an irrelevant order of magnitude faster).

It is visible from Figure 5 that the highest improvement in number of cycles is brought by sending valued nogoods to other ancestors besides the parent. The next factor for improvement with difficult problems (density .3) was the use of SRCs. The use of the structures of the DFS tree

bring slight improvements in number of cycles (when nogoods reach all ancestors) and large improvements in total message exchange.

Experimental comparison with DPOP is redundant since its performance can be easily predicted. DPOP is a good choice if the induced width γ of the graph of the problem is smaller than $\log_d T/n$ and smaller than $\log_d S$ where T is the available time, n the number of variables, d the domain size, and S the available memory of a computer.

8. CONCLUSIONS

The ADOPT distributed constraint optimization algorithm can be used efficiently (in number of cycles) without knowing a DFS tree, typically computed in a preprocessing step, by using valued nogoods tagged with sets of references to culprit constraints. The generalized algorithm is denoted ADOPT-ng. SRCs allow detection and exploitation of dynamically created independences between subproblems (that are due to some assignments). Experimentation shows that it is important to send nogoods to several higher priority agents. DFS trees can still be used in conjunction with the value nogood paradigm for optimization improving the total number of messages. ADOPT-ng versions exploiting DFS trees that we tested so far are also slightly better (in number of cycles) than the ones without DFS trees.

Besides that elegance brought by valued nogoods to the description and implementation of ADOPT in ADOPT-ng, use of SRCs to dynamically detect and exploit independences, as well as generalized communication of nogoods to several ancestors, brings experimental improvements of an order of magnitude.

ABSTRACT

We model social choice problems in which self interested agents with private utility functions have to agree on values for a set of variables subject to side constraints. The goal is to implement the efficient solution, maximizing the total utility across all agents. Existing techniques for this problem fall into two groups. Distributed constraint optimization algorithms can find the solution without any central authority but are vulnerable to manipulation. Incentive compatible mechanisms can ensure that agents report truthful information about their utilities and prevent manipulation of the outcome but require centralized computation.

Following the agenda of *distributed implementation* [16], we integrate these methods and introduce *MDPOP*, the first distributed optimization protocol that *faithfully* implements the VCG mechanism for this problem of efficient social choice. No agent can benefit by unilaterally deviating from any aspect of the protocol, neither information-revelation, computation, nor communication. The only central authority required is a bank that can extract payments from agents. In addition, we exploit structure in the problem and develop a faithful method to redistribute some of the VCG payments back to agents. Agents need only communicate with other agents that have an interest in the same variable, and provided that the distributed optimization itself scales the entire method scales to problems of unbounded size.

1. INTRODUCTION

Distributed optimization problems can model environments where a set of agents must agree on a set of decisions subject to side constraints. We consider settings in which each agent has its own preferences on subsets of these decisions, expressed as relations that define its utility. The agents are self interested, and each one would like to obtain the decision that maximizes its own utility. However, the system as whole agrees (or some social designer determines) that a solution should be selected to maximize the total utility across all agents. Thus, this is a problem of *efficient social choice*. As motivation, we have in mind problems such as meeting scheduling, where the decisions are about when and where to hold each meeting, or scheduling contractors in construction projects.

Agents can of course solve such problems using a central authority that computes the optimal solution. In combination with a mechanism such as the Vickrey-Clarke-Groves (VCG) mechanism, we can also prevent manipulation by agents. However, in many practical settings it is hard to bound the problem so that such a central authority is feasible. Consider meeting scheduling: while each agent only participates in a few meetings, it is in general not possible to find a set of meetings that has no further constraints with any other meetings and thus can be optimized separately. Similarly, contractors in a construction project simultaneously work on other projects, again creating an unbounded web of dependencies that cannot be optimized in a centralized fashion.

Algorithms for distributed constraint reasoning such as ABT and AWC ([21]), AAS [20], DPOP [17] and ADOPT [14] can deal with problems of unbounded size as long as the influence of each agent on the solution is limited to a bounded number of variables. However, the current techniques do not address the problem of making agents truthfully declare their preferences and execute the protocol correctly.

In this paper, we advance the agenda of *distributed implementation* [16], which integrates methods from mechanism design with methods from distributed constraint optimization. In distributing the centralized computation of mechanism design across a system of self-interested agents the key challenge is to ensure that agents cannot gain from deviating from the distributed protocol. In addition to information revelation, agents will now be asked to participate in computation and message passing, both of which can provide new opportunities for manipulation. We describe the first faithful distributed constraint optimization algorithm, implementing the VCG outcome without any trusted third party besides a bank, used to enforce payments. The protocol forms an *ex post* Nash equilibrium [12], so that no agent can benefit by unilaterally deviating, whatever the utility functions of other agents and whatever the constraints. While noting that our protocol *never* runs at a deficit, we also demonstrate how to exploit problem structure in facilitating payment distribution *back* to agents from the bank. To do this we identify components of the problem that define payments that cannot be influenced by some subset of agents, that are then eligible to receive a share of the payments.

After preliminaries, in Section 3 we describe the DPOP [17] algorithm for distributed constraint optimization, which is the focus of our study. Section 4 extends DPOP to compute the VCG outcome and proves that the extended protocol, called MDPOP, is

faithful. We also provide an accelerated version of MDPOP that simultaneously computes the solution to the marginal and main economies, and again establish faithfulness. Section 5 discusses the issue of budget balance and defines our payment redistribution method.

2. PRELIMINARIES

We assume that the social choice problem consists of a finite but possibly unbounded number of decisions that all have to be made at the same time. Each decision is modeled as a variable that can take values in a well-defined domain. There can be side constraints between the variables, and each agent can also have private *relations* that define its utility for decisions.

Modeled as a distributed constraint optimization problem, DCOP($\mathcal{A}$) on agents $\mathcal{A}$ we have:

DEFINITION 1. *An efficient social choice problem is modeled as a distributed constraint optimization problem (DCOP) as a tuple* $< \mathcal{A}, \mathcal{X}, \mathcal{D}, \mathcal{C}, \mathcal{R} >$ *such that:*

$\mathcal{A} = \{A_1, ..., A_n\}$ *is a set of* **self-interested** *agents interested in the optimization problem;*

$\mathcal{X} = \{X_1, ..., X_m\}$ *is the set of* **public** *decision variables;* $P(A_i) \subseteq \mathcal{X}$ *is the sub-domain of variables on which agent* A_i ***could*** *have relations;* $X(A_i) \subseteq P(A_i)$ *are the variables in which agent* A_i *is interested and does have relations;*

$\mathcal{D} = \{d_1, ..., d_m\}$ *is the set of finite* **public** *domains of the variables* $\mathcal{X}$*; each domain is known to all interested agents;*

$\mathcal{C} = \{c_1, ..., c_q\}$ *is a set of* **public** *constraints, where a constraint* c_i *is a function* $c_i : d_{i_1} \times .. \times d_{i_k} \rightarrow \{-\infty, 0\}$ *that returns 0 for all allowed combinations of values of the involved variables, and* $-\infty$ *for disallowed ones; these constraints are known and agreed upon by all agents involved in the respective communities;*

$\mathcal{R} = \{R_1, ..., R_n\}$ *is a set of* **private** *relations, where* R_i *is the set of relations specified by agent* A_i *and relation* $r_i^j \in R_i$ *is a function* $d_{j_1} \times .. \times d_{j_k} \rightarrow \mathbb{R}$ *specified by agent* A_i*, which denotes the utility* A_i *receives for all possible values on the involved variables* $\{j_1, \ldots, j_k\}$ *(negative values can be thought of as costs).*

The optimal solution is a complete instantiation X^* *of all variables in* $\mathcal{X}$*, s.t.* $X^* = argmax_{X \in \mathcal{D}}(\sum_{R_i \in \mathcal{R}} R_i(X) + \sum_{c_i \in \mathcal{C}} c_i(X))$[1]*, where* $R_i(X) = \sum_{r_i^j \in R_i} r_i^j(X)$ *is* A_i*'s utility for this solution.*

Refer to the agents A_i for which $X_j \in X(A_i)$ for some variable X_j as forming the *community* for variable X_j. We will use DCOP($-A_i$) to denote the constraint optimization problem without agent A_i, and refer to this as the "marginal problem without agent A_i."

An agent can also have *private variables*, and relations/constraints imposed on subsets of private variables and public variables. Decisions about private variables, as well as explicit information about these relations and constraints will remain private to an agent.

In addition to defining values for variables, our faithful protocols will also define payments, to be collected (or made) to agents. The only central authority that we require is a *bank* that can enforce these payments. Agents are modeled with quasilinear utility functions, so that agent i's total utility for decision X and payment p made to a bank is $R_i(X) - p$.

The main assumptions made for this paper are as follows:

- The set of variables $\mathcal{X}$, i.e. the number of decisions, is fixed and independent of the participating agents. Moreover, each agent knows the variables that it is interested in.
- Domains $\mathcal{D}$ are known to all interested agents.
- Each constraint $c_i \in \mathcal{C}$ is known to all agents interested in any variable involved in c_i.
- The agents with possible and actual interest in a variable X_i are known to all agents in the community of X_i.
- An agent can communicate with all agents in all communities in which it is a member.
- Agents are modeled as *rational but helpful*, meaning that although self-interested, they will follow a protocol whenever there is no deviation that will make them *strictly* better off.
- No collusion between agents.
- The problem has a feasible solution.
- Catastrophic failure if all agents in a community do not eventually agree on the same value for the variable.
- Every agent has a trusted communication channel with the bank.

To motivate the assumption that all members of a community are known to each other, consider meeting scheduling in which the decision variables are the times and locations of each meeting. Here, we would require that for each meeting there will be a list of participants that have to agree on the time and place. Realize that the only communication that we assume (other than with the bank) is among agents in the same community.

The assumption of catastrophic failure given disagreement is only used to ensure that once the multi-agent system has come to a decision it will be finally *executed.* It is to prevent "hold-out" by an unhappy agent at this final stage. Given that the other agents set their local values to be the agreed upon solution, no agent can benefit by adopting an alternative view of the decision. To motivate this, realize that a scheduled meeting where some participants assumed a different time than others would not be valid, benefitting no one. [2]

A simple "centralized" model of the DCOP($\mathcal{A}$), which we write COP($\mathcal{A}$), can be represented as a *multigraph* (for example Figure 1(a)), with the decision variables as nodes, and (possibly) multiple relations belonging to different agents that involve the same variables. Our complexity results are stated in terms of the induced width of this graph ([3]).

In order to allow multiple agents to express preferences on the same set of variables and *in a distributed fashion*, we adopt a distributed model where each agent has a local replica of the variables that it is interested in (e.g. Figure 1(b).) For each public variable, $X_j \in X(A_i)$, agent A_i has a local copy of X_j, denoted X_j^i. Agent A_i then models its interests as a local problem $COP(X(A_i), R_i)$, by specifying its relations $r_i^j \in R_i$ on the locally replicated variables $X(A_i)$. All copies of the same variable are synchronized between agents through equality constraints. In solving the problem, agents interact with others only through the equality constraints between local replicas of the public variables. [3]

[1]Notice that the second sum is either $-\infty$ if X is an infeasible assignment, or 0 if it is feasible. Thus, optimal solution X^* will always satisfy all hard constraints when that is possible.

[2]On the other hand, this is not an appropriate assumption in market domains where the decision is a trade of goods: it may in fact *not* be catastrophic for a seller to finally renege on an agreed trade. Here, we would need additional techniques such as monitoring to extend out methods. See Shneidman and Parkes [19] for an extended discussion of the problem of final execution of an agreement.

[3]Local, private variables do not show up in inter-agent communication. Agents typically need not solve the internal problem for all

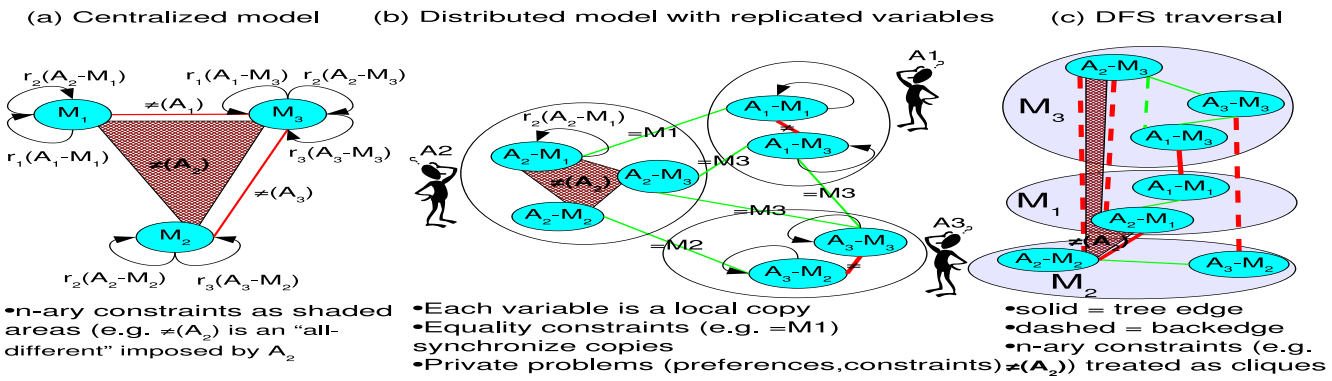

Figure 1: *A meeting scheduling problem, its modeling as a DCOP with replicated variables, and a DFS arrangement*

Example: Meeting Scheduling. This model can be instantiated for distributed meeting scheduling, yielding the PEAV model [13]. Figure 1 shows an example where 3 agents want to find the optimal schedule for 3 meetings. Each agent has as variables the starting times of the meetings it participates in (e.g. A_2-M_1 represents the local copy of the variable representing meeting M_1 for agent A_2). Local *all-different* constraints between an agent's variables ensure that it does not participate in several meetings at the same time. Inter-agent equality constraints between local copies corresponding to the same meeting model the requirement of global agreement. Unary relations on the starting times of the meetings (e.g. $r_2(A_2\text{-}M_1)$) model the preferences of the agents.

2.1 The Centralized VCG Mechanism

The Vickrey-Clarke-Groves (VCG) mechanism (see Jackson [11]) provides a centralized and incentive-compatible (IC) solution to efficient social-choice problems. Indeed, the Groves family of mechanisms (of which VCG is an instance) are the only efficient, IC social choice mechanisms [9]. There is a long tradition of leveraging the VCG mechanism within DAI, going back to Ephrati and Rosenschein [4] who considered the use of VCG mechanisms to achieve consensus.

To use the centralized VCG, each agent would report to a center its relations (and also the domains of variables, and constraints if they were not already known by the center). The center would assign values to variables and determine payments to be made by each agent. The VCG mechanism enjoys a strong form of IC: it is *truthful*, meaning that each agent can always maximize its own utility by reporting true information about its relations, *whatever* the reports of other agents. Truthful reporting is a *dominant-strategy equilibrium* (DSE), which is useful because it frees an agent from modeling the behavior of other agents in computing its equilibrium strategy. Each agent makes a payment equal to the marginal impact of its presence on the rest of the system. In determining this, the center in the VCG mechanism would also solve the marginal problems DCOP($-A_i$) without each agent A_i. Let X^*_{-i} denote the solution to DCOP($-A_i$) and X^* denote the solution to DCOP($\mathcal{A}$). The payment by agent i to the center is:

$$Tax(A_i) = \sum_{j \neq i} \left(R_j(X^*_{-i}) - R_j(X^*) \right), \qquad (1)$$

where $R_j \in \mathcal{R}$ are the relations specified by agent A_j. Thus, agent A_i makes a payment equal to the total marginal negative effect of its presence on the utility of other agents.

combinations of values of the public variables [21].

Realize that in all problem instances we have $Tax(A_i) \geq 0$, for all A_i, with $\sum_{j \neq i} R_j(X^*_{-i}) \geq \sum_{j \neq i} R_j(X^*)$ because agent A_i's presence can only have the effect of changing the values of variables away from the best possible settings just for agents $\neq A_i$. Thus, we always have *weak* budget-balance, with the center running a surplus in all instances of our social choice problem.

The payment by agent A_i can be disaggregated, with $Tax_j(A_i) = R_j(X^*_{-i}) - R_j(X^*)$ denoting the payment made by agent A_i based on its marginal effect on agent A_j. Indeed, it can be further disaggregated to the individual relations of agent A_j. This simple observation will be very powerful in our setting.[4] It will permit a distributed computation of tax payments, where agent A_j computes the payment that should be made by other agents to the bank for their marginal effect on itself; i.e. agent A_j computes $Tax_j(A_i)$ for all $i \neq j$, which will be possible because A_j will know the values on variables of interest in X^* and X^*_{-i}.

2.2 Distributed Implementation

Parkes and Shneidman [16, 19] introduce the notion of *distributed implementation* for social choice problems. A distributed implementation (DI), $d_M = < g, \Sigma, s^m >$, defines an outcome rule $g : \Sigma^n \rightarrow \mathcal{D} \times \mathbb{R}^n$, where $g_1 \in \mathcal{D}$ defines values on variables and $g_2 \in \mathbb{R}^n$ defines the payment by each agent, a feasible strategy space Σ, and a *suggested* (multi-agent) protocol s^m. A protocol d_M is ex post *faithful* if suggested protocol s^m is an *ex post* Nash equilibrium (NE), meaning that no agent can benefit by deviating from the protocol in equilibrium (i.e. given that other agents follow the protocol) and whatever the particular instance of DCOP.

In a DI, the suggested protocol, s^m, combines the information revelation actions of mechanism design with the computational and communication actions of distributed algorithms. Thus, in following s^m an agent is both revealing information about its private relations and assisting in solving the DCOP and computing payments. The outcome rule g defines the assignment of values and payments for all possible termination states, including those that could arise from unilateral deviations. The feasible strategy space Σ, restricts the space of actions available to an agent in all possible states of the protocol, i.e. the messages that an agent can send that are interpretable by the other agents given that they are following the suggested protocol.

Parkes and Shneidman [16] introduced the **partition principle** for the distributed implementation of VCG mechanisms. Briefly, this principle states that a distributed mechanism is an *ex post*

[4] See Feigenbaum et al. [6] for a corresponding disaggregated VCG payment in the domain of shortest-path Internet routing.

faithful distributed implementation of efficient social choice if: (1) optimal solutions are always obtained for $DCOP(\mathcal{A})$ and $DCOP(-A_i)$ given s^m; (2) agent A_i cannot influence either the solution to $DCOP(-A_i)$ or its tax; (3) the optimal solution of $DCOP(\mathcal{A})$ is correctly executed and the corresponding taxes collected.

Loosely, the partition principle holds because no agent can affect its payment for any outcome. Thus, it is in the best interest of every agent to follow the suggested protocol so that the efficient outcome (i.e. the outcome selected in the VCG mechanism) is selected. The only effect of a deviation by an agent is to change either the outcome or some other agent's payment. Truthfulness of VCG then gives faithfulness. The suggested strategy forms an *ex post* NE but not a DSE because it relies on other agents following the strategy; if another agent deviates, e.g. from its role in the computation to solve $DCOP(\mathcal{A})$, then the correct outcome of the VCG mechanism will not be selected.

In related work, Feigenbaum and colleagues [6, 7] introduced the notion of *distributed algorithmic mechanism design*, but emphasized complexity questions rather than the faithfulness that is central to DI; see [19] for a faithful extension. Monderer and Tennenholtz [15] consider a distributed single item auction problem, but focus on communication of messages by self-interested agents rather than distributed computation. Finally, Izmalkov et al. [10] leverage cryptographic methods to convert centralized mechanisms into DIs on fully connected graphs.

3. DISTRIBUTED OPTIMIZATION VIA DPOP

In this section, we instantiate the DPOP algorithm [17] for efficient social choice. DPOP is an instance of Dechter's general bucket elimination scheme [3], adapted for the distributed case. This instantiation runs in three phases, which are very similar to the ones from the standard DPOP protocol. Phase one (section 3.1) constructs $DFS(\mathcal{A})$, which defines the control ordering of the inference algorithm. Phase two is a bottom-up utility propagation, and phase three is a top-down value assignment propagation (see section 3.2). There are some slight differences in phases one and two because we seek to exploit the structure of this DCOP model with replicated variables, for computational efficiency reasons.

Notice that DPOP can be applied to disconnected problems as well: the DFS arrangement is then a DFS forest, and agents in each connected component simply execute DPOP on a tree of that forest. The solution to the (disconnected) problem is then simply the union of optimal solutions for each independent, connected subproblem.

Section 4 will modify DPOP to make it faithful.

3.1 Phase One: DFS Tree Generation

See Algorithm 1. This phase has as a goal to generate a depth-first traversal (DFS) of the problem graph in a distributed manner. A DFS arrangement of a graph G is a rooted tree with the same nodes and edges as G and the property that adjacent nodes from the original graph fall in the same branch of the tree (thus, there are no edges between different branches of the tree). Common definitions of parent, child, pseudoparent, pseudoparent apply. For example, in Figure 1(c), A_2-M_1 and A_2-M_2 are parent/child to each other, and A_2-M_3 and A_2-M_2 are pseudoparent/pseudochild. *Tree-edges* connect parents/children (e.g. A_2-$M_1 - A_2$-M_2), and *back-edges* connect pseudoparents/pseudochildren (e.g. A_2-$M_3 - A_2$-M_2).

First, each agent A_i formulates internally its interests on the variables $X(A_i)$ as $COP(X(A_i), R_i)$, with a replicated variable X_j^i for each $X_j \in X(A_i)$. All agents subscribe to the communities they are interested in, and learn which other agents belong to these communities. [5] In doing this the *problem graph* is constructed. Next, one of the variables, X_0 is chosen as the DFS root. [6] The agents involved in the community for X_0 then randomly choose one of them, A_r as the *leader*. The local copy X_r^0 of variable X_0 forms the root of the DFS. In the case that the problem is initially disconnected then a modification is required to choose multiple root communities, one for each connected component.

Algorithm 1: *Phase One of DPOP.*

DPOP($\mathcal{A}, \mathcal{X}, \mathcal{D}, \mathcal{C}, \mathcal{R}$):

1 Each agent A_i models its interests as $COP_i(X(A_i), R_i)$: a set of relations R_i imposed on a set $X(A_i)$ of variables X_j^i that each replicate each public variable $X_j \in X(A_i)$

2 Each agent A_i subscribes to the communities of $X_i \in X(A_i)$

DFS Generation:

3 The agents $\mathcal{A}$ choose one of the variables, X_0, as the root.

4 Agents in X_0's community elect a "leader", A_r

5 A_r initiates the token passing to construct the DFS

6 At completion, each A_i knows $P(X_j^i)$, $PP(X_j^i)$, $C(X_j^i)$, $PC(X_j^i)$, for all local copies X_j^i.

Second, the agents participate in a distributed depth-first traversal of the problem graph to construct the DFS for problem DCOP($\mathcal{A}$), which we denote $DFS(\mathcal{A})$. (Multiple DFS trees are generated for disconnected problems.) For convenience, we describe the DFS process as a token-passing algorithm in which all members within a community can observe the release or pick up of the token by the other agents. But, this can also be implemented via (private) message passing.

Let us refer to the example from Figure 1, and assume that M_3 was chosen as the start community, and A_2 was chosen within the community as the start node. A_2 creates an empty token, adds A_2-M_3's ID to the token, and then releases it back to the community. Another agent from M_3's community (e.g. A_3) picks up the token, adds its copy of M_3 to the token (A_3-M_3's ID) and releases it again. A_1 picks it up and automatically adds equality constraints between its variable A_1-M_3 and all its corresponding replica variables that precede it in the context of the token (A_2-M_3 and A_3-M_3) (i.e. one tree edge and one back edge.) Notice that the result is that all replicas of a variable are arranged in a chain, and have equality constraints (back-edges) with all the predecessors that are replicas of the same variable.

Agent A_1 also adds its copy of M_3 to the token (A_1-M_3) and as the last agent in community M_3 to receive the token looks to see if it is a member of another community that has yet to receive the token (choosing one at random if such a community exists). Here, agent A_1 is linked to community M_1 and adds its copy of M_1 to the token (i.e. A_1-M_1), and then releases the token in M_1's community, where A_2 picks it up. When a dead end is reached, the last agent backtracks by sending the token back to its parent. In our example, this happens when A_3 receives the token from A_2 in the M_2 community. Then, A_3 sends back the token to A_2, etc. Eventually the token returns on the same path all the way to the root, and then the process is complete. [7]

[5] A community can be e.g. a bulletin board, a mailing list, etc

[6] This can be done e.g. randomly, using any distributed algorithm for random number generation, or by simply picking the variable with the highest ID, etc.

[7] K-ary constraints (involving k variables) are treated like a cliques during the DFS construction. Concretely, in Figure 1, there is a ternary *all-diff* constraint $\neq A_2(M_1, M_2, M_3)$. A_2 then considers

In constructing $DFS(\mathcal{A})$, the DFS traversal is made according to the structure defined by the relations of the agents. Most hard constraints appear thus as backedges in such a DFS tree. By convention, any hard constraint $c_i \in \mathcal{C}$ is assigned to the highest agent in the community of the variable involved in c_i that is lowest in the DFS ordering. For example, in Figure 1(c), assume that there is a constraint between M_2 and M_3 that specifies that M_2 should occur after M_3. With our convention, this constraint becomes a backedge between the 2 communities, and is assigned to A_2 for handling, because $A_2\_M_2$ is the highest variable in M_2's community, which is lower than M_3's community in the DFS. A_2 then handles this constraint in parallel with its own relation $A_2\_M_2$-$A_2\_M_3$.

Realize that the choice of DFS does not change the solution, so the choice of root node, leaders, etc does not affect the incentive properties.

3.2 Phases Two and Three: Inference

Phase 2 is a bottom-to-top pass that propagates aggregated information about the relations towards the root. The *UTIL* propagation starts bottom-up from the leaves and propagates upwards only through tree edges, from children to parents. A *UTIL* message sent by X_i to its parent X_j informs X_j how much utility $u^*_{X_i}(v^k_j)$ each one of its values v^k_j gives to the whole subtree rooted at X_i in the optimal solution.

To compute the *UTIL* message for its parent, X_j has to join the messages it received from all its children, and the relations it has with its parent and pseudoparents. [8] Afterwards, it projects itself out of the join and sends the result to its parent. The result of the projection is in fact the set of optimal utilities that can be obtained by the subtree rooted at this node, plus the relations it has with its parent/pseudoparents, for each combination of values of the parent/pseudoparents (see [17] for details and examples). This projection provides for an efficient algorithm.

A useful optimization for social choice problems can be introduced to handle replica variables. In the example of Figure 1, $A_2\_M_2$, $A_3\_M_2$ and $A_2\_M_1$ all have back-edges: $A_2\_M_2 - A_2\_M_3$, $A_3\_M_2 - A_3\_M_3$ and $A_2\_M_1 - A_2\_M_3$ respectively. These represent the inequality constraints for agents. Normal DPOP would condition $UTIL$ messages on both $A_2\_M_3$ and $A_3\_M_3$ separately. For social choice these will adopt the same values due to the equality constraints, and thus the conditioning can be collapsed into a single dimension, the value of M_3. This is possible because all 3 agents involved, i.e. A_1, A_2 and A_3 know that $A_1\_M_3$, $A_2\_M_3$ and $A_3\_M_3$ represent the same variable.

Phase 3 is a top-to-bottom pass that makes decisions about the value of variables, with decisions made recursively from the root down to the leaves. This "$VALUE$ propagation" phase is initiated by the agent A_r representing the root variable X_0, once it has received *UTIL* messages from all of its children. Based on these *UTIL* messages, the root assigns itself the value v^* that maximizes the sum of its own utility and that communicated by all its subtrees. It then sends a *VALUE*$(X^0_r \leftarrow v^*)$ message to every child. The process continues recursively to the leaves, with agents X_i assigning values to local copies of variables.

3.3 Complexity Analysis of DPOP

It has been proved in Petcu and Faltings [17] that *DPOP* produces a linear number of messages for general distributed optimization problems. Its complexity lies in the size of the *UTIL* messages (the *VALUE* messages have linear size). This is also true for its instantiation to social choice problems.

Let us denote by w the width of the problem graph for the centralized model of DCOP($\mathcal{A}$) (e.g. Figure 1(a)). The induced width of a graph is a topological parameter that captures the density and clustering of the graph [3]. It is roughly defined as the *maximal number of overlapping tree paths between any pair of different vertices*. In the example from Figure 1, $w = 2$. Let $D = \max_m |d_m|$ denote the maximal domain of any variable.

THEOREM 1. *The number of messages passed is $2 \times m$, $(n-1)$ and $(n-1)$ for phases one, two and three respectively, where n and m are the number of nodes and edges in the distributed model.*

The maximal amount of computation on any node in DPOP is $O(D^{w+1})$, and the largest UTIL message has $O(D^{w+1})$ entries, where w is the width of the centralized problem graph.

Sketch of Proof. Follows from the analysis of DPOP in Petcu and Faltings [17], and the fact that equivalent variables use up only one dimension in the *UTIL* messages (see Section 3.2), and that a dimension is not projected out immediately as it reaches the first target variable, but only when it reaches its top most copy. □

The complexity of DPOP for social choice problems is exponential in the tree width of the centralized graphical model, but not the decentralized graphical model which includes the replicated variables. This is due to the special handling of replica variables described in Section 3.2.

4. MDPOP: A FAITHFUL PROTOCOL FOR DISTRIBUTED OPTIMIZATION

In this section we extend the DPOP algorithm to define *MDPOP*, and prove that MDPOP is a faithful implementation of distributed constraint optimization, terminating with the outcome of the VCG mechanism. We first provide a simple extension, that we call *simple*-MDPOP, before describing our preferred extension, that we call MDPOP.

Algorithm 2: *Simple-MDPOP.*

1 Run DPOP for $DCOP(\mathcal{A})$ on $DFS(\mathcal{A})$; find X^*
2 **forall** $A_i \in \mathcal{A}$ **do**
3 Run DPOP for $DCOP(-A_i)$ on $DFS(-A_i)$; find X^*_{-i}
4 $\forall A_j \neq A_i$, compute $Tax_j(A_i) = R_j(X^*_{-i}) - R_j(X^*)$
5 $\forall A_j \neq A_i$, report $Tax_j(A_i)$ to the bank
6 Bank deducts $\sum_{j \neq i} Tax_j(A_i)$ from A_i's account
7 A_i implements X^* as solution to its local $COP(A_i)$

Algorithm 2 describes simple-MDPOP. The algorithm is presented for a setting in which the main problem and the subproblems are connected but extends immediately to disconnected problems, as discussed in the previous section and without new incentive considerations. Notice that the protocol sets up, and then solves, $n+1$ DPOP protocols, one for the main problem and one for the n marginal problems, with each agent A_i removed in turn. Once these $n+1$ stages are complete every agent A_j has sufficient local knowledge of the solutions $\{X^*, X^*_{-1}, \ldots, X^*_{-n}\}$ to compute the tax payment that every other agent A_i, for $i \neq j$, should make to the bank because of its marginal effect on agent j. Each agent will finally respect decision X^*, to avoid catastrophic failure.

THEOREM 2. *The simple-MDPOP algorithm is a faithful distributed implementation of the optimal solution to a DCOP, and terminates with the outcome of the VCG mechanism.*

the variables in the scope of this constraint to be a fully connected component, which produces the result from Figure 1(c).

[8] A k-ary relation is introduced in this join only once, by the lowest node in the DFS tree, which is part of its scope. E.g. in Figure 1(c), the constraint $\neq A_2(M_1, M_2, M_3)$ is introduced by $A_2\_M_2$.

PROOF. Follows from the partition principle [16]. First, DPOP computes optimal solutions to DCOP($\mathcal{A}$) and $DCOP(-A_i)$ for all $A_i \in \mathcal{A}$ when every agent follows the protocol. Second, agent A_i cannot influence the solution to $DCOP(-A_i)$ because it is not involved in that computation. The DFS is constructed and then inference performed by the other agents, who completely ignore A_i's variables and constraints, and any messages that agent A_i might send. Moreover, agent A_i is not required to perform any message passing in solving for $DCOP(-A_i)$. Note that any hard constraints that A_i may have handled in $DCOP(\mathcal{A})$ are reassigned automatically to some other agent in $DCOP(-A_i)$.

Notice that $DCOP(-A_i)$ could become disconnected without the presence of agent A_i. However, as noted in the beginning of Section 3, DPOP would still solve $DCOP(-A_i)$ correctly. Finally, agent A_i cannot prevent the correct calculation and reporting of the tax it should pay because this is done by agents $A_j \neq A_i$. The bank collects payments and all agents finally set local copies of variables as in X^* to prevent catastrophic failure. (Notice that agent A_i will not deviate as long as other agents do not deviate. Moreover, if agent A_i is the only agent that is interested in a variable then its value is already optimal for agent A_i anyway.) □

In particular, notice that we get from the partition principle that no agent has an interest in obstructing the choice of root community or leader agent in Phase one of DPOP, or in the information-revelation, computation and message passing in Phases two and three of DPOP. Also, no agent A_i can usefully influence its payment by misreporting the local utility of another agent A_j, as $UTIL$ messages are exchanged. While this could change the select of X^* or X^*_{-k} for some $k \neq \{i, j\}$, it would *not* change the utility information used in finally determining agent A_i's payments because only the utility information local to A_j and known to A_j is used in computing the component of A_i's payment due to its effect on A_j.

Note on antisocial behavior: While it is true that an agent A_j has no immediate self-interest in reporting the payment another agent should make, it does have a long-term self-interest if it wants other agents to be truthful (e.g. imagine a system where over time agents realize that the correct payments are not being collected from others). Reporting exaggerated taxes hurts other agents, but does not increase one's own utility, so this is excluded by our assumption that the agents are self-interested but helpful.

4.1 Full-MDPOP

In *simple-MDPOP*, the computation to solve the main problem is completely isolated from the computation to solve each of the marginal problems. The full *MDPOP* algorithm leverages the computation already performed in solving the main problem in solving the marginal problems whenever this is possible and without breaking incentive properties.

This enables the algorithm to scale well to problems where each agent's influence is limited to a small part of the entire problem. [9]

The first stage of MDPOP solves the main problem just as in Simple-MDPOP, running DPOP($\mathcal{A}$). Once this is complete, each marginal problem is solved in parallel. To solve $DCOP(-A_i)$, a DFS-tree is constructed as a modification to DFS($\mathcal{A}$), retaining as much of the structure as possible. This maximizes the reuse of $UTIL$ messages. The new tree, $DFS(-A_i)$ must be constructed in a way that is non-manipulable, i.e. without allowing agent i to interfere with its construction, and also to ensure correctness. This requires that communities of variables that remain connected in $DCOP(-A_i)$ remain connected in the $DFS(-A_i)$ tree when edges that link to nodes owned by A_i are disabled in solving $DCOP(-A_i)$. For instance, in Figure 2, A_1-M_1−A_1-M_3 is a tree edge in $DFS(\mathcal{A})$, and its removal disconnects $DCOP(-A_1)$).

[9]For example, in a meeting scheduling problem with thousands of agents, any one agent only participates in a few meetings, in a rather restricted circle of acquaintances.

Algorithm 3: *MDPOP.*

1 Run DPOP for $DCOP(\mathcal{A})$ on $DFS(\mathcal{A})$; find X^*
2 **forall** $A_i \in \mathcal{A}$ **do**
3 **Create** $DFS(-A_i)$ **by adjusting** $DFS(\mathcal{A})$**:**
exclude all variables X^i_j and relations that belong to A_i;
the highest descendant of each excluded X^i_j that has a back edge with an ancestor of X^i_j turns it into a tree-edge;
4 **Run DPOP for** $DCOP(-A_i)$ **on** $DFS(-A_i)$:
children/parents of each excluded X^i_j recompute their *UTIL* messages and restart propagations;
reuse *UTIL* msgs from $DPOP(\mathcal{A})$ not influenced by A_i;
5 Compute and levy taxes as in simple-MDPOP;
6 A_i implements X^* as solution to its local $COP(A_i)$;

Phase One of MDPOP for a marginal problem. Consider DPOP($-A_i$). In building $DFS(-A_i)$ from $DFS(\mathcal{A})$, existing links that were back-edges in $DFS(\mathcal{A})$ can be turned into tree-edges in $DFS(-A_i)$ as necessary to keep it connected. This preserves as much as possible of the tree structure. Figure 2 shows an example of a common $DFS(\mathcal{A})$, adjusted for each marginal problem using this idea. For example, A_2-M_3−A_2-M_1 is a back-edge in $DFS(\mathcal{A})$, but becomes a tree-edge in $DFS(-A_1)$ to compensate for the loss of edge A_1-M_1 − A_1-M_3. The algorithm works by considering each of the nodes X_i belonging to A_i in turn. For each X_i that will be excluded from DPOP($-A_i$), all nodes below X_i check the path from the root to themselves, and the list of nodes reachable from their children (both these pieces of information are available after $DFS(\mathcal{A})$ is constructed). The highest node below X_i that has a back edge pointing to a node above X_i converts this edge into a tree edge and converts its pseudo parent into a parent.

Thus, no additional links are created, as we use only existing ones, previously designated as back-edges. Realize that this conversion, in converting back edges to tree edges, cannot increase the induced width of $DFS(-A_i)$ above the one of $DFS(\mathcal{A})$, therefore *UTIL* messages can only decrease in size.

Phase Two of MDPOP for a marginal problem. Each marginal problem is then solved on $DFS(-A_i)$. Notice that the parent and children of excluded nodes will have to recompute their messages from $DPOP(\mathcal{A})$ to account for the new structure and initiate the corresponding propagation for $DPOP(-A_i)$.

Subsequently, any message can be reused iff it comes from a subtree that does not contain any of A_i's variables, because A_i could not have influenced it. E.g. in $DPOP(-A_1)$, A_2-M_1 is a child of $A_2-M_1 \in A_1$. It has to recompute a *UTIL* message and send it to A_2-M_3. To do this, it can reuse the message sent by A_2-M_2 in $DPOP(\mathcal{A})$, because the sending subtree does not contain A_1. By doing so, it reuses the effort spent in $DPOP(\mathcal{A})$ to compute the messages $A_3-M_2 \rightarrow A_2-M_2$ and $A_2-M_2 \rightarrow A_2-M_1$.

THEOREM 3. *The MDPOP algorithm is a faithful distributed implementation of the optimal solution to a DCOP, and terminates with the outcome of the VCG mechanism.*

Sketch of Proof. From the partition principle [16]. First, agent i cannot prevent the construction of a valid DFS for $DCOP(-A_i)$ because in the construction of $DFS(-A_i)$ from the main DFS, all transformations are initiated by neighbors of A_i, and all links with A_i are simply dropped. Second, agent i cannot influence the execution of DPOP on $DCOP(-A_i)$ because all messages that A_i

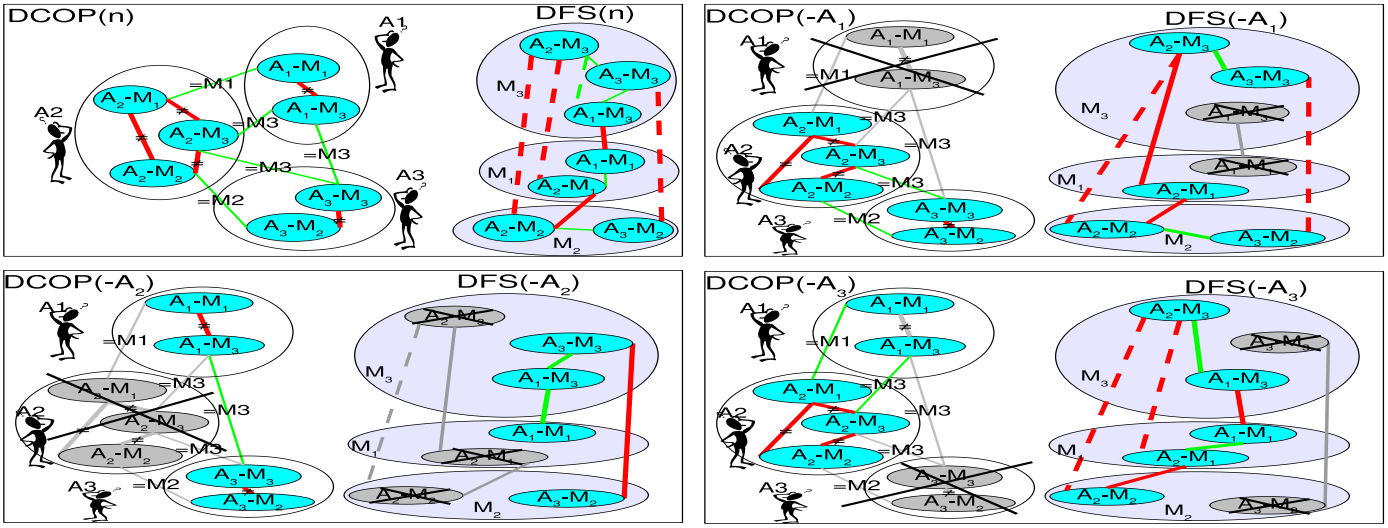

Figure 2: *Each agent A_i is excluded in turn from the optimization $DCOP(-A_i)$. $DFS(-A_i)$ is adapted from $DFS(\mathcal{A})$.*

influenced in the main problem $DCOP(\mathcal{A})$ are recomputed in the new structure. This follows from the fact that every link where agent A_i was responsible for computing a message is eliminated by its neighbors and that all these propagations are restarted. □

5. INCENTIVE COMPATIBLE VCG PAYMENT REDISTRIBUTION

No social choice mechanism can be efficient, incentive-compatible, and individually rational while at the same time guaranteeing exact budget-balance [8]. [10] In our setting, where there are no positive externalities, the VCG mechanism runs at a surplus with the bank receiving a net payment from agents. While these taxes cannot be simply redistributed among the agents, a tax payment *can* be refunded to an agent A_l as long as that agent has no influence on the computation of the payments it receives. This general idea was suggested by Ephrati and Rosenschein ([4]), and recently explored by Faltings [5] and Cavallo [2].

The most straightforward way to implement this idea is to consider any agent that does not influence any of the optimizations that are used in computing a certain part of the VCG tax as eligible to receive this tax. However, this approach would not maintain incentive-compatibility, as an agent with only a small influence on some aspect of the problem could gain an advantage by misstating its preferences to become non-pivotal and thus receive a possibly much larger tax payment.

Faltings [5] suggests to deal with this problem by forcing an agent A_l to be non-pivotal independently of its declarations by simply ignoring it in the optimization. In this way, it is guaranteed that the agent does not have an influence on the tax computation and thus can receive it without creating unwanted incentives. While the mechanism may be forced to choose a suboptimal solution, [5] shows through experiments on randomly generated problems that the expected utility loss from suboptimality is much smaller than what would result from wasting the taxes.

However, a drawback of this approach is that in a large optimization problem, some agent would not be considered at all in the entire problem. It would be more advantageous if various agents could receive *some portion* of the tax in return for *some* reduction of their influence on the solution.

Consider the VCG payment portion:

$$tax_j(A_i) = r_j(X^*_{-i}) - r_j(X^*)$$

that is paid in Algorithm 2 by agent A_i with respect to relation r_j. Let $r_j \in R_k$, i.e. r_j was posted by agent A_k.

We designate an agent A_l, $l \notin \{k, i\}$ to receive this payment as a refund. A straightforward way to choose A_l would be to take an agent that did not influence the values of any of the variables in r_j in the solution. However, this would destroy incentive-compatibility, since an agent may now have an incentive to hide its interest in order to be eligible to receive the refund. Similarly, an agent could have an interest to make other agents look pivotal to increase its own chance of receiving a refund.

To avoid such influence, A_l needs to be chosen independently of the agents' declarations. Our algorithm does this as follows:

1. For each agent A_l, we use the set $P(A_l)$ of the variables on which the agent could possibility express interest and ignore its declarations when they involve other variables.

2. For each payment portion $tax_j(A_i)$, choose an agent A_l that will be eligible to receive it, using any criterion that is not related to the agents' own declarations. This can be done by random selection among agents that cannot possibly be part of the community of the variables.

3. Using the declarations of the agents, for each payment portion verify that the agent A_l chosen to receive it indeed cannot have any influence on the values of the variables involved. If there is no possible influence, the agent receives the payment as a refund, if not, it has to be wasted.

We now give a brief description of the third step of the algorithm. This step is important because even an agent not in the community of a variable may still be able to influence relations via the propagation of its effect over the problem graph.

We use the *omnidirectional* utility propagation from the DPOP extension presented in [18]. In this version, messages circulate in

[10] For budget balance in general problems, one can settle for *ex ante* individual-rationality [1] and Bayes-Nash incentive-compatibility, but this requires the mechanism and agents to have common knowledge about a distribution on agent types.

all directions along the DFS tree (parent to children, too). A message from a parent to its child summarizes the utility information from the entire problem except the subtree of that child. Joining messages from the parent and the children gives each node the same global view of the system as the root in the simple DPOP has.

We can characterize the influence that an agent A_l has on a variable X_k by a *label* that contains a value for each member of X_k's domain d_k. The value is "1" if A_l can make X_k take the corresponding value by its declarations, and "0" if it cannot. If A_l posts a relation on X_k, it can make any value the most preferred one, so each position has a "1".

As an example, consider a variable X_k that can take three values `a, b, c`. Let A_l have no influence on any sibling or ancestor of X_k in the DFS ordering, but complete control of the value of X_k. Thus, A_l's label for X_k is `(1,1,1)`. Let X_a be the ancestor of X_k in the DFS ordering with possible values `d, e, f`, and assume that some other agent has imposed the following relation between X_k and X_a:

$X_a =$	d	e	f
$X_k = a$	3	2	1
$X_k = b$	2	3	1
$X_k = c$	4	3	2

Furthermore, let the sum of all other messages arriving at X_a, assuming omnidirectional propagation, be the vector $(5, 5, 5)$, giving the utilities of $X_a = (\mathtt{d}, \mathtt{e}, \mathtt{f})$ in the rest of the problem. Note that this vector is not influenced by A_l.

Agent A_l can influence the value of X_a only through the utilities it gives to the three different values of X_k. Letting these be $U_l(X_k)$, and factoring the utilities reported in the rest of the problem, the propagation would choose the maximum in each row of the following table, indicated in bold:

X_a=	d	e	f
$X_k = a$	$\mathbf{8 + U_l(X_k = a)}$	$7 + U_l(X_k = a)$	$6 + U_l(X_k = a)$
$X_k = b$	$7 + U_l(X_k = b)$	$\mathbf{8 + U_l(X_k = b)}$	$6 + U_l(X_k = b)$
$X_k = c$	$\mathbf{9 + U_l(X_k = c)}$	$8 + U_l(X_k = c)$	$7 + U_l(X_k = c)$

where the chosen row depends on the value of X_k. Now note that A_l can never force $X_a = \mathtt{f}$, since this will never give the maximum utility. Thus, A_l's label for X_a is `(1,1,0)`. Had A_l's label for X_k been `(1,0,1)`, its label for X_a would have been `(1,0,0)`, meaning that only $X_a = \mathtt{d}$ is possible and thus A_l has in fact no possibility to influence X_a's value.

Note that the number of "1"s in a label can never increase during such propagation, since for every choice of input value there can be only one optimal output value. This means that propagation will eventually converge to labels with a single "1". By propagating labels in the same way as propagating messages in MDPOP, we can determine the variables that an agent can potentially influence.

The presence of backedges in the DFS tree somewhat complicates the algorithm. The full algorithm will be described in a longer version of this paper.

6. CONCLUSIONS

We presented a multiagent constraint optimization algorithm for use in efficient social choice problems when agents are self interested and have private information about their utility for different outcomes. Our algorithm is faithful, in the sense that no agent can improve its utility either by misreporting its local information or deviating from any aspect of the algorithm. The only centralized control we assume is that of a bank that is able to receive messages about payments and collect payments. In addition to promoting efficient decisions we also seek to return payments back to agents, to further improve the net utility of outcomes. Future work should provide a comprehensive empirical analysis, in order to understand the scheme's scalability and budget balance properties on realistic problem instances.

ABSTRACT

Distributed Constraint Satisfaction Problems (DCSPs) provide a model to capture a broad range of cooperative multi-agent problem solving settings. Researchers have generally proposed two different sets of approaches for solving DCSPs, backtracking based approaches, such as Asynchronous Backtracking (ABT), and mediation based approaches, such as Asynchronous Partial Overlay (APO). These sets of approaches differ in the levels of coordination employed during conflict resolution. While the computational and communication complexity of the backtracking based approaches is well understood, the tradeoffs in complexity involved in moving toward mediation based approaches are not. In this paper we comprehensively reexamine the space of mediation based approaches for DCSP and fill gaps in existing frameworks with new strategies. We present different mediation session selection rules, including a rule that favors smaller mediation sessions, and different mediation strategies, including a decentralized hybrid strategy based on ABT. We present empirical results on solvable 3-coloring and random binary DCSP problems, that accurately capture the computational and communication tradeoffs between ABT and various mediation based approaches. Our results confirm that under some circumstances the newly presented strategies dominate previously proposed techniques.

1. INTRODUCTION

Distributed Constraint Satisfaction Problems (DCSPs) provide a formalism for representing problems where different agents are each responsible for instantiating different sets of variables subject to constraints. The agents aim to assign values to their variables, such that all constraints are satisfied. Many real-world scenarios can be modeled as DCSPs, such as supply chain coordination [10], product co-design, and distributed meeting scheduling [8]. Some of these scenarios give rise to naturally distributed problems, others benefit from distributed reasoning for privacy or confidentiality reasons.

There have been several distributed algorithms developed for solving DCSPs, each with particular strengths and weaknesses. The DCSP algorithm that has received the most attention is an asynchronous version of Constraint Backtracking (CBT), called Asynchronous Backtracking (ABT) [12]. The original proposal for ABT has seen several improvements [3, 2, 14], and is considered one of the most effective techniques for solving DCSPs.

Recently the multi-agent systems community has become interested in DCSP algorithms for modeling agent coordination tasks. This idea was introduced by Mailler and Lesser in the context of an algorithm called Asynchronous Partial Overlay (APO) [5]. In APO agents involved in a conflict select a mediator to solve a centralized version of a subproblem capturing key elements of that conflict.

APO has been shown to involve significantly less communication than backtracking based techniques, such as ABT, by reducing the amount of unsuccessful instantiation attempts that repeatedly violate the same constraints (*thrashing*) [5]. On the other hand, in contrast with ABT, current versions of mediation based techniques have failed to fully exploit opportunities for concurrent processing. This tradeoff has not been explicitly identified in prior experimental investigations due to somewhat coarse computational complexity measurements.

In this paper we measure computational complexity based on a finer metric recently proposed by Meisels *et. al.* [6], that involves counting non-concurrent constraint checks. Comprehensive testing based on this finer metric reveals tradeoffs that had not been captured previously. Our results involve solvable 3-coloring problems, as well as random binary DCSPs. These results have motivated us to develop a hybrid technique that reconciles the tradeoffs we have identified. The basic intuition of our hybrid technique is to avoid thrashing on solvable problems through coordinated mediation, while maximizing concurrent work in the mediation process itself.

In Section 2 we introduce the DCSP formally, and discuss previous work on measuring problem solving complexity of DCSP algorithms. In Section 3 we discuss ABT and APO,

along with new variations including our decentralized hybrid. Experimental results are presented and discussed in Section 5, and concluding remarks are provided in Section 6.

2. BACKGROUND

2.1 DCSP Definition

The distributed constraint satisfaction problem was first discussed by Sycara *et. al.* and Yokoo *et.al.* as a way of formalizing Cooperative Distributed Problem Solving [12, 10]. A DCSP is formally defined as a constraint satisfaction problem (CSP) of the following form:

- a set of n variables, $V = \{x_1, \ldots, x_n\}$
- a set of discrete finite domains for each variable, $D = \{D_1, \ldots, D_n\}$
- a set of constraints $R = \{R_1, \ldots, R_m\}$ where each $R_i(d_{i1}, \ldots, d_{ij})$ is a predicate on the Cartesian product of the domains of all the variables referenced by that constraint. The constraint is said to be *satisfied* if the assignments of each referenced variable satisfy the constraint.

An agent, i, is said to *know* about a particular set of variables, V_i, and constraints, C_i. We will call the group of agents that agent i is connected to by constraints i's neighborhood, N_i. The goal of the agents is to instantiate their variables so that all constraints are satisfied. As in other work, for the sake of simplicity, we restrict our presentation to situations where each agent controls ("owns") a single variable and knows about all the constraints that refer to that variable. We further limit our discussion to binary constraints (constraints between two variables). It has been shown that more general problems can be reduced to problems that conform to these restrictions. In Section 6 we briefly discuss why the trends observed in this study should extend to these more complex classes of DCSPs.

2.2 Related Work

The original descriptions of ABT and APO appear in [12] and [5] respectively. In empirical studies of APO and backtracking based algorithms, such as ABT and Asynchronous Weak Commitment [11] (AWC), computational complexity measurements were often based on somewhat coarse performance metrics. In particular, these experiments typically did not differentiate between steps that required significantly different amounts of computation, e.g. equally counting as a single step a consistency check in AWC and a full backtracking search in a mediation session. Because they also focused primarily on solvable 3-coloring problems these experiments also raised the question of whether they were representative of other problem classes. In this paper we revisit the coordination tradeoffs involved in solving DCSPs using finer computational metrics and a more extensive class of problem instances - both solvable 3-coloring problems and random binary DCSPs. Our experiments reveal a richer set of performance tradeoffs than had been reported earlier. In addition, we present novel search configurations that aim to reconcile these tradeoffs.

Our empirical analysis uses a metric introduced by Meisels *et.al.* [6] that records the number of non-concurrent constraint checks (NCCCs) associated with different distributed search procedures. This metric distinguishes between complex computational steps involving multiple constraint checks, and much simpler ones. Constraint checks are the preferred computational unit used to measure performance of centralized constraint processing algorithms (see for example [9]). By counting non-concurrent checks the NCCCs metric is akin to the notion of a make-span or throughput measurement in scheduling [4].

The results presented in this paper build on our preliminary work comparing different mediation session selection rules for APO [1].

3. BASIC BACKTRACKING AND MEDIATION ALGORITHMS

This section outlines key features of ABT and APO, focusing on elements that impact computation and communication complexity.

3.1 Asynchronous Backtracking

ABT is an asynchronous implementation of the traditional backtracking search approach to solving centralized CSPs.

A summary of the procedures involved in the original description of ABT is shown in Figure 1. The algorithm begins with an initialization process, during which each agent i is given a static priority, p_i (typically based on lexicographic order). Agent i then arbitrarily assigns a value, d_i, to its variable, x_i, and broadcasts it to all lower priority neighbors. When agent i receives an assignment message from another agent, j, it stores the assignment as a tuple in the set called its *agentview*. Agent i then checks the consistency of its *agentview* and its own assignment. When it finds that its own assignment violates a constraint it tries to assign a value to its variable that resolves consistency. If it cannot find such an assignment it begins the backtrack process, and informs a higher priority agent that its *agentview* is *nogood* (leads to an unsatisfiable situation for the agent)[1]. The algorithm proceeds until all of the agents have variable assignments consistent with their *agentviews*, or one of the agents discovers that the problem is infeasible. For a full description of the ABT algorithm along with proofs of completeness and correctness, the reader is directed to its original description in [12].

An agent executing ABT uses constraint checks[2] to determine the consistency of its variable assignment. Because the agent knows only about the assignments of higher priority agents (as defined in its *agentview*), this amounts to checking each constraint with a higher priority agent. Notice that the original description of ABT involves recording each received nogood as a constraint (see "**when received** `nogood`" in Figure 1). As a result, each learned nogood is among the set of constraints that must be checked for consistency. Since the storage of nogoods can grow exponentially on harder problem instances, checking nogoods as constraints can significantly increase the number of NCCCs used by ABT. It has been shown, however, that agents can avoid much of the constraint checking work associated with nogoods by eliminating them from storage once they become *stale* (they

[1]We are aware that an agent can potentially resolve the subset of its agentview that resulted in the conflict. However, this has been shown to provide little benefit.

[2]Note that this refers to constraint checks in general, whether or not these checks are concurrent.

```
procedure init()
  calculate priority, p_i (usually lexicographic order);
  choose d_i ∈ D_i arbitrarily; set x_i ← d_i;
  agent_view_i ← ∅;
  broadcast();

when received ok?(j, d_j)
  update_agent_view(j, d_j); /* stores j's assignment */
  check_agent_view();

procedure update_agent_view(j, d_j)
  if agent_view_i contains assignment for j then
    remove assignment of j from agent_view_i;
  end if
  agent_view_i ← agent_view_i ∪ {⟨j, d_j⟩};

procedure check_agent_view()
  if ¬consistent(agent_view_i ∪ {⟨i, x_i⟩}, C_i) then
    if choose_value() then
      broadcast();
    else
      resolve_conflict();
    end if
  end if

procedure broadcast()
  for agent j ∈ N_i | p_j < p_i do
    send ok?(i, x_i) to agent j;
  end for

procedure choose_value()
  for d_i ∈ D_i do
    if consistent(agent_view_i ∪ {⟨i, d_i⟩}, C_i) then
      x_i ← d_i; return ⊤;
    end if
  end for
  return ⊥;

procedure resolve_conflict()
  if agent_view_i ≠ ∅ then
    find agent j ∈ agent_view_i with lowest priority, p_j;
    send nogood(i, agent_view_i) to agent j;
  else
    No solution!
  end if

when received nogood(j, agent_view_j)
  for agent k in agent_view_j and not in agent_view_i do
    let d_k be the value of agent k in agent_view_j;
    update_agent_view(k, d_k);
    request that k add i to N_k;
  end for
  let c_j be the constraint that agent_view_j is nogood;
  C_i ← C_i ∪ {c_j};
  check_agent_view();
```

Figure 1: Procedures Defining the Behavior of an ABT Agent i

refer to a branch of the search tree that has already been discarded) [2]. The necessary revisions to ABT for pruning stale nogoods are given in Figure 3.1. When measuring the computational requirements of this revised version of ABT, it is important to take into account the additional checks that have been introduced to determine whether or not a nogood is stale. However, because the number of stale nogoods tends to grow exponentially, the savings typically far outweigh this additional computational cost. We would like to note additionally, that this improvement cannot be used in A WC because priorities are assigned dynamically and stale nogoods may become relevant again. This makes AWC less competitive when measuring computational requirements based on consistency checks. For this reason we do not report experiments with AWC in this paper.

Another configuration of ABT involves having agents read all queued messages before trying to re-assign their variables. In contrast to checking consistency after each incoming assignment update or nogood, agents processes all the information they have received before performing their next consistency check ("**procedure** `check_agent_view`"). This small variation has recently been reported to provide significant improvements [13].

3.2 Asynchronous Partial Overlay

A summary of the procedures involved in a basic mediation framework for DCSPs is given in Figure 3. Procedures that are not redefined are assumed to be identical to the description in Figure 1. The initialization process of a mediation based algorithm proceeds the same way as in ABT. However, when agent i broadcasts its value assignment, it does not consider priority and sends the assignment to all its neighbors. When agent i receives an assignment message it proceeds in the same fashion as ABT to update its *agentview* and check the consistency of relevant constraints. If agent i detects a conflict and cannot resolve it locally by changing the value of its variable it initiates a conflict resolution process. In a mediation based algorithm the this involves agent i inviting all of its neighbors to join a mediation session - the size of the mediation session is defined by agent i's neighborhood. Once all of agent i's neighbors have each either accepted or rejected the invitation, a mediation session begins. A mediation session only involves the agents that have accepted the invitation. An agent can only accept to participate in one mediation session at a time. Agents choose which invitation to accept according to a mediation session selection rule, which we denote $R_{\prec}$. Additional details of the APO algorithm, a specific mediation based implementation, can be found in [5].

In the following Section we review different possible medi-

Figure 3: Mediation DCSP Algorithm Framework (procedures not redefined are given in Figure 1)

ation session selection rules and mediation procedures, and discuss their constraint checking requirements. Independently of the mediation session selection rule and mediation procedure, mediation based agents use constraint checks to determine the consistency of their variable assignments.

4. MAPPING MEDIATION DIMENSIONS

The space of possible mediation strategies has been the subject of limited investigation. In this paper we focus on two mediation dimensions that we have found to have a significant impact on the performance of mediation based algorithms, namely mediation session selection rules and mediation procedures themselves.

4.1 Mediation Session Selection Rules

The mediation session selection rule described in the original APO algorithm is biased toward the selection of larger mediation sessions. Preliminary work reported in [1] presented a computational model along with initial results suggesting that, under certain circumstances, focusing first on smaller sessions can yield significant performance improvements. Intuitively, because mediation sessions may involve full backtrack search, the complexity of large mediation sessions will tend to dominate that of smaller sessions. Accordingly, focusing first on large sessions will lead to unnecessary computational efforts, when smaller sessions are sufficient. In this study we explore the performance impact of mediation session size by examining the following two mediation session selection rules.

- $\boldsymbol{R}_{\prec}^{\texttt{APO}}$: this mediation session selection rule was suggested in the original definition of APO. Agents evaluate invitations based on the size of the mediation session they would lead to, and pick the invitation corresponding to the largest one.
- $\boldsymbol{R}_{\prec}^{\texttt{IAPO}}$: this mediation session selection rule is the inverse of the original selection rule. It instructs agents to choose the smallest mediation session.

These two rules can be implemented by including the size of the inviting agent's neighborhood in each invitation. For all practical purposes the computational complexity of evaluating mediation session invitations using these two rules can be ignored. The evaluation can be performed by each agent in time linear in the number of invitations, which does not exceed the size of the agent's neighborhood. This computation is typically dominated by the computation performed as part of the mediation procedure itself.

4.2 Mediation Procedures

procedure `mediate`^{BB}`(accepted`$_i$`)`
  let I be the CSP instance defined by `accepted`$_i$;
  $P^* \leftarrow$ a conflict minimizing solution to I using BB;
  `broadcast-solution(`P^*`)`;

procedure `mediate`^{BT}`(accepted`$_i$`)`
  let I be the CSP instance defined by `accepted`$_i$;
  $P^* \leftarrow$ a feasible solution to I using CBT;
  `broadcast-solution(`P^*`)`;

procedure `mediate`^{ABT}`(accepted`$_i$`)`
  let I be the sub-DCSP defined by agents in `accepted`$_i$;
  `init()` ABT on I (as described in Section 3.1);

procedure `broadcast-solution(`P`)`
  if $P \neq \emptyset$ **then**
    for $\langle j, d_j \rangle \in P$ **do**
      send `accept_value(`d_j`)` to agent j;
    end for
  else
    No solution!
  end if

when received `accept_value(`d`)`
  $x_i \leftarrow d$;
  `check_agent_view();`

Figure 4: Summary of Mediation Procedures

The mediation procedure originally proposed with APO involved a *mediator* (the agent that sent the invitations) centralizing the sub-problem defined by the agents in the session, and solving it locally. The mediator used a branch and bound search to find a solution that minimized conflicts with agents outside of the session. In this Section we describe the original APO branch and bound mediation procedure, and propose two new mediation procedures (summarized in Figure 4). We introduce a backtrack search mediation procedure to explore the performance tradeoffs involved in finding a conflict minimizing solution. We also introduce a novel hybrid procedure where mediation is performed in a distributed fashion using ABT. This hybrid algorithm helps us explore the performance tradeoffs between concurrency and coordination. The different mediation procedures we examine require different information to accompany `accept_invitation` messages. The requirements are described in detail along with the procedures below.

Branch and Bound (APO-BB): The branch and bound mediation strategy was the method originally proposed with APO. When using this mediation strategy, a mediator must gather all of the information about the local sub-problems of agents involved in the session (the agents that accepted the invitation) including:

- the set of constraints, C_j, that apply to agent j's variable,
- the entire domain of agent j's variable, D_j,
- and a label function defined on agent j's domain, $L_j : d_j \rightarrow \{k_1, \ldots, k_n \mid \text{agent } k_i \text{ will be conflicted with } d_j\}$, that indicates all of the agents known to be in conflict with each of j's values.

This information is used by the mediator to perform a branch and bound search. This search finds a feasible solution, if one exists, to the sub-problem pertaining to agents that are part of the mediation session. The solution minimizes the number of constraints violated for agents *outside* of the session, which can be determined using the label functions. In terms of measuring computation, the branch and bound procedure uses constraint checks as it proceeds to construct all solutions that cannot be ruled out by bounding. However, it does not use constraint checks to determine how many external violations a partial or full solution results in. The number of external violations is simply the size of the set returned by the label function.

Backtracking (APO-BT): This mediation procedure proceeds exactly as the BB variant, except that the mediator attempts to find any feasible solution. The solution may not minimize conflicts with out-of-session agents. Using this mediation procedure, agents need not send fully labeled domains to the mediator[3]. In terms of measuring computation, the backtracking mediation process uses constraint checks in the same fashion as the branch and bound process, except it short-circuits computation as soon as a feasible solution is found.

Asynchronous Backtracking (APO-ABT): We introduce this mediation procedure as a novel hybrid between APO and ABT where mediations are performed using the ABT protocol. This mediation strategy downplays the importance of the mediator, who no longer needs to collect local constraint information from the other agents involved. Because agents can be involved in one session at a time APO-ABT synchronizes the overall problem solving process, while exploiting opportunities for concurrency at the lower level. The ABT mediation process uses constraint checks as described in 3.1.

Any of these three mediation strategies can be used with either of the mediation session selection rules, making for a total of six proposed configurations. Also, each of the mediation procedures uses the values of agents at the time of the mediation as arbitrary starting values. This was suggested in the original specification of APO and helps to respect work done during earlier sessions.

5. EMPIRICAL EVALUATION

5.1 Empirical Setup

The experiments in this paper are intended to compare the performance of the six mediation configurations outlined in the previous section (five of which represent novel configurations), and ABT. We present results from two different sets of experiments, one involving random solvable distributed 3-coloring (D3C) problems and another on random binary DCSP instances. A D3C problem involves each agent choosing one of three colors. The problem is satisfied if no two

[3]Agents may, however, need to inform the mediator of a conflict after assignments have been dictated. This allows the mediator to add an out-of-session agent to its neighborhood to ensure completeness.

agents connected by a constraint share the same color. A random binary DCSP problem involves arbitrary random constraints between pairs of agents. In all of our experiments all of the algorithms were provided with the same instances and initial random values for variables.

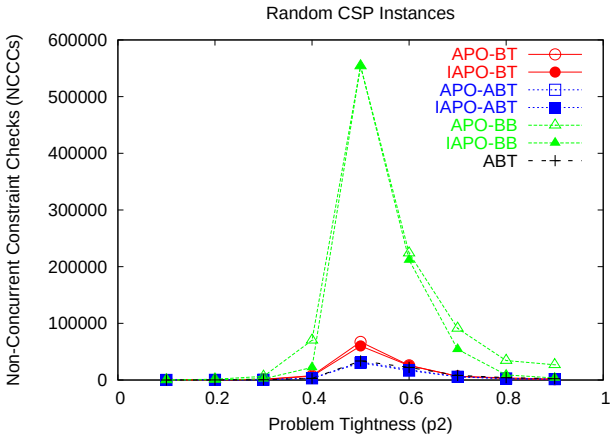
Random binary CSP instances are typically characterized by the number of variables, n, the number of values in each variable's domain, k, the density of the constraint graph, $p1$, and the tightness of the constraints, $p2$ [9]. Our random DCSP experiments use $n = 10$, and $k = 10$. $p1$ specifies the probability that a constraint exists between any two agents. In this paper we fix $p1 = 0.7$, a relatively high density value, behaviors on problems with different values of $p1$ result in similar observations. We vary $p2 = 0.1$ to $p2 = 0.9$, which specifies the probability that two values in constrained agent's domains are in conflict. We draw at least 100 instances for each value of $p2$, and about 500 instances near the phase transition where $p2 \in [0.4, 0.6]$. The "phase transition" refers to an area of the problem parameters where problems transition from being under-constrained, and thus easy to solve, to over-constrained but still difficult to prove infeasible [9].

The D3C instances are characterized by two parameters, the number of agents involved, n, and the number of constraints per agent m. Since we are looking at solvable D3C problems with no phase transition effects, we do not see a need to vary problem density and instead fix $m = 2.7$ (typically considered high density). We vary the number of agents from $n = 15$ to $n = 60$ in increments of 9 (these values must be multiples of 3 to properly guarantee solvable instances). With these instances we examine how the algorithms scale to larger problems that are guaranteed to be solvable. We draw at least 100 instances for each value of n (although some algorithms are removed as they become incapable of scaling based on a 5 minute cpu-time cutoff per instance) according to the method provided in [7], for some larger values of n we draw up to 500 instances to ensure the statistical significance of our results.

The results presented indicate the mean number of messages and non-concurrent constraint checks (NCCCs) used by each algorithm across the different simulations. The NCCCs are measured using the techniques described in Sections 3 and 4, and [6]. We provide 95% confidence intervals when necessary, results missing intervals can be assumed to be significant.

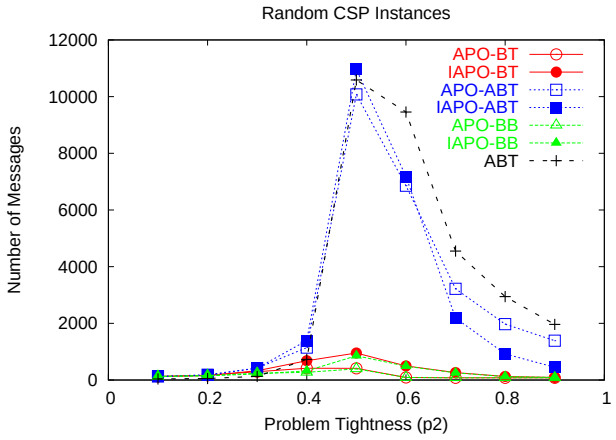
5.2 Results on Random CSP Instances

The NCCC results on random CSP instances are shown in Figures 5(a) and 5(c). Examining these results, we can see that the phase transition is clearly accentuated when $p2 = 0.5$ for all the algorithms. Before this point problems are relatively easy to solve and there is little difference observed. When $p2 = 0.5$ we can see that ABT, with the improvements described in Section 3.1, uses about 30,000 NCCCs on average, which is consistent with results reported in [13]. In addition the APO-ABT and IAPO-ABT hybrids both use about the same amount of NCCCs as ABT itself (see Figure 5(c)). This is not surprising, since about half of the problems in this area require a mediation of the entire network to prove infeasibility, and the hybrid algorithms reduce to running ABT on the whole problem at that point. The branch and bound based algorithms, APO-BB and IAPO-BB, perform poorly during the phase transition, requiring about 200 times more NCCCs than ABT. This is due to the fact that many of these problems must be fully centralized with these procedures to prove infeasibility, and finding the solution that minimizes external conflicts amounts to exploring nearly the entire search tree during each mediation. The backtracking based mediation algorithms, APO-BT and IAPO-BT, require nearly 100 times fewer NCCCs than the branch and bound algorithms, showing that finding external conflict minimizing solutions costs a significant number of NCCCs and provides far less less benefit on random problems. However, the ABT based algorithms use significantly fewer NCCCs than the backtracking ones, showing the cost of centralizing the problem solving effort.



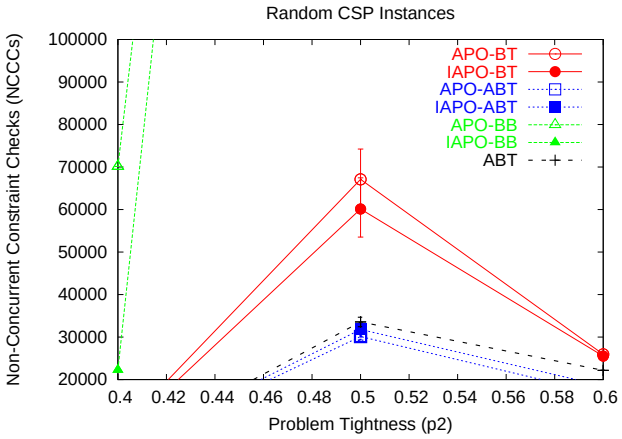
The performance in terms of communication requirements on random instances is shown in Figures 5(b) and 5(d). These results are basically a mirror image of the NCCC results, with ABT and the ABT based mediation algorithms requiring on average about 30 times more messages than the other algorithms (again this is consistent with results reported for ABT in [13] and [5]). Additionally we can see from the results in Figure 5(d) that the mediation techniques with the IAPO preference rule use about twice as many messages as those with the APO preference rule. This is not surprising considering that the IAPO preference rule chooses smaller sessions and therefore needs more of them.

5.3 Results on Solvable D3C Instances

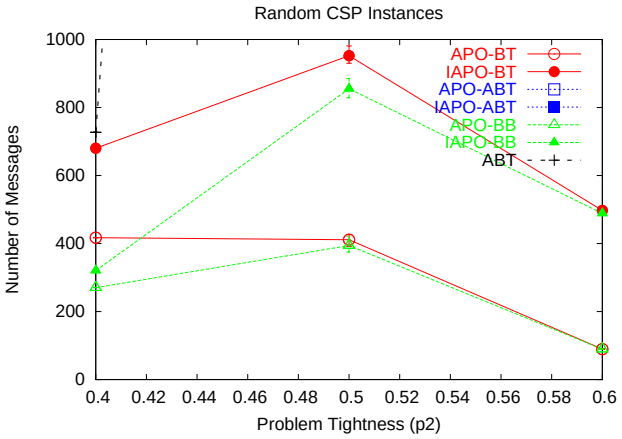


The NCCC results for solvable D3C instances are shown in Figure 6(a). These results provide some very interesting contrasts with the random CSP NCCC results. The algorithm that performs best on the solvable D3C instances by a large margin is our IAPO-BB algorithm. This algorithm was the only one capable of solving 60 agent problems within an allotted 5 cpu-minutes per instance, and it was able to solve smaller instances orders of magnitude faster than the other algorithms. Recall that on the random CSP instances the branch and bound based algorithms performed nearly 200 times *worse* than the other algorithms, yet on the high density solvable instances our IAPO-BB scales extremely well. What we are seeing is that on high-density solvable instances the benefit of finding solutions that minimize conflicts outside of a mediation session far outweighs the extra work necessary to do so.

Another interesting result on the solvable D3C instances is the benefit of the IAPO selection rule over the APO selection rule. All of the variants with our IAPO selection rule used significantly fewer NCCCs than their APO-based counterparts. Favoring smaller mediation sessions over larger ones, as IAPO does, helps mediators avoid solving unnecessarily large problems until absolutely needed. Our results suggest that on solvable D3C instances it is often not necessary to mediate over larger groups, and consequently IAPO avoids some of the unnecessary computation of APO. These findings are consistent with preliminary results we had reported in [1].



When we look at the handful of algorithms that were able to solve 51 agent instances we can see that only the ABT-based algorithms remain along with IAPO-BB. Among the ABT-based algorithms it is interesting to note that both our APO-ABT and IAPO-ABT hybrid algorithms require much fewer NCCCs than ABT itself on average (the IAPO-ABT algorithm requiring significantly fewer). This begins to



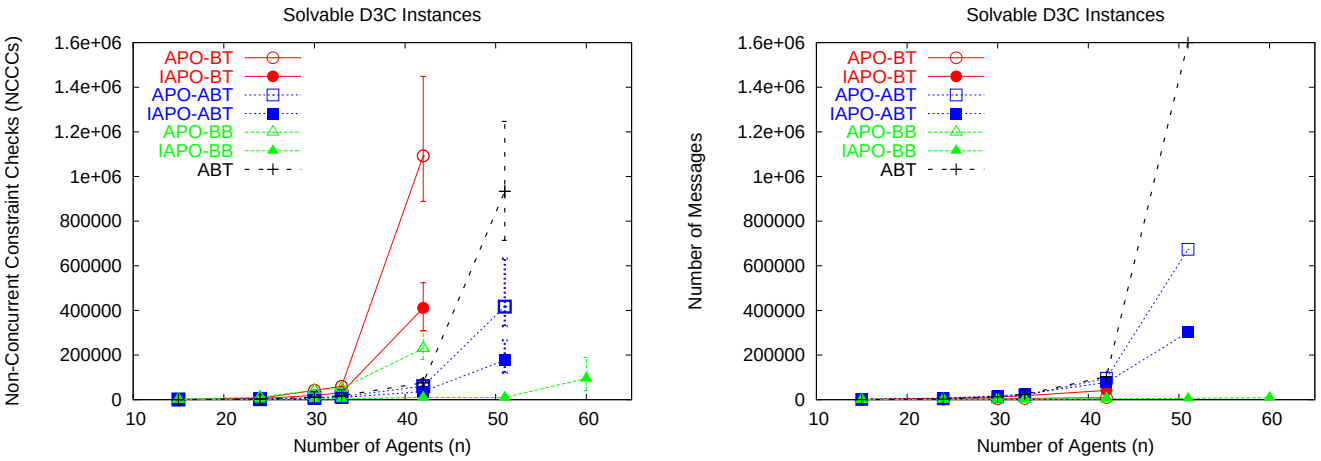
(a) Mean NCCCs

(b) Mean Messages

(c) Mean NCCCs with 95% confidence intervals (zoomed from Figure 5(a), $p2 = 0.4$ to $p2 = 0.6$)

(d) Mean Messages with 95% confidence intervals (zoomed from Figure 5(b), $p2 = 0.4$ to $p2 = 0.6$)

Figure 5: Performance on Random DCSP Instances, $(n = 10, k = 10, p1 = 0.7)$



show the benefits of partially synchronizing problem solving efforts on solvable D3C instances to cut back on the amount of backtracking in ABT. The fact that all three of these algorithms perform significantly better than the BT-based algorithms shows the benefit of distributing work load on larger problem instances.

When we look at the performance in terms of communication requirements for solvable D3C instances in Figure 6(b), it is not surprising to find that all of the centralized approaches use significantly fewer messages than the decentralized ones. What is interesting is the fact that our APO-ABT and IAPO-ABT hybrid algorithms both used fewer messages than ABT itself (recall these two used fewer NCCCs as well). Not only that, but the IAPO variant, IAPO-ABT, used fewer messages than the APO variant, whereas on the random instances the opposite was true. Both of these observations are due to the fact that the mediation based techniques required less backtracking than ABT and among the mediation based techniques, the IAPO variant required less backtracking than the APO variant. On the solvable D3C instances the decrease in backtracking during problem solving led to less communication as well.

6. CONCLUSION

In this paper we provided a comprehensive abstraction for the space of DCSP mediation based approaches. In the process we identified gaps in existing frameworks, and proposed new effective strategies to fill them. The new strategies include a mediation session selection rule that favors smaller mediation sessions, a centralized mediation approach that shortcuts a significant amount of excess computation on random instances, and a decentralized asynchronous mediation strategy based on ABT.

Our empirical results represent the first truly comprehensive view of the tradeoffs between backtracking and mediation based approaches for DCSPs. We tested the different algorithms on solvable 3-coloring and random binary DCSPs.

(a) Mean NCCCs with 95% confidence intervals

(b) Mean Messages

Figure 6: Performance on Solvable D3C Instances, ($m = 2.7$)

Our results confirmed that our newly proposed strategies in this paper dominate previous techniques under some circumstances. Specifically, our mediator selection rule that favors smaller sessions, IAPO, dominates the previously used rule that favors larger ones, APO, in computational complexity across all instances. IAPO also dominates APO in communication complexity on solvable D3C instances. Additionally, our hybrid decentralized mediation strategy based on ABT is as good as ABT in communication and computation on random instances, and strictly better in both areas on solvable D3C instances. This suggests that the benefits of synchronization for DCSPs reported elsewhere [5, 13] may exist primarily on hard solvable instances.

7. ACKNOWLEDGEMENTS

The research reported in this paper has been funded by the National Science Foundation under ITR Grant 0205435. The authors would also like to thank Roie Zivan and Amnon Meisels for their help calibrating the NCCC metric.

ABSTRACT

Distributed constraint optimization (DCOP) has emerged as a useful technique for multiagent coordination. While previous DCOP work focuses on optimizing a single team objective, in many domains, agents must satisfy additional constraints on resources consumed locally (due to interactions within their local neighborhoods). Such resource constraints may be required to be private or shared for efficiency's sake. This paper provides a novel *multiply-constrained DCOP* algorithm for addressing these domains which is based on mutually-intervening search, i.e. using local resource constraints to intervene in the search for the optimal solution and vice versa. It is realized through three key ideas: (i) transforming n-ary constraints to maintain privacy; (ii) dynamically setting upper bounds on joint resource consumption with neighbors; and (iii) identifying if the local DCOP graph structure allows agents to compute exact resource bounds for additional efficiency. These ideas are implemented by modifying Adopt, one of the most efficient DCOP algorithms. Both detailed experimental results as well as proofs of correctness are presented.

1. INTRODUCTION

Distributed Constraint Optimization (DCOP) [1,6,9,11] is a useful technique for multiagent coordination with applications in distributed meeting scheduling and distributed factory and staff scheduling [8]. In a DCOP, cooperative distributed agents, each in control of a set of variables, assign values to these variables, so as to optimize a global objective function expressed as an aggregation of utility functions over combinations of assigned values.

While recent advances in efficient DCOP algorithms are encouraging [1, 6, 9, 11], these algorithms focus on optimizing a single objective and fail to capture the complexities that arise in many domains where agents must adhere to resource constraints, e.g. budgets or fuel. These resource constraints necessitate multiply-constrained DCOP algorithms that optimize a global objective, while ensuring that resource limits are not exceeded. While in some domains agent must keep these resource constraints private (e.g. travel budgets in distributed meeting scheduling [8]), in others resource constraints may be non-private (e.g. overtime limits in staff allocation for distributed software development).

There are three main challenges that must be addressed in designing multiply-constrained DCOP algorithms. First, agents' n-ary resource constraints add to DCOP search complexity. Hence, agents must quickly prune unproductive search paths. Second, harnessing state-of-the-art DCOP algorithms (henceforth, referred to as "singly-constrained" DCOP algorithms) is crucial. However, existing algorithms are not deisgned to handle resource constraints that are local, possibly private and defined over n-ary domains. Third, algorithms must exploit constraint revelation to gain efficiency when privacy is not required. (Unlike work which uses cryptographic techniques in DisCSP/DCOP for privacy [12, 15], we do not insist on such watertight privacy, given potentially significant communication and computational overheads.)

This paper presents a novel multiply-constrained DCOP algorithm which employs *mutually-intervening searches* to address the first challenge above: while an agent immediately intervenes in the search for the global optimal if its local resource constraint is violated, opportunistic search for the global optimal solution obviates testing all partial solutions for resource constraint satisfaction. There are three key ideas in this algorithm, which are facets of mutually-intervening search: constraint-graph transformation, dynamically-constraining search and local acyclicity. The first idea, *constraint-graph transformation*, is motivated by the second challenge above: harnessing singly-constrained DCOP algorithms for multiply-constrained DCOPs. The key innovation is in efficiently employing virtual variables to enforce an agent's resource constraints within the singly-constrained DCOP algorithms. These variables indicate resource constraint violations with asynchronous communications of high negative costs, which preemptively prune search paths. Yet, for correctness and privacy preservation, we restructure the DCOP graph and appropriately place the virtual variables in that graph. The following two ideas address the third challenge above by exploiting the privacy-efficiency tradeoff. In *dynamically-constraining search*, an agent reveals to its neigh-

bors an upper-bound on any non-private resource constraint. When optimizing the global objective function, its neighbors only select values that abide by the bounds, improving algorithmic efficiency. The final idea, *local acyclicity*, further improves efficiency in locally acyclic DCOP graphs by allowing the communicated resource bounds to be tightened without sacrificing algorithmic correctness. In particular, we define T-nodes, which are variables whose local graph acyclicity allows for the dynamic use of exact bounds and do not require virtual variables. We show that these tighter bounds can not be applied at non-T-nodes.

While we illustrate these ideas by building on top of Adopt, one of the most efficient DCOP algorithms [9], our techniques could be applied to other algorithms, e.g. OptAPO, SynchBB [6, 14]. We present a multiply-constrained Adopt algorithm that tailors its performance to three situations: 1) when a resource constraint must be kept private, 2) when a constraint is sharable but the variable is not a T-node, and 3) when a constraint is sharable and the variable is a T-node. These different techniques can be employed simultaneously by different variables in the same problem. We experimentally compare these techniques and illustrate problems where agents gain the most efficiency by sharing resource constraints and problems where agents lose no efficiency by maintaining privacy.

2. PROBLEM DEFINITION

2.1 DCOP

A DCOP [1, 9, 11] consists of n variables, $\{x_1, x_2, \ldots, x_n\}$, assigned to a set of agents who control the values they take on. Variable x_i can take on any value from the discrete finite domain D_i. The goal is to choose values for the variables such that the sum over the set of constraint cost functions (f_{ij}) is minimized, i.e. find an assignment, A, s.t. F(A) is minimized: $F(A) = \sum_{x_i,x_j \in V} f_{ij}(d_i, d_j)$, where $x_i \leftarrow d_i, x_j \leftarrow d_j \in A$. Variables x_i and x_j are considered neighbors since they share a constraint.

In the example in Figure 1, x_1, x_2, x_3, and x_4 are variables each with domain {0,1} and identical f-cost functions on each link (shown for the x_1 to x_2 link), $F(x_1 \leftarrow 0, x_2 \leftarrow 0, x_3 \leftarrow 0, x_4 \leftarrow 0) = 4$ and the optimal assignment would be ($x_1 \leftarrow 1, x_2 \leftarrow 1, x_3 \leftarrow 1, x_4 \leftarrow 1$). While the above commonly used definition of DCOP emphasizes binary constraints, *general DCOP representations* may include n-ary constraints.

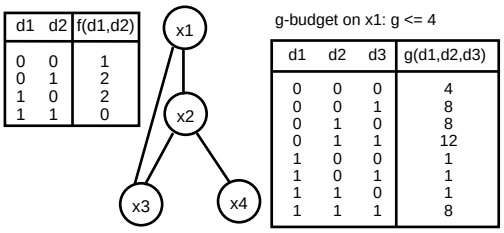

Figure 1: Multiply-Constrained DCOP graph

2.2 Multiply-Constrained DCOP

In Multiply-Constrained DCOP we make use of n-ary DCOP constraints by adding a new cost function g_i on a subset of x_i's links and a g-budget G_i which the accumulated g-cost must not exceed. Together this g-function and g-budget constitute a g-constraint. Figure 1 shows an example g-constraint on x_1. In the example, if x_1, x_2, x_3 each take on the value of 1 (leading to an optimal f-cost) then the g-cost is 8, which violates x_1's g-budget of 4. Since g-cost functions cannot be merged with f-cost functions, each value must be selected based on both f and g, and hence this is a multiply-constrained DCOP. It is straightforward to extend this framework to multiple g-constraints on a variable.

In general, the combined g-cost can be an arbitrary function on the values of x_i and its neighbors.[1] We define g-constraints to be private or shared. If a g-constraint can be shared and the g-cost function is the sum of the g-costs of the links impinging upon x_i, we can improve efficiency by exploiting the additive nature of the function. In the rest of the paper, we assume such additivity for shared g-constraints but make no such assumption for private g-constraints. Given the g-cost functions and g-budgets, we now modify the DCOP objective to be: find A s.t. F(A) is minimized: $F(A) = \sum_{x_i,x_j \in V} f_{ij}(d_i, d_j)$, where $x_i \leftarrow d_i, x_j \leftarrow d_j \in A$
and $\forall x_i \in V$
$g_i(d_i, \{d_j | x_j \in neighbors(x_i)\}) \leq G_i$

Multiply-Constrained DCOP is situated within the space of general DCOP representations mentioned in Section 2.1. However, it emphasizes three features: (i) n-ary (g-cost) constraints, (ii) private g-constraints, and (iii) the need to exploit the interaction between f- and g-constraints for pruning the search space. No current DCOP algorithm, including leading algorithms, is able to address all three issues. Specifically, Adopt [9] can handle (ii) but not (i) or (iii). OptAPO [6] and DPOP [11] handle (i) but not (ii) or (iii).

2.3 Motivating Domains

In this section we demonstrate the need for multiply-constrained DCOP algorithms with two example domains. These domains require agents to optimize an f-cost function and yet adhere to (private) g-constraints.

Distributed Meeting Scheduling: When members of organizations in separate locations collaborate, personal assistant agents must optimize their meeting schedules and yet adhere to travel budgets. Consider the example in Figure 2, where researchers, A, B, C and D are divided between organizations at Loc1 and Loc2. A and C need to meet, and B and D also need to meet. A and C are group leaders who manage travel budgets for their groups and wish to keep budgetary constraints private.

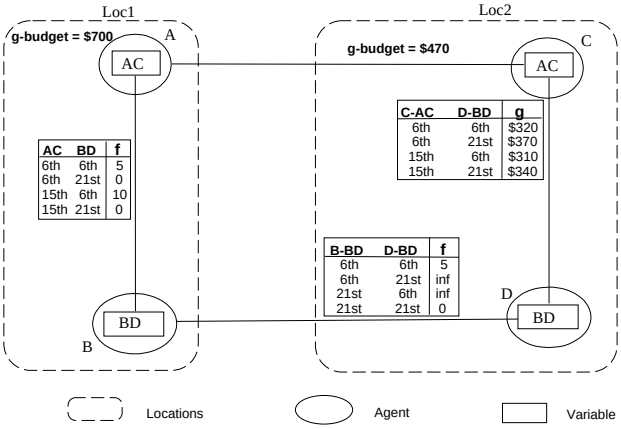

Figure 2: Meeting Scheduling Example

Multiply-constrained DCOP allows us to model this problem. We assume that agents share all their scheduling preferences (the exact representation of these preferences is not important for this example). The domain of each variable is a tuple of time-of-meeting

[1]While for simplicity we assume that the set of f-neighbors and g-neighbors are the same, this is not necessary.

and location, e.g. {6th Oct at Loc1, 15th Oct at Loc2}. The f-cost expresses agents' scheduling preferences and that they must agree on the meeting time (or else receive an infinite cost). The f-cost function between C and D reflects C's preference that the BD meeting precede the AC meeting (for readability not all of the f- and g-functions are shown in Figure 2). Since a meeting may require flying to that destination, the g-cost represents travel costs. The cost varies depending on the date of travel and whether all members are traveling on the same day and can share a cab. C has a travel budget of $470, represented via a g-budget on C's variable AC. C must pay for expenses incurred by C or D in either the AC or BD meeting if they are held at Loc1. A and C may not wish to reveal their budgets (hence private g-constraints).

Distributed Software Development: Many software companies have campuses across the globe and teams collaborate across both distances and time zones [3, 5]. While interdependent tasks within a project must be scheduled for their timely completion, a team liaison must videoconference — often after normal workhours — with the team to which the code is being sent to facilitate the handoff. Figure 2 shows an example involving five tasks $\{t_1, \ldots, t_5\}$, where agents in Team1 must complete t_1 and t_4 and Team2 must complete t_2, t_3 and t_5. The domain values are times at which a task can be completed. The f-function captures both the temporal precedence constraints and a preference function over the potential times (e.g. t_1 must complete before t_2, and prefer t_1 to start early in the day). A team liaison from Team1 must videoconference with Team2 during the first hour of t_2 and t_3, requiring the liaison to work overtime. To avoid burnout corporate policy may limit liaison overtime to 8 hours, establishing a non-private g-constraint.

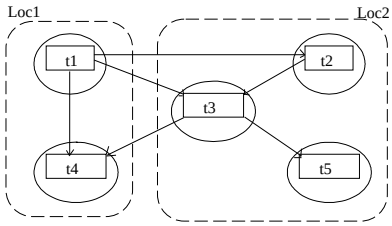

Figure 3: Software Development

3. BACKGROUND: ADOPT

Adopt [9] is an asynchronous complete DCOP algorithm. Adopt has been discussed in detail in the literature [1, 2, 9], so we provide only a brief description. Adopt organizes variables into a Depth-First Search (DFS) tree in which constraints are allowed between a variable and its ancestors or descendants, but not between variables in separate sub-trees. The constraint graph in Figure 1 is organized as a DFS tree. x_2 is a child of x_1 and x_3 is a descendant (but not a child) of x_1. In this paper, we will use the terms variable and node interchangeably.

Adopt employs two basic messages: VALUE and COST.[2] Assignments of values to variables are conveyed in VALUE messages that are sent to variables lower in the DFS tree, that share a constraint with the sender. For example, x_1 will send its VALUE messages to x_2 and x_3. To start, variables take on a random value and send out VALUE messages to get the flow of computation started. A COST message is sent from children to parents indicating the f-cost of the sub-tree rooted at the child (e.g. x_3 will send its COST messages to x_2 and x_2 sends COST messages to x_1). A variable keeps its current assignment until the lower bound on cost accumulated, i.e. the lower bound of its children's sub-trees plus the f-cost of its constraints with its ancestors, exceeds the lower-bound cost of another assignment. When this occurs, the variable will *opportunistically* switch its value assignment (unexplored assignments have a lower bound of zero). The root's upper and lower bounds represent the upper and lower bounds on the global problem; when they meet the optimal has been found and the algorithm terminates. Since communication is asynchronous, messages have a context, i.e. a list of the variable assignments in existence at the time of sending, attached to them to help determine information relevance.

[2]Adopt also uses THRESHOLD messages for improved efficiency, but this is orthogonal to the contributions in this paper.

4. MULTIPLY-CONSTRAINED ADOPT

This section is organized as follows: Section 4.1 describes the key ideas in Multiply-Constrained Adopt (MCA), Section 4.2 describes MCA in detail, and Section 4.3 provides correctness and complexity results.

4.1 Basic Ideas

The mutually intervening approach of MCA is realized through four techniques: constraint-graph transformation, dynamically constraining search, local acyclicity and exploiting local independence.

Constraint-graph transformation To exploit existing DCOP algorithms and maintain privacy, we add virtual variables to enforce n-ary g-constraints. The virtual variables asynchronously communicate infinite costs on g-constraint violations, preemptively pruning search paths, e.g. in Figure 4a, x'_1 is added to represent a constraint between x_1, x_2, x_3. While using extra variables to enforce n-ary constraints using binary ones has appeared in the centralized CSP literature [13], the novelty of our contribution is threefold. First, we embed these virtual variables in a singly-constrained DCOP algorithm and prove the correctness of the resulting asynchronous multiply-constrained DCOP algorithm. To that end, we restructure Adopt's DFS tree and appropriately place the virtual variable in the tree. Second, since such constraint-graph restructuring can change local acyclicity properties of other nodes, the preprocessing identifies and preserves local acyclicity properties where feasible. Third, by encapsulating an n-ary constraint in a virtual variable owned by the original variable's owner and placing it as a leaf in the DFS tree, we can protect the privacy of both the g-function and the g-budget.

Dynamically Constraining Search When permissible, it is important to exploit g-constraint revelation to gain efficiency in the f-optimization. We achieve this by requiring descendant nodes to only consider assignments that will not violate their ancestors' g-constraints. Specifically, we pass each descendant a bound (termed *g-threshold*) specifying how large a g-cost it can pass up, limiting its domain. This g-threshold represents an exact bound when the local graph is acyclic and an upper bound otherwise. If a value fails to satisfy an ancestor's g-threshold, nodes will not explore this value for f-optimality. Additionally, the opportunistic search for an optimal f necessitates checking for g-constraint violations only for those value combinations that are of low f-cost. Thus, the searches dynamically constrain each other, leading to performance improvements.

Local Acyclicity (T-nodes) The notion of local acyclicity is captured formally in our definition of T-nodes: variable x_i is a T-node if all neighbors of x_i lower in the DFS tree are children of x_i. In Figure 1, x_1 is not a T-node because x_3 is not its child, but x_2, x_3 and x_4 are all T-nodes. T-nodes enable the calculation of exact g-thresholds and elimination of virtual variables because their children respond independently to allocated g-thresholds.

Figure 4: Multiply-Constrained Adopt Pseudo-code

Exploiting Local Independence In applying different techniques to different nodes in a single problem, we exploit the locality of the g-constraints.

4.2 MCA Algorithm Description

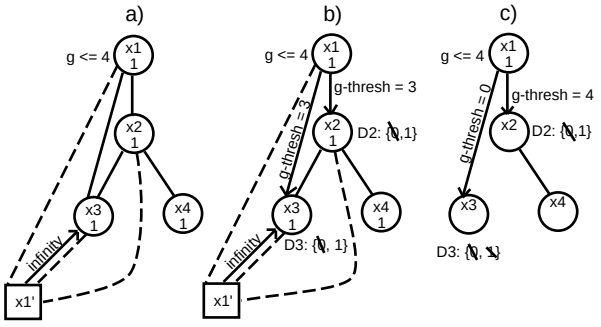

Figure 5: a) MCAP b) MCAS c) MCASA

Figure 4 presents pseudo-code for MCA. To emphasize new elements we include only brief descriptions of functionality unchanged from Adopt [9]. Lb and ub refer to the lower and upper bounds on children's f-costs for each value d_i while LB and UB refer to the overall lower and upper bound at x_i. MCA uses three subalgorithms: (i) MCA Private (MCAP) is used when a constraint may not be revealed, and it uses constraint-graph transformation, (ii) MCA Shared (MCAS) is used when a constraint is non-private but the variable is not a T-node, and it employs constraint-graph transformation and dynamically constraining search, and (iii) MCA Shared and Acyclic (MCASA) is utilized when a constraint is non-private and the variable is a T-node, and it uses dynamically constraining search. We take privacy to mean that neither the g-constraints nor the variables involved are explicitly revealed to other agents. We will discuss each technique separately and then indicate how they interact in the unified algorithm.

4.2.1 MCAP

An example snapshot of MCAP's execution is shown in Figure 5a. MCAP searches for an optimal solution for f and when an assignment violates a g-constraint, a feedback signal of infinite cost is sent to the cluster of nodes involved, zero cost otherwise (lines 60-63 in Figure 4). The feedback is sent by a virtual variable (x'_1) which is responsible for enforcing the g-constraint of a single variable (x_1); the virtual variable is controlled by the agent that owns the original variable (lines 3-5). The feedback is sent to the lowest priority variable involved in the violated constraint (x_3). Using the f-cost optimization mechanisms of Adopt, the feedback will propagate to the node(s) that must change their values to find the optimal satisfying solution. Specifically, if a variable (e.g. x_3) receives an infinite cost for all of its domain values, it will send a COST message to its parent (e.g. x_2) indicating an lb and ub of ∞ which will prompt the parent to change its value. Since feedback must be able to percolate up to all the nodes in a constraint, Adopt's DFS tree must be restructured to put all the variables in a g-constraint in the same subtree (lines 6-8). MCA preprocessing creates the virtual variables and places them as leaves, lower in the DFS tree than the variables in the g-constraint they enforce (lines 10-11). We revisit preprocessing of DFS tree in Section 4.2.4.

4.2.2 MCAS

While feedback signals maintain the privacy of the g-constraints and the variables involved by encapsulating the g-constraint in-

side a variable, MCAP's partial search of unsatisfying assignments slows the algorithm. When a g-constraint is non-private, we reveal the g-function of a link to those nodes connected to it and use this information to implement MCAS and MCASA shown in Figures 5b and 5c respectively.

MCAS and MCASA exploit g-function revelation by having nodes send their descendants g-thresholds (line 52) indicating that the descendant may take on no value with a g-cost greater than the g-threshold. In the snapshots from Figures 5b and 5c we can see the g-thresholds being passed down from x_1 to x_2 and x_3 (as discussed earlier, we assume that the g-functions are additive here). If the variable is not a T-node (in MCAS), the g-thresholds for a child (x_l) are an upper bound: the total g-budget minus the minimum g-cost that could be consumed by each of the other links ($G_i - \sum_{x_j \in Neighbors(x_i) \neq x_l} min\ g_{ij}(d_i, d_j)$). In Figure 5b, the total g-budget at x_1 is 4, and each link consumes at least 1, so the g-thresholds are 3. Given this bound, a node can prune values from its domain (e.g. 0 is pruned from the domain of x_3) leading to speedups over MCAP.

4.2.3 MCASA

For T-nodes, it is possible to calculate an exact bound (MCASA) enabling more values to be pruned out and further speeding up the search (e.g. x_1 in 5c now a T-node, calculates exact bounds). Calculating the exact bounds requires a node to maintain a mapping from potential g-thresholds to lower bounds on f-costs (GFmap) for each of its children. GFmap is dynamically initialized for the current value from the link function (line 17-18; line 50) and then updated as COST messages arrive (line 38). A T-node uses these g-threshold to f-cost mappings to calculate how to split its remaining g-budget (its initial g-budget minus the g-cost consumed on each of the links with its higher priority neighbors) among its children. This calcOptimalSplit function can be implemented using a straightforward dynamic program and thus is omitted from the pseudo-code. Since x_i's lb and ub for the current context now depend upon the way x_i splits its g-budget among its children, we store lb and ub based upon x_i's current split. We reset lb and ub to 0 and ∞ respectively whenever x_i changes its split (line 39) as well as when the context changes (line 28). If a node can't satisfy any of its g-thresholds, it will send up a cost of ∞ which will cause its ancestors to switch their values (line 45).

4.2.4 Combining Techniques

Until now we have discussed each technique separately. However, the techniques may be applied simultaneously to different nodes within the same problem. Since the g-constraints are local constraints, we only need worry about situations where a parent and a child are using different techniques: (i) Parent = MCAS/MCASA, Child = MCAP: The child can restrict its domain based upon the g-threshold of its parent and the parent will automatically change its value if the child's virtual variable passes up an infinite cost. (ii) Parent = MCAP, Child = MCAS/MCASA: The child will automatically adjust its value if the parent's virtual variable passes up an infinite cost and the child's technique makes no difference to the parent.

One key issue is whether the tree transformations can turn a T-node somewhere else in the tree into a non-T-node. Two steps can cause links to be added: (i) adding empty links between x_i's children to force them into the same subtree (lines 6-8) and (ii) adding a virtual variable and empty links to each of the variables in the g-constraint it represents (lines 10-11). If a link is added between two children of a T-node, then despite having no f-function or g-function it can turn a T-node into a non-T-node. For instance, in

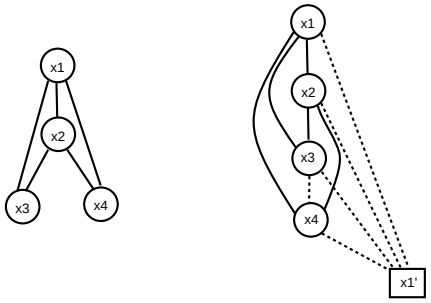

Figure 6: a) original constraint graph b) after adding x'_1

Figure 6, x_1 has a g-constraint with x_2, x_3 and x_4. During preprocessing, a link must be added between x_3 and x_4 to keep them from being in separate subtrees and one must be chosen (arbitrarily) to be the parent of the other (x_3 is made parent of x_4). x_4's COST messages no longer flow directly to x_2 but are sent via x_3 where they are combined with x_3's local costs. This combination prevents x_2 from calculating an exact bound and renders it no longer a T-node.

In contrast, in Figure 4a the addition of virtual variables and their accompanying links, does not change a T-node to a non-T-node. While x_2 is originally a T-node, the addition of the virtual variable x_1' creates a lower priority neighbor for x_2 that is not a child. However, in this case, x'_1 is a virtual variable, i.e. it has no f-functions or g-functions on any of its links and it has no domain of its own. Since x'_1 need be given no g-threshold, the fact that it is not one of x_2's children does not prevent x_2 from being a T-node.

With these two cases in mind, preprocessing (lines 1-11) starts by walking through the tree in priority order adding in the empty links between children where necessary and adjusting the priorities accordingly. Once a node, x_i, has been determined to be a T-node no links added between its lower priority non-neighbors will change x_i into a non-T-node, so one sweep of the tree is sufficient to correctly determine which nodes are T-nodes. After this sweep the virtual variables themselves can be added as leaves without causing any of the previously determined T-nodes to lose that property.

4.3 Correctness and Complexity of MCA

In this section we will again separate out the proofs for each technique for the sake of clarity. As previously described, the interaction of the techniques in the combined algorithm does not change their properties. Recall in the following that a context is the set of variable assignments upon which a piece of information is predicated.

PROPOSITION 1. *For each node x_i for the current context, MCAP finds the assignment whose f-cost, local cost (δ) plus the sum of each of x_i's children's (x_l's) costs, is minimized while satisfying the g-constraint:*

$$OPT(x_i, context) \stackrel{def}{=}$$
$$min_{d \in D_i}[\delta(d) + \sum_{x_l} OPT(x_l, context \cup (x_i, d))]$$
$$\quad if\ g_i(d_i, \{d_j | x_j \in Neighbors(x_i)\}) \leq G_i$$
$$\infty\ otherwise$$
$$where\ \delta(d) \stackrel{def}{=} \sum_{x_j \in ancestors} f_{ij}(d_i, d_j)$$

Proof: To show this we start from the correctness of the original Adopt algorithm [9]. Adopt will find at every node x_i:

$$OPT'(x_i, context) \stackrel{def}{=}$$
$$min_{d \in D_i}[\delta'(d) + \sum_{x_l} OPT'(x_l, context \cup (x_i, d))]$$
$$where\ \delta'(d) \stackrel{def}{=} \sum_{x_j \in ancestors} f_{ij}(d_i, d_j)$$

To show that MCAP finds $OPT(x_i, context)$ we show that 1) it

never returns an assignment containing a violated g-constraint, unless the g-constraint is unsatisfiable and 2) it finds the minimum f-cost solution.

The proof of part 1) starts with the fact that the virtual variables introduce an infinite f-cost into the subtree containing the violated constraint. This infinite f-cost enters lower in the priority tree than any variable in the constraint which allows the normal flow of COST messages to eventually carry it to all of the involved nodes. Since any assignment that does not violate the g-constraint will have a finite f-cost, it follows from the correctness of Adopt that by choosing the assignment that minimizes f, MCAP will never take on an assignment that violates a g-constraint unless the g-constraint is unsatisfiable. Part 2) follows directly from the correctness of Adopt because the virtual variables report a zero cost if all constraints are satisfied, which means that by Adopt's normal mechanisms it will find the minimum f-cost solution. ■

Proving that MCAS is correct requires a minor addition to the MCAP proof from Proposition 1 which is shown below.

PROPOSITION 2. *If the g-constraint for each node x_i is $\sum_{x_j \in Neighbors(x_i)} g_{ij}(d_i, d_j) < G_i$, then no satisfying solution can contain on link l_{il} a g-cost greater than $G_i - \sum_{x_j \in Neighbors(x_i) \neq x_l} min\ g_{ij}(d_i, d_j)$.*

Proof: Each link consumes a certain minimum g-cost, and we are only subtracting the sum of the absolute minimum costs on all links. ■

We next turn to MCASA; if we can prove the g-thresholds are assigned optimally, then taken with original Adopt's correctness it will show that MCASA is correct. After that we will show that when a node is not a T-node then exact bounds do not apply.

PROPOSITION 3. *For each T-node x_i, MCASA always terminates with an optimal division of the g-budget given d_i and the current context.*

Proof by Contradiction: Throughtout the proof we assume $x_k \in Children(x_i)$ and we assume there are no T-nodes as descendents of x_i – using induction we can generalize. Assume MCASA terminates with g-thresholds g'_{ik} $(\forall x_k)$ which are not optimal. Thus there exists another set of g-thresholds (g^*_{ik}) s.t. $\delta(d_i) + \sum_{x_k} min\ lb(d_i, x_k)$ where $d_k \in \{D_k | g_{ik}(d_i, d_k) \leq g_{ik}*\} < \delta(d_i) + \sum_{x_k} min\ lb(d_i, x_k)$ where $d_k \in \{D_k | g_{ik}(d_i, d_k) \leq g'_{ik}\}$. Since local cost $\delta(d)$ is constant for all g-thresholds, we will drop it. To have been selected, g'_{ik} must have seemed optimal based on current information at some point. To distinguish these two states of knowledge we coin the following terms: $f_{actual}(g_{ik}, x_k)$ is the f-cost (specifically $min\ lb(d_i, x_k)$ where $d_k \in \{D_k | g_{ik}(d_i, d_k) \leq g_{ik}\}$) when all costs have percolated up from all descendants and $f_{current}(g_{ik}, x_k)$ is the current lower bound on f-cost. When g'_{ik} is selected:

1. $\sum_{x_k} f_{actual}(g'_{ik}, x_k) > \sum_{x_k} f_{actual}(g^*_{ik}, x_k)$
2. $\sum_{x_k} f_{current}(g'_{ik}, x_k) < \sum_{x_k} f_{current}(g^*_{ik}, x_k)$
3. $f_{current}(g_{ik}, x_k) \leq f_{actual}(g_{ik}, x_k)$ for any g_{ik}
4. $\sum_{x_k} f_{current}(g_{ik}, x_k) \leq \sum_{x_k} f_{actual}(g_{ik}, x_k)$

Since there are a finite number of nodes in the tree below x_i, before termination $\sum_{x_k} f_{current}(g'_{ik}, x_k) = \sum_{x_k} f_{actual}(g'_{ik}, x_k)$ will become true. At this point:

$$\sum_{x_k} f_{current}(g'_{ik}, x_k) = \sum_{x_k} f_{actual}(g'_{ik}, x_k)$$

$$\sum_{x_k} f_{current}(g'_{ik}, x_k) > \sum_{x_k} f_{actual}(g^*_{ik}, x_k) \quad \text{by (1)}$$

$$\sum_{x_k} f_{current}(g'_{ik}, x_k) > \sum_{x_k} f_{current}(g^*_{ik}, x_k) \quad \text{by (4)}$$

Thus based upon current information ($f_{current}$) MCASA will switch from g'_{ik} to $g_{ik}*$ because it has a lower associated f-cost. This contradicts our assumption that MCASA will terminate with g-thresholds g'_{ik}. ■

If x_i is not a T-node, then MCASA is not guaranteed to find the assignment whose f-cost, local cost (δ) plus the sum of x_i's children's costs, is minimized while satisfying the g-constraint. We can show this with a counter-example.

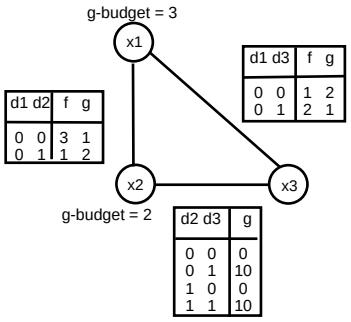

Figure 7: MCASA fails on non-T-nodes

As we can see in Figure 7, x_1 is a non-T-node since x_3 is a child of x_2 not x_1. If we assume that x_1 has a g-budget of 3 and only one value in its domain, then it must choose how to split its g between its two children. Based upon the functions on the links, it will choose to give a g-threshold of 2 to x_2 and 1 to x_3, leading to a predicted f-cost of 2 + 1 = 3. This effectively removes the value 0 from x_3's domain and causes the link between x_2 and x_3 to incur a g-cost of 10 which in turn leads x_2's g-constraint to be unsatisfiable for any g-threshold it could receive from x_1 (Since x_2 tries out both values under given threshold of 2). Since no matter what g-threshold it assigns to x_2, x_2's g-constraint is violated (leading to an infinite f-cost), x_1 infers that the problem is unsatisfiable. It is at this point that condition (3) from the previous proof has been violated since x_1 estimates $f_{current}(gt, x_2) = \infty$ whereas $f_{actual}(gt, x_2) = 4$ where $gt \in \{1, 2, 3\}$. This counter example is based on having just a g-function on the $x_2 - x_3$ link, however, similar examples can be constructed using just an f-function or both an f- and a g-function on the link. Modifications to MCASA to make these cases feasible is an issue for future work. ■

We now turn to MCA complexity. The original DCOP problem is NP-hard. By illustrating a solution to the multiply-constrained problem which only adds a linear number of additional nodes we suggest that the complexity class has not worsened. With respect to space, a key feature of Adopt is that its space complexity is linear in the number of nodes, n, specifically $|D_i|\,n$. In MCAP and MCAS, the space used at each regular node is the same, but we add up to n virtual variables, so the space complexity for MCAP and MCAS is $(|D_i| + 1)n$. In MCASA there are no virtual variables, but each node stores a g-to-f mapping for each of its children. This causes the space complexity to be $|D_i|\,n + G_i n$.

5. EXPERIMENTAL RESULTS

This section presents five sets of experiments. The first compares the performance of MCAP, MCAS and MCASA on four settings that were motivated by the domains in Section 2.3. Setting 1 com-

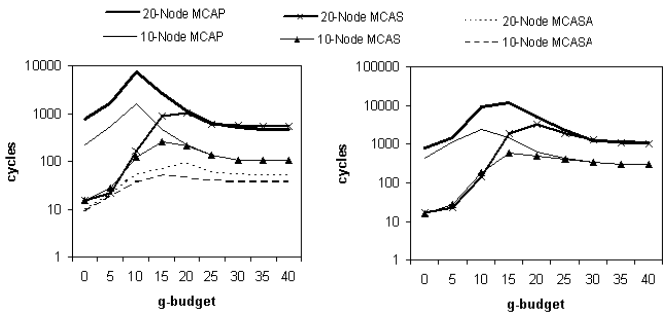

Figure 8: g-budget vs. run-time for a) 100% T-node problems b) 85% T-node problems

prised 20-node problems, with 3 values per node, an average link density of 1.9 and maximum link density of 4. It had 100% T-nodes and both the f- and g-costs were randomly chosen from a uniform distribution varying from 0 to 10. Setting 2 is similar to setting 1, except that the graph was 85% T-node (which increased the average link density to 2.2) to allow for comparison of the impact of T-nodes. Setting 3 (setting 4) is similar to setting 1 (setting 2), except that it is a 10-node problem. We created 15 sets of constraint functions for each of our domain settings, i.e. each data-point in our graphs is an average of 15 problem instances.

To highlight the tradeoff between the techniques, we show the performance of each technique when applied to all the nodes in a problem i.e. we either apply MCAP to all the nodes or MCAS or MCASA. There are a total of 1350 different runs summarized in the two graphs given all the g-budgets tested. Figure 8a shows the average run-times of MCAP, MCAS, MCASA in settings 1 and 3. The x-axis shows the g-budget applied to all variables and ranges from 0, which is unsatisfiable, to 40, which is effectively a singly-constrained problem. The y-axis shows runtime – run-time is measured in cycles where one cycle consists of all agents receiving incoming messages, performing local processing and sending outgoing messages [9]. The y-axis is logarithmically scaled.

The graphs show that due to privacy, MCAP has the poorest performance. The upper bounds calculated by sharing information in MCAS improve performance, while the exact bounds and lack of tree-restructuring in MCASA give it the best performance. The maximum speedup of MCAS over MCAP is 744 for setting 1 and 209 for setting 3, while the maximum speedup of MCASA over MCAS is 937 for setting 1, and 190 for setting 3. Figure 8b demonstrates similar results for setting 2 and setting 4. Only MCAP and MCAS results are shown given the switch to 85% T-node problems in these settings (we cannot apply MCASA to all the nodes in these settings). The switch from 100% T-node to 85% T-nodes causes a significant increase in run-time (note the y-axes are not identical).

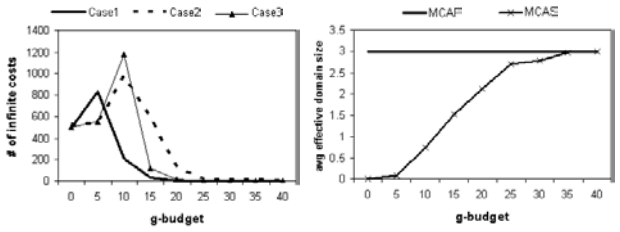

Figure 9: a) g-budget vs. number of infinite cost messages b) g-budget vs. number of values per domain

For all of the subalgorithms the runtime curve has a distinct inverted U-shape to it: the run-times are lowest at high g-budgets (no resource constraints) or at low g-budgets (tight resource constraints). Figure 9a begins to provide an explanation by plotting the g-budget on the x-axis and the total number of infinite cost messages received by any variable in the problem – due to g-constraint violation – on the y-axis. The figure shows results from three representative runs of MCAP on setting 3. We can see the same hump appearing at a g-budget of 10 and diminishing to almost 0 at a g-budget of 20. This agrees with the fact that the maximum g-cost on a link is 10 and the average link density is 1.9 (there are still one or two infinite cost messages all the way up to a g-budget of 35 because the maximum link density is 4). The larger number of infinite cost messages in the mid-g range indicates that it potentially takes longer to discover unsatisfiability of solutions, leading to longer run-times and hence the hump shape.

In all settings, for tighter g-budgets, the MCAS algorithm outperforms MCAP, however, for looser g-budgets, there is no difference in performance. Figure 9b provides an explanation based on the fact that MCAS sends g-thresholds that potentially prune descendents' domain values. We plot the g-budget on the x-axis and the average number of values remaining in the domain of a variable running MCAS on the y-axis. The numbers are plotted as an average over all nodes over all 15 problem instances of setting 3. For comparison, we also provide results of MCAP, which performs no pruning and hence is a flat line. This figure shows that when g-budgets are tight, MCAS provides significant pruning, but when g-budgets are loose MCAS upper-bounds provide no pruning (in comparison with MCAP) and thus there is no efficiency loss due to privacy. The domain sizes converge at a g-budget of 25, which is also where the runtimes converge in Figure 8.

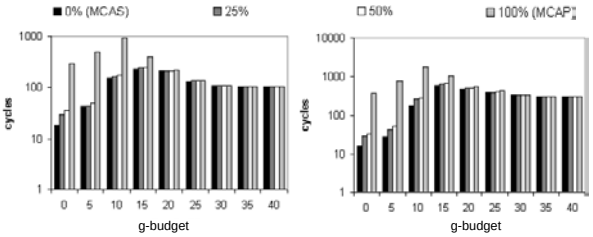

Figure 10: g-budget vs. runtime, varying percentages of private constraints: a) 100% T-node and b) 85% T-node problems

While we have performed several other explorations of privacy-efficiency tradeoffs in our techniques, space limitations preclude an extensive discussion. For example, one set of experiments demonstrate the benefits of the per-node application of the MCAP and MCAS techniques. Here, we took the examples from settings 1 and 2 from Figure 8a and b and randomly assigned first 25% and then 50% of the nodes to have private g-constraints while the remaining were assumed to be non-private. We then compared their performance to that of MCAP (100% private) and MCAS (0% private). In order to isolate the effect of privacy, not graph structure, we did not exploit T-nodes. The results are shown in Figure 10a and b. The x-axis again shows the g-budget applied and the y-axis measures the runtime in cycles on a logarithmic scale. Each bar in the graph shows an average over the 15 instances and we can see that as the percentage of nodes whose additional constraint is private increases, the runtime increases for smaller g-budgets. Interestingly, the increase in run-time is not proportional to the increase in the number of private g-constraints; there is a significant jump in run-time when all nodes have private g-constraints. However, as in Figure 8, when the g-budget on each variable is loose enough the

runtimes converge because no pruning takes place.

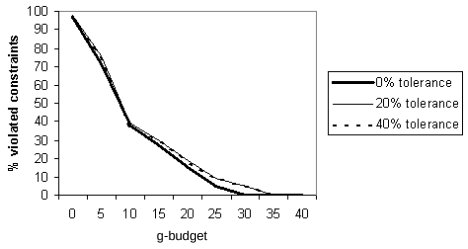

Figure 11: g-constraint violation by Adopt

While we developed MCA, one question was whether singly-constrained algorithms could automatically satisfy the g-constraint simply by loosening their tolerances on optimal solutions. We examined this by measuring the degree to which the g-constraint is violated by Adopt when ignoring g but specifying a tolerance on f. Figure 11 shows the results with each data point representing an average over 5 randomly generated runs. The x-axis gives the g-budget applied to each variable and again varies from 0 to 40. The y-axis is the percentage of nodes whose g-constraint was not satisfied by the solution obtained by Adopt. The tolerance is a percentage of the difference between the optimal and maximum cost solutions. The key result is that even with a large 40% tolerance on f, large numbers of g-constraints are violated with small g-budgets. Thus, running singly-constrained algorithms with tolerances is inadequate in addressing multiply-constrained DCOPs.

6. CONCLUSION AND RELATED WORK

This paper introduces a novel algorithm for multiply-constrained DCOPs, where agents must not only optimize a global objective, but must also satisfy resource constraints within their local neighborhoods. These resource constraints may be defined over an overlapping set of the variables in the original optimization constraints and they may be private constraints. Leading DCOP algorithms of today [9, 11, 14] are unable to fully address multiply-constrained DCOP problems; in particular, they are unable to exploit the interaction between the searches for the global optimal and local satisfaction, or address the privacy-efficiency tradeoffs engendered. To remedy this situation, this paper presents a novel multiply-constrained DCOP algorithm based on mutually-intervening search, which is operationalized via three ideas: (i) transforming the constraint graph to allow private n-ary constraints to be enforced; (ii) revealing upper-bounds on (resource) costs to neighbors, in order to gain efficiency while sacrificing privacy; (iii) identifying a local graph structure property – T-nodes – which allows agents to gain further efficiency by providing exact bounds on resource costs to neighbors. These ideas were realized via the MCA algorithm, which builds on Adopt, currently one of the most efficient DCOP algorithms. We proved the correctness of MCA, and presented detailed experimental results, illustrating the profile of the privacy-efficiency tradeoffs.

In terms of related work, we have already discussed the relationship of multiply-constrained DCOP and MCA with singly-constrained DCOP algorithms, such as Adopt, OptAPO and DPOP [9, 11, 14]. While we build on top of Adopt, we recognize that no DCOP algorithm currently dominates all others across all domains. However, the techniques developed here would transfer to other algorithms, e.g. MCAS and MCASA style techniques could be applied to algorithms like OptAPO. Whether DPOP [11] could similarly benefit from our techniques is an issue for future work.

Also related is previous work in multi-criteria collaboration [7, 10] which looks at finding a pareto-optimal for multiple objectives rather than optimizing a single objective subject to resource constraints. Furthermore, unlike our research, that work does not build on the recent theoretical or algorithmic advances in DCOPs. Approaches to multi-criteria constraint satisfaction and optimization problems have tackled the problem using centralized methods [4], but we focus on a distributed problem, which requires designing algorithms where agents function without global knowledge.

ABSTRACT

Numerous problems in software coordination, operations research, manufacturing control and others can be transformed in constraint optimization problems (COPs). Moreover, most practical problems change constantly, requiring algorithms that can handle dynamic problems.

In this paper we present the dynamic constraint optimization ant algorithm (DynCOAA) that can solve dynamic COPs. DynCOAA is specifically designed for dynamic problems, as it is based upon the ant colony optimization (ACO) meta-heuristic that has already proven its merit in other dynamic optimization problems. DynCOAA is a distributed algorithm that is suited for a one-on-one mapping between variables and hosts, but it can effectively accommodate multiple variables per host. We compared our algorithm to two existing algorithms for dynamic constraint optimization: DynAWC and DynDBA. We find that DynCOAA outperforms DynAWC and DynDBA on some problems, while remaining competitive on others.

1. INTRODUCTION

Numerous problems in software coordination, operations research, manufacturing control and others can be transformed in constraint satisfaction and constraint optimization problems (CSPs and COPs). In many practical applications there is not one static CSP or COP that has to be solved: practical problems change often. Changes can happen either because additional information is added to the model, or because of a changing nature in the problem that one tries to solve. An example of a changing problem is a GPS navigation system that has to recalculate the route when the car does not follow the proposed route.

When solving a changed version of a CSP or COP, the changed problem is often similar to the old problem: it only differs in a few constraints or variables. While it is possible that a small change in the problem creates a big change in the optimal solution, in most practical cases the optimal solutions of such similar problems do not differ a lot. E.g. in the GPS system when a car goes forward instead of turning left, the initial positions are almost the same and it may suffice to take the next left turn. Changing problems are called dynamic constraint satisfaction/optimization problems (DynCSP/DynCOP).

In this paper, we present a new distributed algorithm for constraint optimization that is specifically designed for dynamic problems. It is based upon the ant colony optimization (ACO) meta-heuristic [1]. In ACO, the environment of the multi-agent system represents the problem that has to be solved and the agents use this environment to give feedback to one another. This makes ACO-based algorithms naturally suited for dynamic problem solving, as changes in the problem are reflected automatically in the environment of the agents. In spite of this inherent suitability for dynamic problem solving, to this date and to the best of our knowledge, the dynamic constraint optimization ant algorithm (DynCOAA) that we present in this paper is the first distributed algorithm for dynamic constraint satisfaction or dynamic constraint optimization that uses the ACO meta-heuristic.

We compare DynCOAA to two other algorithms: the complete algorithm DynAWC [6] and the non-complete algorithm DynDBA [3]. We use two different cases for evaluating the algorithms. When the three algorithms are used to solve artificial graph coloring problems, DynDBA turns out to be the most effective algorithm. But when a real-world problem – scheduling ships that transport liquified natural gas – is tested, our DynCOAA clearly beats the other two algorithms.

In the following section we present our dynamic constraint optimization ant algorithm (DynCOAA) and the algorithms we use for comparison. Section 3 describes the tests we performed and the results we found. Section 4 concludes this paper with an overview of our findings and some pointers for future work.

2. ALGORITHMS

In this section we present the dynamic constraint optimization ant algorithm (DynCOAA). The construction of the graph struc-

ture and the behavior of the agents for a static problem are described in [4, 5]. When adding or removing variables or values in a dynamic problem, the corresponding nodes and edges have to be added or removed on the appropriate hosts. When adding or removing constraints, references to those constraints must be registered or deregistered with the appropriate nodes. While it is possible to leave all existing pheromone trails unchanged and only to initialize new edges with the default pheromone quantity, better results can be achieved with dynamic ACO algorithms when all pheromone quantities are equalized to a certain degree. We use the Restart-Strategy that they describe in their paper, using a λ_R value of 0.5, which gave the best results in their experiments. This means that all pheromone quantities are set to the average of the previous pheromone quantity and the default pheromone quantity.

The first algorithm we compare DynCOAA to is DynBDA. This is a non-complete algorithm, based on the Distributed Breakout Algorithm (DBA) and first introduced by [3]. DynDBA is said to be a good algorithm for fast-changing dynamic problems.

The second algorithm we use is DynAWC. This is a complete algorithm that uses nogood recording [6]. The processing of nogoods allows it to reuse information that was found in a previous search after a modification to the problem was made.

3. EXPERIMENTAL RESULTS

In this section we discuss the results of the tests we have done to compare DynCOAA with DynAWC and DynDBA. The three algorithms were implemented in C++, using the same constraint processing engine. We compare the algorithms for two different categories of problems. The first category of problems, discussed in Sect. 3.1, is artificial graph coloring problems. In Sect. 3.2 we discuss the results of a real-world problem, in which a schedule for a number of ships that transport liquified gas must be assembled. Section 3.3 gives an interpretation of the obtained results.

3.1 Graph Coloring Tests

For our first series of tests, we use the same problems as can be found in [3], i.e. graph coloring problems with 30 variables, which require a coloring with 3 colors. Graph densities varied over $\{2.0; 2.3; 2.5\}$. These densities represent the three different phases of the phase transition for random 3-coloring graphs (respectively mostly satisfiable; within the transition; and mostly unsatisfiable). The number of changes between successive problems, indicated by δ, varied over $\{2; 4; 6; 8; 12\}$, where 6 changes means that 3 constraints were removed from the problem and 3 constraints added to the problem, so that the overall density remained unchanged. For each combination of graph density and change rate δ, 20 problems were constructed, each consisting of an initial COP and 100 successive COPs.

As proposed in the future work section of [3], we measured the real-time performance of the algorithms: for each successive COP, the algorithms could calculate during 2 seconds. The best solution at each moment in time was stored. This form of measurement provides a more realistic indication of the performance than can be obtained through cycle-based tests.

Table 1 gives an overview of the results of the three algorithms. The table includes the average time (in seconds) that passed before all 20 problems found the first solution, the average cost of that first solution and the average cost of the best solution that was found after 2 seconds.

When looking at the table, an interesting observation can be made. DynCOAA needs about 5 times longer to calculate its first solution than is necessary for DynDBA and DynAWC. This is due to the fact that DynCOAA uses a swarm of 5 agents, who all need

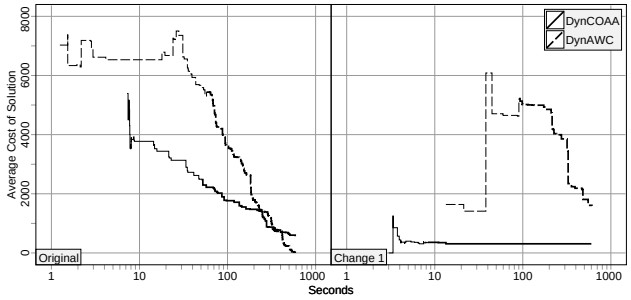

Figure 1: Anytime curves for DynCOAA (solid line) and DynAWC (dashed line) when assembling a schedule for ships. DynDBA was unable to find any solution.

about the same amount of time. But when we look at the final solution of DynCOAA and DynAWC during changes, DynCOAA clearly beats DynAWC, even though it takes about 5 times longer to find its first solution. The result of DynDBA remains better the that of DynCOAA.

As a conclusion, we can say that for these dynamic graph coloring problems, DynDBA is the best algorithm, closely followed by DynCOAA.

3.2 Real-World Ship Scheduling Tests

For our second series of tests, we decided to use a real-world problem instead of an artificial problem. This real-world problem is to assemble a schedule for transport ships. The ships transport liquified natural gas from different ports around the world to one destination port. Using data provided by Tractebel Engineering [2], the algorithms had to calculate a schedule for 7 ships, for a period of three months.

After a decent schedule had been found, we simulated a storm: one of the ships got delayed for three days. The algorithms had to recalculate the schedule, incorporating the delay. The goal was twofold: to obtain a good schedule, but also to leave the individual schedules for the 6 ships that did not get stuck in the storm as unchanged as possible.

This problem is quite complicated: the original scheduling problem is made up of a total of 69 variables and 101 constraints. The variable domains contain up to 200 possible values. 76 constraints are hard constraints (those have to be obeyed in each valid solution: it are constraints with a weight of infinity) and 25 are soft constraints, used for optimizing the cost function. 57 of the hard constraints are binary constraints. All other hard constraints involve at least 19 variables. The soft constraints even involve all variables. A solution with a cost of 1000 means that the local transport rate in the destination port has to deviate from the optimal rate during a total of one day (in smaller intervals distributed over the three months). At a cost of 2000, it has to deviate during a total of 2 days, etc.

Each of the three algorithms made 20 schedules. For the original schedule as well as for the storm-adaptation, 10 minutes of calculation were allowed. The parameters that were used for the DynCOAA are the same as described in Sect. 3.1, except for the swarm size, which was increased to 30. The anytime curves for this problem are shown in Fig. 1.

The first thing to notice is that DynDBA is missing from Fig. 1. During the 10 minutes of calculation time, none of the 20 runs were able to find any valid schedule (one that satisfies all hard constraints). The most probable reason for this is that a number of the constraints are global constraints, making it very hard for a lo-

Table 1: Results of testing DynCOAA, DynAWC and DynDBA on 30-node, dynamic 3-coloring problems. Averages over 20 problem instances per Density-δ combination. Time is expressed in seconds.

cal search algorithm to find a solution. Because no initial schedule was found, DynDBA could not even begin to search for a solution after the change.

The two algorithms that did find a valid solution did so in all 20 runs. But the behaviors of DynCOAA and DynAWC were completely different for the original and the changed problem. For the original schedule, it took both algorithms about 1 minute to find a first solution for all 20 runs. The average solution of DynCOAA was twice as good as the average solution of DynAWC at that time. The average solution of DynAWC quickly became better and after 10 minutes DynAWC had found an almost perfect solution in all 20 runs, while DynCOAA still had a cost of about 550.

As for the schedule after the storm, it took DynCOAA less than 10 seconds to find a valid schedule in all 20 runs. Even more, the first average solution was almost as good or even better than the last average solution before the storm. DynCOAA could further improve this first schedule to end at an average cost of about 300 after 10 minutes of calculation. DynAWC on the other hand took almost 100 seconds to find a first solution in all 20 runs. The first average solution had a cost of about 5000. In the remaining time, the solution could be improved to less than 2000, but this still was a lot higher than the average solution of DynCOAA.

One of the reasons of the slower response rate of DynAWC is the preprocessing of the nogoods. After 10 minutes of calculation for the initial schedule, more than 10.000 nogoods had been accumulated. It took DynAWC about 10 seconds to filter out the nogoods that had become invalid after the change. By that time, DynCOAA had already found a new solution.

3.3 Evaluation

The results of DynDBA are the most dissimilar when we look at the behavior over the two different categories of tests. For the artificial graph coloring problems, it was the clear winner of the three algorithms. For the real-world ship scheduling problems, it could not find any solution.

DynCOAA and DynAWC on the other hand behave rather similar for the two different categories of problems. For the first, static problem, DynAWC is a better choice. But when the static problem becomes a dynamic problem by changing some constraints, DynCOAA reacts faster to those changes and finds a better solution.

4. CONCLUSIONS AND FUTURE WORK

In this paper we presented DynCOAA. It is based on the ACO meta-heuristic and designed from the start for solving dynamic constraint optimization problems (DynCOPs). We compared this algorithm against two other algorithms in two different categories of problems: artificial graph coloring problems and real-world ship scheduling problems.

There are two important conclusions that can be drawn from this comparison: (1) DynCOAA is suited for solving DynCOPs, as it beats DynAWC in all two and DynDBA in one of the two categories of problems, and (2) Choosing the right algorithm for a specific problem is very important, because the performance of algorithms can depend greatly on the type of problem.

This work has been funded by the Institute for the Promotion of Innovation through Science and Technology in Flanders (IWT-Vlaanderen)

ABSTRACT

Distributed Constraint Optimization (DCOP) is rapidly emerging as a prominent technique for multiagent coordination. Unfortunately, rigorous quantitative evaluations of privacy loss in DCOP algorithms have been lacking despite the fact that agent privacy is a key motivation for applying DCOPs in many applications. Recently, Maheswaran et al. [3, 4] introduced a framework for quantitative evaluations of privacy in DCOP algorithms, showing that early DCOP algorithms lose more privacy than purely centralized approaches and questioning the motivation for applying DCOPs. Do state-of-the art DCOP algorithms suffer from a similar shortcoming? This paper answers that question by investigating the most efficient DCOP algorithms, including both DPOP and ADOPT.

1. INTRODUCTION

Promising approaches in distributed constraint optimization (DCOP) [5, 7], enable distributed conflict resolution and coordination while maintaining users' privacy. Indeed, maintaining privacy is a fundamental motivation in DCOP [5, 7, 9]. One approach to privacy in DCOP is to use cryptographic techniques [11] that ensure watertight privacy but require the use of external servers or computationally intensive cryptographic operations. Instead, we focus on an approach in which researchers provide metrics for quantifying the privacy loss in DCOP algorithms [1,3,4,6,10]. If we can bound privacy loss in specific DCOP algorithms, then cryptographic techniques may be avoidable in situations where they are impractical.

There are three key weaknesses in the previous work on privacy loss analysis in DCOP. First, recent cross-algorithm privacy loss analysis focused on a limited number of DCOP algorithms but indicated that these algorithms preserve less privacy than a centralized approach [3], seriously undermining a key motivation for these algorithms. Thus, it is crucial to analyze some of the most used and most recent DCOP algorithms to see whether they are similarly undermined and to measure their cross-algorithm performance. Two notable omissions in previous analysis are ADOPT [7] and DPOP [8], both among the most efficient DCOP algorithms.

This paper overturns the significant negative results from [3, 4] by providing positive privacy results for several DCOP algorithms not considered in [3, 4]. This paper analyzes ADOPT, DPOP and SynchID [7], three recent DCOP algorithms, via a large-scale experimental investigation of privacy loss in DCOP algorithms in the VPS (Valuations of Possible States) analysis framework [3, 4], using several distributed meeting scheduling scenarios.

A predecessor to the recently introduced algroithms above, SynchBB [2] is an early algorithm for DCOP. Previous work has provided a comparison of privacy loss of a centralized approach with SynchBB, suggesting that the centralized approach may lead to lower privacy loss. Hence, this paper focuses on the remaining algorithms above. These algorithms were chosen because they present novel design choices, or occupy a prominent place in the algorithmic space. The following describes key characteristics of these algorithms:

Adopt is an asynchronous complete DCOP algorithm, guaranteed to find the optimal solution. In Adopt, an agent communicates only one value from its domain at a time, or one message indicating the cost of an assignment to a set of variables at a time.

SynchID is an iterative deepening algorithm similar to Adopt, with two primary differences: agents are organized into a linear chain, rather than a tree, and messages are sent synchronously.

DPOP [8] is an synchronous complete DCOP algorithm, using a tree topology. DPOP is a variable elimination algorithm, where all relevant information is sent up the tree in one large message.

SynchBB or synchronous branch-and-bound, was studied in [4]. However, we focus on a slightly modified SynchBB where information irrelevant to the problem is not communicated.

2. EXPERIMENTAL METHODOLOGY

We focus our investigation on privacy loss in the distributed meeting scheduling problem, since this domain presents inherent privacy concerns [1, 4]. However, the results of this work can be generalized to other DCOP settings where privacy matters.

We define a meeting/event scheduling problem based on the for-

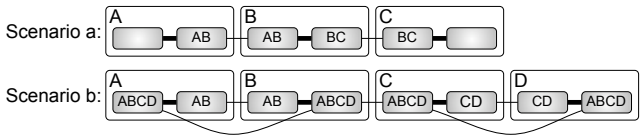

Figure 1: Scenarios: Transparent boxes represent agents and the dark, inner boxes are meeting variables. Thick lines are intra-agent contraints and thin lines are inter-agent constraints.

malism of [5], expressed using the PEAV-DCOP representation [5], which is motivated by privacy considerations.

Scenarios in PEAV-DCOP: The majority of scheduling instances in a functional personal assistant agent system will consist of a small number of meetings that need to be negotiated simultaneously. While larger-scale problems may present themselves, if privacy is a critical factor, the coordination protocols must be effective for these small-scale instances. We consider two scenarios of three (A, B, C) or four (A, B, C, D) agents. The PEAV-DCOP graphs in Figure 1 show the events, labeled by their attendees, and decomposed into variables and constraints.

2.1 VPS: Measuring Privacy Loss

The Valuation of Possible States (VPS) framework [4] was proposed to quantitatively evaluate privacy loss among a group of agents $R_1 \cdots R_n$. Quantification of privacy loss in VPS is based on a valuation on the other agents' estimates about (i.e. a probability distribution over) an agent's possible states. There are three key elements in VPS: (i) agent R_n's private information, modeled as a state $s_n \in S_n$, where S_n is a set of possible states that R_n may occupy; (ii) other agents' estimates about agent R_n's possible states, expressed as a probability distribution $\mathbb{P}_n((S_n)^{N-1})$, (iii) the utility that agent R_n derives from the distribution of other agents' beliefs about R_n's states, yielding value function $\mathbb{V}_n(\mathbb{P}_n((S_n)^{N-1}))$. Note that $\mathbb{P}_n((S_n)^{N-1}) = [\mathbb{P}_n^1(S_n)\ \mathbb{P}_n^2(S_n)\ \cdots \mathbb{P}_n^N(S_n)]$, where $\mathbb{P}_n^j(S_n)$ provides agent R_j's probability distribution over states of agent R_n.

Before negotiation, each agent knows only that the other agents exist in one of $|\mathcal{V}|^T$ possible states. Afterwards, each agent will be modeled by all other agents whose estimate of the observed agent is captured by $\mathbb{P}_n((S_n)^{N-1})$. In this analysis, we focus on the information-theoretic analysis introduced in [1] or the EntropyTS metric [3]. Privacy loss between two agents is studied on a per-timeslot basis, averaged over all timeslots.

We can scale this function and average the privacy loss between all pairs of agents such that the valuations span [0 1] with zero is no loss and one is complete loss of privacy.

2.2 Inference Algorithms

Based on the VPS framework, we define a process by which agents can infer information about other agents while running various DCOP algorithms, in order to measure the likely privacy loss between agents in a DCOP. All inference experiments for all algorithms (including the centralized method) start with the same initial assumptions. We assume that the constraint graph and the valuation of each *meeting* is known to all agents, but the valuations of *time slots* are private. These assumptions are exactly as in [3, 4], allowing comparison of the results; in addition, for the scenarios with few meetings, it is reasonable to assume that the valuations for meetings are public knowledge. Based on these assumptions, we developed the following methods for agent inference for SynchID, Adopt and DPOP.

Centralized: In a centralized algorithm, the agents all send their valuation information to one agent, who computes the result and returns. In every case the centralized agent can "infer" the valuations perfectly [4]. Since we express our results as an average of each agent's privacy loss, the privacy loss of the centralized algorithm is $\frac{1}{N}$ where N is the total number of agents.

SynchID: SynchID is a synchronous algorithm in which agents are ordered in a chain, and messages are passed up and down the chain. An upward message from agent R_n contains a number m_n, which is equal to the best currently known total reward for the subchain of agents under and including R_n. For PEAV, the total reward for the chain is equal to the sum of differences between the valuation of a scheduled meeting and the valuation of the time slot it occupies for every scheduled meeting for every person. We henceforth use $\Delta_{R_n}^{E_k}(t) = V_n^k - V_n^0(t)$ to denote the change in utility to the nth agent for scheduling the kth event at time t. When agent R_n receives an upward message it knows that m_n = a sum of Δ terms lower in the chain from R_n.

To illustrate how possible states can be eliminated in SynchID, we outline the inferences that one can make from messages received in Scenario a. In SynchID, upward messages to agent R_n contained information of the form:

$$m_n = \sum \Delta_{R_n}^{E_k}(t_{E_k}) + \sum \Delta_{R_n}^{E_k}(\tilde{t}_{E_k}), \quad (1)$$

where the summations include events downstream from R_n. t_{E_k} is the time of an event E_k when that time is known to R_n (because R_n is a participant in event E_k), and $\tilde{t}_{E_k}$ is the time of an event E_k when that time is not known to R_n. For example, since B knows when meeting BC is scheduled, as well as the value of meeting BC, a message from C to B (m_B) allows B to know $V_C(t_{BC})$ (the valuation vector component of C at the time at which meeting BC is scheduled). Similarly, a message from B to A (m_A) allows A to know $v_B(t_{AB}) + v_B(\tilde{t}_{BC}) + v_C(\tilde{t}_{BC})$, where $\tilde{t}_{BC}$ is some time not equal to t_{AB}, but otherwise unknown to A. Each of these relations allows the observing agent to reduce the number of possible states the other agents could be in. We obtain the privacy loss for SynchID by allowing each agent to collect these relations, iterate over them, and test each relation against a list of possible states for the other agents, discarding states that conflict with any of the relations.

Adopt: Adopt contains the same type of upward messages as in SynchID, but, due to its asynchrony, it may be impossible for agents to tell how many Δs are contained in the reward component of each message. When a message is received, we know it contains rewards for at least one agent more than the previous message it sent. However, due to asynchrony, our agent might have included more descendants in the message. So, for our inference, we use a $\leq$ sign. The inference equation is:

$$m_n \leq \sum \Delta_{R_n}^{E_k}(t_{E_k}) + \sum \Delta_{R_n}^{E_k}(\tilde{t}_{E_k}), \quad (2)$$

This relation changes to an equality in the special case when only one agent is downstream from agent R_n.

DPOP: In the DPOP algorithm, each agent sends exactly one cost message to its parent. This message is a table of all possible assignments of constrained upstream events and the aggregate costs of those assignments to the agents downstream of R_n. Each entry in the table is used to create inference rules as in equation 1. The events in the entry are the $\Delta_{R_n}^{E_k} t_{E_k}$ terms and other events with participating agents downstream of R_n are the $\Delta_{R_n}^{E_k} \tilde{t}_{E_k}$ terms.

SynchBB: Inference rules for SynchBB are as described in [4].

3. EXPERIMENTAL RESULTS

In this section, we present experimental results from two scenarios. We compare privacy loss in the studied algorithms according to the EntropyTS metric and we introduce a new metric to highlight privacy benefits of distribution over centralized approaches.

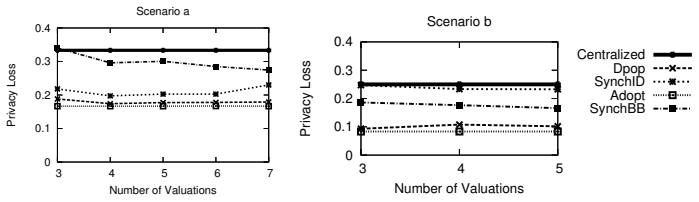

Figure 2: Privacy loss comparisons of the different algorithms.

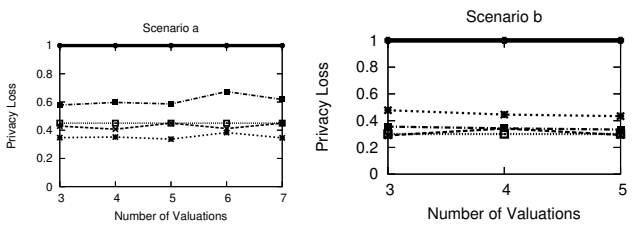

Figure 3: Algorithms compared using the MAX metric.

For the three agent scenario, we varied V, the number of valuations, from 3 to 7 while holding the number of timeslots = 3. For the four agent scenario, for reasons of computational complexity, we varied $|\mathcal{V}|$ from 3 to 5 while holding $T = 3$. For each $(T, |\mathcal{V}|)$ pair, we performed 10 runs per algorithm. For each run, the privacy loss for each agent was measured using the inference algorithms given in Section 3. The systemwide privacy loss was expressed as the arithmetic mean of each agent's privacy loss: $\sum_N \mathbb{V}_n/N$.

In each of our graphs, each data point is an average of 10 runs, and we provide statistical significance results to support our main conclusions. We use a chain topology for all algorithms, to allow fair comparison, since not all algorithms can use a DFS tree.

Cross-algorithm comparison: Figure 2 shows the comparison of privacy loss for the four algorithms mentioned above, for two scenarios, as well as providing a comparison of privacy loss with the centralized approach. The *x*-axis plots the different number of valuations (with number of time-slots fixed at 3) and the *y*-axis plots privacy loss. The thick horizontal line shows the centralized approach, for scenario a (three agents), its privacy loss is 0.33, but for scenario b (four agents) it is 0.25. We use the EntropyTS metric as the metric for privacy loss in this result. We obtained results for other metrics, and mostly these metrics agree with the conclusions drawn using the EntropyTS metric.

We conclude the following from Figure 2: (1) All algorithms but SynchBB have a privacy loss that is lower than the centralized approach. In contrast with the negative results presented in [4], which illustrated DCOP algorithms as having worse privacy loss than a centralized approach, this is a significant positive result. Indeed, the privacy loss in Adopt and DPOP is less than half that of the centralized approach. Furthermore, statistical tests show that Adopt performs better than centralized in all scenarios and DPOP performs better than centralized in all but one (significance level of 5%). (2) DPOP and Adopt had similar privacy loss, despite their vastly different approaches. Despite DPOP's one-shot communication of all information, it performed surprisingly well in terms of privacy loss. Adopt does perform slightly better than DPOP for privacy loss, but not to the level anticipated. (3) Adopt significantly outperformed SynchID in terms of privacy protection. The asynchrony in Adopt was expected to be significantly detrimental to privacy due to the increased numbers of messages. Instead, we found that the uncertainty introduced by asynchrony as to which agents participate in each cost message provides significant privacy gains compared to synchronous algorithms such as SynchID. (4) Despite modifications to improve privacy, SynchBB still performed the worst in terms of its privacy loss; often worse than centralized. The key reason for SynchBB's low performance is its bi-directional messaging of cost information. Thus, it is important to avoid bi-directional cost propagation in DCOP algorithms when privacy is a goal.

MAX metric: In Figure 2, we measured the loss of privacy between pairs of agents, averaged to find the systemwide privacy loss. The effect of one agent learning more than others, and gaining an asymmetric advantage over them, is not considered. The MAX metric addresses this effect by considering only the single agent that learns the most information about other agents (by EntropyTS), rather than the mean of the individual privacy loss figures. Thus, a centralized algorithm will have a value of 1, since the MAX agent learns all the information. Figure 3 shows the results for all the algorithms according to the MAX metric. The number of valuations is plotted on the *x*-axis and the privacy loss is plotted on the *y*-axis.

The MAX metric suggests that there is always a privacy benefit obtained by using DCOP algorithms, even those that perform worse than centralized by our other metrics, when the major privacy concern is one agent accumulating excessive knowledge. In the MAX metric, DPOP and Adopt tended to outperform SynchBB, while SynchID varied widely from scenario to scenario.

4. CONCLUSION

Distributed Constraint Optimization (DCOP) is rapidly emerging as a tool for multiagent coordination. Previous work [4] showed a negative result on privacy loss in early DCOP algorithms, casting doubt on the efficacy of DCOP in privacy requiring domains. This paper presents an investigation of several leading algorithms, including ADOPT and DPOP, and overturns earlier negative results. Our metrics show DCOP algorithms outperforming a centralized approach, with DPOP, SynchID and ADOPT performing best.

ABSTRACT

We present a new polynomial-space algorithm for solving Distributed Constraint Optimization problems (DCOP). The algorithm, called NCBB, is branch and bound search with modifications for efficiency in a multiagent setting. Two main features of the algorithm are: (a) using different agents to search non-intersecting parts of a search space concurrently, and (b) communicating lower bounds on solution cost every time there is a possibility the bounds might change due to changed variable assignments. The first leads to a better utilization of computational resources of multiple participating agents, while the second provides for more efficient pruning of search space.

Experimental results show that NCBB has significantly better performance than another polynomial-space algorithm, ADOPT, on random graph coloring problems. Under assumptions of cheap communication it also has comparable performance with DPOP despite using only polynomial memory as opposed to exponential memory for DPOP.

Cooperative distributed problem solving in agent systems

1. INTRODUCTION

In recent years Distributed Constraint Optimization (DCOP) [2] has received considerable attention as a powerful paradigm for multiagent coordination. Example applications include target tracking in distributed sensor networks [7] and distributed event scheduling [1].

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. Several efficient distributed algorithms for solving DCOP have been developed recently, both optimal (Synchronous Branch and Bound, ADOPT [7], OptAPO [5], DPOP [8]) and approximate (Iterative Distributed Breakout). Of the optimal algorithms ADOPT, DPOP and OptAPO have the best performance to date [5, 7, 8]. However, more work is needed to make optimal DCOP algorithms efficient enough for real-life problems.

In this paper we present a decentralized algorithm, called No-Commitment Branch and Bound search (NCBB), for solving DCOP, that addresses the problem of performance. It is based on well-known branch and bound search [3]. It runs several concurrent search processes in different partitions of search space. This enables one to speed up the search due to parallelization and also reduces the amount of information that has to be synchronized among agents. We demonstrate that NCBB performs better than ADOPT on distributed graph coloring problems under a variety of metrics. When communication is cheap, it also has comparable performance with DPOP despite using only polynomial memory as opposed to exponential memory for DPOP.

2. DCOP

A Distributed Constraint Optimization problem consists of a set of variables $V = \{x_1, \ldots, x_n\}$, a set of discrete finite domains for each of the variables $D = \{D_1, \ldots, D_n\}$ and a set of constraints $F = \{f_1, \ldots, f_m\}$ where each constraint is a function $f_i : D_{i_1}, \ldots, D_{i_j} \rightarrow \mathcal{N} \cup \infty$. Each variable is controlled by an agent that can communicate with other agents. The goal of the agents is to find an assignment for all the variables $B^* = \{d_1, \ldots, d_n | d_i \in D_i\}$ such that the global cost, $\sum_{i=1}^{m} f_i$, is minimized. DCOP is NP-complete.

In this article we consider a restricted version of DCOP. We assume all the constraints to depend on exactly two variables, although our approach can in principle be extended to k-ary constraints. We also assume that each variable is controlled by an independent agent and use the terms *agent* and *variable* interchangeably.

We will use the term *constraint graph* to refer to a graph where variables are nodes and two nodes have an edge between them if and only if they share a constraint. We also assume that two agents have a direct communicational link if and only if they share a constraint.

3. NCBB ALGORITHM

Before the algorithm can be executed, the agents need to be prioritized in a depth-first search (DFS) tree, in which

```
function mainLoop()
1  if (¬ IAmRoot) updateContext();
2  while (true)
3    search();
4    if (IAmRoot ∨ updateContext()) break;
5  end while;
6  costs[resultValue] = 0;
7  (for ∀ y ∈ chldren) subtreeSearch(resultValue, y);
8  (for ∀ y ∈ children) send "STOP" to y;
end mainLoop;

function updateContext()
10 while (true)
11   receive message m from y ∈ ancestors;
12   if (received "search") bound ← m.BOUND; return false;
13   else if (received "y=d")
14     context[y] ← d;
15     send LB(x,context,indx_y) - LB(x,context,indx_y-1) to y;
16   else if (received "STOP") return true;
end if; end while; end updateContext;
```

Figure 1: Main loop for agent x

each agent has a single parent and multiple children. Constraints are only allowed between agents that are in an ancestor-descendant relationship in the DFS tree. An agent does not have information about all its ancestors or descendants, but only about those with whom it shares a constraint.

The purpose of such an ordering is to decompose the global cost function: given the assignments to all ancestors, agents in a given subtree can work on minimizing their part of the solution cost independently of agents in other subtrees. Any constraint graph can be ordered into some DFS tree using distributed algorithm from [4].

3.1 Auxiliary definitions

In further explanation all variables names refer to local variables of the considered agent.

DEFINITION 1. *Agent cost for agent x and assignment B*

$$AgentCost(x, B) \equiv \sum_{y \in ancestors_x} f_{x,y}(B(x), B(y))$$

where $B(x)$ is the value of x under assignment B.

DEFINITION 2. *For agent x, assignment B and integer* $k \in 0..|ancestors_x|$ *denote LB(x,B,k)*

$$LB(x, B, k) = \min_{d_x \in D_x} \min_{B_1 \in B|_{ancestors_x[1..k]}} AgentCost(d_x, B)$$

where $B|_{vars}$ is the set of all assignments that agree with B on the values of variables in $vars$.

3.2 Initialization

During the initialization stage agents compute global upper and lower bounds on the solution cost. Each agent chooses its value greedily given values of its ancestors so as to minimize its *AgentCost*. The costs are propagated up the tree and `bound` variable of the root agent takes the value

$$bound = \sum_{x \in V} AgentCost(x, B_{greedy}) - \sum_{x \in V} LB(x, \emptyset, 0).$$

`bound` variable of an agent plays the role of an upper bound on the cost of this agent's subtree. Thus one can see that NCBB uses nontrivial lower bounds on the solution cost during the search. This idea is closely related to preprocessing

```
function search()
20 idle ← children;
21 costs ← ∅; unexplored ← ∅; anncdVals ← ∅;
22 minCost ← LB(x, context, |ancestors|);
23 for ∀ d ∈ D : AgentCost(d,context) ≤bound + minCost
24   costs[d] ← AgentCost(d,context) - minCost;
25 end for;
26 for (∀ d ∈ D : costs[d] ≠ ∅) unexplored[d] ← children;
27 while (unexplored ≢ ∅ ∨ anncdVals ≢ ∅)
28   while idle ≢ ∅
29     choose child ∈ idle; idle ← (idle \ child);
30     choose d : child ∈ unexplored[d];
31     unexplored[d] ← (unexplored[d] \ child);
32     if (¬ subtreeSearch(d, child) ∧
33             (∃ c ∈ D: child ∈ unexplored[c]))
34       idle ← (idle ∪ child);
35   end if; end while;
36   if anncdVals ≢ ∅
37     receive cost_y from y ∈ children;
38     d ← anncdVals[y]; anncdVals[y] ← ∅;
39     costs[d] ← costs[d] + cost_y;
40     if (costs[d] > bound) prune();
41     else if (unexplored[d] ≡ ∅) ∧ (y ∉ ∪_{c∈D} anncdVals[c])
42       bound=costs[d]; resultValue = d; prune();
43   end if; end if;
44   (if ∃ c ∈ D: child ∈ unexplored[c]) idle ← (idle ∪ child);
45 end while;
46 if (¬ IAmRoot) send min_{d∈D} costs[d] to parent; end if;
end search;

function subtreeSearch(d, child)
50 send "x=d" to all descendants[child]; anncdVals[child]=d;
51 for ∀ y ∈ descendants[child]
52   receive cost_y from y; costs[d] ← costs[d] + cost_y; end for;
53 if (costs[d] > bound) prune(); anncdVals[chld]=∅;
54   return false;
55 else
56   send "SEARCH, BOUND=bound-costs[d]" to child;
57   return true;
end if; end subtreeSearch;
```

Figure 2: Main search loop subroutines for agent x

heuristics for lower bound estimation for ADOPT [1] that resulted in speedups by an order of magnitude.

3.3 Main loop

After initialization all agents execute the main search loop listed in Figures 1 and 2. An agent x does not start actively searching until it receives a $SEARCH$ message from its parent (line 12). Before this message is sent by x's parent, all x's ancestors select their values and announce them to their descendants. Therefore, when x receives a message to start searching, it has consistent knowledge about the relevant ancestors' values.

The `search` function contains two most distinct features of the algorithm. One of them is the method of branching: when x selects the next value to explore on a given subtree, it may choose a value different from those announced to x's other subtrees (30). For each value an already known part of the total cost is stored and updated (see `costs` variable). Because a particular value is generally used at different times for different subtrees, one can take into account the

costs for already completed subtree searches and compute a tighter upper bound on the solution cost for the next subtree (`subtreeSearch`, (52, 56)). It can be viewed as running simultaneous search processes in different parts of search space, and exploits inherent parallelism of the problem.

The second major feature of NCBB is eager propagation of cost lower bound changes. As agent x learns about its ancestors' assignments, it can compute $LB(x, context_x, k)$ for larger and larger k. Every time x receives a message with the value of its ancestor y, it immediately sends back the amount of change in lower bound on x's *AgentCost* (15). This leads to more precise lower bounds on partial assignment optimal cost at the point of control (agent y in this case) and in turn to better pruning.

An agent keeps track of the solution costs known so far for each one of its values (`costs` map), which subtrees have not yet explored which of its values (`unexplored`) and what value is currently used in what subtree (`anncdVals`). It updates this information as the subtrees return their search results (lines 39,52).

4. ALGORITHM PROPERTIES

PROPERTY 1. *NCBB always terminates after finite time.*

PROPERTY 2. *The amount of memory required for agent x is $O(|D_x| \times |neighbors_x|)$.*

PROPERTY 3. *After terminating, resultValue variables values of all agents form optimal variable assignment B^*:*

$$B^* = \arg\min_B \sum_{i=1}^{m} f_i(B)$$

PROPERTY 4. *The number of messages processed by any agent between receiving SEARCH message and reporting results in corresponding $cost_x$ message is $O(|D_x| \times |neighbors_x|)$. Also, the size of each message does not depend on the problem, i.e. algorithm uses only messages of size $O(1)$.*

5. EVALUATION

The main metric for evaluation was concurrent constraint checks (CCC) [6]. It combines computational and communicational cost of solving the problem and allows for parallelism. The unit of cost is time needed to perform one constraint check. The cost of a message is defined in terms of constraint checks and does not depend on message size. It is easy to add CCC as a benchmark for a simulated distributed system by adding a special field with a value of local "tick counter" v to every message. Upon receiving the message, the receiver updates its counter value according to

$$v_{receiver} = \max\{v_{receiver}, v_{sender} + cost_{message}\},$$

When an agent evaluates a constraint, v is increased by 1. The cost of solving the problem is the maximal value of v over all agents.

Fig. 3(a), 3(b) and 3(c) show the dependency of the problem solving cost on the number of variables for sparse (3(a)) and dense (3(b), 3(c)) settings. The respective message costs were $cost_{message} = 10^3, 0, 10^6$ ($cost_{message} = 0$ corresponds to pure computational cost of an algorithm). In Fig. 3(d) one can see the total number of messages sent by all agents during the solution process depending on the problem size.

Summarizing the experimental results, we conclude that for almost all parameter settings NCBB performance-wise dominates ADOPT, and DPOP dominates NCBB. However,

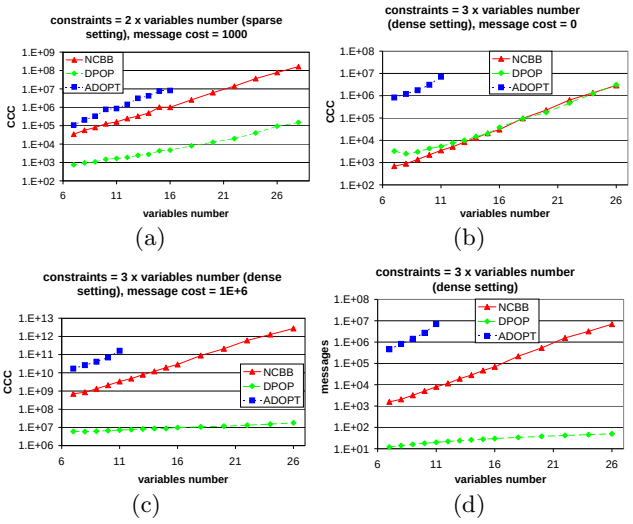

Figure 3: NCBB performance results

DPOP requires exponential memory on each agent, so it is not always applicable. For example, nodes in sensor networks have scarce memory, and it is enough even for one agent to not have enough space for DPOP to fail. For such applications NCBB may be the optimal choice given its performance advantage over another polynomial algorithm and the fact that NCBB is itself polynomial-space.

6. CONCLUSIONS

We have presented a novel backtracking-based algorithm for solving DCOP. It has polynomial memory requirements and uses messages of constant size. It offers significant performance improvements over the state of the art polynomial-memory algorithm ADOPT, and thus may be the optimal choice for settings with scarce memory, such as sensor nets.

ABSTRACT
This paper proposes a general solution model using agent technology in order to solve two critical open issues in the course timetabling problem: application-specific issues and dynamic-constraint issues. In our solution model, each agent in the system represents a constraint in the course timetabling problem. Compared to existing course timetabling solutions, the proposed agent solution model has much better generality, flexibility, dynamics, modularity and scalability.

Keywords: Multi-agent Architecture, Timetabling Problem

1. INTRODUCTION
There are fundamentally two open issues in the course timetabling problem [1-3, 8]. One is the application-specific issue in which a solution to one course timetabling problem may not be suitable for another one. The other is the dynamic-constraint issue in which the course timetabling problem becomes much harder when the constraints change dynamically. This paper proposes a general solution model using agent technology [4, 5, 9, 10] and attempts to solve the above issues using a system design approach. In this paper, the agent technology is based on the TEEMA (TRLabs Execution Environment for Mobile Agents) platform [7].

2. AN AGENT SOLUTION MODEL
No matter how different they are, any course timetabling problem will have certain common hard constraints: 1) no student has more than one course at the same time; 2) only one course is scheduled in a classroom at any one time; 3) the classroom assigned to any course is large enough to hold all enrolled students. Identifying the common hard constraints provides the basis to establish a general solution model for the course timetabling problem using agent technology.

A course is an event involving course name, class time, classroom and people, i.e., students and instructors. There are a set of constraints which govern the relationships between these entities. In the proposed agent solution model, each agent represents a constraint in the course timetabling problem. The model includes the following agents: the **CHC** Agent which represents the **C**ommon **H**ard **C**onstraints (identified above); the **HC** Agents which represent other additional **H**ard **C**onstraints (such as no class scheduled during the lunch break time); the **SC** Agents which represent the **S**oft **C**onstraints (such as no student assigned more than two classes consecutively). There is only one CHC Agent in the system. The number of HC and SC Agents depends on the specific course timetabling problem. The constraint agents are independent of one another. The system design is presented in three different modes of operation: the passive mode, the active mode and the parallel-active mode.

2.1 Passive Mode

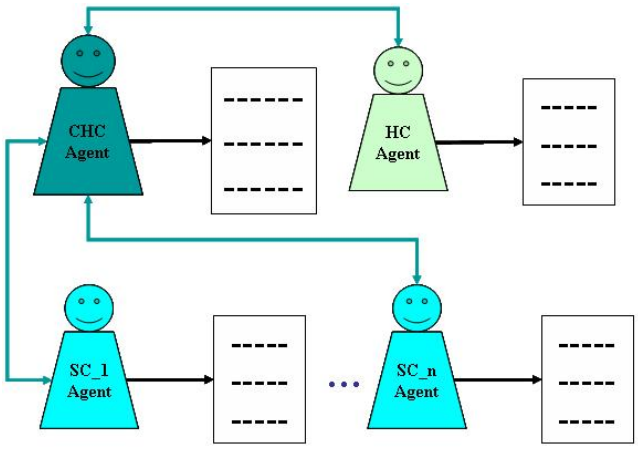

Figure 1. Passive mode of the general solution model

As shown in Figure 1, the passive mode general solution model is composed of one CHC Agent, one HC Agent and a number of SC Agents. The hard constraints can be represented by one HC agent (as shown in the figure) or a number of them (similar to the soft constraints). In order to simplify the illustration, only one HC

Agent is used. Generally, there are more than one soft constraint in the course timetabling problem. So in the solution model, the soft constraint agents are represented by the SC_1 Agent through SC_n Agent and the value of n depends on the number of soft constraints. The notepad symbol in the figure represents a course timetable. The solid polyline with bi-directional arrows between agents represents their communication. These symbol conventions will also apply in subsequent figures.

During the course timetabling process, the CHC Agent first produces a basic feasible course timetable consistent with the common hard constraints. Thereafter it sends a copy of the basic feasible timetable to each of other constraint agents. Each constraint agent evaluates the timetable based on its own constraint and sets penalty points on the number of constraint violations. These evaluations are sent to the CHC Agent and it develops an overall evaluation result on the basic feasible timetable. Following this, the CHC Agent creates a small disturbance to the timetable and guarantees that the disturbance does not violate the common hard constraints. The small disturbance can be realized by either moving one course to another available position in the timetable or exchanging the positions between two or three courses. As a timetable improvement proposal, the disturbance is sent to the constraint agents for evaluation. The constraint agents evaluate the proposal and provide feedback to the CHC Agent. After developing a new overall evaluation result on the modified timetable, the CHC Agent decides if the modified timetable represents an improved schedule. If the modified timetable is accepted, the CHC Agent will adopt it as the current best timetable and inform other constraint agents to make the same change. In this way, the system can guarantee that at any moment the course timetable carried by each agent is exactly the same. If the modified timetable is rejected, the CHC Agent will discard it. The CHC Agent then continues looking for a new proposal attempting to further improve the timetable. This process is repeated until all the constraints violations are eliminated and a final course timetable satisfying all the constraints is found. On the other hand, if the constraints violation can not be reduced further, the course timetabling process will go to the active mode described in the next subsection.

In this timetabling mode, only CHC Agent makes proposals and all the other constraint agents passively receive and evaluate proposals. For this reason we call this the passive mode.

2.2 Active Mode

The active mode is presented in Figure 2. From the figure it can be seen that each constraint agent has connections to all of others. In addition, there is a token which is passed around between the constraint agents. Only the agent owning the token has the right to make proposals to try to improve the course timetable and the proposals are guaranteed not to violate its own constraint. If a proposal violates the common hard constraints, it will be rejected because all timetables must always be basic feasible course timetable, even if they do not reduce other constraint violations. Otherwise, the timetabling process is similar to that described in the previous section.

In the active mode, all the agents equally contribute to improve the course timetable based on their own constraints. This allows the constraint violations to be reduced more effectively and efficiently. That is also the reason it is called the active mode.

If a solution can not be found after the token has been passed for a certain number of rounds among all the agents, the timetabling process is ended. Like other existing metaheuristics course timetabling solutions [6], the proposed method can not guarantee an optimal solution satisfying all the constraints. However, it has some key advantages over other existing methods which are identified in later sections.

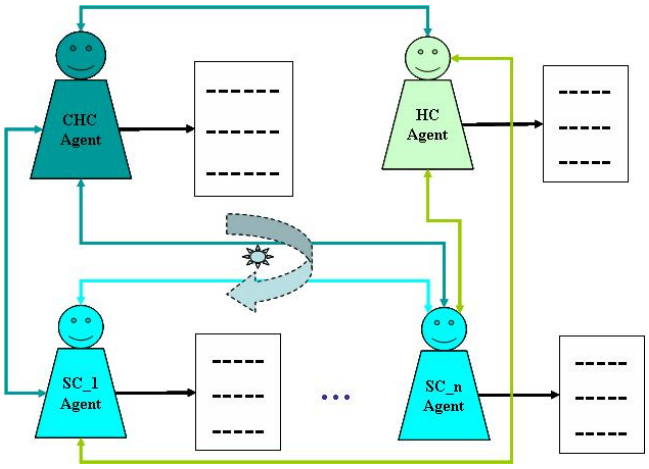

Figure 2. Active mode of the general solution model

2.3 Parallel-active Mode

The active mode can be further modified to make the token unnecessary allowing all the constraint agents to work in parallel. In this situation, the CHC Agent acts as a mediator to judge if the proposals are valid or not. Furthermore, each agent can adopt a different algorithm to create a hybrid and parallel course timetabling solution model. In such an operation mode, the system control would be much more complex, but it could be expected that the problem may be solved more quickly and more effectively.

3. EXPERIMENTAL RESULTS

The problem instances from Metaheuristic Network (http://www.metaheuristics. org/) are chosen to demonstrate the behavior of the new model. The problem description [6] is presented as follows:

The timetabling problem consists of a set of events to be scheduled in 45 timeslots (5 days of 9 hours each), a set of rooms in which events can take place, a set of students who attend the events, and a set of features satisfied by rooms and required by events. Each student attends a number of events and each room has a size. A feasible timetable is one in which all events have been assigned a timeslot and a room so that the following hard constraints are satisfied: 1) no student attends more than one event at the same time; 2) the room is big enough for all the attending students and satisfies all the features required by the event; 3) only one event is in each room at any timeslot.

Currently only the CHC Agent (representing the above three common hard constraints) and one SC agent (representing one of soft constraints in [6]: no student has a class in the last timeslot of

a day) have been implemented. The solution satisfying all the three common hard constraints and the mentioned soft constraint can be found through cooperation between the CHC Agent and SC Agent.

A portion of course timetabling results is shown in Figure 3. There are 45 timeslots (5 days of 9 hours each) and they are denoted by 0 through 44 in the implemented program. Timeslots No.8, 17, 26, 35, 44 are the last timeslots for each day of the week. Classrooms are denoted by integer numbers starting from 0. In the figure, the timeslot No.8 has no course scheduled. This is consistent with the soft constraint that students not have to attend the last timeslot of the day.

Time_Room	Room Size (No. of Students)	Event
	MONDAY	
7_0	9(9)	E28
7_1	2(2)	E74
7_2	3(3)	E29
7_3	11(10)	E25
7_4	15(15)	E32
Time Slot No.8: No event scheduled on this time slot!		
	TUESDAY	
9_0	9(9)	E31
9_1	2(2)	E83
9_2	3(3)	E88
9_3	11(11)	E37
9_4	15(15)	E43

Figure 3. A portion of course timetable

4. DISCUSSION AND FUTURE WORK

Although the quantitative assessment of the proposed solution model as compared with other existing course timetabling methods [6] has not been fully performed, some important qualitative advantages can be identified. Because each constraint agent is an independent module in the solution model, new constraint agents can be easily added into or removed from the timetabling system. This means that the dynamic-constraint issue is resolved through the system design. The proposed system design is extremely flexible, for example, course agents which represent individual courses can be added into the system. This would allow the proposed solution to adapt to the dynamic changes in schedule mandated even by individual courses.

The system design solves the application-specific issue in the course timetabling problem by allowing the user to select appropriate HC and SC Agents for their specific problem domain. The specific problem domain constraint agents make the solution model application-specific. Therefore the proposed solution is very general and flexible. The solution model's modularity means it can have any number of agents added into or removed from the system. This means there is a good scalability for the system as well.

The agents in the system can be mobile agents. In such a situation, the solution model can be used in the distributed environment and can take advantage of distributed problem solving. If the parallel- active mode (discussed in the subsection 2.3) is adopted, the proposed solution model will have the ability to solve problems in parallel.

To summarize, the advantages of the proposed solution model in this work over other existing approaches are as follows:

- Dynamic Problem Solving
- Good Flexibility and Generality
- Good Scalability and Modularity
- Distributed and Parallel Problem Solving

In order to explore the complete solution model, other soft constraint agent modules will be implemented. The parallel-active timetabling mode will also be investigated. Finally, quantitative comparison between the proposed solution model and other existing models will be made.

5. CONCLUSION

The proposed multi-agent general solution model for the course timetabling problem presented in this paper overcomes two key difficulties of the timetabling problem: application-specific issues and dynamic-constraint issues. The experimental results indicate that our model develops promising avenue of research in the course timetabling problem. It is reasonable to anticipate that the proposed solution model can be adapted to other scheduling problems.

ABSTRACT

The Multiagent Agreement Problem (MAP) is a special form of Distributed Constraint Optimization (DCOP) that requires agents to choose values for variables to satisfy not only their own constraints, but also equality constraints with other agents. We introduce the AdoptMVA algorithm, an extension of the existing Adopt algorithm, designed to take advantage of MAP domains where agents often control multiple variables. We also propose an approach to agent ordering which leverages known ordering techniques from the centralized and distributed constraint satisfaction literature and applies them to MAPs. By combining ordering at the agent level with orderings at the variable level, we hope to obtain efficient global orderings. While the contributions discussed in this paper are applicable to general DCOPs, we focus our evaluation on MAPs because we feel it is a significant problem class worthy of specific attention.

Distributed Constraint Satisfaction/Optimization

1. INTRODUCTION

The Multiagent Agreement Problem (MAP) is an instance of the more general Distributed Constraint Optimization Problem (DCOP) and is a convenient framework for representing coordination problems where multiple agents must come to an agreement for example on the time of a meeting or a joint action [7][5]. We propose AdoptMVA as an extension of the existing Adopt algorithm to operate more efficiently on MAPs where agents own multiple variables. The key idea is to use centralized search procedures to solve each agents' subproblem, in conjunction with the distributed Adopt algorithm to solve the broader problem. We show that when variable ordering is controlled for, AdoptMVA completes in fewer cycles than original Adopt on MAPs.

It is well known that the choice of variable ordering can have a large effect on the performance of a constraint-based search algorithm. Indeed, the choice of variable ordering becomes an even more important issue when we have multiple variables per agent. We define a set of inter-agent ordering heuristics for ordering at the macro-agent level and evaluate their comparative performance on MAPs using AdoptMVA. We present a general technique for converting existing effective variable orderings into effective agent orderings. In summary, by combining inter-agent ordering and intra-agent ordering heuristics and inventing AdoptMVA to exploit them, we enable a hierarchical approach to variable ordering in DCOP.

2. MULTIAGENT AGREEMENT PROBLEM

The Multiagent Agreement Problem (MAP) [7] is a special class of DCOP [6] in which a variable can be shared among multiple agents. The model can be made equivalent to a DCOP by giving copies of the variable to each agent and using inter-agent equality constraints to ensure agreement. We will use MAP definitions to aid in explaining experiments described in this paper. The components of MAP are defined as follows:

- $\mathcal{A} = \{A_1, A_2, ..., A_n\}$ is a set of *agents*.
- $\mathcal{V} = \{V_1, V_2, ..., V_m\}$ is a set of *variables*.
- $\mathcal{D} = \{d_1, d_2, ..., d_k\}$ is a set of *values*. Each value can be assigned to any variable.
- *participants*$(V_i) \subseteq \mathcal{A}$ is the set of agents assigned the variable V_i. The participants are responsible for choosing the value of V_i.
- *vars*$(A_i) \subseteq \mathcal{V}$ is the set of variables assigned to agent A_i.
- For each agent A_i, C_i is an *intra-agent* constraint that must be defined *only* over the variables in *vars*(A_i). C_i can be used to model an agent's local preferences for certain values.[1]
- For each variable V_i, an *inter-agent* "agreement" constraint is satisfied if and only if the same value from $\mathcal{D}$ is assigned to V_i by all the agents in *participants*(V_i).

[1]This is a generalization of the model introduced in [7] where C_i was required to evaluate to either true or false.

3. ADOPTMVA

The existing Adopt algorithm can be trivially adapted to handle problems in which an agent owns multiple variables by treating variables within an agent as virtual agents. However, this previous approach has the drawback that it artificially segments problem information within an agent and fails to take advantage of the full information sharing that is possible. We aim to eliminate this inefficiency by allowing full sharing of information within an agent. Our approach is to create a single process for each agent and allow it to control all of the variables owned by the agent. Then, a centralized search procedure is used to find the optimal solution for the agent's subproblem. We call this **AdoptMVA**, for Multiple Variables per Agent.

In the Adopt formalism, a value assignment to a set of variables is called a context and is defined as follows [6].

- Definition: A *context* is a partial solution of the form $\{(x_j, d_j), (x_k, d_k)...\}$. A variable can not appear in a context more than once. Two contexts are *compatible* if they do not disagree on any variable assignment. *CurrentContext* is a context which holds an agent's current knowledge of variable values for higher priority neighbors.

As defined in MAP, we let $vars(A_i) \subseteq \mathcal{V}$ denote the variables owned by agent A_i. We then denote a context $s \in S$ where S is the set of all possible assignments to variables in $vars(A_i)$ and s is a particular one of those assignments.

Whereas previously an agent owned only a single variable and so its cost was determined only by its constraints with other agents, we now must define a function that also includes the cost of constraints between variables *within* an agent. We define the *local cost* δ for a particular value assignment s made by agent A_i for the variables it owns as:

$$\delta(s) = \sum_{(x_j,d_j)\in s} \sum_{(x_i,d_i)\in s} f_{ij}(d_i, d_j) \quad + \sum_{(x_j,d_j)\in CurrentContext} \sum_{(x_i,d_i)\in s} f_{ij}(d_i, d_j) \tag{1}$$

The first half of the definition sums the constraints between every possible pairing of variables within an agent, and the second half evaluates the constraints between each of the agent's variables and all of the external variables in its *CurrentContext*.

An agent computes a *lower bound for a solution s* using lower bound costs received from its children, denoted as $lb(s, x_l)$.

- Definition: $LB(s) = \delta(s) + \sum_{x_l \in Children} lb(s, x_l)$ is a *lower bound* for the subtree rooted at A_i when A_i chooses solution $s \in S$.

Similarly for an *upper bound on solution s*:

- Definition: $UB(s) = \delta(s) + \sum_{x_l \in Children} ub(s, x_l)$ is an *upper bound* for the subtree rooted at A_i when A_i chooses solution $s \in S$.

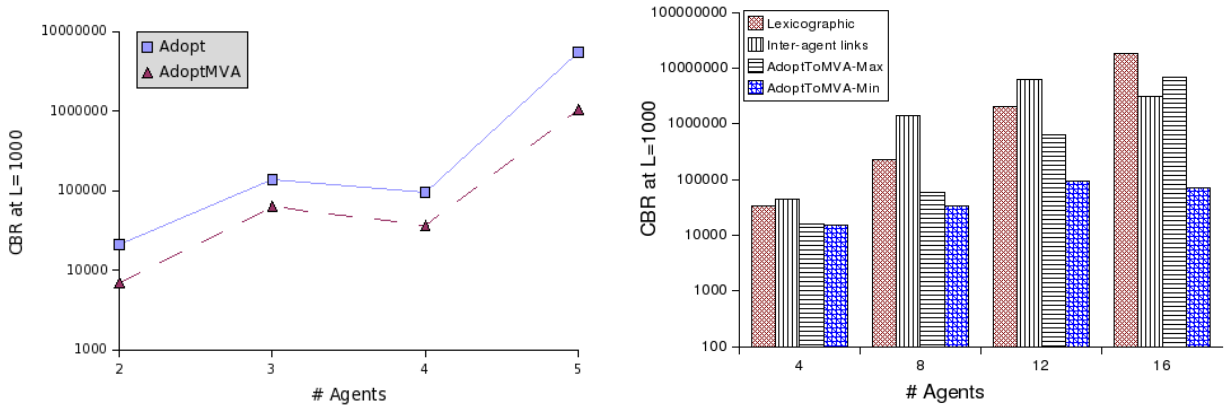
The overall lower and upper bounds for A_i are the minimums over the bounds for all possible solutions in S:

- Definition: $LB = min_{s \in S} LB(s)$ is a *lower bound* for the subtree rooted at A_i.

- Definition: $UB = min_{s \in S} UB(s)$ is an *upper bound* for the subtree rooted at A_i.

Algorithm 1: AdoptMVA Branch & Bound search

```
depth ⟵ 0
cost ⟵ 0
bestCost ⟵ ∞
procedure search( s ∈ S, depth, cost ):
if depth == s.size() then
    bestSolution ⟵ s
    bestCost ⟵ cost
    return;
end
V_i ⟵ variable at depth (order determined by variable ordering)
Domain ⟵ D_i
Reorder Domain with best-first heuristic (move current value of V_i in best known solution to be first)
for d_i ∈ Domain do
    s{V_i} ⟵ d_i
    cost+ = Σ_{(x_j,d_j)∈s} f_ij(d_i, d_j) +
    Σ_{(x_j,d_j)∈CurrentContext} f_ij(d_i, d_j)
    if depth == s.size() − 1 then
        cost ⟵ cost + Σ_{x_l∈Children} lb(s, x_l)
    end
    if cost < bestCost then
        search( s, depth+1, cost )
    end
    s{V_i} ⟵ null
end
```



The above definitions are based on the original Adopt definitions [6] with the main change being that lower and upper bounds are now calculated using a local solution context s rather than a single variable x_i. Also, the most important change to the local cost δ is that it now includes the cost of intra-agent constraints.

In order to properly communicate the values of an agent's local variables to the other agents in the problem, we also have to modify Adopt's VALUE messages and its handling of COST messages. In particular, VALUE messages must now include the values of all variables owned by the agent, rather than just a single variable value. Therefore, we extend VALUE messages to include a solution context:

- **Definition:** *VALUE(* $s_i = \{(x_j, d_j), (x_k, d_k), ...\}$ *)* is the form of the new VALUE messages sent to neighbors lower in the tree.

Finally, each agent uses a centralized Branch & Bound search [4] to find the optimal solution to its local variables, given the values of its ancestors in the Adopt hierarchy, and knowledge of the costs of its children. The search is used to calculate both the lower and upper bounds (LB and UB) on the agent's variables. Algorithm 1 shows pseudo code for the lower bound search (upper bound search is identical except $lb(s, x_l)$ is replaced with $ub(s, x_l)$). The value ordering is a best-first heuristic that puts the best domain value first in the search order for a given variable, where the best value is taken from the current best solution (if known).

Also note that the cost calculation in each step of the recursive search is not exactly the same as the δ function in Equation 1. Rather, the true cost of δ is reached at the bottom of the recursion because we add in the lower or upper bounds from our children at the end. This is so we don't redundantly calculate this cost at each recursion. If a bound for a child at the given solution s is not

(a) AdoptMVA versus Adopt

(b) AdoptMVA agent ordering heuristics

Figure 1: Experimental results on MAPs in the meeting scheduling domain.

known, the lower bound defaults to 0 and the upper bound to ∞.

4. ORDERING HEURISTICS

We define four inter-agent orderings, which are macro-level variable orderings used to determine the parent/child relationships in AdoptMVA.

- **Lexicographic** - Agents are ordered alpha-numerically by agent name. This is an uninformed heuristic.
- **Inter-agent constraints heuristic** - Agents are ordered recursively by the number of inter-agent constraints to already ordered agents. Ties are broken by the number of inter-agent constraints to currently unordered agents, and then lexicographically. This is a similar to the existing Brelaz variable ordering heuristic [1] except rather than counting all constraints, we only count inter-agent constraints.

The next two orderings were created based on the theory that many effective variable ordering heuristics exist and so converting them to an agent ordering might produce similar results. In particular, we can convert any given global variable ordering to an agent ordering by assigning agent priorities based on the priorities of variables within that agent. Given a prioritization of variables, a general technique for computing agent A_i's agent priority is as follows:

$$priority(A_i) = max_{\forall V_j \in vars(A_i)}\, priority(V_j).$$

Below are two heuristics that instantiate this theme.

- **AdoptToMVA-Max** - We first compute a global variable ordering using Brelaz [1], and then convert it into an agent ordering for AdoptMVA using the above conversion.
- **AdoptToMVA-Min** - This is the same as AdoptToMVA-Max except that agent priorities correspond to the *minimum* priority variable within each agent.

We will present experimental results for the four agent ordering heuristics. Although not presented here, we also investigated a set of heuristics suitable for MAP for ordering variables *within an agent*, i.e., intra-agent variable orderings. We evaluated their comparative performance and are able to identify an intra-agent variable ordering heuristic for MAP that is the most efficient of the ones tested.

5. RESULTS

We conducted experiments on MAPs used to model a meeting scheduling domain. More results than those presented here are available [2]. We present results in terms of the Cycle-Based Runtime (CBR) metric [3] which we believe is a more informative and fairer metric because it more closely approximates true distributed run-time than the previously used synchronous cycles metric. The formula for CBR is $CBR = Cycles * L + CCC$, where cycles is the number of synchronous cycles consumed by the algorithm, L is a factor indicating the relative communication speed, and CCC is the total number of concurrent constraint checks.

First, we compare the performance of AdoptMVA versus Adopt. To ensure a level playing field, we control for agent ordering using a static lexicographic agent ordering for both algorithms. We found that when agent ordering is controlled for, AdoptMVA has a lower CBR than Adopt (see Figure 1a). The results show that AdoptMVA would perform better than Adopt in systems with a high communication cost (L=1000).

Next, we compare four agent ordering heuristics on MAPs. Figure 1b shows our results. AdoptToMVA-Min was the best performing heuristic on the problems tested. We also saw that the agent ordering can make a tremendous difference. For some of the problems in Figure 1b, the difference between two heuristics is one or two orders of magnitude in size.

ABSTRACT
In this paper, we present the most important features of SeSAm, a modeling and simulation platform for multi-agent simulations. Based on a declarative, explicit model representation and visual programming, it allows implementing models on specification level. Optimizing compilation allows efficient simulation of the explicit model representation. It was successfully applied in different areas, like biology, traffic or logistics simulation.

1. INTRODUCTION
Agent-based simulation offers quite a lot of advantages compared to traditional (also microscopic) approaches, like the elegant representation of heterogeneous populations situated in heterogeneous environments, the explicit embodiment of local effects, or the possibility of flexible interaction between entities based on intelligent behaviour. These properties are the reason why the use of agent-based simulation becomes more and more popular. However, the development of a useful agent-based simulation makes great demands on the modeller as the properties that complicate the development of a multi-agent system also apply here. On a technical level this refers to concurrent processes, in-transparent feedback loops, etc. Additionally when constructing simulation models the freedom of design is restricted as the relation to the original system has to be established. The effort required for producing a structurally valid model with appropriate parameter settings, may be really high. A useful tool for modelling and simulation is highly valuable especially for modellers that are no programming experts. Meanwhile, a number of tools and frameworks for supporting the development of agent-based simulations are available. Most of them consist of a (Java-) class library that has to be extended by model-specific program code.

At the department of Artificial Intelligence and Applied Computer Science at the University of Würzburg (headed by Frank Puppe), we developed a modelling and simulation environment that combines concepts of declarative high-level model representation and visual programming. The initial aim behind our efforts was to provide a tool for beginners in modelling and programming. Scientists working mostly empirically should be equipped with a tool that allows them use modelling and simulation. The SeSAm team is headed by Franziska Klügl and currently consists of Rainer Herrler, Manuel Fehler, Cornelia Triebig and Gustavo Kuhn Andriotti. Also, several students are continuously contributing to SeSAm.

Besides usage in teaching, SeSAm is applied in several projects for simulation of social insects, reproduction of shopping behaviour, route-choice models in traffic simulation. Beyond such traditional application areas of agent-based simulation, SeSAm forms the technical base for virtual high bay warehouses that are used for software tests, requirements engineering or employee training.

SeSAm contains all components that are necessary for a useful simulation and modelling environment. Additional features – like debugging or refactoring – are inspired by tools for general software development and make SeSAm a valuable tool for rapid prototyping of agent-based simulations. The overall components are depicted in figure 1.

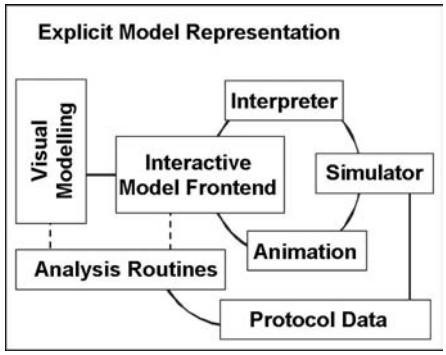

Figure 1: Components of the SeSAm system

In the following we want to focus on some innovative aspects, ignoring others like automatic calibration, integrated evolution, etc.

2. MODEL REPRESENTATION

Models are represented declaratively to assure the separation between simulator and actual model. The high-level modeling language consists of elements on different levels: So called primitives – agent actions, predicates for perception or other functions for processing information – are responsible for translating the declarative representation to executable code. With each model element a code fragment is associated that actually may realize the manipulations or queries. The description of a primitive is augmented with information concerning arguments or return value.

The state of agents, resources or the environment is represented by a body consisting of state variables. Behavior is specified using an activity graph that is derived from UML. An activity of an agent corresponds to a special state variable that determines the next action sequence of an agent. Rules are used for transition between activities. Thus, this agent behavior language has the power of a standard programming language. Not only agent models that are based on behavior description are represent-able using activity graphs, but – in combination with complex data structures – also simple agent reasoning may be reproduced.

Additional language elements allow a clear and efficient overall model representation. Examples are aggregated activities, which again may contain a complete activity graph, leading to a hierarchical structure. Model-specific primitives, data types or features enhance model entities with additional abilities. The language is extensible based on a plugin concept. Using the same language elements, the instrumentation and definition of experiment scripts containing several, differently configured simulation runs, can be managed. All information concerning the model is stored in a XML-file.

3. VISUAL PROGRAMMING

Based on the declarative model representation, visual programming is consequently applied not only for implementing the structure and behaviour of the agents and their environment, but also for data output generation, experiment scripting or constructing an interactive simulation GUI. The SeSAm design is based on the following principles:

- Complexity is hidden from beginners, but experts are allowed to use the full power
- Similar elements are always edited using similar editors
- No path for implementing a simulation model is a priori given, editors are accessible from all reasonable contexts
- Fault safety based on syntax tests and restriction of all input possibilities to syntactically correct ones.
- Documentation facilities for all model elements.

All elements of a SeSAm model and an executable simulation experiment are accessible via a central hierarchy. Structures are edited using forms, behaviour using graphs and situations may be constructed using maps. For activity transition rule conditions and all primitive calls, dialogs with three parts are given. On the left side the current function tree, in the middle possible absolute values and on the right side a list of all primitives that may be appropriate in the current model context. See figure 2 for a sample of screenshots.

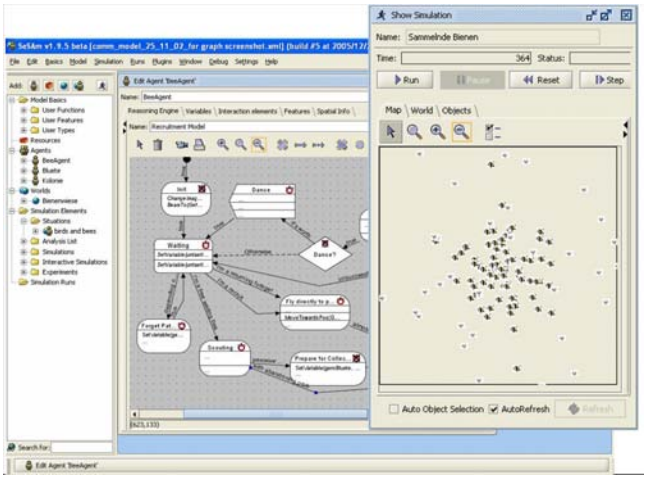

Figure 2: Screenshot of the SeSAm system: in the background an activity graph, in foreground a standard animation window.

Usability of SeSAm for development of agent-based simulation is additionally supported based on features known from modern software development environments. A stepper allows stepping through the behaviour of agents on the action level, a debugger allows to set break points for supporting the search for errors. A list of pre-defined refactoring actions helps to improve the model implementation design. However, a comfortable modelling environment is useless, if the actual simulations are not executable in sufficient speed. Therefore the declarative model representation is not interpreted directly, but compiled using optimization methods from compiler design.

Model-specific extensions or additional functionalities that are not available in standard SeSAm, can be added based on a plugin concept that enables to add primitives, data types or editors. A number of plugins, e.g. for data base connectivity, FIPA-ACL communication between simulated and real-world (JADE) agents, Ontology import (from Protegé projects) are downloadable from the SeSAm web site. Plugins also exist for different spatial representations like 2d continuous (standard), 3d or GIS vector data.

4. AVAILABILITY

SeSAm is developed under the LGPL license. Currently (Februar 2006), SeSAm 1.9.5 and several plugins may be downloaded for free from our SeSAm webpage: www.simsesam.de. We are preparing version 2.0 that will be available in summer 2006. SeSAm is based on Java 1.5, thus versions and comfortable installers for all popular operating systems are available. The possible number of simulated agents is depending on the memory configuration of the computer SeSAm runs on. Usually 512 MB are sufficient for larger models 1 GB and more are advisable.

Reasoning Under Uncertainty, Large-Scale Systems, Visualization

1. INTRODUCTION

Our Criticality-Sensitive Coordination (CSC) agents are designed to enhance the performance of a human-team working together in uncertain and dynamic settings by monitoring and adapting their plans as dictated by the evolution of the environment. Such situations model military scenarios such as a coordinated joint operations or enterprise settings such as multiple-project management. Among the many challenges in these situations are the large space of possible states due to uncertainty, the distributed / partial knowledge of current state and plan among the agents and the need to react in a timely manner to events that may not be in the original model. In fact, reaction alone is often insufficient as in environments where success depends on completing sequences of coupled actions, one needs to anticipate future difficulties and enable contingencies to alleviate potential hazards.

2. SYSTEM DESCRIPTION

To deal with these challenges, the CSC agents are constructed with components that interact in a multi-tiered manner with functionalities that operate in various time-scales and reasoning domains. The system architecture is depicted in Figure 1. The highest level of reasoning is performed by three components: (1) the deliberative scheduler, (2) the opportunistic scheduler, and (3) the downgrader. The deliberative scheduler is triggered when it has been determined that a portion of the existing plan is anticipated to fall below a certain likelihood of success. It then performs *dynamic partial-centralization* of the relevant agents and nodes in the plan, extracts potential solutions and proposes schedule modifications to remedy the problem. Due to the complexity of this task and the nature of the anticipated failure, this process occurs over several decision epochs with decision windows that begins slightly in the future. The opportunistic scheduler performs schedule modifications in the near-term. Using only local information, it is capable of making decisions on a faster time-scale, and buffers the existing plan by utilizing free resources. This provides robustness by increasing the probability of success and generating opportunities to obtain higher quality outcomes. The downgrader complements the previous two components by freeing resources both in the near-term and the future based on the evolution of the system up to the present. The schedule, estimates of system state and metrics of uncertainty are kept in the state manager which communicates with the state managers of other agents to distribute and collect locally visible and locally relevant information. The *profiles* capture the probability of success (p) and the importance (α) for the activities in the plan and are propagated in a decentralized manner. Each agent has profiles and schedules both for itself, for remote agents that affect it directly and for plan components for which it is responsible. The local schedule information is sent to an execution controller which interacts with the environment. This component is isolated such that it can operate at a much faster time-scale than the decision epoch intervals, such that the agent can continue to function even under high computational burdens in other components of the system.

3. DEMO DESCRIPTION

The capabilities of the system and the complexities of the problem are illustrated in a scenario where two subteams, represented by CSC agents Alpha and Bravo, participate in a three-phase joint project/operation. Intiially, they agree to engage in Plan A, which involve each agent's subteam performing certain activities at each phase. However, they can fall back to Plan B, which involves different activities at each phase, if needed. The activities are not independent as one may need to perform a certain activity in an earlier

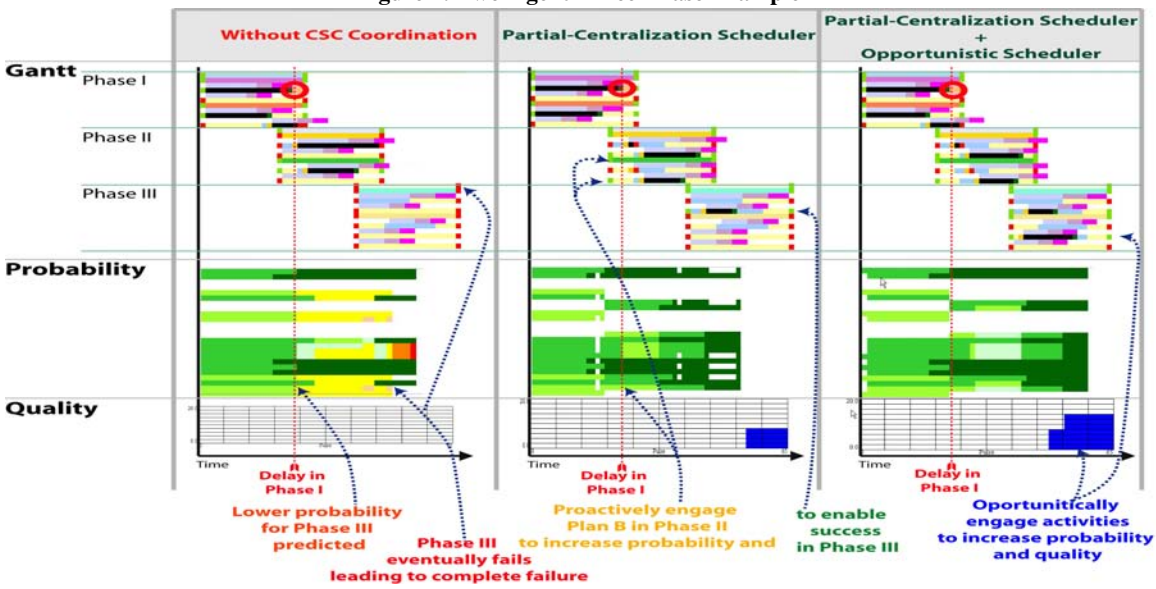

Figure 1: CSC Agent Architecture

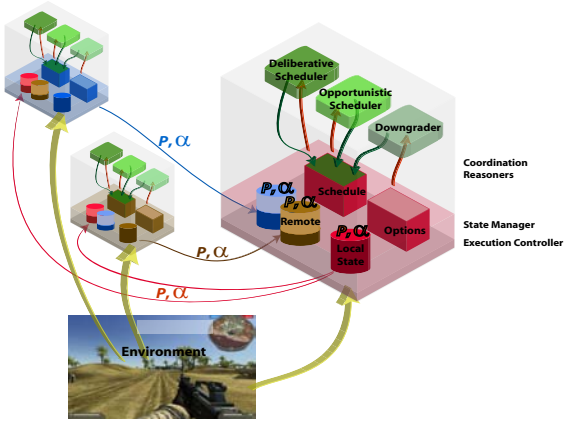

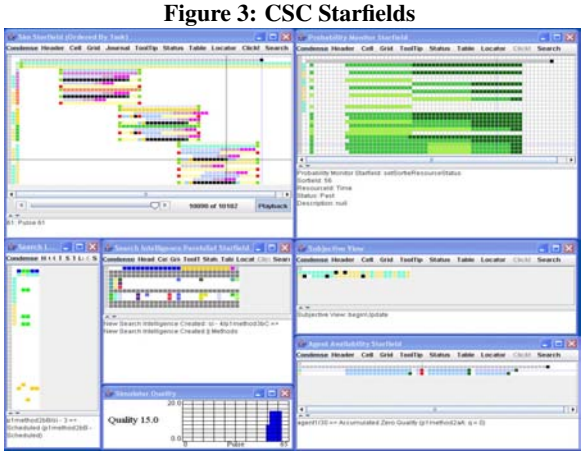

Figure 3: CSC Starfields

phase to have the option of performing an activity in a later phase. Thus, the necessity of anticipation in the presence of uncertainty. A depiction of an evolution is shown and discussed in Figure 2.

Without CSC, the initial plan can be undermined in many ways. A delay of an activity in Phase 1 cascades the delay on to Phase 2 implying a high chance of failure. While Phase 2 might succeed despite the failure of a single activity within it, Phase 3 will be completely damaged due to dependencies of activities across multiple phases. However, the various components of CSC interact to allow adverse circumstances to be ameliorated with ease. The state manager for the agent will detect in Phase 1 itself that the probability of success for activities in Phase 3 have fallen below critical levels and will instantiate dynamic partial-centralization by calling the deliberative scheduler. The deliberative scheduler will then consider alternatives, in this case Plan B, and install new activities in the second phase and third phase. The downgrader frees up the resources in Phase 2 that were operating under the directives of Plan A, such that they are available for Plan B to execute. Finally, the opportunistic scheduler utilizes resources that were freed up in Phase 3 (by the downgrader) to add an activity that enhances the quality of the solution.

4. STARFIELDS

One of the unique and extremely beneficial aspects of CSC is the vast suite of tools (referred to as *starfields*) available for visualizing various components and the evolution of the system. These tools offer the ability to observe behavior at a macro-level. This helps a user quickly and accurately gauge system behavior and also provides the ability to isolate individual components at particular instants in time which is an invaluable aid in debugging. A snapshot of selected starfields is displayed in Figure 3. A key functionality of starfields is the ability to play back any evolution in time to observe the system at chosen instants. This allows a user to identify exactly when and how the system identifies and resolves problems. Another key feature is the ability to search and cross-reference activities and plan components, which offers the capability to isolate an activity in multiple starfields and see how it couples with activities in other phases of the plan. The starfields facilitated rapid modification, development and debugging in addition to aiding in the understanding of the underlying problem which becomes difficult to grasp as the scale becomes large. A movie of the demonstration can be downloaded from *http://www.isi.edu/~szekely/csc/aamas06/csc-demo-v01.html*.

Synergistic Integration of Agent Technologies for Military Simulation

ABSTRACT

To perform large-scale coordination in real-world environments requires that many individually complex technologies come together to form integrated solutions. We present an application where several key technologies are integrated into a unified system via a multiagent infrastructure. We show how the synergistic behavior among heterogeneous technologies results in a significant improvement over the performance of the individual technologies acting alone. Critical extensions were required to the language describing required behavior to allow the pieces to work together. Initial experimental results show system performance on a task of coordinating a military convoy in an adversarial environment was significantly improved when all technologies worked together. However, experiments with a human user in the loop showed that significant advances must still be made before such systems can be fielded in the real-world.

MultiAgent Coordination, Simulation

1. INTRODUCTION

Autonomous coordination has rapidly progressed over recent years, with significant advances in both specific algorithms[7] and complete approaches to coordination being successfully demonstrated[6]. High bandwidth, widely available, low cost communcation and improvements in algorithm scalability are allowing significant advances in the number of agents able to be efficiently coordinated[9, 11]. Moreover, advances in artificial intelligence[8] and robotics mean that the robots and agents being coordinated are significantly more individually intelligent than in most previous multi-agent systems. This progress is quickly putting important, exciting applications of multiagent technology within reach. However, because there have been relatively few demonstrations of large scale, highly complex multi-agent systems, it is unclear whether existing automated coordination techniques are sufficient for these very complex systems or whether key challenges remain.

Many exciting multi-agent and multi-robot applications have been demonstrated in recent years. Systems including RETSINA-OOA[4] and the Electric Elves[2], have demonstrated coordination of heterogeneous sets of entities to achieve complex objectives. However, in many of these systems, much of the intelligence can be attributed to the coordination, with the individual agents being relatively simple, e.g., web services. Some military simulation environments involve both very complex individual technologies and large numbers of heterogeneous entities, but do not typically make extensive use of state-of-the-art automated coordination technology[1]. Thus, despite the obvious potential for automated coordination of large numbers of intelligent heterogeneous entities, there is a lack of sufficiently high fidelity systems that can expose key remaining challenges. Moreover, in most of these systems effective user control was not required, yet many real-world applications cannot be deployed without such control.

To better understand the challenges of complex coordination of intelligent entities, we have developed a simulation environment, called Sanjaya, where successful performance requires effectively dealing with these type of challenges. Sanjaya is a large scale military simulation where many realistic issues including uncertain sensing, diverse terrain, an intelligent adversary, large numbers of units and complex plans, are modeled. A sophisticated terrain analysis agent[5] provides the team with expected locations of opposing forces and safe paths for travel. A sensor fusion process is available to take sensor readings from multiple sources and reduce uncertainty when distinguishing between opponent and civilian vehicles. Importantly, a human commander has high level control and makes decisions to strike identified opponents. Each of the system components is able to use input from the other components and provide input to those components. Intuitively, synergies should occur in Sanjaya, since the various agents should be able to mutually provide each other

with input to improve performance.

A variety of distinctly different approaches to coordination exist, developed to meet specific goals and have specific properties. Due to the dynamic nature of the fundamental task of moving and protecting convoys of ground vehicles, we choose to apply *teamwork* based coordination, since it is designed to be flexible and robust, key requirements for this domain[3]. The specific proxy-based implementation of teamwork that we use executes user designed *team oriented plans* instantiated at runtime from templates[10]. While team oriented plans have been used extensively in the past, when attempting to apply them to this domain, we encountered two key problems, both related to the production and use of information during coordination. First, the plans did not have sufficient semantic content to allow the proxy to determine where information produced during plan execution should be directed. For example, when the terrain analysis agent generated a least resistance path, it could not determine what to do with the path. Second, some tasks within a plan could not be initiated until other tasks within the plan produced information to completely specify the task, but there was no way of specifying this. For example, a task for protecting a convoy could not be allocated until the path of the convoy was determined. Extensions adding additional semantics, but not changing the declarative nature of the TOP's were implemented.

While automated coordination and intelligent robot and agent technology is rapidly advancing, human intelligence is staying constant. Several previous investigations have shown that human interaction with intelligent distributed systems is extremely difficult, sometimes even leading to poorer performance than the system on its own[12]. A key interface design issue is how much of the underlying intelligence to make opaque to the user and how much to make transparent. In Sanjaya, we took the approach that when the details of the intelligence reasoning were not critical to the human's reasoning, they were made completely opaque. We performed an initial set of user tests with some users being in control of a system with all the intelligent agents performing and another set of users using a less intelligent system with the same interface. Our results showed that users actually performed relatively better with a less intelligent system, indicating that significant advances need to be made before users can exert effective control over very complex multiagent systems.

2. SANJAYA

Sanjaya is a constructive simulation supporting simulation of ground, air and unmanned aerial vehicles. The scenario being tested consists of five convoys of ground vehicles each supported by a group of unmanned aerial vehicles (UAVs), traveling across a 50km by 50km map defended by 20 opposing tanks. This is a challenging scenario for a number of reasons.

The UAVs have a limited sensing range, and there are not enough of them in the scenario to patrol the entire map. Obviously intelligent coordination is necessary to use the UAVs efficiently. When an opponent has been found the UAVs may be used to attack the oppoent, but in doing so the UAV destroys itself. As we have a limited number of UAVs in the scenario, each UAV used to attack further reduces our ability to sense, and to destroy any further opponents found.

Sanjaya simulates an uncertain sensing environment. Sensor readings return a list of possible classifications of sensed objects, with a probability associated with each classification. In the scenario being simulated, sixty trucks, representing civilian noncombatants, are placed on the map and may be confused with enemy forces. UAVs, are a limited resource and must be conserved to attack those entities that we are reasonably certain are actual opposing forces. This means that we must have a reasonably high confidence classification of a sensed entity as a military, non civilian entity before we issue a command to attack it.

Unlike other currently available simulation environments, Sanjaya simulates the kind of uncertainty and confusion that can occur in large scale coordination in real-world environments. We find this type of simulator necessary to study the challenges that large scale real-world coordination poses. Furthermore, this type of simulator is necessary to determine potential synergies that can occur while coordinating complex entities and technologies.

Results illustrate that the infrastructure was able to produce synergies between the individual technologies. However, individual technologies did not always improve overall performance. Importantly for the future deployment of complex multiagent systems, initial user testing showed that users were not able to take full advantage of available technology and often made system performance worse.

{Nathaniel.Gemelli, Robert.Wright, James.Lawton, Andrew.Boes}@rl.af.mil

ABSTRACT

Asynchronous Chess (AChess) is a platform for the development and evaluation of real-time adversarial agent technologies. It is a two-player game using the basic rules of chess with the modification that agents may move as many pieces as they want at any time. Modifying chess in this way creates a new robust, asynchronous, real-time game in which agents must carefully balance their time between reasoning and acting in order to out-perform their opponent. As a fast-paced adversarial game, many challenges relevant to real-world applications arise which give it merit for study and use.

1. INTRODUCTION

We present Asynchronous Chess [2] as a real-time adversarial software-agent demonstration and competition for AAMAS 2006. Asynchronous Chess (AChess) is a platform for the development and evaluation of real-time adversarial agent technologies. It is a two-player (i.e. *agent*) game using the basic rules of chess with the modification that agents may move as many pieces as they want at any time. Modifying chess in this way creates a new robust, asynchronous, real-time game in which agents must carefully balance their time between reasoning and acting in order to out-perform their opponent. As a fast-paced adversarial game, many challenges relevant to real-world applications arise which give it merit for study and use. We believe AChess will be of added value to researchers in the Artificial Intelligence field, and be well received as an AAMAS demonstration/competition.

2. ACHESS DESCRIPTION

AChess is a chess-like game. In the game, players are allowed to move as many pieces as they wish at any point during the game. It has the same board, the same pieces, and the same piece movement patterns as standard chess. The main difference between AChess and regular chess is that it removes the rule in which players must take turns. There are other differences between AChess and standard chess that were found to be necessary to make AChess a well-defined game. These differences include:

1. Any piece may be moved at any time as long as the piece is not already in the process of moving.
2. Pieces, including knights, traverse paths through squares to reach their destinations instead of teleporting.
3. Pieces traverse individual squares at specified rates that are specified based on the piece type (i.e. King, Queen, Bishop, Knight, Rook, Pawn).
4. Pieces cannot change directions while a move is being carried out. Agents must wait for a piece to finish its current movement before submitting a new move for the piece.
5. There is no check-mate. Kings must be captured.

3. ACHESS FEATURES AND CHALLENGES

AChess is a fully observable environment. A central server acts as a referee and supplies both players with a complete view of the game environment. This view includes the current positions of all the pieces and which pieces are currently in the process of moving. The only information agents do not have is where the moving enemy pieces are moving to and exactly how long it has been moving.

AChess is a stochastic environment. There is randomness in the AChess system. AChess simulates continuous time with extremely fine-grain discrete time steps. In the event that two or more pieces attempt to enter a square at the same time, the server randomly chooses one to enter the square. The other pieces are either killed or prevented from

moving. This challenges agents to handle the uncertainty in the environment.

AChess is an episodic environment. Agents in competition will compete in a set of matches consisting of a series of games between two agents. This will give agents with learning capabilities a chance to repeatedly measure their performance against competitors and learn from their experience.

AChess has an extremely large state and search space that the agents must manage. A normal game of chess has a search space size on the order of 10^{40} [1]. AChess has an exponentially larger search space because of the ability to move more than one piece, and potentially all the pieces, asynchronously. In addition, pieces can be in a state of movement (*not even on a square!*) which drastically increases the size of the state space.

Finally, AChess challenges agents with heterogeneous capabilities. The agents must effectively utilize pieces with different movement rates and movement patterns. This challenge is missing in many other competitive agent environments and is one of the more interesting features of AChess.

4. ENVIRONMENT ARCHITECTURE AND LOGISTICAL REQUIREMENTS

The AChess environment/server is implemented in Java and communicates to the agents with strings of text over standard TCP/IP sockets. This enables interested parties to develop their agent solutions using any language or platform they choose. It also allows the agents, environment, and visualizations to be resident on separate platforms, which in turn helps to prevent competitors from interfering with each other or the performance of the environment itself.

For the competition the matches will be run across four machines, two of which will be identical platforms for the agents (each team), over a local area network. One machine will host the AChess server (the environment), and the last machine will host the visualizations. Four machines are required to enable each agent, the server, and the visualization to have their own computing platform. The machines will all be using the same operating system and be configured to be identical platforms for all competitors. The final decision on the operating system will be made at a later date and will be made based on competitor preference and logistic considerations.

5. COMPETITION DESCRIPTION

The competition will be run as a tournament consisting of rounds. Agent implementations will compete against one another in matches which will consist of a specified number of games. The final number of games in a match will be decided just before the start of the tournament and will be based on the number of entries. A large number of games per match are preferred, but the number of games may need to be small in the interest of time. The winner of a match will be determined by which agent was able to accumulate the most wins during the course of the match. Winners of matches will proceed to the next round until ultimately there is a single winner.

For the conference we will invite any and all interested parties to enter their own AChess agent into the competition. Well before the conference a version of the AChess environment will be provided to the public (via download) along with an API for agent development. Competitors will have to submit a final version of their agent to be used in the competition by a specified date.

In the competition the board will be the standard 8 by 8 square sized board. Pieces will be positioned in the standard chess layout at the start of the game. The piece rates, which determine how quickly pieces may traverse individual squares, will be defined at a later date.

ABSTRACT

$\mathcal{A}$-**globe** [2, 1] is a freeware, simulation-oriented multi-agent platform featuring agent migration, communication inaccessibility simulation and high scalability with moderate hardware requirements. Using dedicated simulation messaging together with 2D and 3D visualization support, large agent systems can be engineered, tested and visualized on a single machine. $\mathcal{A}$-**globe** agents are fully-fledged JAVA agents, each with its own independent thread, that can autonomously migrate between platforms running on different hosts. Thanks to the separation of simulation and agent code, deployment of agents to embedded devices is straightforward. The platform is not natively FIPA-compliant, as the inter-operability was sacrificed to offer superior scalability and efficiency.

Figure 2: ACROSS scenario visualization.

1. A-GLOBE SIMULATION SUPPORT

$\mathcal{A}$-**globe** includes a special infrastructure for environmental simulation. Besides the *actor agents* that play roles in the simulated world, *environment simulation agents* (ES) are located in a dedicated master container. Instead of using messages, they communicate with actor agents by *topic messaging*, container-to-container messaging specifically reserved for environmental simulation, as shown in Fig. 1. Topic messaging is managed by GIS Service – a special $\mathcal{A}$-**globe** service to which the actor agents subscribe to receive various topics. If such a topic is received by the container, it is distributed to all subscribed agents. Note that all agents in the container receive the same data, because the environment perception shall be identical for all collocated agents. In addition, the agents who wish to act on the environment can submit topics to the GIS service. These topics are then sent to all ES agents in the master container subscribed to receive the topic. ES agent can be responsible for nearly any simulation layer. However, *accessibility agents*, who control the existence of communication links between agent containers, occupy a privileged place between ES agents. $\mathcal{A}$-**globe** message layer uses this information to actually prevent messaging between inaccessible nodes. Simulated accessibility can depend on many factors, typically including the distance.

2. ACROSS DEMONSTRATION

To illustrate the concepts of the platform design we will present the ACROSS scenario – Agent Complex Reasoning Simulation System that uses the $\mathcal{A}$-**globe** features to create a relatively rich world where diverse types of agents can interact. A simplified economy on an island based on Java (Indonesia) geography is simulated, see Fig. 2 and 3. Currently, we use this scenario as a common base for multiple research targets, where we need to investigate interactions between a relatively high number of fully-fledged agents. In the scenario we solve a logistics problem in a non-collaborative environment with self-interested agents. Agents that are part of the scenario have no common goals and their cooperation is typically financially motivated.

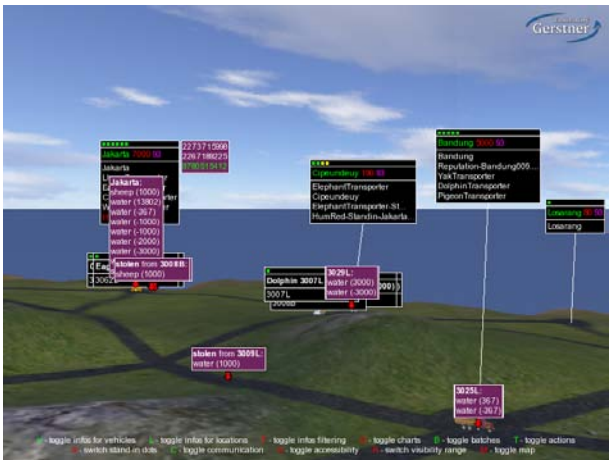

Figure 3: Representation of physical cargo in the ACROSS scenario.

3. ATC DEMONSTRATION

Our second demonstration illustrates how agents can be used for the negotiation-based de-confliction in the Air-Traffic Control (ATC), Fig. 4 and 5. The agents are responsible for aircraft simulation and airways planning. The core of the system consists of (1) the server component – that simulates positions of aircraft and other objects in the simulated world, aircraft hardware, weather conditions, communication ranges; and (2) the plane component – agents simulating aircraft behavior. One of them – a *pilot agent* is the main control unit of the simulated aircraft handling negotiation-based de-confliction. It processes radar data and communicates with the respective pilot agent. Each plane has its own flight mission which can be time constrained.

The system has been integrated with three external geographical and tactical data sources available online: NASA, U.S. Geological Survey (USGS) and Geographic Names Information System (GNIS) database. The system also provides real-time 2D/3D visualization: either locally and/or via a remote web client running inside any compliant internet browser.

4. CONCLUSION

Both demonstrated systems illustrate unique $\mathcal{A}$-**globe** features: superior scalability and efficiency, that allows us to define complex agent societies on restricted resources and advanced simulation support that clearly separates simulation and visualization from agent decision-making.

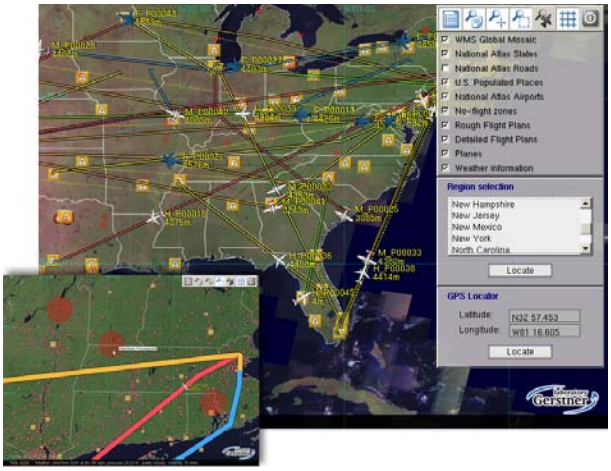

Figure 4: ATC system integrates several external data sources.

1. UAV COLLISION AVOIDANCE

As technology advances, unmanned aerial vehicles (UAVs) are capable of more complex missions. Miniaturization results in a migration of capability from larger to smaller UAV platforms and in cost reduction. According to the DoDs Unmanned Aircraft Systems Roadmap 2005-2030, military UAVs are now required to execute intelligence, surveillance, reconnaissance, strike, suppression of enemy air defense, electronic attack, communications, aerial delivery, and resupply missions. It is therefore evident that UAV developments require a more intelligent and autonomous airspace and mission management approach then ever.

The modern battlespace may be crowded with urban buildings, manned and unmanned aircraft, restricted operational zones, and direct and indirect fire. For UAVs to avoid colliding in such a crowded environment is challenging. We suggest an intelligent way to detect potential collisions and find alternative routes. Our suggested solution is based on centralized and distributed coordination approaches. The autonomous airspace management system will choose, in real time, the suitable solution that will assure collision avoidance.

The airspace management system will consider the following approaches:

1. Centralized, in which an airspace management center detects possible collisions and applies alternative routes for them
2. UAV deconfliction, in which the airspace management center detects potential collisions but allows the UAVs to find alternatives
3. UAV detection, in which the airspace management center informs each UAV of its neighbors, thus allowing the UAV to detect and adjust its own flight plan
4. Distributed, in which the airspace management center is completely incommunicable, and the UAV must become aware of its neighbors, detecting and deconflicting prospective collisions
5. Isolated, in which there is no communication between the airspace management center and the UAVs or between UAVs

2. SYSTEM APPROACH AND PATH PLANNING

Our UAV path planning is defined by complex Bezier curves that express the physical constraints of a UAV, such as maximum speed, minimum turning radius, velocity, and acceleration. Two points and two vectors representing the entrance and exiting speed of the UAV define a Bezier curve. In this demonstration, each UAV has its own mission defined as a tuple of destination (longitude, latitude, altitude), deadline, and utility. The utility is the dimension we sum across all the UAVs to estimate the overall success. A mission is achieved if the UAV reaches its destination before the deadline. There is no partial utility, because each mission is achieved or not achieved. At the beginning of the simulation, all UAVs have a valid path (not necessarily conflict free) that meets the deadline. The first step of the algorithm is to detect if there is a possible conflict in any UAV paths. We use an octree algorithm to quickly find all conflicts. A conflict is composed of a 4D point in space (longitude, latitude, altitude) and time and all UAV paths that intersect at this 4D point. The list of conflicts is then passed to a solver that finds new conflict-free paths. This process is obviously iterative, because choosing a different path may result in one or more conflicts.

To add complexity, we have introduced a manned aircraft (controlled by a joystick connected to the system) that each UAV must avoid while maintaining the maximum number of deadlines and missions. The manned aircraft broadcasts only its position and heading, and all the UAVs must adapt their path to not collide with it. To handle the manned aircraft, each UAV considers a set of possible paths and checks all of them for possible conflicts.

Our demonstration is composed of two laptops. One laptop runs the manned aircraft user interface with the joystick; the other laptop runs the simulation and our deconfliction algorithm. The accompanying screenshots illustrate the simulation and user interface

design, experimentation

1. INTRODUCTION

The Multi-Agent Coordination and Control (MACC) testbed is a modelling and simulation environment for manufacturing control.

Manufacturing control is the operational level of production planning and control. It is the decision making activity concerned with the short-term and detailed assignment of operations to production resources.

The testbed uses a multi-agent Manufacturing Execution System (MES), developed at K.U.Leuven PMA [1]. A MES is a manufacturing control information system that supports the execution on the shop floor. This support ranges from tracing the execution to supervising the process control systems, the routes that products follow and the assignment of operations to production resources.

Current MES implementations do not support handling of disturbances. Disturbances are handled by operators on the shop floor today. If deliveries are late, clients change orders or machines break down, they try to deal with the problem, respecting the given requirements as good as possible (e.g. due date).

Operators on the shop floor however only have limited insight on how the rest of the system will react as a consequence of their decisions. Therefore they mainly rely on their experience in dealing with the disturbances they encounter.

Using multi-agent technology, the PMA multi-agent MES supports operators in taking these decisions, improves their insight in the consequences these decisions will have and allows for self-organization.

The testbed consists out of several tools:

- a modelling tool
- a web-based simulation service
- a simulation log browser

Results of the simulation can be twofold: studying the dynamics of the modelled systems or calculating performance criteria.

The testbed tools are written in Java and run on any platform supporting Java.The tools can be started from the website without seperate software installation (http://www.mech.kuleuven.be/benchmarking).

2. TESTBED ARCHITECTURE

The architecture of the testbed is structured into three main software components:

2.1 Test-Bench Assistant

The Test-Bench Assistant is a visual environment for assisting the designer of a test-bench case in inputting all the main data of the industrial case he/she wants to propose to the scientific and industrial community.

The data, describing an industrial case, comprise [2]:

- The production system taken as a reference (production system model):
  - the structural features: the physical configuration of the production system.
    - the physical components (workstations, transporters, storage) and their capabilities (sawing, milling, ...).
    - the layout of the plant
  - the technological features: the process plans of the products being processed in the plant
  - optionally, a planning indicating start, end times and the machine to be used for the various operations.
- Dynamic information about the industrial case :

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. Figure 1: The test bench assistant

– The plant scenario:

events or activities related to the functioning of manufacturing physical components (e.g. machine breakdowns, stochastic variations on setup times and operation processing times)

– The operational scenario:

* Production orders
* Expected due dates and release dates
* Disturbances like stock breackage, or changes in orders, due dates or release dates.

2.2 TestBed Simulator

A web-based simulation tool for the experimentation, testing and performance analysis of submitted scheduling strategies (without visualisation). The simulation tool takes the input of the test-bench assistant and generates a simulation log, describing the state of the factory and the short term forecasts through the simulation run. Any performance measures can be calculated, based on this log.

2.3 The log browser

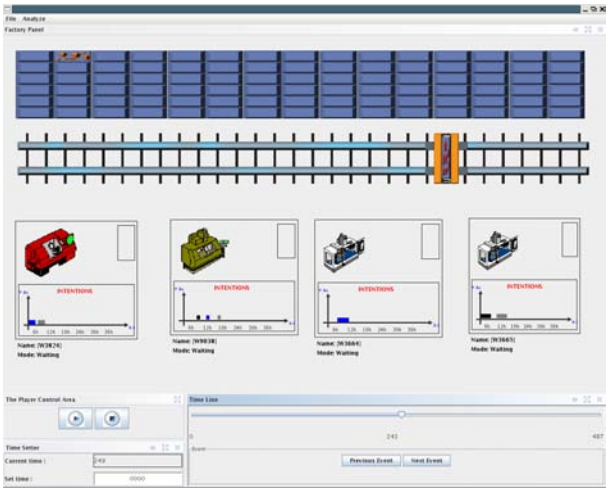

Figure 2: The log browser

The log browser visualizes the simulated factory, the production execution and the short-term forecasts.

A short term forecast indicates the work that has to be carried out in the next shift(s). This forecast automatically adapts in case of changing circumstances (new orders, delays in execution, missing parts, ...).

3. BENEFITS

The testbed provides the following benefits:

- Providing a common base for integrating manufacturing control and scheduling strategies into existing systems.

  The case model has to be modelled only once and can be combined with different control strategies. If new strategies are available, they can be tested on the case.

  The control strategy does not have to solve the whole problem. If no solution is given for part of the problem, the agents in the MES self-organize.

- Provide more insight to operators on the shop floor when taking decisions.

  The short term forecast described earlier, supports operators by providing the possible short-term future states of the underlying system. When changing jobs sequences or the starting time of a job (e.g. for maintenance), every entity involved gets an updated forecast.

- Provide more insight to developers in the applicability of their algorithm in various industrial cases.

  The testbed allows to collect industrial cases and to make them available to the research community. This shortens the time for conducting experiments significantly and increases the industrial relevance of the results.

4. FUTURE WORK

Future efforts aim to expand the possibilities for integrating planning strategies into the MES. For now, the MES follows the planning if it is feasible. If not, it searches a feasible alternative. Subject of further work is to allow the MES to search the feasible alternative that corresponds the most to the original planning [3].

Furthermore, the design of the MES allows to provide plug-ins, e.g. a custom scheduler for a physical component or a custom strategy for chosing between alternatives for a production order. In the future, the test-bed assistant will provide a graphical interface for this task.

This manuscript presents work supported by the K.U.Leuven Research Fund (Concerted Research Action on Agents for Coordination and Control).

ABSTRACT

We demonstrate our game theory-based Texas Hold'em poker player. To overcome the computational difficulties stemming from Texas Hold'em's gigantic game tree, our player uses automated abstraction and real-time equilibrium approximation. Our player solves the first two rounds of the game in a large off-line computation, and solves the last two rounds in a real-time equilibrium approximation. Participants in the demonstration will be able to compete against our opponent and experience first-hand the cognitive abilities of our player. Some of the techniques used by our player, which does not directly incorporate any poker-specific expert knowledge, include such poker techniques as bluffing, slow-playing, check-raising, and semi-bluffing, all techniques normally associated with human play.

1. INTRODUCTION

In environments with multiple self-interested agents, an agent's outcome is affected by actions of the other agents. Consequently, the optimal action of one agent generally depends on the actions of others. Game theory provides a normative framework for analyzing such strategic situations. In particular, game theory provides the notion of an *equilibrium*, a strategy profile in which no agent has incentive to deviate to a different strategy. Thus, it is in an agent's interest to compute equilibria of games in order to play as well as possible.

Games can be classified as either games of *perfect information* or *imperfect information*. Chess and Go are examples of the former, and, until recently, most game playing work in AI has been on games of this type. To compute an optimal strategy in a perfect information game, an agent traverses the game tree and evaluates individual nodes. If the agent is able to traverse the entire game tree, she simply computes an optimal strategy from the bottom-up, using the principle of *backward induction*. This is the main approach behind minimax with α-β-pruning. These algorithms have limits, of course, particularly when the game tree is huge, but extremely effective game-playing agents can be developed, even when the size of the game tree prohibits complete search.

Current algorithms for solving perfect information games do not apply to games of incomplete information. The distinguishing difference is that the latter are not fully observable: when it is an agent's turn to move, she does not have access to all of the information about the world. In such games, the decision of what to do at a node cannot generally be optimally made without considering decisions at all other nodes (including ones on other paths of play).

The *sequence form* is a compact representation [7, 5, 10] of a sequential game. For two-person zero-sum games, there is a natural linear programming formulation based on the sequence form that is polynomial in the size of the game tree. Thus, reasonable-sized two-person games can be solved using this method [10, 5, 6]. However, this approach still yields enormous (unsolvable) optimization problems for many real-world games, most notably poker. In this research we apply automated abstraction techniques for finding smaller, strategically similar games for which the equilibrium computation is faster. The resulting strategies can then be used as approximate solutions to the original game. We have chosen poker as the first application of our equilibrium approximation techniques.

2. POKER

Poker is an enormously popular card game played around the world. The 2005 World Series of Poker featured more than $100 million dollars in prize money in several tournaments. Increasingly, poker players compete in online poker rooms, and television stations regularly broadcast poker tournaments.

Due to the uncertainty stemming from opponents' cards, opponents' future actions, and chance moves, poker has been identified as an important research area in AI [2]. Poker has been a popular subject in the game theory literature since the field's founding, but manual equilibrium analysis has been limited to extremely small games. Very recently, there has been considerable progress in tacking larger games. In a recent paper [4], we developed automated abstraction techniques, and applied them in computing *optimal* strategies for Rhode Island Hold'em poker [9], a smaller version of Texas Hold'em that is still over four orders of magnitude larger than previously solved poker games.

2.1 Texas Hold'em

Texas Hold'em is perhaps the most popular version of poker. It is the game that is used to determine the world champion at the annual World Series of Poker. In the demonstration we will be playing *heads-up*, in which there are just 2 players (in this case, a human player versus our player). The players alternate turns being player 1 and player 2. Player 1 is considered the *small blind*, and player 2 is the *large blind*. Before any cards are dealt, the small blind contributes one chip to the pot, and the large blind contributes two chips to the pot. Both players then receive two cards each, face down; these are known as the *hole cards*.

After receiving the hole cards, the players take part in one betting round. The small blind goes first. Each player may check or bet if no bets have been placed. If a bet has been placed, then the player may *fold* (thus forfeiting the game), *call* (adding chips to the pot equal to the last player's bet), or *raise* (calling the current bet and making an additional bet). In Texas Hold'em, the players are usually limited to four raises each per betting round. In this betting round, the bets are in increments of two chips.

After the betting round, three community cards are dealt face up. These cards are called the *flop*. Another betting round take places at this point, with bets equal to two chips.

Another community card is dealt face up. This is called the *turn* card. Another betting round takes place at this point, with bets equal to four chips.

A final community card is dealt face up. This is called the *river* card. Another betting round takes place at this point, with bets equal to four chips.

If neither player folds, then the *showdown* takes place. Using the seven available cards (the two hole cards and five community cards), the players form their best 5-card poker hands. The player who has the best 5-card poker hand takes the pot. In the event of a draw, the pot is split evenly.

3. TECHNICAL OVERVIEW

The main contribution of our work is the application of automated abstraction techniques to a real-world game. Previous work has been limited to much smaller games. In this section we give a brief overview of our development of a Texas Hold'em poker player. A detailed description of our player is available in a separate paper [3]. There are two types of abstraction employed in our approach: state-space abstraction and round-based abstraction.

In our previous work [4] we developed techniques for *automatically* reducing the size of a game tree (a form of state-space abstraction) in order to make equilibrium-finding algorithms practical. We apply our algorithm, *GameShrink*, to the various game trees we encounter in the computation of strategies.

In addition to state-space abstraction, we also employ round-based abstraction. In our approach, we first solve for an approximate equilibrium for a truncated game involving only the first two rounds. We do this by solving a large linear program in an off-line computation. After the turn card appears, our player computes updated card probabilities based on observed behavior, and then computes an equilibrium approximation for the third and fourth rounds in *real-time*. The abstractions we employ in computing this equilibrium approximation are *dynamically* determined based on the information (*i.e.* community cards) revealed so far in the game. This allows our computation to focus on the specific portion of the game tree relevant to the current hand.

Round-based abstraction has been used in previous poker work [9, 1]. The primary difference with our approach is the fact that strategies are computed dynamically, using observed information to achieve a closer approximation. Furthermore, the sizes of the individual models are larger. For example, optimal strategies for pre-flop Texas Hold'em have been computed [8]. This approach requires modelling 169 distinct hands. Our model not only considers 169 hands in the first round, but also 2465 hands in the second round. Solving this model requires 18.8 GB of RAM and takes 7.1 days. In addition, our abstractions are automatically computed, rather than manually designed by an expert.

Some features of our computed strategies include poker techniques such as bluffing, slow-playing, check-raising, and semi-bluffing, all techniques normally associated with human play. In this demonstration, participants will compete with our opponent and will experience these strategies first-hand.

ABSTRACT
A near real time multi agent based system for scheduling ocean fleets has been developed. The ocean scheduling problem has relatively low numbers of cargos and vessels to deal with but it is highly complex in terms of constraints and numbers of options. It also has a high rate of events affecting the schedule and different fleet operators have differing goals for the parameters of their schedule. This variability is dealt with by storing knowledge of this in ontology.

1.INTRODUCTION
Based on the multi-agent and semantic web technologies, Magenta's Ocean i-Scheduler exhibits behavior that is fundamentally different from behavior of conventional schedulers. For example, it: refers to business domain knowledge while generating schedule options; reviews and if necessary modifies previously made decisions when a problem situation changes; plans users' activities (sequences, options, iterations) taking into account user defined goals, strategies and constraints; designs and conducts experiments to improve decision making; constructs models of problem situations; explains its decisions to users and works on scheduling continuously improving the specified enterprise value without a need to be switched on by users.

2.DEMONSTRATED FEATURES
The Ocean planning and scheduling domain is characterized by:

- Typically a few (<10) orders per day to be planned
- One vessel carries one cargo
- One voyage has one collect and one drop operation
- Refueling (bunkering) is a critical operation
- Canals (Suez, Panama) have specific logic of operation
- All vessels have their own, unique parameters
- Voyages times measured in a few to over 100 days
- Many options to consider in planning, with scope to make changes to plans
- Multiple objectives for fleet schedule (minimize idle days, minimize days when ship carries ballast rather than cargo, and maximize voyage profits etc.)

The Ocean i-Scheduler uses agents operating in a virtual market place to generate options for assigning cargos to ships and options for dealing with events that affect the schedule. Events that can be handled include:

- arrival of new cargo
- cargo parameters changed
- vessel late
- vessel early
- cancel cargo
- vessel breakdown
- re-schedule cargo
- owner events such as Off-hire or Dry-dock

The system has agents representing vessels, ports, cargoes, and customers. They operate in a virtual market and use ontology to understand parameters of the fleet, ports and canals, and to understand the objectives of the fleet as a whole. Events are planned by creating a new agent to represent that event. Vessels which are potentially affected by the event are selected. For each selected vessel a new variant of the schedule is built. The variants are built using a journey time matrix and a set of scheduling algorithms. The scheduling algorithms are hierarchical in nature. First an Open Slot' search is carried out. Is there a vessel available to take the cargo at the desired time? If not is it possible to 'Shift' an existing cargo in time so that the vessel can then take the new cargo? If not is it possible to 'Swap' the cargo with another cargo and then reschedule the replaced cargo? This can involve a deep combinatorial analysis of swap options. The variants are ranked according to the decision making logic (DML) in the ontology. The DML is user adjustable and can be weighted towards optimizing several objectives as described above.

The agent negotiations are an auction type competition for resources. The market has a concept of virtual money that the

agents use in their negotiations. Demand agents bid for resources using their money. Decisions are made based on all agents trying to achieve the best return for themselves. The agents are created and destroyed on demand as events occur and new schedules accepted.

This incremental planning approach to new events allows near real time responses to events (typically options are generated in a few tens of seconds) and presents a human scheduler with a set of ranked options to choose from.

2.1System Features Based on the Multi-Agent and Semantic Web Technologies

- Near real time incremental planning
- Decision making logic for defining user-specific preferences. This would typically be a trade of between minimizing costs, maximizing revenue, and maximizing customer service or service level agreements.
- Support of ocean-specific constraints (e.g. sizes of vessels versus port capabilities and canal sizes)
- Key Performance Indicator (KPI) calculation mechanism (fleet, vessel and voyage KPIs) and possibility to define, store and add new KPIs in ontology
- Event-driven continuous planning of fleet resources as demands (new orders) and fleet events occur
- Scheduling/rescheduling vessels according to "maximize profit of the fleet as a whole" criteria
- Support of scheduling of majority of ocean fleet events.

2.2User Interaction with the System

- Rich visual and text based reports
- Support of main users: executive team, scheduler team, chartering team, IT team;
- Decision making audit trail that keeps records;
- Decision making queue that provides strong visualizations, simulations and analytics to help users compare schedule options, drill into details, consider how to overcome potential constraints and then make decisions that will be immediately be updated into fleet schedule;
- Web-based UI with multi-user environment.

3.RELATED PROJECT

The first commercial customer for Magenta's Ocean i-Scheduler is Tankers International (TI), one of the largest VLCC (Very Large Crude Carriers) oil tanker pools in the world which is using Magenta's multi-agent technology to schedule its fleet in real time. The oil transportation market is extremely volatile with transportation costs fluctuating on a daily basis. Therefore, TI has to be able to deal with unexpected circumstances and operate from an optimized schedule. The Magenta's Intelligent Fleet Scheduler allows TI to assess potential cargoes in the marketplace, match these against its vessels' specifications and calculate voyage profitability. Within TI scheduling system, Magenta's multi-agent technology works by allocating a single agent to each element of entire fleet. Unlike other traditional systems, agents are also able to resolve conflicts as they are not bound by rigid rules and work around problems. Furthermore, having presented the best solutions to the operations team, the agents continue to work to provide alternative solutions to ensure that any unforeseen factors, such as changing freight rates or vessel positions, are reacted to dynamically.

The multi-agent Intelligent Fleet Scheduler allows Tankers International to

- Dynamically schedule ships in a fleet to respond to new cargo opportunities in real time; plan/re-plan to find options and suggest a decision, support decision-making process for planning and implementing of these plans; react to unforeseen changes in contracts, coming of new contracts or canceling of existing ones; enable cooperation of several vessels for executing of one order;
- Capture scheduling knowledge that was previously kept in the head of one scheduling specialist;
- Simulate complex dynamic solutions on the market of oil transportation for the estimation of effectiveness of made decisions: "what-if"?
- Simulate individual behavior models of tankers, ports, routes and orders: agents find knowledge about these objects in their ontologies and flexibly adapt themselves to the current situation.

4.CONCLUSIONS

The following features provided by using the multi-agent technology will be demonstrated during the demo session:

- Near real time scheduling;
- Capturing of business domain knowledge and decision-making logic in the ontology;
- Scheduling engine supports complex planning features in a flexible way: canal passage, bunkering operation;
- Support of wide range of fleet events;
- Powerful mechanisms for KPIs calculation;
- Easy to play "what-if" games;
- Current workflow allows analyzing/comparing options and market opportunities;
- Web-based user-specific reports and dashboards
- Teamwork support.

Participatory, Embodied, Multi-Agent Simulation

ABSTRACT
We will demonstrate the integration of a software-based multi-agent modeling platform with a participatory simulation environment and real-time control over a physical agent (robot). Both real and virtual participants will be able to act as agents in a simulation that will control a physical agent. The backbone of this demonstration is a widely used, freely available, mature modeling platform known as NetLogo.

1. WHY IS INTEGRATION GOOD?
Multi-agent simulation is a powerful technique used to encode real-world simple rules in virtual agents and then simulate their interactions [1]. Participatory simulations are similar to multi-agent simulation except individuals play the role of the virtual agents, sometimes in combination with the virtual agents [2]. In addition, an extensive amount of multi-agent research has gone into examining how to embody agent control within a physical entity [3]. All three of these areas are concerned with the creation, manipulation, and development of agents in one form or another. Thus combining these three disparate systems in to one unified platform would be useful. Of course, multi-agent simulation platforms, participatory simulation systems, and robotic systems have all been demonstrated to a large degree in the past. However many of these systems were not designed to be integrated, and thus combining these existing platforms is difficult if not impossible.

We will demonstrate a single platform (NetLogo) that supports simulated agents, participatory agents and physical agents [4]. Moreover this platform is freely available, widely used, and easy to learn. By enabling all three types of interaction to be combined in one modeling environment NetLogo facilitates development of systems and simulations that combine these aspects without the need for learning multiple platforms and then attempting to connect them to each other.

2. A MULTI-AGENT MODELING PLATFORM (NETLOGO)
NetLogo is a mature multi-agent modeling platform. It has been developed for over 8 years at the Center for Connected Learning and Computer Based Modeling which is under the leadership of director Uri Wilensky and is currently located at Northwestern University [4]. NetLogo has an estimated twenty thousand current users. With NetLogo, one can model complex systems with thousands of interacting agents, and study the connection between the micro-level rules and the macro-level "emergent" patterns. Agents can be either moving entities or stationary cells as in a cellular automaton. Thousands of these agents follow rules in the simulated system, acting in parallel and affecting other agents, both moving and stationary. NetLogo has found use by many natural and social scientists as a research tool and has also been adopted as a successful element of curriculum by hundreds of educational institutions. The emergent phenomena modeled span a wide range of domains including ecosystems, economies, organizational change, and molecular interactions and reactions. Figure 1 illustrates a typical NetLogo model of flocking behavior.

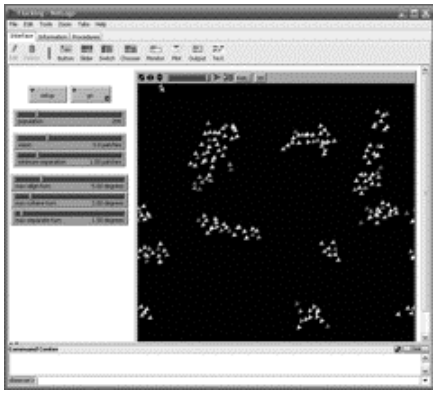

Figure 1: A NetLogo Model of Flocking Behavior.

3. PARTICIPATORY SIMULATION (HUBNET)

In a participatory simulation individuals act out the roles of agents in a complex system [2]. The behavior of the whole system is not defined ahead of time but instead emerges from the participation of various individuals in the simulation. This emergent behavior can then be displayed back to the group as a whole through a central server with the results usually projected on a screen at the front of the room. **HubNet** is the name we have given to the NetLogo architecture designed to enable individuals to participate in a simulation of a complex dynamic system. HubNet enables many users at individual computers or other devices to control the behavior of agents and to view the aggregated results on a joint display. The individual devices can be a mix of different hardware systems (programmable calculators, computers, or handheld devices) that are able to run the Java-based NetLogo platform. The network layer implements flexible communication protocols that include the ability to upload and download data sets, monitor key-presses at the individual level, support real-time interaction as in network computer games, and form collaborative groups of various sizes (e.g., peer to peer, small groups, and whole-group modes). Figure 2 illustrates a HubNet setup just before it was utilized in a classroom.

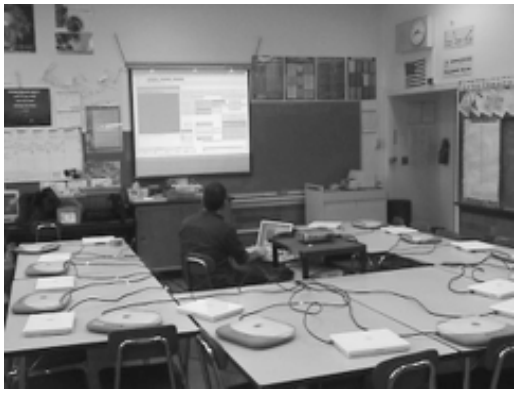

Figure 2: A HubNet Setup About To Be Used.

4. INPUT/OUTPUT TO THE REAL WORLD (NETLOGOLAB)

The **NetLogoLab** module enables users to perform real-time sensing and control, using a standard serial port robotics interface [3]. With various kinds of sensors (temperature, chemical composition, pH, humidity, light, distance, etc.), modelers can feed their models with environmental data, process it, and then control various kinds of actuators (motors, light bulbs, relays, LEDs). Being completely integrated into NetLogo, this module can make use of all the features of the modeling environment. Applications range from model calibration and validation to building robots, interactive simulations and autonomous vehicles. For this demonstration, we will connect a robot to the NetLogo model, and then let it be controlled in three scenarios: a self-contained pre-programmed agent-based model, a sensor-enable apparatus activated by environmental variables (such as human presence, light or temperature) and by humans interacting in a networked simulation, using HubNet. There will also be some basic construction and electronics materials for participants to modify the physical agents and try out different ideas for sensing and control. Figure 3 illustrates a typical NetLogoLab experiment.

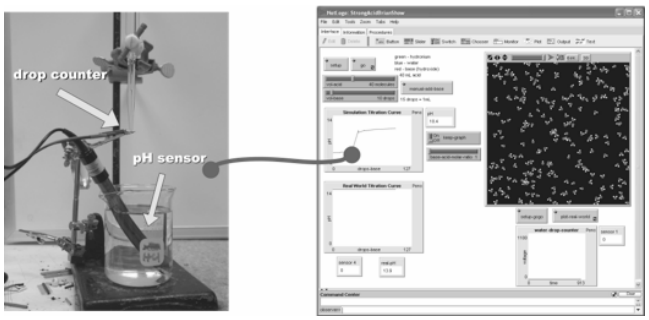

Figure 3: A Typical NetLogoLab Experiment.

5. INTEGRATION AND SUMMARY

The **NetLogo** platform provides the backbone for the integration and the place where the virtual agents are located. **HubNet** then provides a distributed interface into that platform for users to participate with the simulation. **NetLogoLab** then provides an output from the NetLogo platform to control robotic agents, as well as sensor input. In our demonstration we will begin by showing off NetLogo and a few of the hundreds of models that are built in to the NetLogo models library. From there we will progress to demonstrating both the HubNet and the NetLogoLab technologies independently. Finally, we will combine all of these aspects in a participatory simulation where people will work with virtual agents to control a robotic device.

To recapitulate, we plan to demonstrate all three aspects of the NetLogo modeling platform separately, then combine them in a simple proof-of-concept simulation to demonstrate the power behind a platform that seamlessly integrates virtual, participatory, and robotic agents in one package. We feel that this demonstration will excite and entertain a wide variety of researchers who are looking for an easy to learn, powerful multi-agent platform to utilize for experimentation within one of these three fields or any combination.

ABSTRACT

The ability to create reliable, scalable virtual organisations (VOs) on demand in a dynamic, open and competitive environment is one of the challenges that underlie Grid computing. In response, in the CONOISE-G project, we are developing an infrastructure to support robust and resilient virtual organisation formation and operation. Specifically, CONOISE-G provides mechanisms to assure effective operation of agent-based VOs in the face of disruptive and potentially malicious entities in dynamic, open and competitive environments. In this paper, we describe the CONOISE-G system, outline its use in VO formation and perturbation, and review current work on dealing with unreliable information sources.

1. INTRODUCTION

The engineering of systems using approaches that establish a fixed organisational structure is not sufficient to handle many of the issues inherent in open multi-agent systems (in particular, heterogeneity of agents, trust and accountability, failure handling and recovery, and societal change [1, 2]). Such issues are becoming increasingly important in the context of Grid computing, which aims to enable resource sharing and coordinated problem-solving in dynamic, multi-institutional virtual organisations (VOs) [1]. VOs provide a way of abstracting the complexity of open systems to make them amenable to application development. The organisational structure, participant responsibilities, synchronisation concerns and economic mechanics of the VO are hidden from the VO user.

While the notion of VOs underpins the vision of Grid computing, the conditions under which a new VO should be formed, and the procedures for its formation, operation and dissolution, are still not well-defined. This automated formation and ongoing management of VOs in open environments thus constitutes a major research challenge, a key objective of which is to ensure that they are both agile (can adapt to changing circumstances) and resilient (can achieve their aims in a dynamic and uncertain environment). In addition to traditional constraints that relate to issues such as resource management and bidding strategies, we must also consider softer constraints relating to contract management, trust between VO participants and policing of contracts.

The CONOISE-G project (Grid-enabled Constraint-Oriented Negotiation in an Open Information Services Environment, website at *http://www.conoise.org*) is directed at addressing just these issues. It seeks to support robust and resilient VO formation and operation, and aims to provide mechanisms to assure effective operation of agent-based VOs in the face of disruptive and potentially malicious entities in dynamic, open and competitive environments.

In particular, to operate an effective VO in open, dynamic and competitive environments, it is essential that we also consider how to encourage good interactions, and cope effectively with bad ones. In our view, this requires that QoS levels are monitored, that uncertainty in participant behaviour, possibly arising from self-interest and strategic lying and collusion, is minimised, and that mechanisms for recognising and addressing contract violations once they have occured are established. Addressing these concerns is integral to the wide-scale acceptance of the Grid and agent-based VOs.

2. THE CONOISE-G ARCHITECTURE

In essence, the CONOISE-G architecture comprises several different agents, including *system agents* and *service providers* (SPs), as in Figure 1. The former are needed to achieve core system functionality for VO formation and operation, while the latter are involved in the VO itself.

Copyright 2006 ACM 1-59593-303-4/06/0005 ...$5.00.

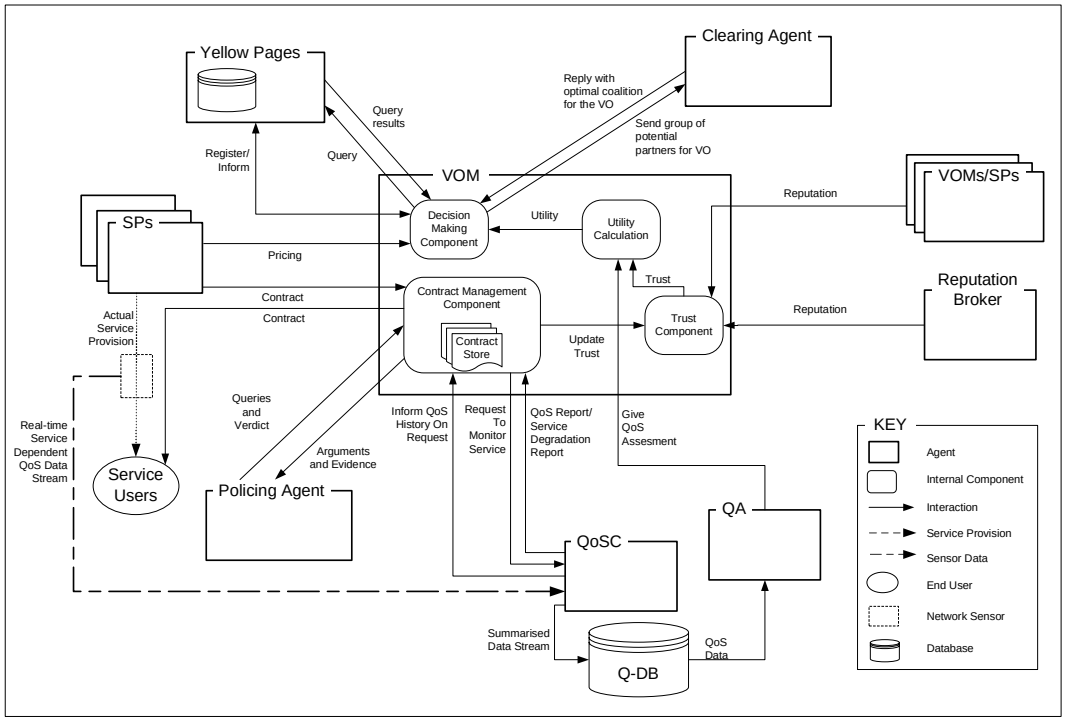

Figure 1: The CONOISE-G architecture

Assuming that service providers have already advertised their services to a Yellow Pages agent (YP), the VO formation process starts with a particular SP acting on behalf of a user, the Requester Agent (RA), which analyses the requester's service requirements, locates the relevant providers through the YP, and then invites the identified providers to bid for the requested services. The quality and trustworthiness of the received bids are assessed by the Quality Agent (QA) and the trust component respectively, and the outcome is combined with the price structure by a Clearing Agent (CA) [3] to determine which combination of the services/providers will form an optimal VO (in terms of price, quality and trust) for the requester. At this point, the VO is formed and the RA takes on the role of VO Manager (VOM), responsible for ensuring that each member of the VO provides its service according to contract.

During the operational phase of the VO, the VOM may request the QoS Consultant (QoSC) to monitor any services provided by any members of the VO, and any member of the VO may invoke the Policing agent to investigate any potential dispute regarding service provision. Ultimately, our aim is for monitoring to take place to inform the user when the actual service level diverges from the agreed service level. At present, however, this is achieved by configuring the levels of QoS for each service that will cause the QoSC to alert the VOM, using predetermined service provision and quality level simulations. When the QoS provision of a service in the VO falls below an acceptable level of service, or some breach of contract is observed, the QoSC alerts the VOM, which initiates a VO re-formation process; relevant information is fed into the trust component to ensure that the provider concerned is penalised to an appropriate level by updating its record of trust.

In this re-formation process, the VOM issues another message to the YP requesting a list of SPs that can provide the service previously provided by the failed SP. As before, the YP identifies possible SPs, bids are received and evaluated, resulting in the CA determining the best SP to replace the failed provider. At this point, the VOM re-forms the VO with the new SP replacing the old one, and instructs the QoSC to stop monitoring the old SP and to monitor the new one instead.

3. CONCLUSIONS

The work described in this paper takes an approach in which issues relating to the formation and operation of robust VOs in the dynamic environments with unreliable agents are considered. In contrast to the "brawn" of the Grid, we have concentrated on the "brains" [1] — on the development of techniques for autonomous problem-solving in VOs. Thus, we have described an agent architecture for re-forming VOs in the face of unreliable information, through the use of a range of techniques that support robust and resilient VO formation and operation for application to realistic electronic commerce scenarios.

ABSTRACT

We demonstrate the basic features and advantages of Automated Argument System based on Logic of Multiple-Valued Argumentation by applying it to three convincing arguments: (i) Argument-based recommender system, (ii) Schedule management system and (iii) An integrated system of semantic web reasoning and argument-based reasoning.

1. INTRODUCTION

Arguing is a powerful tool we use individually and socially in the daily life. This is also true in agents' world. Computational argumentation has been accepted as a social computing mechanism or paradigm in the multi-agent systems community.

Argumentation is by nature a logic of reasoning under uncertain or changing information environment. Logic of Multiple-valued Argumentation (LMA) was built on top of Extended Annotated Logic Programming EALP [7]. It is a very generic logic of multiple-valued argumentation in the sense that it allows to specify various types of truth values depending on application domains and to deal with uncertain arguments under the speci ed truth values.

Permission to make digital or hard copies of all or part of this work for personal or classroom use is granted without fee provided that copies are not made or distributed for profit or commercial advantage and that copies bear this notice and the full citation on the first page. We are going to demonstrate our system with three convincing arguments: (i) Argument-based recommender system, (ii) Schedule management system and (iii) An integrated system of semantic web reasoning and Argument-based reasoning. In doing so, we connect three sites on the Internet: Hakodate conference site, Niigata University in Niigata and Shibaura Institute of Technology in Saitama, where arguing agents and a mediator agent reside in.

2. OUTLINE OF EALP AND LMA

EALP (Extended Annotated Logic Programming) is an expressive logic programming language we formalized for argumentation. The basic language constituents are literals associated with annotations as truth-values or epistemic states of agents. LMA is A Logic of Multiple-valued Argumentation constructed on top of EALP. In this logic, three notions of negation: epistemic, ontological and default negation play a crucial role in argumentation since they turn to yield a momentum or driving force for argumentation. We have soundness and completeness for LMA under the x-point semantics based on the acceptability of arguments and the dialectical proof theory [7]. LMA was implemented in C++/Java and Prolog, where each agent has its own knowledge base in EALP, and a complete lattice of truth values and argument engine are shared among agents concerned (see Figure 1).

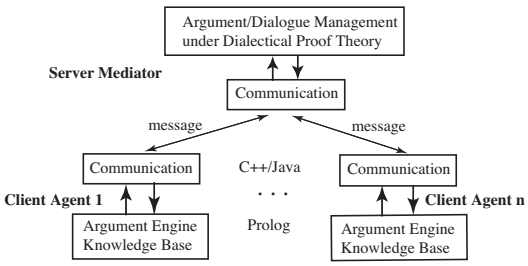

Figure 1: Argument system architecture

3. ARGUMENTS IN DEMONSTRATION

3.1 Argument-based recommender system

Chesñevar and Maguitman propose ArgNet, a recommender system that integrates a traditional web search engine with a defeasible argumentation framework [2]. We demonstrate an improved version of ArgNet by using our LMA in place of their two-valued argumentation framework, so that LMA with its truth-values specialized to $\mathcal{FOUR} = (\{\bot, \mathbf{t}, \mathbf{f}, \top\},$) allows for uncertain argumentation.

3.2 Schedule management system

Schedule management problems are typical targets for which agent systems have been developing their capabilities such as interaction, negotiation, cooperation and so on. We demonstrate a new approach to realizing a schedule management system as LMA-based argumentation system. Then participating agents use not only calendar information but also preferential knowledge base of their own in EALP. The truth values used is a complete lattice of the unit interval of reals $\Re[0, 1]$.

3.3 An integrated system of semantic web reasoning and argument-based reasoning

We will demonstrate an integrated system of semantic web reasoning and argument-based reasoning.

Semantic Web has started to attract much attention as the next-generation web technology. In 2004, the W3C recommended the OWL Web Ontology Language as standard ontology languages for the Semantic Web, which has three increasing expressive sublanguages, namely OWL lite, OWL DL, and OWL full. On the other hand, as shown by Horrocks and Patel-Schneider [6], ontology entailment in OWL Lite and OWL DL reduces to knowledge base (un) satis - ability in the description logics such as the DL $\mathcal{SHIF}$(D) and the DL $\mathcal{SHOIN}$(D) respectively. Though tableaux theorem proving techniques have been commonly used with respect to reasoning ontologies expressed by description logics (or DL, for short), quite recently, many logic programming approaches have been proposed such as Heymans et al.'s method [5] , Baral's method [1] and so on which make use of *answer set programming* (or ASP, for short) [4].

In such progress of the Semantic Web technology, we have implemented a prototype system for the Semantic Web reasoning which can handle ontologies expressed by the DL $\mathcal{SHOIN}$(D) or OWL DL, and can be accessible to and from LMA-based argument system (specialized to two values $\{f, t\}$) on the Web (see Figure 2). It consists of three components, that is, ontology translations done in two steps and ontology reasoning via ASP as follows:

1. Translation of ontology expressed by OWL DL into the one expressed by the DL $\mathcal{SHOIN}$(D) (or vice versa) though the current prototype does not support XML schema primitive datatypes as well as datatype roles.
2. Translation of ontology expressed by DL into *Disjunctive Logic Programs* (or DLPs, for short) based on Heymans et al.'s method or Baral's method,
3. Query evaluation w.r.t. knowledge base (i.e. ontologies) expressed by a DLP using the ASP solver *dlv* [3].

The translation of the rst component is established by using XSLT. With respect to the second component, let $KB = Tbox \cup Abox$ be a knowledge base which is a nite set of axioms expressed by $\mathcal{SHOIN}$(D). Then an axiom F is a *logical consequence*of KB, denoted $KB \models_{DL} F$, i every model of KB satis es F.

Heymans et al. considers the DL $\mathcal{ALCHODQ}(\sqcup, \sqcap)$ which di ers from the DL $\mathcal{SHOIN}$(D) by its lack of transitive roles, inverse roles, and data types. In their method, $\mathcal{ALCHODQ}(\sqcup, \sqcap)$ knowledge base are expressed by *conceptual logic programs* (or CLPs, for short) whose syntax is the restricted DLP. CLPs extend Answer Set Programming with, possibly in nite, open domains, which leads, in general, to undecidable reasoning. Thanks to restricting the syntax of DLPs, reasoning with the resulting CLPs can be reduced to nite, normal Answer Set Programming, for which e cient ASP solvers (e.g. *dlv*)[3] are available.

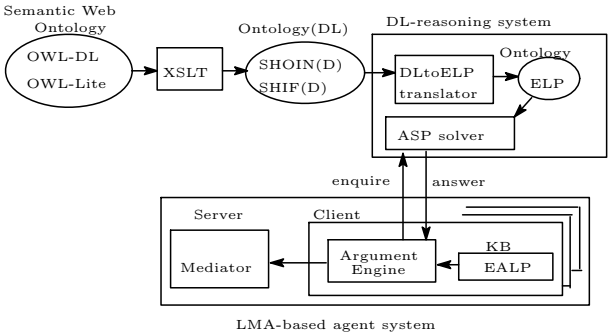

Figure 2: WebArg system architecture

In the demonstration, we show how the semantic web reasoning brie y described above interacts with LMA-based argumentation system. It then attempts to construct arguments with both the usual knowledge base and the ontology knowledge provided by the semantic web reasoner.

ABSTRACT

Conventional information fusion architectures are challenged by developments in sensor networks that allow individually-owned (and thereby selfish) sensors to interact and share data. Given this, we advocate the use of tools and techniques from computational mechanism design, a field at the intersection of computer science, game theory and economics, to address the challenges posed by these networks. These techniques allow us to engineer networks with desirable system-wide properties, in which sensors are represented as selfish rational agents, each attempting to fulfill their own individuals goals. In this paper, we present the work of the Argus II DARP project (`http://www.robots.ox.ac.uk/~argus/`) and we demonstrate the application of mechanism design within a real world information fusion sensor network scenario.

1. INTRODUCTION

Multi-sensor networks (MSN) are being deployed in a wide variety of application areas ranging from military sensing to environmental monitoring and traffic control. Such networks consist of a number of sensors connected via a communication network. Each sensor is able to sense their local environment, but can also make use of data transmitted from neighbouring sensors in order to improve the accuracy of their own measurements (e.g. by combining their own noisy observation, with the observations from a number of other sensors, in order to reduce the final uncertainty).

To date, research in sensor networks has mainly concentrated on using cooperation among distributed sensors [3]. At its core, this approach involves determining the exchanges of observed data between the sensors that results in the maximum gain in information across the whole sensor network. However, this approach overlooks the fact that in some applications each sensor may be individually-owned by different stakeholders. In such cases, the sensors are operating in a competitive rather than cooperative environment, and thus, they may attempt to optimise their own gain from the network, at a cost to the performance of the entire system.

To address the challenges of building sensor networks which exhibit desirable system-wide properties, despite the competitive behaviour of the constituent sensors, the Argus II DARP project (a collaboration between two academic partners: the University of Southampton and the University of Oxford, and three industrial partners: BAE SYSTEMS, QinetiQ and Rolls-Royce — see `http://www.robots.ox.ac.uk/~argus/` for more details) is exploring the application of computational mechanism design within information fusion scenarios.

2. INFORMATION FUSION SCENARIO

In this work, we consider a real world aerial surveillance scenario such as that posed in disaster relief contexts, where multiple emergency response agencies, with aerial vehicles of different capabilities, must interact in order to locate casualties. The sensor network is formed from sensors that are mounted onboard these aerial vehicles. Each sensor is provided with an imprecise estimate of its own location by the navigation system of the aerial vehicles to which it is mounted, and it is tasked with detecting and tracking multiple targets within a *region of observation* immediately surrounding itself. Within its region of observation, the sensor is able to estimate the position of each target by making noisy or imprecise measurements of the range and bearing of the target from itself. However, in order to better resolve the uncertainty in these position estimates, the sensors must acquire target observations from neighbouring sensors and then fuse these observations with their own.

The sensors are connected together via a communication network that has a limited bandwidth, and thus, there must be some coordination to determine which data should be sent to which sensors in order to make best use of this limited global resource. However, since each sensor is owned by a different stakeholder, it is thus selfishly seeking to maximise the accuracy of its own target position estimates. As a result, each sensor has a positive disinclination to share its observations since in doing so, it will occupy valuable bandwidth which may be used to receive observations from other agents. Thus, we use techniques from mechanism design to engineer a protocol that incentivises the sharing of observations, whilst also ensuring that the global resource of communication bandwidth is used effectively.

However, in order to apply the tools of mechanism design we

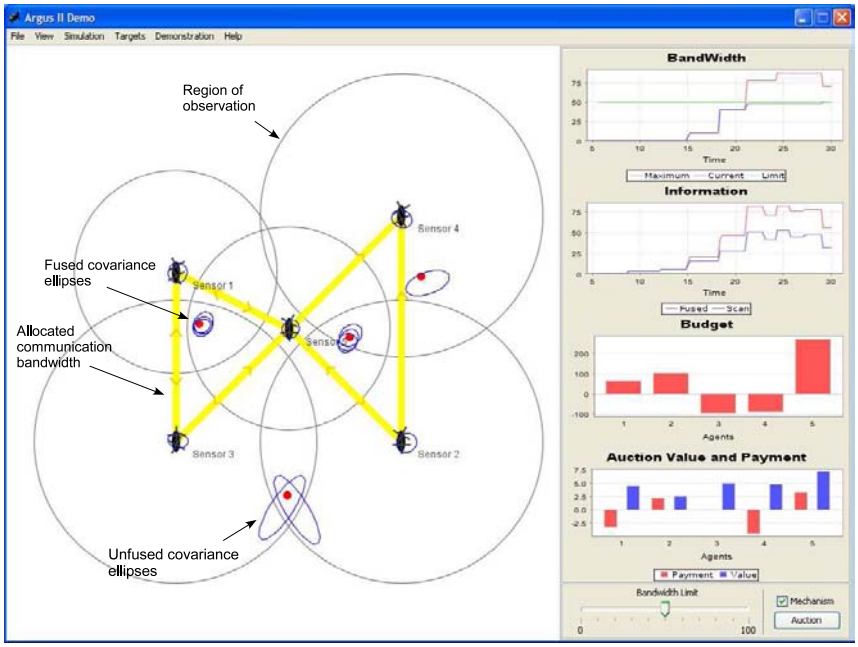

Figure 1: Example sensor network system showing the auction allocation in process and the resulting communication allocation.

require a metric that allows us to assign a value to the observations provided by each sensor. In our work, we have derived a metric based on the Fisher information of these observations [4]. This measure is related to the precision of the observations, and thus sensors that make range and bearing measurements with greater precision, generate observations with greater information content, and hence greater value. This metric is particularly attractive as when independent observations are fused, the information content of the fused observation, is simply equal to the sum of the two individual observations.

Adopting this measure allows us to develop a protocol, whereby an independent auctioneer allocates the communication bandwidth based on the valuations of observations supplied by the individual sensors. Thus far, we have focused our research onto a class of direct mechanisms that are said to be strategy-proof or incentive compatible [1, 2]. That is, the sensors have a dominant strategy to truthfully reveal the information content of their observations to the auctioneer (they thus have no incentive to engage in complex strategic behaviour). Such an outcome is achieved through the payments that the sensors must make (or collect) for receiving (or transmitting) observations. These payments are calculated by the auctioneer in order to align the individual goals of the sensors with the overall system-wide goals of the system designer. By incentivising truthful reporting of the information content of observations from the sensors, the auctioneer is then able to ensure that the bandwidth is allocated efficiently (i.e. to maximise the information gain of the entire network).

3. DEMONSTRATOR

To demonstrate the application of this mechanism, the information fusion scenario, the auction mechanism, and the individual sensors have been implemented within a fully asynchronous Java simulation environment. Figure 1 shows a screen shot of this simulator in operation. The main view shows the measurements and communication of the individual sensors that make up the sensor network. The graphs to the right record metrics of the entire system such as the total information gain of the network, the utilisation of the available bandwidth, and the outputs of the auction process.

4. CONCLUSIONS

In this work, we have demonstrated an effective and efficient control mechanism for sensor networks, in which the constituent sensors are owned by different stakeholders that have their own goals and objectives. Our system has a principled valuation metric based on the Fisher information of a sensor's observations and uses computational mechanism design to engineer a sensor network with a particular desirable system-wide property (in this case, the efficient use of limited bandwidth capacity), despite the selfish goals and actions of the individual sensors. Whilst this research is ongoing, and is currently focusing on how the role of the auctioneer may be distributed amongst the sensors within the network, it is clear that computational mechanism design offers an invaluable and powerful set of tools and techniques to address the challenges posed by these scenarios.

5. ACKNOWLEDGMENTS

The work reported on here undertaken as part of the ARGUS II DARP (Defence and Aerospace Research Partnership). This is a collaborative project involving BAE SYSTEMS, QinetiQ, Rolls-Royce, the University of Oxford and the University of Southampton, and is funded by the industrial partners together with the EPSRC, MoD and Dti.

Component Agent Framework for domain-Experts (CAFnE) Toolkit

Gaya Jayatilleke John Thangarajah Lin Padgham Michael Winikoff

RMIT University
Melbourne, AUSTRALIA
{gjayatil,johthan,linpa,winikoff}@cs.rmit.edu.au

ABSTRACT

The Component Agent Framework for domain-Experts (CAFnE) toolkit is an extension to the Prometheus Design Tool (PDT). It uses the detailed design produced by PDT with further annotations by domain experts to automatically generate executable code into a desired agent platform. The key feature of CAFnE is that it allows domain experts with limited programming skills to easily build and modify agent systems.

Agent Software Engineering, Methodologies, Tool Support

1. INTRODUCTION

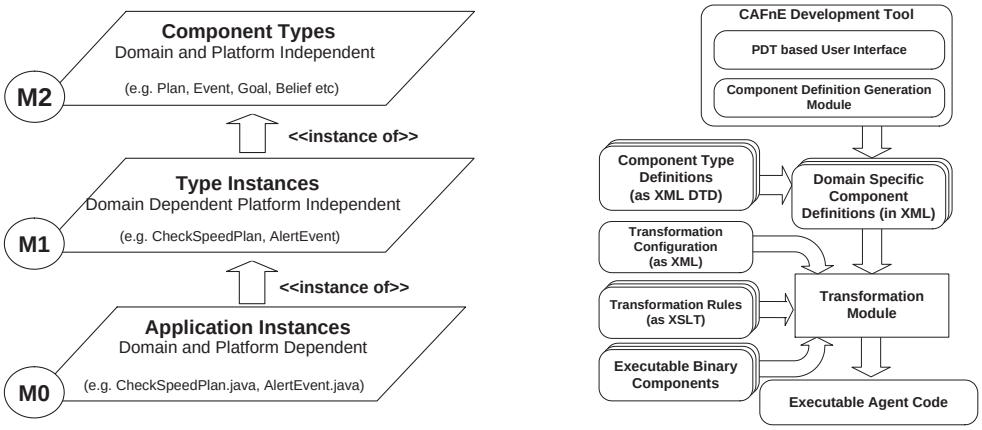
The Prometheus Design Tool (PDT) [4] supports the design and development of multi-agent systems using the Prometheus methodology [5]. While the methodology supports all phases of development PDT in its current state only supports the system specification and design phases.

The Component Agent Framework for domain-Experts (CAFnE) [1] toolkit was built to allow domain experts with limited programming skills to easily build and modify agent systems. This is a result of the experience gained in working with a group of meteorologists on an agent-based weather alerting system [3]. It is often the case that domain experts are the ones who identify modifications in complex domain applications. However, they have less support for making these changes.

The CAFnE extension to PDT supports the design and implementation of BDI style agent applications. It uses a set of components that define BDI style agents such as event, goal, plan and belief. By adopting a strict structure for these components and visual modelling, CAFnE is able to provide an environment for domain experts to maintain agent systems. The toolkit is based on the concepts of model-driven development and component-based software engineering[2]. Figure 1-(a) shows the layered definition approach used in CAFnE. The toolkit works at the M1 layer and automatically generates the runtime code at the M0 layer.

In addition to using the design artifacts in PDT, CAFnE allows domain experts to use *Attributes* to define the environment and the internal beliefs of each agent of the system; and uses execution units called *Steps* within plans to specify plan behaviour.

CAFnE takes these components from the design and first creates a domain dependent but platform independent component model of the application. This model is then transformed by a *transformation module* into a specific agent platform that can be compiled and executed. Currently we have developed a transformation module for the JACK[1] agent platform. Similar modules for other platforms can be integrated into CAFnE. Figure 1-(b) provides an overview of the various modules in CAFnE.



2. FEATURES OF THE TOOL

Integrated Development Environment: CAFnE provides a GUI based integrated development environment (IDE) for visual modelling, code generation, compilation and execution of agent applications. In addition to standard features such as design diagrams, CAFnE provides various features that help a domain expert in maintaining an application. The IDE includes an agent instance diagram where initial agent instances can be defined. Users can go into specific details of an agent instance as providing initial belief data values and start up plans to run when the agent instance is created at runtime.

Domain Expert Orientation: CAFnE incorporates various measures in order to allow domain experts with limited agent programming knowledge to build and modify agent applications. CAFnE uses a simplified BDI agent model that is easy to comprehend. By providing diagrammatic representations of the agent application at different levels, CAFnE helps the user in understanding the system. With its automated code generation, CAFnE has reduced programming tasks to editing diagrams and providing necessary parameter values for components. The Attribute based definition of the environment and the internal beliefs, allows the tool to prompt the user with possible parameter or attribute name lists at input boxes. This greatly helps the users in not having to remember parameter names and eliminating errors in input values. The toolkit also has tracing features to help track execution at runtime (see below).

(a) Layered Components Definitions

(b) Overview of the Toolkit Modules

Figure 1: An Overview of CAFnE

Agent Platform Independent: In line with Model Driven Development principles [2], CAFnE uses a platform-independent model (see Figure 1-a). Platform specific code is generated using transformation rules (Figure 1-b). One consequence of this approach is that what the model which the user works with is not specific to a given platform. Changing CAFnE to target an alternative platform is simply a matter of providing alternative transformation rules. This is easiest if the alternative platform is also BDI-like.

Error Checking: CAFnE includes a consistency checker that validates the application model against a set of rules that define the components and relationships between them. In other words, these rules check whether the model created by the user is internally consistent with the meta model used by CAFnE. The errors detected range from warnings such as an agent not having incoming data, to more serious errors such as missing parameters in steps.

Tracing: Basic "Tracing" options provided in the tool help track the execution of the agent system. With event-plan based execution of BDI agents having a lot of asynchronous processes, tracing such events as plan firing, goal raising and belief updating, helps identify errors in the application.

Support for Component Reuse: CAFnE allows for easy reuse of components such as plans, events and beliefs used in the application. Users can copy and paste components across agents and within agents, with the toolkit checking for any inconsistencies in these actions. To support this process the toolkit has features such as automated linking of components when copies are made. Step components used in Plans go beyond the boundary of a single application and allow reuse across applications. It is easy to define additional Steps, and a Step defined in one application can be reused in another application as long as it is provided with the correct input and output parameters.

3. DISCUSSION

We recently conducted an evaluation of CAFnE using five senior forecasters from the Bureau of Meteorology in Melbourne, with varying levels of programming experience, none of whom had developed an agent system before. They were able to rapidly become familiar with the CAFnE concepts and make changes to an existing design for a weather alert system, such as adding the ability to alert on wind data, as well as temperature.

A number of other agent-oriented software engineering methodologies have tool support including Tropos[2] and MaSE[3]. Tropos tool support consists of a number of separate tools that cover different aspects of the software engineering process. None of these tools provide support for transforming design into executable agent code. The JACK Design Environment (JDE) allows design diagrams to be specified and supports automatic code generation and execution. The JDE however is tailored specifically for JACK and requires the user to understand JACK-specific concepts, as well as the JACK programming language.

Currently CAFnE is a stand-alone application developed with the same graphical model as PDT and takes a PDT design file as input. There are still some features that we would like to add to CAFnE, for example, backward propagation (that is, changes in the CAFnE descriptor propagated to the design diagrams) and visualization tools for users to understand the dynamics of a multi-agent system.

This work was done in collaboration with the Australian Bureau of Meteorology and Agent Oriented Software Pty. Ltd. and was also supported by the Australian Research Council (Linkage Grants LP0347025 and LP0453486).

ABSTRACT

We will demonstrate distributed conflict resolution in the context of personalized meeting scheduling. The demonstration will show how distributed constraint optimization can be used to facilitate interaction between cognitive agents and their users. The system is part of the CALO personal cognitive assistant that will also be explored during the demonstration.

DESCRIPTION OF DEMONSTRATION

The Cognitive Assistant that Learns and Organizes—CALO—is a personal assistive agent designed for a busy knowledge worker. The name was inspired by the Latin word *calonis*, "soldier's servant," because the goal of the project sponsor, the U.S. Defense Advanced Research Projects Agency, is to create a cognitive system that can reason, learn, and respond to surprise in order to assist in military situations.

The CALO project brings together leading computer scientists and researchers in artificial intelligence, perception, machine learning, natural language processing, knowledge representation, multimodal modal dialog, cyber-awareness, human-computer interaction, and flexible planning. The single research focus of all these experts is to create an integrated agent system that can "learn in the wild"—that is, adapt to changes in its environment and its users' goals and tasks without programming assistance or technical intervention.

An integral part of the work of any busy decision maker, whether military or civilian, is the management of her time. In particular, the management of interactions with other people, including colleagues and customers, involves careful meeting scheduling and calendar adaptation. As such, time management and scheduling capabilities are central to the CALO system. CALO exists in an open, unbounded environment, where issues of privacy, authority, adjustable autonomy, cross-organizational scheduling, and uncertain availability of participants abound. PTIME [1] is an autonomous agent integrated within the larger CALO agent [2]. The goal of PTIME is to carry partial responsibility for managing the user's calendar and the scheduling of meetings, thus decreasing the user's need for complex interactions with other humans to plan when to meet or how to reorganize their calendars. PTIME absorbs much of the responsibility for handling negotiations and decreasing the communication overload while keeping the user informed about the state of the process.

PTIME agents in collaboration with their users are autonomous, self-interested entities that manage their users' own calendars. They are, in effect, single-calendar schedulers dependent on other agents to coordinate shared calendar entities. The functional architecture of a single agent is shown in Figure 1. The scheduling task is viewed as a shared goal of the user and the agent. For a PTIME agent, global utility is thus secondary to maximizing the local utility of its user, which typically includes a component valuing cooperation with others [4]. This is in contrast to most distributed scheduling systems [5], which aim to maximize some notion of global schedule quality (e.g., [3]).

Hence, PTIME supports two forms of collaboration: between itself and its user and between itself and the PTIME agents of other users [1]. PTIME also extends the notion of collaboration from inter-agent negotiation to the collaborative dialog between agents and their human users; the collaborative scheduling process is separated from the scheduling algorithms, to enable interaction with the user and other PTIME agents. This interaction forms the framework for learning and adjustable autonomy. The collaborative interface is shown in Figure 2.

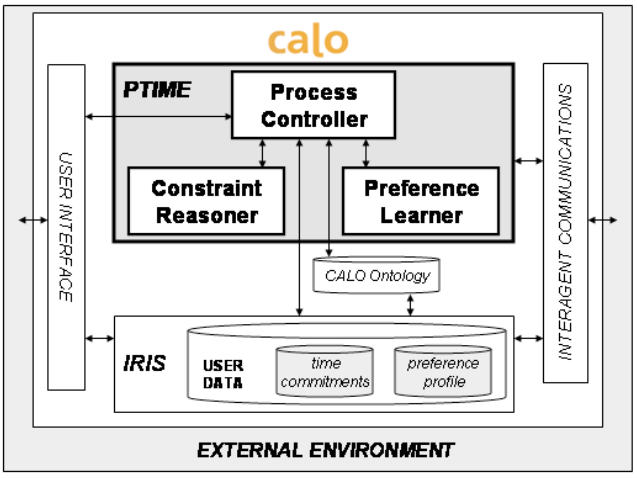

Figure 1: Architecture of a PTIME Agent

User studies confirm that other participants' constraints and preferences often influence the meeting organizer's decisions [4]. When PTIME decides which of many possible schedules to present to the user, it reasons about how each candidate schedule will affect others. This requires PTIME to retrieve from all affected parties their schedules, their preferences, and how the proposed schedule affects them. Once a user selects a schedule from those presented, PTIME must negotiate with the agents of the other parties to resolve conflicts within each schedule.

To determine the effect of a particular schedule on others, PTIME uses a distributed querying mechanism, based on a Distributed Constraint Optimization (DCOP) protocol that obtains a cost reflecting the rescheduling effort required as a result of a proposed schedule. The scope of negotiation within the DCOP algorithm is controlled heuristically. The cost for users that do not respond (i.e., communication with their CALO fails) is estimated using the most recent knowledge about their schedules and their negotiation history.

When the user organizing a new meeting selects a candidate schedule, PTIME invites all other meeting participants, with a justification for the request. All conflicts are then resolved by other users who, in turn, will either resolve the conflicts with other CALOs or choose to not attend.

Our demonstration will take the user through a scheduling task involving the resolution of conflicts with other participants. It will illustrate the PTIME process including the specification of a scheduling problem, inter-agent negotiation, the dialog with the user, and a subset of CALO system functionality.

ABSTRACT

Being able to realistically simulate humans in emergency response activities is a key challenge for advancing the field of information technology for emergency response. Building good human models enables testing information technology solutions in any emergency response simulated scenario. This paper presents an agent behavior model for mimicking peoples's behavior on emergency response activities. The accompanying demo demonstrates a concrete model for evacuations integrated with an emergency drill simulation environment.

1. INTRODUCTION

Information Technology (IT) enables better information flow from source to consumers. It changes the quality and amount of information humans have during emergency response and, thus, influences the decisions humans make. In order to evaluate the impact of IT solutions in emergency response, special attention on human models that emphasize the role of information in the decision-making process is needed.

We model the decision-making process as an information processing system [4]. In our approach, we determine the relevant information variables for each decision. The information abstraction process converts agent observations of the scenario (obtained via raw sensory data) into relevant information variables. Our agents use this information to make decisions. The decision-making model is tested and calibrated with an emergency drill simulation environment– DrillSim. The rest of the paper is organized as follows. Section 2 sets the context by introducing DrillSim. Section 3 presents our agent model. Section 4 describes how our model integrates and calibrates with DrillSim. The paper then concludes with the conclusions and future work.

2. DRILLSIM

DrillSim [1] is a multi-agent emergency response simulation system. The system consists of a multi-agent simulator and a pervasive space. The multi-agent simulator models an emergency response activity where each agent represents a person. The pervasive space captures a drill of the activity in the real space. The system allows both a real drill and a simulation of a response activity to be played out simultaneously. This way, the whole activity takes place in an hybrid world–the merging of the real drill and the simulation. DrillSim is a system for testing IT solutions for disaster response. This testing is enabled due to the plug-and-play capabilities of the system that allow plugging IT solutions for disaster response, thereby translating IT metrics (e.g., delay, QoS) to emergency response metrics (e.g., evacuation time, casualties).

3. AGENT BEHAVIOR MODEL

Each agent in DrillSim represents a person in the response activity. Agents are the key constituents of the activity and take decisions based on their awareness and their cognitive characteristics. Agent behavior (Figure 1) in our model is motivated by the information processing model of [4]. Agents take some action every t time units. For this purpose, an agent acquires awareness of the world around it (i.e. event coding), transforms the acquired data into information, and makes decisions based on this information. Then, based on the decisions, it (re)generates a set of action plans. These plans dictate the actions the agent attempts before going to sleep again. For example, hearing a fire

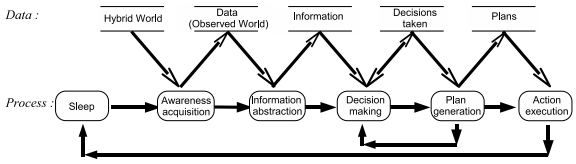

Figure 1: Agent Behavior process.

alarm results in the decision of exiting a floor, which results in a navigation plan to attempt to go from the current location to an exit location on the floor, which results in the agent trying to walk one step following the navigation plan.

Awareness acquisition: Awareness acquisition is the process of coding events into data, thus adding data to the agent's observed world. An agent's observed world is composed of the information it knows a priori (e.g., a map of the building) and the events it observes during its life.

Information abstraction: Based on its observed world, the agent translates the acquired awareness into information. Information is a set of variables that take values between 0 and 1. Note that, information abstraction is a cognitive process and varies between individuals. It depends on factors such as underlaying social networks [5] and the agent's cognitive characteristics.

Decision making: The decision making step is based on a probabilistic model over an artificial neural network [3] (i.e. a time-discrete recurrent artificial neural network). This allows for explicitly modeling the importance of each piece of information on each decision, setting the emphasis on the impact of information on decision making rather than on the reasoning process itself. The characteristics of the neural network parameters (i.e. activation function, weights matrix) are set according to the agent's role and calibrated through running real emergency response drills within the DrillSim environment.

Planning of actions and execution: For every decision an agent decides to take, the agent generates a plan of actions if no previous plan exists or if the previous plan is invalid. Planning may also involve taking further decisions. These decisions are also decided at the decision-making neural network above presented. After plan generation, the agent attempts an action from each plan. The most basic actions are walk and speak. For example, given a navigation plan, the agent walks one step more of the computed path.

4. INTEGRATION WITH DRILLSIM

An initial prototype of DrillSim with the agent behavior here described has been implemented in Java and JADE [2]. This prototype provides a GUI (shown during the demo) that allows real humans to observe and interact with the drill simulation. Figure 2 shows a snapshot of the GUI. In particular, it allows a user to start the simulation, pull the fire alarm, input a hazard, get an arbitrary view of the simulation in 2D or 3D, get a 3D view of what an agent is viewing, send messages to other agents, control an agent, and get statistics of the evacuation.

5. CONCLUSIONS AND FUTURE WORK

Providing realistic agent behavior for simulating emergency response activities will definitely catalyze information technology research in emergency response. Realistic agent behavior enables simulating emergency response activities for evaluating different information technology solutions. We propose to model agent behavior as an information processing system based on five steps: Awareness acquisition, information abstraction, decision making, plan generation, and action execution. This five-step process translates raw events observed by the agent to concrete actions. The agent behavior is integrated and demonstrated with DrillSim. The instrumented environment of DrillSim allows calibrating the decision-making model.

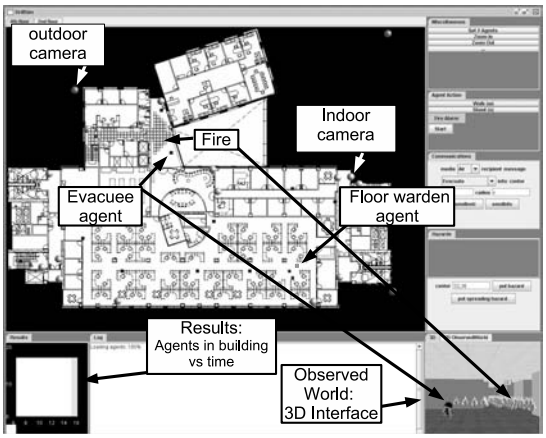

Figure 2: Snapshot of the prototype.

Thoroughly modeling agent behavior is a complex task and calibrating it using real data is indeed challenging. Our future work involves exhaustively calibrating our decision-making model and making it more comprehensive.

6. ACKNOWLEDGMENTS

We would like to thank the rest of the DrillSim team for their dedication to the DrillSim project. This research has been supported by the National Science Foundation under award numbers 0331707 and 0331690.

ABSTRACT

This paper presents an overview of ITSUMO, a microscopic traffic simulator based on cellular automata. The implementation uses agent technologies with a bottom-up philosophy in mind. We give an overview of the system and some details of its modules (data, simulation, driver and information/visualization).

Categories and Subject Descriptors

Human Factors

1. INTRODUCTION AND MOTIVATION

The increasing urban mobility challenges traffic engineers, urban planning experts, and researchers involved with optimization and information technology. Urban mobility both produces information and increases the demand for it. In order to produce the information to be broadcasted, a fast simulation model is necessary. We use the Nagel–Schreckenberg approach [3] which is a microscopic model for traffic simulation based on cellular–automata (CA).

The motivation for the development of the simulation module is threefold. First, although several similar tools exist, these are built normally with the objective to tackle isolated problems. Second, in general, one has no access to the source code regarding both commercial and academic tools. Finally, we see this domain as a very rich area for experimenting some agent-based techniques, especially modelling and simulation of drivers (agents).

Therefore, driven by the incentives given by Brazilian funding agencies regarding free software, we have developed ITSUMO – Intelligent Transportation System for Urban Mobility [4]. One of the aims of the project is to create an information system for urban mobility capable of integrating different functionalities, such as a simple traffic control (mostly based on control of traffic lights), traffic management and real-time information providing via internet and/or mobile phone. The idea is to distribute the system under free-software license. The system has been used to investigate route choice scenarios [1], as well as control (refer to `http://www.inf.ufrgs.br/~mas/traffic/itsumo/demo` for screen shots and other publications).

To address these objetives, it is possible to define drivers as intelligent agents and to plug each driver model as a module in the simulation system. This approach is in contrast with the current models, which are purely reactive and ignore drivers' mental states (informational and motivational data). The kernel of the simulator was programmed using the object-oriented paradigm. The idea is that anyone can aggregate further code when necessary. A XML-based database, used to define the network objects, and a visualization module are also part of the package.

2. MICROSCOPIC SIMULATION MODEL

Basically, there are two approaches to model traffic movement: the macroscopic and the microscopic. The former is mainly concerned with the movement of platoons of vehicles, focusing on the aggregate level. It considers only averaged vehicle densities but not individual traffic participants. In the microscopic model of simulation, each object can be described as detailed as desired, thus permitting a more realistic modeling of drivers' behavior. In the microscopic approach both travel and/or route choices may be considered, which is a key issue in simulating traffic since those choices are becoming increasingly more complex. Also, individual traffic lights can be modelled according to several approaches, from classical off-line coordination to recently proposed ones (negotiation, communication-free, via game theory, reinforcement learning, swarm intelligence, etc). In fact we have been using this model and simulator to investigate different aspects of the problem: route choice, traffic lights coordination and control, etc.

In order to achieve the necessary simplicity and performance, we use the Nagel–Schreckenberg model [3]. In short, each road is divided in cells with a fixed length. This allows the representation of a road as an array where vehicles occupy discrete positions. Each vehicle travels with a speed based on the number of cells it currently may advance without hitting another vehicle. The vehicle behavior is expressed by rules that represent a special form of car–following behavior. This simple, yet valid microscopic traffic model, can be implemented in such an efficient way that is good enough for real-time simulation and control of traffic. Given that every vehicle has a nonnegative integer speed (v, limited to $vmax$), the following four rules are verified simultaneously for all vehicles in a CA way: movement (each vehicle advances v cells at each time step); acceleration (each vehicle's speed is increased by one

unit, up to $vmax$ or the gap – the number of empty cells in front of a vehicle); interaction (if the vehicle ahead is too close, v is decreased by one unit; and randomization (vehicles decelerate with probability p in order to simulate the nondeterministic dynamics of vehicle movement). Although these rules might seem too simplistic, investigations reported in the literature showed that the cellular automaton model is capable of reproducing macroscopic traffic flow features including realistic lane changing behavior.

3. DESCRIPTION OF THE SIMULATOR

ITSUMO can use both off-line information (maintained by different providers), and on-line (e.g. traffic flow). The information regarding the network is stored in a XML file. In addition to the CA approach, one can also define other driver decision-making procedures via a special, optional, module. If the user does not define particular classes of drivers, then the simulation is performed using the standard driver model described in Section 2. A visualization module retrieves data originated from the microscopic simulation and exhibits a graphical representation of the traffic simulation. The ITSUMO system is thus composed by four distinct modules: the data module, the simulation kernel, the driver definition module, and the visualization module.

3.1 Data Module

This module creates, updates, and stores (XML file) both the static and the dynamic objects to be used in the simulation, as for instance the cartesian coordinates of the intersections. The main attributes are described below:

- **General Settings**: topology name, traffic system orientation (right-handed, left-handed), cell size, frequency of sensor measurements, deceleration probability, etc.;
- **Network**: network name and its settings;
- **Node**: cartesian coordinates of the intersection;
- **Street, Section, Laneset, Lane**: street name, section name, whether it is preferential, delimiting nodes, laneset length, maximum speed, and width for the lane;
- **Turning Probabilities**: set of allowed vehicle movements and their probabilities;
- **Signal Plan**: set of lane-to-laneset allowed movements in a specific order, cycle time and offset;
- **Sink and Source**: nodes for removal and insertion of vehicle according to given values;

3.2 Simulation Module

This module was developed using C++ over the microscopic model presented before. However it also solves an issue inherent to the basic microscopic model described in Section 2, namely the difficulty to represent urban scenarios.

The simulation occurs in discrete steps and is implemented as a series of updates in the drivers' decisions of movement, followed by simultaneous updates in the vehicles' positions in the network. Each update in a node or traffic light may modify its current behavior. The simulation output can be formatted according to the user needs. The most usual formats are the "cell map" and the "laneset occupation map". The former indicates which portions of the lane are occupied by which vehicle, providing the most detailed output possible. On the other hand, the "laneset occupation map" is a high-level output which specifies the rate of occupation (density) for each laneset in the network.

3.3 Driver Modelling Module

Modeling drivers' behavior can be approached in different ways, depending on the purpose of the simulation. In most cases, the objective is to simulate the collective or macroscopic behavior. However, this behavior emerges out of individual ones. Simple algorithms, like the Nagel–Schreckenberg model, can be used to describe vehicles movement without loosing significant simulation fidelity with reality. However, other behaviors can be implemented, normally out of two different components: decision about movement and planning. The former is responsible for a vehicle's short-time movement, while the planning decision is related to a more sophisticated decision-making, e.g. which direction to turn and what to do when facing a jam.

3.4 Visualization Module

This is the module that allows the graphical visualization – either in a macroscopic or microscopic level – of the simulation results. At a macroscopic level, the visualization considers only data which reflect the overall behavior of the network, providing an useful tool to capture the big picture of what is happening in a specific scenario. It is useful to provide this kind of information via the internet, as it has been the case in [2]. The microscopic level provides an interface through which one can see, both in 2D and 3D manner, individual vehicles movement. In order to obtain a more realistic and detailed visualization, these modules are developed using OpenGL, enabling features such as walk-through navigation and detail-focused interfaces.

The visualization of data at microscopic level is the kernel of the information system for the traffic engineer and/or the urban planning experts. At this level, the whole system can be used to perform *what-if* simulations.

4. FINAL REMARKS

The ITSUMO system is capable of dealing with several aspects of the simulation of a traffic scenario, such as the driver behavior, traffic lights coordination, traffic jam prediction, among others. The ITSUMO system provides an useful tool to simulate traffic conditions and to support urban planning tasks.

We plan to extend ITSUMO to consider other kinds of information such as those related to weather forecast and information providing via internet and/or mobile phone.

ABSTRACT

The current state of the art in agent technology sees that several implementations of agent frameworks exist. However, there is little agreement on the terms and concepts used to describe such systems, which is a significant barrier towards adoption of these technologies by industry, military and commercial entities. A clear definition of terms and concepts at an appropriate level of abstraction is needed to facilitate discussion, evaluation and adoption of these emerging agent technologies. In this paper, we argue that a *reference model* for agent-based systems can fill this need. We discuss what a reference model is, why one is needed for agent-based systems, and our proposed methodology for creating such a reference model. While the complete model is a work in progress, we present a preliminary version to motivate further discussion from the agents community at large. It is our hope that ultimately a wider community of practice will assume responsibility for the standardization similar to the way that the well-known seven-layer Open Systems Interconnection (OSI) reference model was a driving force underlying communications standards.

Intelligent Agents, Reference Model

1. INTRODUCTION

The ultimate goal of the Agent-Based Systems Reference Model (ABSRM) is to provide a technical recommendation for a reference model for those who develop and deploy systems based on agent technology. The ABSRM should allow for existing and future agent frameworks to be compared and contrasted as well as to provide a basis for identifying areas that require standardization within the agents community. As such, the aim of the ABSRM is to

- establish a taxonomy of terms, concepts and definitions needed to compare agent-based systems;
- identify functional elements that are common in agent-based systems;
- capture data flow and dependencies among the functional elements in agent-based systems;
- specify assumptions and requirements regarding the dependencies among these elements.

As a reference model, the ABSRM will make no prescriptive recommendations about how to best implement an agent-based system; nor is the objective to advocate for any particular approach, architecture or framework. In its broadest sense, an agent-based system for the purposes of the ABSRM simply describes a software platform for building agents and supporting their communications and collaboration. An agent-based system may consist of many different kinds of agents operating across a heterogeneous set of platforms and hosts.

One novel aspect of our approach is to create the reference model based on a forensic analysis of existing agent-based systems. The reference model developed in this document is based on static and dynamic software analysis of existing agent frameworks. Examined frameworks include Cougaar, JADE, RETSINA, and others. Anyone building an agent framework would have to recreate or reproduce some portion of the functionality or components in these existing frameworks (i.e., to enable communications, to enable agent startup and shutdown, etc). By analyzing existing frameworks and the agent-based systems they can be used to build, we can avoid the debate concerning "what is an agent" and simply document the existing state-of-the-art systems that are called agent-based. The model aims to document a superset of the features and functional concepts in the set of existing agent frameworks. Given that there is significant variation between existing frameworks and the functions they may provide, the reference model should describe at an abstract layer the complete set of functional components across all examined agent frameworks.

It is important to note however that the reference model is not confined to being a description of capabilities of existing systems —it serves as a basis for situating the complete set of functions that anyone may want or need to have in an agent-based system. For example, security for mobile agent code is currently a vastly challenging problem that lacks a satisfactory solution. However,

the lack of any established, uniform and generally accepted security system for mobile agents does not prevent the reference model for including a description of the security functions and facilities that an agent-based system may provide.

2. WHAT IS A REFERENCE MODEL?

A *reference model* provides appropriate abstractions for facilitating adoption, adaptation and integration of evolving technologies [18]. Any generic model that has specific examples can be considered to be a reference model. Reference models are known to play a key role in understanding a given domain, establishing the domain as a scientific discipline, facilitating collaboration and promoting competition towards maturing technology relevant to the domain. Reference models emerged since the 1980s as a result of the success of the Open Systems Interconnection seven-layer reference model (ISO/IEC 7498-1:1994: Open Systems Interconnection Basic Reference Model) [3] [4] [15] that revolutionized the way communications systems developed. This model was developed as an International Standards Organization (ISO) effort. Another successful example of a reference model that has been developed by the ISO is one for archiving systems and is known as the Reference Model for an Open Archival Information Systems (OAIS) (ISO 14721:2003). In motivating and developing a reference model for agent systems, we draw heavily on these examples of existing successful reference models.

As these existing reference models demonstrate, reference models do not prescribe how functions and systems should be implemented. Instead, reference models provide the patterns of the solution for transforming vague notions into real-world implementation. Reference models simplify problem solving, to enable others to practice their discipline with a solid foundation. Software professionals, in particular use reference models to better understand abstractions and their potential for reuse.

3. WHY A REFERENCE MODEL?

Reference models are a necessity in a confusing, rapidly changing technology environment. As noted in [18], reference models are becoming more commonplace in fields of various human endeavors. The power of compelling reference models of knowledge can not be underestimated as a tool for technical leadership facilitating conclusions from a sound understanding of the problem space and solution domain. Thus, we argue that a reference model would be very useful tool to identify, assess and facilitate R&D and acquisition of agent technology for a wide variety of applications.

One particular application of agent-based systems is in military domains. Agent-based systems are being proposed to enhance and automate applications for collecting, presenting, storing, producing and sharing domain information. A future force is envisioned to be highly autonomous, modular, scalable, and flexible through the agentization of applications and services. This is especially true for complex system of systems (SoS). SoSs are large-scale, net-centric and include a variable mix of multi-department heterogeneous intelligent agents, humans-in-the-loop, and unmanned autonomous components and subsystems. Examples of complex SoSs in the US Army are the Army Battle Command System of the Current Force [1] and the Future Combat System of the Future Force [2]. Systems that would be found in a Joint Service (Army, Navy, Marine and Air Force) SoS are depicted in Figure 1.

Heterogeneous intelligent agents promise to enable conflict resolution between and among applications and services engaged in competition, negotiation, mediation and arbitration, to assist humans-in-the-loop, and to control unmanned autonomous systems and robots.

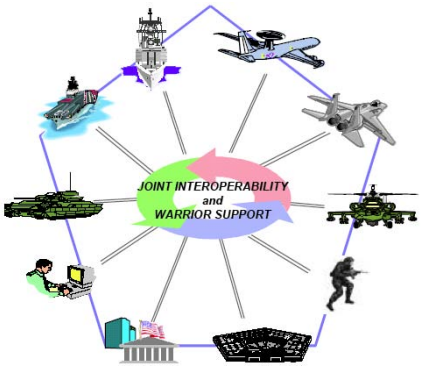

Figure 1: A Joint Service Battle Command is an intended future application for intelligent agent systems.

Agents are anticipated to play an important role in realizing dynamically varying mixed initiative capabilities to command and control manned as well as unmanned assets. As systems become increasingly complex, modularity as promoted by agent technology will become the key to reuse, scalability, and an open architecture. In addition, these design goals are a key to a manageable and affordable transformation from current to future force capabilities.

A reference model for intelligent agents would motivate the benefits of the technology by formalizing key concepts of both behavior and structure essential to enable agent technologies to reduce information collection, storage and sharing latency, workload, presentation overload and clutter for Battle Commanders and their staff. The recognition of the need and the investment to develop a unifying ontology for intelligent agent software across the domains of the systems in an enterprise-wide System of Systems (SoS) are shown to be crucial if not pivotal to the success of such SoS engineering efforts which are inherently multi-disciplinary and collaborative.

4. HOW TO CONSTRUCT A REFERENCE MODEL?

We take a quantitative and evidentiary approach to create a reference model based on a forensic analysis of existing agent-based systems. There are many agent frameworks available today: from companies, from academia and from the open source community. These frameworks have emerged from several large governmental and private research and development programs and have been used in the creation of many successful military and commercial systems. This suggests that a sensible approach towards building a reference model begins with examination of these existing systems and attempts to construct the model in a bottom-up fashion.

Reverse engineering (RE) is an ideal technique for examining and understanding existing systems. In RE, one obtains the software modules that comprise the subject systems by performing software analysis. By grouping, abstracting and querying data in different ways, information can be gleaned that simple observation of code may not find. Conventionally, RE is used to produce data that can allow for documentation and understanding of the software systems and for verification of any existing software documentation. For our purposes, we hypothesize that this data can also be analyzed and abstracted to obtain a reference model. In this section, we describe a specific RE technique we are using called *static analysis*. We also provide an overview of an additional RE technique that we will use in our future work: *dynamic analysis*.

4.1 Static Analysis

Static analysis is the analysis of software using its source code as the primary artifact. The system needs not be executing in order to obtain the appropriate data. Instead, source code or intermediate code is inspected to find the software modules, data structures, data flow, methods and metrics appropriate to the system.

This type of analysis yields many benefits, such as code-rewriting and vulnerability detection, but for purposes of our reference model, the primary goal is to use static analysis to produce a data repository from code that can be queried to find the primary software subsystems. This facilitates the transition from analyzing subject systems to identifying software modules that might fit the overall abstract system defined by the reference model. We describe two of the software analysis tools that we used: Bunch and JadeSniffer.

Bunch[1] is a clustering tool intended to aid the software developer and maintainer in understanding, verifying and maintaining a source code base, especially when when documentation of is nonexistent or outdated. The process proceeds in two steps. First, information from the source code is used to construct a directed graph that represents the key components, and the dependencies between these components. This directed graph, which we refer to as the Module Dependency Graph (MDG) of the system, has nodes as program units such as files or classes, and edges between the nodes as relationships between those modules such as function calls or inheritance relationships.

In the second step, Bunch uses the MDG to find a "good" clustering for the system. In particular, Bunch processes the MDG and produces as output a clustered MDG which includes all of the original source code and dependencies clustered into logical subsystems. Bunch can also use pre-defined clusters to measure or improve the quality of the system's clustering. The output from Bunch can be visualized by several popular graph visualization tools.

The Jade Sniffer[2] is a tool developed specifically to analyze Jade multi-agent systems. Jade is a FIPA-compliant agent framework, so a tool of this type is helpful to analyze behavior patterns and relate them to FIPA-compliant systems. This is accomplished by tracking messages between agents at the Virtual Machine level. The Sniffer itself claims to be a FIPA-complaint agent, like the Jade framework it analyzes. Using this tool together with Jade's logging services, we hope to produce sequence diagrams and message history that occurs between the agents; this provides a detailed view of the agent system behavior from a dynamic analysis perspective.

4.2 Dynamic Analysis

Dynamic analysis also collects data on software systems, but it does so by inspecting the system during execution. This analysis can vary widely by implementation, but one approach is to build a data repository of program behavior. This repository holds information on data flow, object instantiation, the call graph, interprocess communication, network or filesystem I/O activity, and so on. This analysis assists the production of the reference model by providing more sophisticated justification than static analysis alone. For example, dynamic analysis inspects the system as it is running and often breaks the system down into "features", e.g., code components that are actually used to provide some behavior. Moreover, dynamic analysis can obtain data on behavior-specific aspects of the system such as threading and I/O, that could not be found using static analysis. Finally, dynamic analysis can assist in cases where source code is not available for static analysis to be performed.

5. EXISTING AGENT FRAMEWORKS

We describe three of the agent frameworks we have investigated to date: Cougaar, Jade and RETSINA. For each framework, we describe several of their functional concepts which were discovered and verified through a combination of static analysis of source code and accompanying documentation.

5.1 Cougaar

Cougaar (Cognitive Agent Architecture)[3] is a Java-based architecture for the construction of large-scale distributed agent-based applications. It was developed over two DARPA-sponsored research programs spanning eight years of effort. The goal of Cougaar is to provide developers with a framework to implement large-scale distributed multiagent applications with modular agent features and requiring minimal consideration for the underlying architecture and infrastructure. Below we describe a few of the key functions of Cougaar.

- *Directory Services:* Each agent is provided a unique name. This name is often similar to a network domain name based on the category and type of role that agent will have (though this is simply by convention). Cougaar provides a White Pages function that maps agent names to their locations. A Yellow Pages was also introduced to handle searches for agents and their locations based on their attributes or capabilities. Yellow Pages is built on top of UDDI, and a number of servers can provide the distributed Yellow Pages service.

- *Messaging:* Cougaar features a distributed blackboard, in which agents in a particular domain communicate with each other. Figure 2 shows a diagram obtained from applying the Bunch reverse engineering tool to the source code of Cougaar's blackboard component. In Cougaar, a software developer creates plugins that use a common language and protocol. These plugins publish objects to the blackboard, and receive objects from the blackboard according to an agent's subscriptions. To facilitate transmitting data to and from other agents, relay attributes are stored to show what information is desired from and appropriate for which agents. Alternatively, instead of storing actual recipient addresses, an agent can address a message based on attributes of the agent within the community.

- *Conflict Management:* To facilitate conflict management, an agent within the Cougaar architecture can form a group with other agents that share a similar goal or function. These

[3]http://cougaar.org

communities together form additional communities or a society. When the Cougaar society is active, new nodes may dynamically join the society, and may leave as well. To coordinate activities, nodes create functional relationships such as producer/consumer (service-based) relationships or superior/subordinate (delegation based) relationships. In order for agent communication to occur, there must exist established relationships between them.

5.2 Jade

Jade[4] is a Java based agent platform that is built upon a number of FIPA standards, including Agent Management Specification [9], Agent Communication Language (ACL), and the ACL Message Structure. Thus, Jade is structured as a FIPA compliant agent platform in which agents, the agent management system and the directory facilitator interact independently with a common message transport system.

- *Directory Services:* Agents are registered, named, and looked up via FIPA standard implementations. An Agent Management System (AMS) is provided for name lookups, and a Directory Facilitator is provided for agent lookups. Based on the location of the agent (local or remote), an agent name lookup will find the physical location of the agent and the Jade subsystem will forward the message over the appropriate I/O channels.

- *Messaging:* A peer-to-peer conversation occurs between agents. This is implemented via a FIPA standard, in which an Initiator and Responder agent communicate with each other through message passing. Feasibility Preconditions are met before the message is sent, and a Rational Effect are defined as to what the Initiator agent should expect (but not assume) upon receipt and processing of the message by the responder. Agents can inform each other or make requests, and they can be responded to with a not-understood, refusal or agreement response, and so on. In addition, agents may subscribe to messages provided by other agents based on their content.

- *Mobility:* Jade supports migration of agents to other hosts. This is done by copying or serializing the agent across the network. The jade-mobility-ontology is provided to ensure that agents are always aware of their physical location. At a minimum, agent mobility is described by an ontology that contains the agent's name and destination. It can also contain an agent profile which contains the OS that the agent resides / will reside within. It can also specify the system and language of the agent.

5.3 RETSINA

RETSINA[5] is developed by the Robotics Institute of Carnegie Mellon University. RETSINA is developed in C++ but is platform independent. Agent systems can be run on a number of different platforms and hosts (including handheld systems) and can be implemented in a number of languages.

- *Directory Services:* The ANS (Agent Name Service) is provided to map an agent by name to a physical location. This location is not bound to a particular physical medium such as TCP/IP, but instead can be any location that physically defines a method to contact the agent. In addition to a naming service, attributes and services of each agent are cataloged when it joins the society by *middle agents* called "Matchmakers." These matchmakers provide agent lookup based on a service query, and can also send notifications when new agents join the society that meet the specified criteria.

- *Messaging:* Messages are either direct or multicast to agents based on their services or attributes. Message passing can be synchronous or asynchronous, and can occur between multiple agents simultaneously via a threaded architecture. RETSINA also separates the physical communications model from the protocol, language and ontology. KQML is used as the agent communication language in RETSINA. As part of the language, each message passed between agents contains both the content and the structure (ontology, language, sender, conversation, etc.) of that message.

- *Semantic Interoperability:* A shared dictionary defines the meanings of content of KQML messages.

6. TOWARDS A REFERENCE MODEL

We describe a preliminary, partial reference model for agent-based systems. The portions of the model we present include a high-level view organized as a set of layers and a functional decomposition of an agent-based system.

6.1 Layered View of an Agent-Based System

An **Agent-Based System** is comprised of agents and their supporting framework and infrastructure which provide fundamental services and operating context to the agents. Our model defines framework, platform and host layers, which mediate between the agents and the external environment. This layered model can be organized vertically as shown in Figure 3. Each layer is described as follows:

- The **Agents** layer consists of agents that perform computation, share knowledge, interact and generally execute behaviors in order to achieve application level functionality. We make few assumptions about the Agent layer except to state that agents are *situated* computational processes—instantiated programs that sense and effect an environment in which they exist. We make no assumptions about the internal processing structures of an agent. An agent could be built with a complex cognitive model or it could be a simple rule-based system. Given the vast array of tasks envisioned for agent systems, it is not the role of a reference model to limit or define what an agent is.

- The **Framework** layer provides standardized functionality specific to supporting agents. A framework typically provides support services such as conflict management, directory and naming services, security, and agent administration services such as monitoring and allocating resources to the executing agents. The major benefit of employing an agent framework is to provide standardization of services and functionality to agents that exist within the framework. The end result is that agents written within a particular framework are easily interoperable with one another. In other agent-based systems, the framework may be trivial or merely conceptual, for example if the services are merely a collection of system calls or are compiled into the agents themselves.

- The **Platform** layer provides more generic computing infrastructure. The platform contains the software components that

[4]http://jade.tilab.com/

[5]http://www.cs.cmu.edu/ softagents/retsina.html

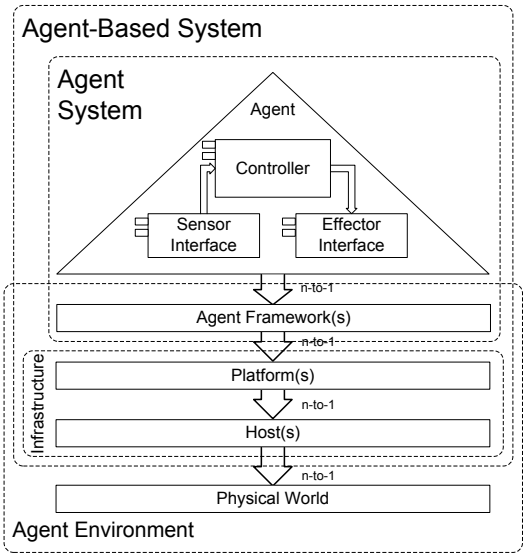

Figure 3: An Agent-Based System is made up of layers.

are available to the agent framework, but are not packaged along with it. Elements such as operating systems, user interface libraries, database software, device drivers, and message transport or socket libraries are in this layer. These services are often provided by third parties and it is unlikely that an agent-based system will provide its own implementation of the platform functions.

- The **Host** layer contains the hardware devices on which the above layers operate. This layer includes not only the physical computing devices such as a desktop computer or handheld device, but also the hardware that provides interaction with the environment such as robot sensors and effectors, cameras, displays, GPS receivers, etc.

- **Environment** is the physical world in which the agent-based system exists and operates.

Each layer can support many entities from the layers above it—many agents may execute on a single framework, many frameworks may execute on a single platform, and so on.

6.2 A Functional View of an Agent-Based System

This section presents a view of an agent-based system as a set of abstract functional concepts that support overall system execution. For example, *administration* and *security* are two abstract functional concepts we define. Our use of the rather abstract term "concept" here is deliberate. The more concrete (and perhaps more familiar) UML term "component" could be used, but we wished to reflect the idea that a function often does not correspond directly to what we might think of as a component, i.e., a clearly delineated piece of the system. Similar to the aspect-oriented software engineering view, we view a functional concept as something that emerges out of complex interactions between pieces of software and hardware located in different layers of the agent-based system.

It is important to note that we make few prescriptions about whether and how each functional concept is implemented. The way in which functional concepts are instantiated may vary significantly in structure, complexity and sophistication across different agent-based system implementations. Indeed, some agent-based systems may not even possess some of the functional concepts we will describe. Our aim here is to describe what the function is in abstract terms so that one can determine if the function exists in a given system, or to verify its existence if it is claimed to exist within a given system.

A functional concept is described through a brief definition and a set of primitive operations that implement the function which we call a Process Model. We define Administration, Security, Conflict Management, and Messaging concepts. Other functional concepts that are part of the model but not described here are Mobility, Semantic Interoperability, Directory Services, and Logging.

6.2.1 Administration

Definition: *Administration functionality a) facilitates and enables supervisory command and control of agents and/or agent populations and b) allocates system resources to agents. Command and control involves instantiating agents, terminating agents, and inspecting agent state. Allocating system resources includes providing access control to CPUs, User Interfaces, bandwidth resources, etc.*

Administration functionality may be implemented in various ways. For example, the framework may perform all the administration functions directly, or there may be (multiple) agent(s) in the agent layer that perform agent administration functions by commanding and controlling other agents, or there may be elements of both approaches in a given system. For convenience of exposition below, we will use the term "administrator" to encapsulate all the administration functions although administration functions may not necessarily implemented with a single administrator.

To further facilitate the exposition of the following process model, consider as an example a hypothetical system that uses agents to monitor message traffic on a communication network. The number of agents required to perform adequate monitoring may be contingent upon the complexity of the network topology or the priority of monitoring relative to other system goals. As both the network topology and priority changes, an administrator is employed to manage the network monitoring agents.

Process Model: Agent administration functionality is described by the following set of processes:

- *Agent Creation* The act of instantiating or causing the creation of agents. In our example, the administrator may determine that there are too few network monitoring agents to adequately maintain a minimum level of security. Therefore, new network monitoring agents will be created.

- *Agent Management* The process by which an agent is given an instruction or order. For example, if it is determined that the greatest security threat is over HTTP traffic, the administrator may request that the network monitoring agents focus their analysis on HTTP traffic.

- *Resource Control* The process by which an agent's access to system resources is controlled. For example, the administrator may determine that security is of less priority than CPU usage. Therefore, it can reduce the available CPU time of the network monitoring agents.

- *Agent Termination* The process by which agents are terminated (*i.e.*, their execution is permanently halted). For example, the administrator might determine that there are too many network monitoring agents and decide to remove those in saturated regions of the network.

6.2.2 Security

Definition: *The purpose of security functionality is to prevent execution of undesirable actions by entities from either within or outside the agent-based system while at the same time allowing execution of desirable actions. The goal is for the system to be useful while remaining dependable in the face of malice, error or accident.*

Process Model: Security functionality is described by the following processes.

- *Authentication* A process for identifying the entity requesting an action. Common examples include user name/password credentials and use of public/private keys for digital signatures.
- *Authorization* A process for deciding whether the entity should be granted permission to perform the requested action. A common example in file system security is maintenance of a permission list for each file, which specifies the allowable actions for a given user. Another example includes a web server denying requests when it gets overloaded.
- *Enforcement* A process or mechanism for preventing the entity from executing the requested action if authorization is denied, or for enabling such execution if authorization is granted. A common example for preventing access to information is to encrypt it. Permission to access the information is granted by providing the entity a decrypted copy or providing the entity the means to decrypt it, e.g., the encryption key.

Some general technologies for achieving security include authorization models and mechanisms; auditing and intrusion detection; cryptographic algorithms, protocols, services, and infrastructure; recovery and survivable operation; risk analysis; assurance including cryptanalysis and formal methods; penetration technologies including viruses, Trojan horses, spoofing, sniffing, cracking, and covert channels.

6.2.3 Conflict Management

Definition: *Conflict management functionality facilitates and enables the management of interdependencies between agents activities and decisions. The goal is to avoid incoherent and incompatible activities, and system states in which resource contention or deadlock occur.*

As an example, a framework may allow designation of superior/subordinate relationships between agents and provide generic conflict resolution services based on these relationships. The Cougaar framework does this. Similarly, a framework may provide a multiagent task planning language, such as TAEMS [17], that can be used to reason about the interactions between agent actions and to detect plan conflicts.

Process Model: Conflict management functionality is described by the following processes.

- *Conflict avoidance*. A process or mechanism for preventing conflicts. Examples of such processes include multiagent planning algorithms (both on-line and off-line) that take care to produce action plans that do not have conflicts.
- *Conflict detection*. The process by which it can be determined when a conflict is occurring or has occurred. One example includes a plan execution monitoring algorithm that is able to sense when the actions of agents are in conflict. Another example includes performing logical inference over different agents beliefs to determine when they are inconsistent with one another.
- *Conflict resolution*. The process through which conflicts between agent activities are resolved. Negotiation, mediation and arbitration are common mechanisms for facilitating conflict resolution.

Some general technologies for conflict management in agent systems include argumentation and negotiation, distributed constraint reasoning, game theory and mechanism design, multiagent planning, norms, social laws and teamwork models.

6.2.4 Messaging

Definition: *Messaging functionality facilitates and enables information transfer among agents in the system.*

This concept is associated specifically with the mechanisms and processes involved in exchanging information between *agents*. Although information exchange via messages can and often does occur between other parts of the system, for example between an agent and its framework, between frameworks, between a host and its platform, etc., such information transfer is not included because it is in a sense at a lower level. Our concept of messaging is at a higher level than that associated with network traffic or interprocess communications.

Messaging involves a source, a channel and a message. Optionally, we can designate a receiver but we admit models in which messages do not have a specific intended receiver. For example, signaling in the environment like smoke signaling, a light flashing morse code, etc, are examples of messaging where there is no designated receiver.

Process Model: The functionality is described by the following processes.

- *Message Construction* The process through which a message is created once a source agent has determined it wishes to deliver a particular message chosen from a finite or infinite set of messages. No commitments are made here in regard to the form, structure or content of a message. For the purposes of this model it is sufficient to discuss messages as an abstract object. The information to be delivered is simply the fact that a particular message was chosen among the set of all messages that could have been chosen.
- *Naming and Addressing* A mechanism for labeling the message with its intended destination or route. Directory white page services are a common mechanism to facilitate this function. Broadcast, multicast and group messaging also all fit within this model.
- *Transmission* The actual transport of the message over the channel. This may be a one-shot transmission or a continuous stream. One common model is messaging an agent on another host involves going through the platform to the host's network hardware, then out into the environment (via wire or air), and back in symmetrically to the receiver.
- *Receiving* The process for acquiring the transmitted information so that is usable by the receiver. This may be as simple as pulling the message off of a queue or more elaborate, e.g., going through a translator.

Some other areas of interest in messaging functionality include notions of best effort delivery, QoS and guaranteed delivery/timeliness.

7. RELATION TO EXISTING STANDARDS

Existing standards for agent-based systems can be used concurrently with a reference model. A reference model describes the abstract functional elements of a system. A reference model does not impose specific design decisions on a system designer. Existing standards such as the Knowledge Interchange Format (KIF), KQML, those developed by the Foundation for Intelligent Physical Agents (FIPA), and even some non-agent specific standards have a place in the reference model and in fact are needed by the reference model. The reference model states that a component needs to exist, the standards tell someone how to design it.

A reference model also does not define an architecture. A reference model can drive the implementation of multiple architectures in the same way that an architecture could drive multiple designs, or a design could drive multiple implementations. In the same way, this reference model is not an attempt to impose (or even define) standards for the implementation of an agent-based system. It is an attempt to describe the abstract layers and concepts that may exist in such a system.

We have classified existing standards for agent-based systems roughly into five categories:

- *General* standards that are higher-level, and less specific. Examples include the FIPA Abstract Architecture [5] and FIPA Agent Management [9] standards.
- *Communication* standards that deal with both the actual logistics of communications and the information being communicated. Examples include KIF [14], KQML [16], FIPA ACL Message Structure [8], and FIPA Message Transport Service.
- *Coordination protocol* standards for coordinating actions of agents. Examples include the FIPA Contract Net Interaction Protocol [10] and FIPA Recruiting Interaction Protocol [13].
- *Representation and Encoding* standards for encoding messages for transmission. Examples include FIPA Bit Efficient ACL [6] and FIPA XML ACL [7].
- *Ontologies* standards for knowledge representation. Examples include FIPA Device Ontology [11] and FIPA QoS Ontology [12].

8. FUTURE WORK

Our goal is to continue refinement of the reference model in consultation with the broader agents community. We will be making available an on-line interactive discussion forum, similar to a Wiki, for facilitating further development of the ABSRM.

ABSTRACT

The Deep Space Network (DSN) is a central part of NASA's infrastructure for communicating with active space missions, from earth orbit to beyond the solar system. Consisting of more than a dozen major ground antennas at three sites spaced around the globe, it must be carefully scheduled to satisfy the requirements of the various mission users, subject to many constraints. Scheduling the communication services for these missions is a fairly large scale negotiation problem since each mission cannot give up control of its spacecraft. While we will give details of this problem, this paper focuses more on describing an agent that provides scheduling advice to a single user within a collaborative scheduling system being developed. This agent can provide guidance to the user about feasible and optimal solutions to the problem they are working on. We describe our recent work in modeling the complexities of user requirements, and then scheduling and resolving conflicts on that basis.

1. INTRODUCTION

The NASA Deep Space Network (DSN) is an international network of antennas that supports interplanetary spacecraft missions and radio and radar astronomy observations for the exploration of the solar system and the universe. The network also supports selected Earth-orbiting missions. The DSN consists of three deep-space communications facilities placed approximately 120 degrees apart around the world: at Goldstone, in California's Mojave Desert; near Madrid, Spain; and near Canberra, Australia. This geographic placement permits constant observation of spacecraft as the Earth rotates.

Each of the DSN sites supports antennas of sizes 26m, 34m, and 70m, along with a variety of receivers and other equipment that can be configured to support all the different kinds of communications requests that must be handled. Fig. 1 shows a picture of one of the largest antennas, the 70m antenna at Goldstone, California, along with one of the 34m antennas at this same complex.

Fig. 1: The 70m antenna at the Deep Space Network Goldstone complex in the California Mojave desert. At the right can be seen one of the 34m antennas.

The missions supported by the DSN include all of NASA's deep space missions, such as the planetary exploration spacecraft at Mars (the Mars Exploration Rovers Spirit and Opportunity, Mars Odyssey, Mars Global Surveyor) and Saturn (Cassini-Huygens); cometary explorers such as Deep Impact and Stardust; and missions such as Voyagers 1 and 2 that are leaving the solar system entirely. Other missions supported include observatories such as Chandra (X-ray) and Spitzer (Infrared), in Earth orbit or near Earth orbit. A total of about 20 spacecraft are currently allocated resources in a typical near-term scheduling period, while at the writing of this paper, 61 missions are being scheduled over the ~10 year horizon.

In this paper we will describe the nature of the DSN negotiation problems, i.e. the allocation of DSN resources to the missions that request them. We will discuss our progress in modeling the requirements of the missions, and in generating schedules that meet these requirements. We will discuss how an agent can automate the negotiation process, and we describe an agent that helps automate conflict resolution in what is currently a manual and iterative process. Key elements of our approach include tools for visualizing the schedule in various ways, and a search engine that looks for possible resolutions of conflicts to suggest to the user. We conclude with a discussion of future research and implementation directions.

2. THE DEEP SPACE NETWORK SCHEDULING PROBLEM

Currently, DSN schedules are manually generated out one year in the future. The nearer term portion of the schedule (up to 8 weeks out) considers the specific equipment and personnel to be allocated to a communications event. Beyond this interval, the schedule is concerned primarily with scheduling *tracks*, each of which is an allocation of an antenna to a mission over a specific time period. Tracks are typically one to eight hours in duration and must be placed within a *viewperiod* for that particular mission, i.e. when the spacecraft is visible (within specified geometric limits) from that antenna. A typical week will contain about 370 scheduled tracks. In this paper we are concerned with mid-range (8-week to 6-month) and long-term (beyond 6-months) schedules.

2.1 Constraints

Among the constraints that come into play when generating the DSN schedule are the following:

- A spacecraft can only be scheduled to use an antenna when it is within view: this is primarily a geometric constraint and can be pre-computed ahead of time into a set of usable viewperiods for each mission/antenna pair
- No two spacecraft can use the same antenna at the same time, with the exception that multiple spacecraft in view can downlink at the same time, but only one can uplink. Thus, for example, the multiple missions currently at Mars can share antennas for some activities.
- Tracks have *setup* and *teardown* durations that typically range from 10 minutes to an hour. (The combined setup, track and teardown is called an *activity*.) These setups and teardowns can be scheduled outside of the spacecraft viewperiod but generally cannot overlap other activities on the same antenna.

2.2 Requirements

The missions that use the DSN initially specify their requirements in high-level terms of hours/week per antenna, with more detailed specifications communicated informally (verbally or email) by the missions to the schedulers. One of the challenges faced in automating the DSN scheduling problem is that of defining a representation that can capture the details and subtleties of the individual mission's requirements. The representation must be highly expressive, since mission requirements can incorporate any of the following elements:

- *And/Or* groupings and alternatives. Missions must be able to specify conjunctions of requirements (such as multiple antennas at the same or different times). Such a conjunction means that all of the subrequirements must be satisfied at the same time in order for the requirement to be satisfied. In addition, disjunctive requirements may be specified, such that at most one requirement of a set of alternatives must be satisfied. In general, these requirements can be organized into an AND/OR tree, which is an ideal way to capture the combination of groupings (and) and alternatives (or) that arise when specifying a mission's requirements in detail.
- *Timing*. Tracks may have specified start times and durations, both of which may have allowable ranges.
- *Antennas*. Missions may specify one or more alternative antennas on which a track may be scheduled. They may specify groups of antennas, any one of which is acceptable for a particular type of track.
- *Repetitions*. Track repetitions may be specified in general as requirements, over some time period, on the number of tracks, their durations, overlap, and time gaps to neighboring tracks. All of these quantities may have ranges on them. So, for example, a mission might specify repetition requirements such as "seven tracks/week, of duration 5 to 8 hours with no gap longer than 20 hours between adjacent tracks".
- *Overrides*. In some cases, missions need to override a general requirement with a more specific one based on knowledge of ongoing activities. For example, a general requirement for a telemetry downlink every 10 hours may be superceded around the time of a maneuver with a requirement for continuous coverage.
- *Activity start and end times* for most missions must be scheduled on five-minute boundaries.

2.3 Negotiation

Missions are responsible for generating their own schedules, and although these may be automatically generated, conflicts will arise when two or more missions prefer the same antenna or equipment. While primary missions have priority over extended missions (those for which the primary mission has already been completed), there are no other precedence relations on missions or their particular requirements.
Thus, conflicts must be negotiated. If conflicts cannot be resolved, they are escalated, and a committee decides who wins. Currently, there are bi-weekly meetings up to four hours long where mission representatives and scheduling personnel try to resolve two weeks of conflicts scheduled about a half year into the future. General loading conflicts predicted beyond the half year are worked out twice a year in a meeting of more than 100 staff. Other meetings are held month-to-month. Outside of that mission representatives "horse trade" allocations to get what they need. While most missions get what they need, this process is obviously time-consuming and expensive.

There is an opportunity to significantly automate this negotiation. Using an automated scheduler to recommend solutions can greatly reduce human effort in finding resolutions to conflicts, but it does not relieve the communicative part of the negotiation process. One approach is to use an automated multi-objective scheduler to try to find solutions that favor all missions involved. This can reduce the number of rejections and counterproposals in the negotiation. Another complementary approach is for the mission to allow an agent to generate proposals and responses on its behalf. While the human user would not want an agent to make all decisions, in some cases the decision is obvious. For example, the agent should always refuse proposals to reschedule a critical track, and the agent should always accept proposals that fulfill unmet requirements. For proposals to which the agent may not respond, the agent can make suggestions, including counterproposals (based on multi-objective scheduling). As the user gains more confidence with the agent, it can define situations in which the agent is allowed to respond. Not only can this reduce the human involvement in negotiation, but also more negotiations can take place in order to create better overall schedules. If the use of such agents is adopted, distributed scheduling research could have great impact on this problem.

3. AUTOMATING DSN SCHEDULING

Our approach to automating the DSN scheduling problem is illustrated in the architecture diagram of Fig. 2. At the top are shown schematically the DSN data sources such as viewperiods and current schedules in various stages of completion and conflict resolution. This information is available via web services and network databases.

The Interactive User Environment, depicted in the lower left of Fig. 2, consists of a graphical requirements editor, a schedule timeline display function, and a local repository for requirements.

The Scheduling Agent, shown in the lower right of Fig. 2, incorporates three major approaches to schedule generation and repair: a local heuristic search technique and a set of systematic backtrack algorithms, and an intelligent assistant that suggests alternative schedule changes to the user. The API allows the scheduling computation to be done remotely on a grid while making it easier to switch out scheduling algorithms or intelligent assistants. In the following we describe each of these elements in more detail.

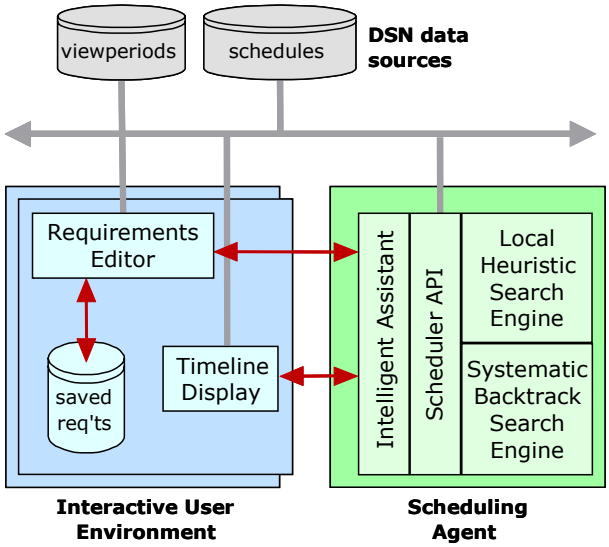

Fig. 2. Architectural overview of automated DSN scheduling

3.1 Interactive User Environment

The variety and complexity of the requirements described above provide a challenge for users. To help create and modify mission requirements, we have developed a graphical requirements editor that handles the full expressiveness of the requirements specification for the DSN. Fig. 3 shows a screen snapshot of this editor: on the left is a tree that represents the AND/OR tree of requirements and sub-requirements. As a node is selected, all of its attributes are displayed on the right side of the panel where they may be edited by the user, including the selection of antennas, timing, segmentation, and repetition. Requirements may be saved for further editing, or sent on to the scheduler as described below.

The timeline display provides the user with visual insight into the evolving schedule. We have adapted a standard Gantt-chart view and added additional features to make it easier to navigate and drill down for more information. These features displayed in Fig. 4, 5, and 6 include:

- activity start and end times, as well as setup and teardown times indicated by faint gray bars
- a schedule difference display that visually highlights tracks added, tracks deleted, and tracks changed. Changed tracks

can be clicked with the mouse to reveal a table display of the track attributes before and after, color encoded to show exactly which attributes have changed

- a metric-shaded background, to help visually spot regions of interest in the schedule. In the example shown, the shading is by gap duration in a 24h period, such that the bright shades of red indicate times with a scarcity of contacts.

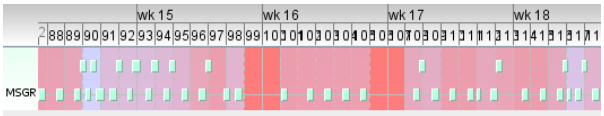

Fig. 6: Example of metric shaded background in the Gantt view

3.2 Local Heuristic Search

We have adapted the Aspen scheduler [10] to schedule all of the requirement types described above. This adaptation consists of two major components:

(1) a *mapping* from mission requirements (as described above) into Aspen's native modeling language [10]. A large portion of this mapping makes straightforward use of Aspen's built-in modeling features, including tasks and their hierarchical expansion into subtasks; temporal relationships; states; resources (consumable and nonconsumable); and parameters and their relationships. In some cases we have exploited Aspen's extension point mechanism to define external functions that can be invoked by Aspen. Details are provided in [11].

(2) a *set of heuristics* to drive Aspen's iterative repair-based search. These heuristics are based on "conflicts" in the schedule, such as state, resource, or temporal constraint violations, un-expanded hierarchical tasks, or un-propagated parameter dependencies. Part of the conflict selection and repair process incorporates randomness to help ensure a broad exploration of the search space. For a further description of the heuristics, see [11].

We have conducted experiments to gauge the performance of Aspen in this domain, with satisfactory results. In one experiment, we generated a full artificial schedule of 1861 tracks from periodic track requests in 39 CPU minutes. Modifications to this schedule were much faster: emergency antenna downtime or additional tracks were scheduled in 0.2 CPU seconds. Another experiment scheduled a week (274 tracks) of actual user requirements of the form of "*x* tracks of duration *y* on antennas (*a* & *b*) or (*c* & *d*)," resolving 77 out of 79 conflicts in 151 CPU seconds.

While the stochastic heuristic search technique embodied in Aspen has many advantages in this domain, it also has some disadvantages. The most important of these is that Aspen's search is not complete: it may fail to find a solution even if one exists. If solutions are sparse, the local search process may simply fail to find any in the time allotted (the "needle in a haystack" situation). To address this, we have complemented Aspen's search approach with several systematic search algorithms, as described in the next section.

3.3 Systematic Backtrack Search

We have implemented several systematic search algorithms based on constraint propagation and backtracking search. This approach, when appropriately limited in scope, can definitively answer the question of whether a solution exists and can additionally provide suggestions as to which requirements are overconstraining a problem, thus making it unsolvable.

The systematic search algorithms we have implemented are based on the following:

- search over time and resource assignments that start from the existing schedule (with or without constraint violations), so that alternatives "close" to the existing schedule are searched first
- tracks to assign are selected using a most constrained first heuristic
- backtracking is "fail fast", such that whenever any track has all domain values (times and resources) in conflict, the search immediately backtracks
- node and arc consistency is maintained based on track duration, view period windows, and resource availability

In addition to a basic backtracking search algorithm, we have also implemented an A* optimizing search, based on an objective that is a function of the time and resource assignments for each track. We have implemented several different objectives:

- Minimum total change: the smallest possible shifts in track times and antenna assignments for all tracks under consideration
- minimum number of missions affected by changes: this will allow more and larger changes, provided the number of missions impacted is smaller (thus limiting the number of parties who have to negotiate the changes)
- an overall preference function on track start times $\Sigma f_i(t_s)$ that can express mission-specific preferences on when tracks are scheduled

Systematic search can be exponentially costly even with these techniques, so we bound its application by considering the following:

- limit to only a subset of the fully expressive requirements language
- limit the time horizon of the schedule considered
- limit the activities to consider, by locking a substrate of activities on the schedule and search only over a subset which is allowed to move
- limit the CPU time expended in the search

Our experience to date indicates that frequently there are "pockets" of conflicts that occur together, which have limited impact on the schedule as a whole. In this situation, systematic search can be bounded and yet still provide valuable insight into solution possibilities.

To investigate the performance of the systematic search algorithms, we ran a number of experiments on mid-range and short-term schedules. These first of these was on a 14 week period after the initial conflict resolution process. We considered each day in the schedule separately, and ran three different systematic search algorithms on each:

- **BT1**: standard depth-first backtrack search
- **BT2**: same, but tracks were prohibited from changing their antenna assignments
- **A***: search for all "minimum change" schedules

The results are illustrated in Fig. 7. Of the 98 days examined, 28 had track resource/timing conflicts, ranging from one to four per day. Of those 28 days, one had no feasible solution and would have to have requirements relaxed in some manner by the respective missions. The other 27 had solutions that were quickly found with BT1, in an average time of 10ms. The typical change was relatively small: an average 1.9±1.4 tracks were changed, with a total time shift (summed over all tracks) of 6.8±11.5 hours. BT2 only found one improvement over the solutions found by BT1. Most of the solutions found by BT1 (16 out of 27) were optimal by the "minimum change" metric described above. In 5 cases, the A* search found better solutions, and in 6 cases A* was stopped at a 1000s run time limit before finding any optimal solutions. The computational cost of A* was both higher and more varied than BT1 or BT2: the mean run time was 18±52s.

As noted, this schedule represents the time after initial conflict resolution has been worked on by the schedulers and the mission users. We also selected a 2-week schedule snapshot taken before this conflict resolution process and ran the same experiments. The results are shown in Fig. 8. In this case 13 of the 14 days show conflicts, all of which were quickly resolved with BT1. The typical changes were much larger, however: an average 4.0±4.2 tracks were changed, with a total time shift of 19.7±26.9h. This reflects the smaller effort expended to resolve conflicts at this stage in the scheduling process. The A* algorithm found better solutions for 6 days, and no improvements for another 4 days. The A* runtime showed greater variability at 71±229s.

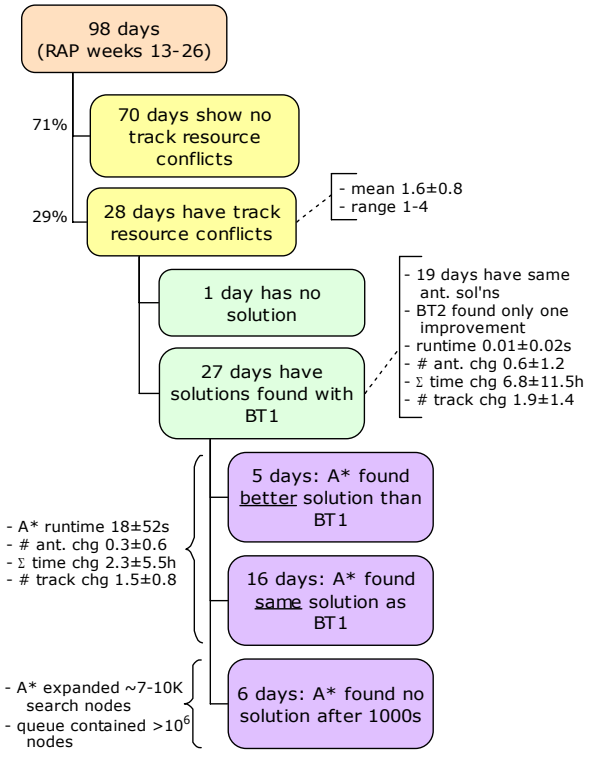

Fig. 7: Experimental results on a 98-day schedule span

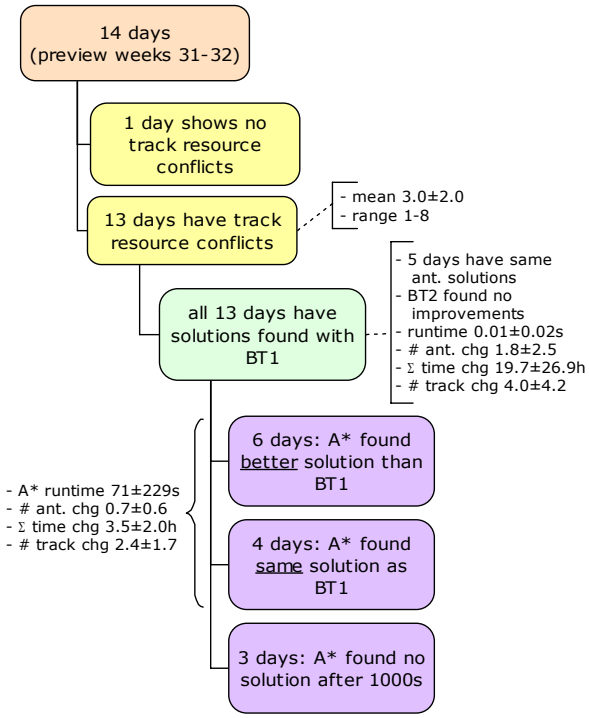

Fig. 8: Experimental results on a 14-day schedule before conflict resolution

3.4 Intelligent Assistant

The conclusion from these experiments is that systematic search can help identify solution possibilities when sufficiently bounded. We have integrated this functionality into the user interface elements described above by implementing an intelligent assistant that consists of

- a *filtering mechanism*, currently text-based, to allow the user to focus attention on a subset of the schedule: by time, mission, resource, etc.
- multiple *background asynchronous search processes* that run on the filtered problem and utilize the systematic search algorithms described above.

A snapshot of this interface is shown in Fig. 9. The intelligent assistant's background processes run automatically, starting whenever the filter criteria are changed by the user. They may be canceled by the user at any time, and they display current status as they run, both in a progress bar and in a textual status message. The BT1 and BT2 algorithms complete so quickly in our experiments (<10ms) as to be essentially instantaneous. The A* algorithm is much slower and more variable in duration: the status displayed in the progress bar shows how many of the total tracks have been successfully scheduled so far. In each case, when complete, the user can mouse over the status display to see a popup window with more detail, and can then click the "More" button to open a Gantt chart view of the schedule generated by the algorithm, along with highlighted differences from the original schedule.

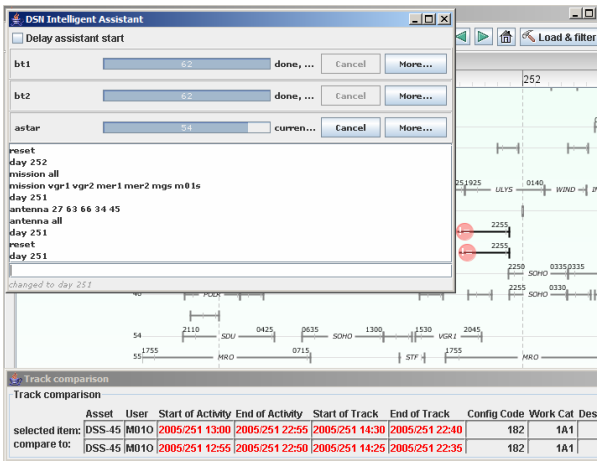

Fig. 9: Intelligent assistant dialog and display

By being unobtrusive, the intelligent assistant can provide the user with additional information at the precise time when the user is interested. Results are displayed immediately when they are calculated, and the user can cancel an ongoing search simply by revising the search criteria, which also automatically starts a new search using the new criteria. If the assistant generates an interesting schedule, the user can "drill down" into the details in a very straightforward manner.

4. RELATED WORK

There have been a number of previous investigations of DSN scheduling automation. The Operation Mission Planner (OMP-26) used heuristic search to allocate 26m antennas to missions and linear programming to adjust track time intervals [1]. Other automation projects were research efforts and were never deployed. LR-26 was a customisable heuristic scheduler that utilized Lagrangian relaxation [2], while the Demand Access Network Scheduler (DANS) employed an iterative repair technique [3]. Other graphical planning tools that have been used for forecasting, analysis, and interactive scheduling include TIGRAS [4] and FASTER [5]. Our approach combines some of the strengths of these systems, as well as incorporating innovative elements in both scheduling search and in schedule visualization.

Other scheduling domains pose problems that have similar characteristics to the DSN mid- and long-term scheduling problem. The Air Force Satellite Control Network (AFSCN) also schedules large numbers of satellites and ground stations but is limited to one day at a time. For this oversubscribed problem, there appear to be significant "plateaus" in the search space, that make strategies that take larger search steps more effective [6, 7]. Another related problem is that of fleets of Earth observing satellites with onboard resource limitations as well as tight viewperiod constraints [8]. In these problems, where the requests are prioritized, the goal of finding a best subset to fit on a

schedule has been addressed by a greedy approach with texture-based heuristics [9].

Automated sequence generation for spacecraft is different in that the horizon of interest is smaller (e.g. one week for an orbiter, one day for a rover) and the model of the spacecraft is very intricate. Safety is the highest priority in sequence scheduling, but efficiency is the goal of DSN resource allocation. Thus, the scheduling problem is very different.

5. DISCUSSION

We have developed and described a "hybrid" approach to automating DSN scheduling. An overall schedule for some time period can be generated based on the complex merged requirements from the different missions: for this phase, we make use of the ASPEN framework which implements an iterative repair-based search strategy. We have complemented this with a set of systematic search algorithms that work on an appropriately bounded region of the search space. We have embedded these algorithms in an agent that runs unobtrusively to provide timely information to the user engaged in rescheduling and resolving schedule conflicts. The agent can provide feedback immediately as it draws conclusions. For example, it may be possible for the scheduling agent to rapidly determine that there are no feasible solutions to a specific conflict situation, so a user can move on to consider changing the requirements or negotiating with another mission. Similarly, the agent may identify an optimal set of choices to resolve a conflict so that the user's time can be better spent in choosing among them rather than trying to find a solution by manual experimentation. We have found that, while systematic search does not always find timely solutions, it frequently does very quickly provide valuable help to the interactive user.

Future research and implementation directions include the following:

- further integration of the iterative repair and systematic search engines, to best exploit the advantages of each in a broader range of circumstances
- investigation of modelling and performance tradeoffs in mapping mission requirements into representational elements for the scheduler engines
- incorporating additional optimization criteria into the systematic search algorithm, to provide users with more insight into potential schedule modifications

6. ACKNOWLEDGEMENTS

The research described in this paper was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

Using Multiagent Teams to Improve the Training of Incident Commanders*

Nathan Schurr, Pratik Patil, Fred Pighin, Milind Tambe,
University of Southern California, Los Angeles, CA 90089, {schurr, pratiksp, pighin, tambe}@usc.edu

ABSTRACT

The DEFACTO system is a multiagent based tool for training incident commanders for large scale disasters. In this paper, we highlight some of the lessons that we have learned from our interaction with the Los Angeles Fire Department (LAFD) and how they have affected the way that we continued the design of our training system. These lessons were gleaned from LAFD feedback and initial training exercises and they include: system design, visualization, improving trainee situational awareness, adjusting training level of difficulty and situation scale. We have taken these lessons and used them to improve the DEFACTO system's training capabilities. We have conducted initial training exercises to illustrate the utility of the system in terms of providing useful feedback to the trainee.

1. INTRODUCTION

The recent hurricanes that have hit the gulf coast of the US have served to reaffirm the need for emergency response agencies to be better prepared for large scale disasters. Both natural and man-made (terrorism) disasters are growing in scale, however the response to these incidents continues to be managed by a single person, namely the incident commander. The incident commander must monitor and direct the entire event while maintaining complete responsibility. Because of this, incident commanders must start to be trained to handle these large scale events and assist in the coordination of the responding team.

In order to fulfill this need and leverage the advantages of multiagents, we have continued to develop the DEFACTO system (Demonstrating Effective Flexible Agent Coordination of Teams via Omnipresence). DEFACTO is a multiagent based tool for training incident commanders for large scale disasters (man-made or natural).

Our system combines a high fidelity simulator, a redesigned human interface, and a multiagent team driving all of the behaviors. Training incident commanders provides a dynamic scenario in which decisions must be made correctly and quickly because human safety is at risk. When using DEFACTO, incident commanders have the opportunity to see the disaster in simulation and the coordination and resource constraints unfold so that they can be better prepared when commanding over an actual disaster. Applying DEFACTO to disaster response aims to benefit the training of incident commanders in the fire department.

With DEFACTO, our objective is to both enable the human to have a clear idea of the team's state and improve agent-human team performance. We want DEFACTO agent-human teams to better prepare firefighters for current human-only teams. We believe that by leveraging multiagents, DEFACTO will result in better disaster response methods and better incident commanders.

Previously, we have discussed building our initial prototype system, DEFACTO [8]. Recently, the Los Angeles Fire Department (LAFD) have begun to evaluate the DEFACTO system. In this paper, we highlight some of the lessons that we have learned from our interaction with the LAFD and how they have affected the way that we continued to design of our training system. These lessons were gleaned from LAFD feedback and initial training exercises.

The lessons learned from the feedback from the LAFD include: system design, visualization, improving trainee situational awareness, adjusting training level of difficulty and situation scale. We have taken these lessons and used them to improve the DEFACTO system's training capabilities.

We have also performed initial training exercise experiments to illustrate the utility of the system in terms of providing useful feedback to the trainee. We ended up finding that allowing more fire engines to be at the disposal of the incident commander sometimes not only didn't improve, but rather worsened team performance. There were even some instances in which the agent team would have performed better had the team never listened to human advice at all. We also provide analysis of such behaviors, thereby illustrating the utility of DEFACTO resulting from the feedback given to trainees.

2. MOTIVATION

In this section, we will first start with an explanation of the current methods for training that the LAFD currently use. Then we explain some of the advantages that our multiagent approach has over these methods.

The incident commander's main duties during a fire shoulder all responsibility for the safety of the firefighters. In order to do this, the incident commander must have constant contact with the firefighters and have a complete picture of the entire situation. The incident commander must make certain that dangerous choices are

(a) Current Incident Commander Training Exercise

(b) Fire Captain Roemer using the DEFACTO training system

Figure 1: Old vs. New training methods

avoided and the firefighters are informed and directed as needed.

We were allowed to observe a Command Post Exercise that simulated the place where the incident commander is stationed during a fire (see Figure 1(a)). The Incident commander has an assistant by his side who keeps track on a large sheet of paper where all of the resources (personnel and equipment) are located. A sketch of the fire is also made on this sheet, and the fire and fire engines' location is also managed.

The Command Post is currently simulated by projecting a single static image of a fire in an apartment. In the back of the room, several firefighters are taken off duty in order to play the role of firefighters on the scene. They each communicate on separate channels over walkie talkies in order to coordinate by sharing information and accepting orders. The fire spreading is simulated solely by having one of the off-duty firefighters in the back speaking over the walkie talkie and describing the fire spreading.

The LAFD's current approach, however, has several limitations. First, it requires a number of officers to be taken off duty, which decreases the number of resources available to the city for a disaster during training. Second, the disaster conditions created are not accurate in the way that they appear or progress. Since the image that the incident commander is seeing is static, there is no information about state or conditions of the fire that can be ascertained from watching it, which is contrary to the actual scene of a disaster response. Furthermore, the fire's behavior is determined by the reports of the acting fire fighters over the walkie talkie, which at times might not be a plausible progression of fire in reality. Third, this method of training restricts it to a smaller scale of fire because of the limited personnel and rigid fire representation.

Our system aims to enhance the training of the incident commanders (see Figure 1(b)). Our approach allows for training to not be so personnel heavy, because fire fighter actors will be replaced by agents. By doing this we can start to train incident commanders with a larger team. Through our simulation, we can also start to simulate larger events in order to push the greater number of available resources to their limit. Also, by simulating the fire progression, we can place the Incident commander in a more realistic situation and force them to react to realistic challenges that arise.

3. SYSTEM ARCHITECTURE

In this section, we will describe the technologies used in three major components of DEFACTO: the Omni-Viewer, proxy-based

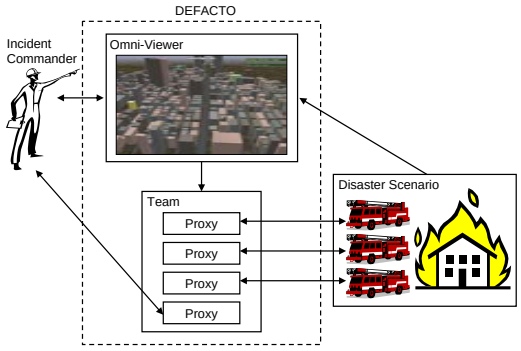

Figure 2: System Architecture

team coordination, and proxy-based adjustable autonomy. The Omni-Viewer is an advanced human interface for interacting with an agent-assisted response effort. The Omni-Viewer has been introduced before [8], however has since been redesigned after incorporating lessons learned from the LAFD. The Omni-Viewer now provides for both global and local views of an unfolding situation, allowing a human decision-maker to obtain precisely the information required for a particular decision. A team of completely distributed proxies, where each proxy encapsulates advanced coordination reasoning based on the theory of teamwork, controls and coordinates agents in a simulated environment. The use of the proxy-based team brings realistic coordination complexity to the training system and allows a more realistic assessment of the interactions between humans and agent-assisted response. These same proxies also enable us to implement the adjustable autonomy necessary to balance the decisions of the agents and human. This architecture has been described in a more extended fashion in [8]; we present a brief report here.

DEFACTO operates in a disaster response simulation environment. The simulation environment itself is provided by the RoboCup Rescue Simulator [3]. To interface with DEFACTO, each fire engine is controlled by a proxy in order to handle the coordination and execution of adjustable autonomy strategies. Consequently, the proxies can try to allocate fire engines to fires in a distributed manner, but can also transfer control to the more expert user (incident

commander). The user can then use the Omni-Viewer to allocate engines to the fires that he has control over. In our scenario, several buildings are initially on fire, and these fires spread to adjacent buildings if they are not quickly contained. The goal is to have a human interact with the team of fire engines in order to save the greatest number of buildings. Our overall system architecture applied to disaster response can be seen in Figure 2.

3.1 Omni-Viewer

Our goal of allowing fluid human interaction with agents requires a visualization system that provides the human with a global view of agent activity as well as shows the local view of a particular agent when needed. Hence, we have developed an omnipresent viewer, or Omni-Viewer, which will allow the human user diverse interaction with remote agent teams. While a global view is obtainable from a two-dimensional map, a local perspective is best obtained from a 3D viewer, since the 3D view incorporates the perspective and occlusion effects generated by a particular viewpoint.

To address our discrepant goals, the Omni-Viewer allows for both a conventional map-like top down 2D view and a detailed 3D viewer. The viewer shows the global overview as events are progressing and provides a list of tasks that the agents have transferred to the human, but also provides the freedom to move to desired locations and views. In particular, the user can drop to the virtual ground level, thereby obtaining the perspective (local view) of a particular agent. At this level, the user can fly freely around the scene, observing the local logistics involved as various entities are performing their duties. This can be helpful in evaluating the physical ground circumstances and altering the team's behavior accordingly. It also allows the user to feel immersed in the scene where various factors (psychological, etc.) may come into effect.

3.2 Proxy: Team Coordination

A key hypothesis in this work is that intelligent distributed agents will be a key element of a disaster response. Taking advantage of emerging robust, high bandwidth communication infrastructure, we believe that a critical role of these intelligent agents will be to manage coordination between all members of the response team. Specifically, we are using coordination algorithms inspired by theories of teamwork to manage the distributed response [6]. The general coordination algorithms are encapsulated in *proxies*, with each team member having its own proxy which represents it in the team. The current version of the proxies is called *Machinetta* [7] and extends the earlier Teamcore proxies [5]. Machinetta is implemented in Java and is freely available on the web. Notice that the concept of a reusable proxy differs from many other "multiagent toolkits" in that it provides the coordination *algorithms*, e.g., algorithms for allocating tasks, as opposed to the *infrastructure*, e.g., APIs for reliable communication. These proxies and their architecture have been discussed in detail in [8].

3.3 Proxy: Adjustable Autonomy

One key aspect of the proxy-based coordination is "adjustable autonomy." Adjustable autonomy refers to an agent's ability to dynamically change its own autonomy, possibly to transfer control over a decision to a human. Previous work on adjustable autonomy could be categorized as either involving a single person interacting with a single agent (the agent itself may interact with others) or a single person directly interacting with a team. In the single-agent single-human category, the concept of flexible transfer-of-control strategy has shown promise [6]. A transfer-of-control strategy is a preplanned sequence of actions to transfer control over a decision among multiple entities. For example, an AH_1H_2 strategy implies that an agent (A) attempts a decision and if the agent fails in the decision then the control over the decision is passed to a human H_1, and then if H_1 cannot reach a decision, then the control is passed to H_2. Since previous work focused on single-agent single-human interaction, strategies were individual agent strategies where only a single agent acted at a time.

An optimal transfer-of-control strategy optimally balances the risks of not getting a high quality decision against the risk of costs incurred due to a delay in getting that decision. Flexibility in such strategies implies that an agent dynamically chooses the one that is optimal, based on the situation, among multiple such strategies (H_1A, AH_1, AH_1A, etc.) rather than always rigidly choosing one strategy. The notion of flexible strategies, however, has not been applied in the context of humans interacting with agent-teams. Thus, a key question is whether such flexible transfer of control strategies are relevant in agent-teams, particularly in a large-scale application such as ours.

DEFACTO has introduced the notion of team-level adjustable autonomy strategies. For example, rather than transferring control from a human to a single agent, a team-level strategy could transfer control from a human to an agent-team. Concretely, each proxy is provided with all strategy options; the key is to select the right strategy given the situation. An example of a team level strategy would combine A_T Strategy and H Strategy in order to make A_TH Strategy. The default team strategy, A_T, keeps control over a decision with the agent team for the entire duration of the decision. The H strategy always immediately transfers control to the human. A_TH strategy is the conjunction of team level A_T strategy with H strategy. This strategy aims to significantly reduce the burden on the user by allowing the decision to first pass through all agents before finally going to the user, if the agent team fails to reach a decision.

4. LESSONS LEARNED FROM INITIAL DEPLOYMENT FEEDBACK

Through our communication with strategic training division of the LAFD (see Figure 1(b)), we have learned a lot of lessons that have influenced the continuing development of our system.

4.1 Adjustable Autonomy in Practice

Our most important lesson learned from talking with the LAFD and seeing their exercises is that adjustable autonomy correctly maps over to what happens in the actual disaster response. The adjusting of autonomy is easily seen as the event scales up and down in size and intensity. For a smaller scale response to, for example, a residential single story house fire, the incident commander will usually make all allocation decisions and thus practice the A strategy. For a larger scale event, a lot of the burden of most allocations are left to the team and other entities in the hierarchy, while the Incident Commander is left to concentrate on the bigger picture. In this case, the Incident commander is notified if a specifically problematic situation, for example not enough resources to attack a particular fire. This strategy is essentially what we refer to as A_TH in our experiments, in which, the team first tries to assign someone to the fire with the resources they have, and if not able to then pass it off to the Incident Commander for help. As the situation were to die down and the size of the team were to decrease, more autonomy would be shifted to the Incident Commander due to an increased ability to make allocations for the team.

It is very helpful to know that these strategies not only are capable of making our agent teams perform well and interface with the Incident Commander, but that they also reflect similar strategies that current firefighting teams are using.

Figure 3: Selecting for closer look at a Fire Engine.

4.2 Questioning the Incident Commander

Another lesson that relates to our agent design is that we learned how a team on the ground may possibly not agree with the command (allocation to a fire) given by the Incident Commander. This will usually be due to the fact that the Incident Commander has a broad global view of the disaster, whereas the agents each have a more detailed local view. This mismatch in information can, at times, lead to detrimental team allocations. In an actual disaster response, this is handled by the allocated team both questioning the order and providing the Incident Commander with the missing information.

This has led us to consider a team of agents that can disagree with human inputs. This issue has not been addressed in our implementation as of yet, but it is relevant given the results that will be presented later in the training exercise experiments. There are experimental settings in which the team performance would have been improved, had they rejected the Incident Commander's input.

4.3 Perspective

Just as in multiagent systems, the Incident commander must overcome the challenge of managing a team that each possess only a partial local view. This is highlighted in fighting a fire by incident commanders keeping in mind that there are five views to every fire (4 sides and the top). Only by taking into account what is happening on all five sides of the fire, can the fire company make an effective decision on how many people to send where. Because of this, a local view (see Figure 4(a)) can augment the global view (see Figure 4(b)) becomes helpful in determining the local perspectives of team members. For example, by taking the perspective of a fire company in the back of the building, the incident commander can be aware that they might not see the smoke from the second floor, which is only visible from the front of the building. The incident commander can then make a decision to communicate that to the fire company or make an allocation accordingly.

The 3D perspective of the Omni-Viewer was initially thought to be an example of a futuristic vision of the actual view given to the incident commander. But after allowing the fire fighters to look at the display, they remarked, that they have such views available to them already, especially in large scale fires (the very fires we are trying to simulate). At the scene of these fires are often a news helicopter is at the scene and the incident commander can patch into the feed and display it at his command post. Consequently our training simulation can already start to prepare the Incident Commander to incorporate a diverse array of information sources.

4.4 Fire Behavior

We also learned how important smoke and fire behavior is to the firefighters in order to affect their decisions. Upon our first showing of initial prototypes to the Incident Commanders, they looked at our simulation, with flames swirling up out of the roof (see Figure 5(a)). We artificially increased fire intensity in order to show off the fire behavior and this hampered their ability to evaluate the situation and allocations. They all agreed that every firefighter should be pulled out because that building is lost and might fall at any minute! In our efforts to put a challenging fire in front of them to fight, we had caused them to walk away from the training. Once we start to add training abilities, such as to watch the fire spread in 3D, we have to also start to be more aware of how to accurately show a fire that the Incident Commander would face. We have consequently altered the smoke and fire behavior (see Figure 5(b)). The smoke appears less "dramatic" to the a lay person than a towering inferno, but it provides a more effective training environment.

4.5 Gradual Training

Initially, we were primarily concerned with changes to the system that allowed for a more accurate simulation of what the Incident Commander would actually see. Alternatively, we have also added features, not because of their accuracy, but also to aid in training by isolating certain tasks. Very often in reality and in our simulations, dense urban areas obscure the ability to see where all of the resources (i.e. fire engines) are and prevent a quick view of the situation (see Figure 6(a)). To this aim, we have added a new mode using the 3D, but having the buildings each have no height, which we refer to as Flat World (see Figure 6(b)). By using this flat view, the trainee is allowed to concentrate on the allocation of resources, without the extra task of developing an accurate world view with obscuring high rise buildings.

4.6 User Intent

A very important lesson that we learned from the LAFD, was that the Incident Commander cannot be given all information for the team and thus the human does not know all about the status of the team members and vice versa. Consequently, this lack of complete awareness of the agent team's intentions can lead to some harmful allocations by the human (Incident Commander). In order for information to be selectively available to the Incident Commander, we have allowed the Incident Commander to query for the status of a particular agent. Figure 3 shows an arrow above the Fire Engine at the center of the screen that has been selected. On the left, the statistics are displayed. The incident commander is able to select a particular fire engine and find out the equipment status, personnel status, and the current tasks that are being performed by the fire fighters aboard that engine. This detailed information can be accessed if desired by the Incident Commander, but is not thrown to the screen by all agents, in order to not overwhelm the Incident Commander.

4.7 Scale

In addition, we have also learned of new challenges that we are currently attempting to tackle by enhancing the system. One of the biggest challenges in order to start simulating a large urban fire is the sheer scale of the resources that must be managed. According to the fire captains, in order to respond to a single high rise building with a few floors on fire, roughly 200 resources (fire engines, paramedics etc.) would need to be managed at the scene. Coordinating such a large number of agents on a team is a challenge. Also, as the incident scales to hundreds of resources, the Incident Commander ends up giving more autonomy to the team or else face

being overwhelmed. We believe that adjustable autonomy will start to play a bigger and more essential roll in allowing for the Incident Commander to monitor the larger situations.

5. LESSONS LEARNED FROM TRAINING EXERCISES

In this section, we will present results and analysis from a set of training exercises. Our initial experimental results have been published earlier [8], however the analysis presented here is new.

5.1 Training Exercises

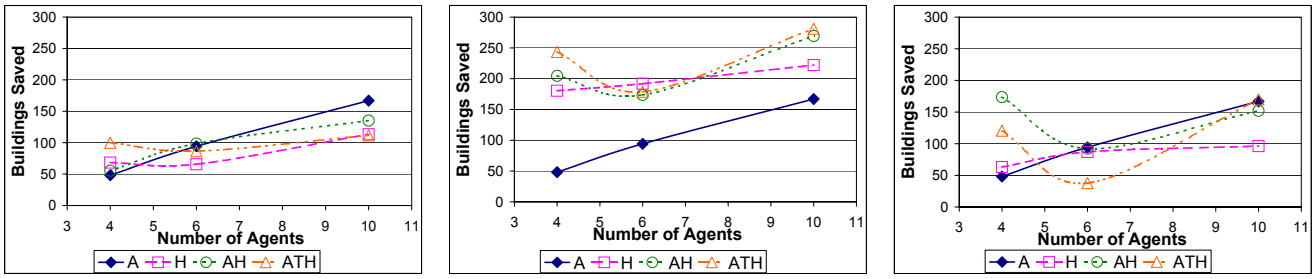
In order to study the potential of DEFACTO, we performed some training exercises with volunteers. These initial experiments showed us that humans can both help and hurt the team performance. The key point is that DEFACTO allows such experiments with training exercises and more importantly allows for analysis and feedback regarding the exercises. Thus trainees can gain useful insight as to why their decisions led to problematic/beneficial situations.

The results of our training exercise experiments are shown in Figure 9, which shows the results of subjects 1, 2, and 3. Each subject was confronted with the task of aiding fire engines in saving a city hit by a disaster. For each subject, we tested three strategies, specifically, H, AH (individual agent, then human) and $A_T H$ (agent team, then human); their performance was compared with the completely autonomous A_T strategy. AH is an individual agent strategy, tested for comparison with $A_T H$, where agents act individually, and pass those tasks to a human user that they cannot immediately perform. Each experiment was conducted with the same initial locations of fires and building damage. For each strategy we tested, varied the number of fire engines between 4, 6 and 10. Each chart in Figure 9 shows the varying number of fire engines on the x-axis, and the team performance in terms of numbers of building saved on the y-axis. For instance, strategy A_T saves 50 building with 4 agents. Each data point on the graph is an average of three runs. Each run itself took 15 minutes, and each user was required to participate in 27 experiments, which together with 2 hours of getting oriented with the system, equates to about 9 hours of experiments per volunteer.

Figure 9 enables us to conclude the following:

- *Human involvement with agent teams does not necessarily lead to improvement in team performance.* Contrary to expectations and prior results, human involvement does not uniformly improve team performance, as seen by human-involving strategies performing worse than the A_T strategy in some cases. For instance, for subject 3 AH strategy provides higher team performance than A_T for 4 agents, yet at 10 agents human influence is clearly not beneficial.

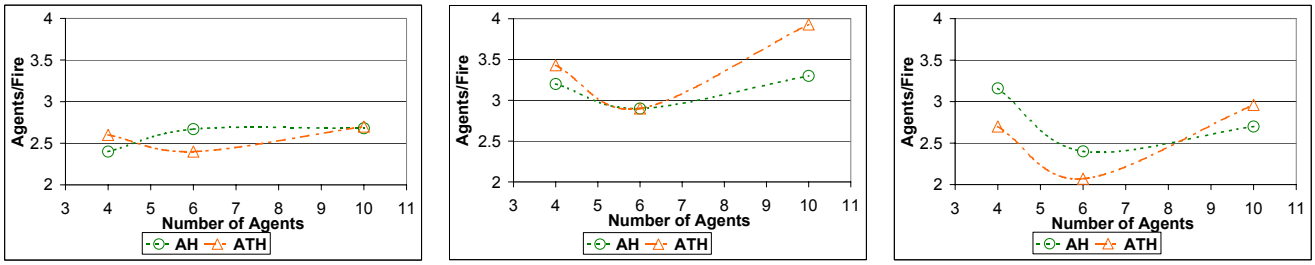
- *Providing more agents at a human's command does not necessarily improve the agent team performance.* As seen for subject 2 and subject 3, increasing agents from 4 to 6 given AH and $A_T H$ strategies is seen to degrade performance. In contrast, for the A_T strategy, the performance of the fully autonomous agent team continues to improve with additions of agents, thus indicating that the reduction in AH and $A_T H$ performance is due to human involvement. As the number of agents increase to 10, the agent team does recover.



- *Complex team-level strategies are helpful in practice*: $A_T H$ leads to improvement over H with 4 agents for all subjects, although surprising domination of AH over $A_T H$ in some cases indicates that AH may also need a useful strategy to have available in a team setting.

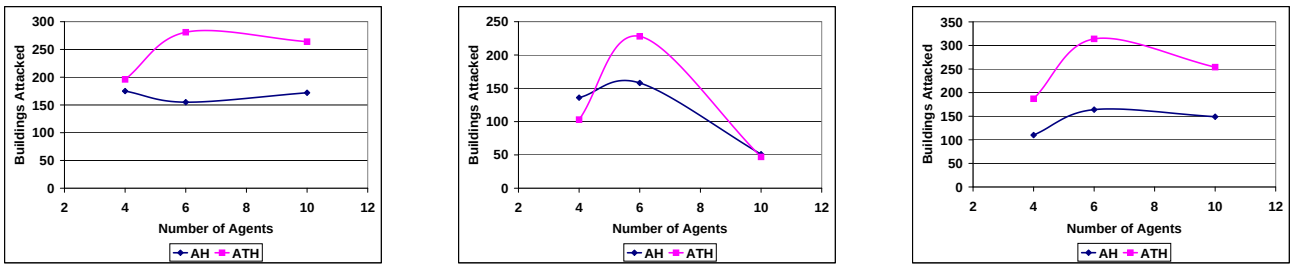
Note that the phenomena described range over multiple users, multiple runs, and multiple strategies. Unfortunately, the strategies including the humans and agents (AH and $A_T H$) for 6 agents show a noticeable decrease in performance for subjects 2 and 3 (see Figure 9). It would be useful to understand which factors contributed to this phenomena from a trainee's perspective.

5.2 Analysis



We decided to perform a more in depth analysis of what exactly was causing the degrading performance when 6 agents were at the disposal of the Incident Commander. Figure 10 shows the number agents on the x-axis and the average amount of fire engines allocated to each fire on the y-axis. AH and $A_T H$ for 6 agents result in significantly less average fire engines per task (fire) and therefore lower average. Another interesting thing that we found was that this lower average was not due to the fact that the Incident Commander was overwhelmed and making less decisions (allocations). Figures 11(a), 11(b), and 11(c) all show how the number of buildings attacked do not go down in the case of 6 agents, where poor performance is seen.

Figures 7 and 8 show the number of agents assigned to a building on the x-axis and the probability that the given building would be saved on the y-axis. The correlation between these values demonstrate the correlation between number of agents assigned to the quality of the decision.



(a) Subject 1 (b) Subject 2 (c) Subject 3

Figure 9: Performance.

(a) Subject 1 (b) Subject 2 (c) Subject 3

Figure 10: Amount of agents assigned per fire.

(a) Subject 1 (b) Subject 2 (c) Subject 3

Figure 11: Number of buildings attacked.

We can conclude from this analysis that the degradation in performance occurred at 6 agents because fire engine teams were split up, leading to fewer fire-engines being allocated per building on average. Indeed, leaving fewer than 3 fire engines per fire leads to a significant reduction in fire extinguishing capability. We can provide such feedback of overall performance, showing the performance reduction at six fire engines, and our analysis to a trainee. The key point here is that DEFACTO is capable of allowing for such exercises, and their analyses, and providing feedback to potential trainees, so they improve their decision making, Thus, in this current set of exercises, trainees can understand that with six fire engines, they had managed to split up existing resources inappropriately.

6. RELATED WORK AND SUMMARY

In terms of related work, it is important to mention products like JCATS [9] and EPICS [4]. JCATS represents a self-contained, high-resolution joint simulation in use for entity-level training in open, urban and subterranean environments. Developed by Lawrence Livermore National Laboratory, JCATS gives users the capability to detail the replication of small group and individual activities during a simulated operation. At this point however, JCATS cannot simulate agents. Finally, EPICS is a computer-based, scenario-driven, high-resolution simulation. It is used by emergency response agencies to train for emergency situations that require multi-echelon and/or inter-agency communication and coordination. Developed by the U.S. Army Training and Doctrine Command Analysis Center, EPICS is also used for exercising communications and command and control procedures at multiple levels. Similar to JCATS however, EPICS does not currently allow agents to participate in the simulation. More recently multiagents have been successfully applied to training navy tactics [10] and teams of Uninhabited Air Vehicles [1, 2]. Our work is similar to these in spirit, however our focus and lessons learned are based on the train of Incident Commanders in disaster rescue environments.

In summary, in order to train Incident Commanders for large scale disasters, we have been working on the DEFACTO training system. This multiagent system tool has begun to be used by fire captains from the Los Angeles Fire Department. We have learned some valuable lessons from their feedback and the analysis of some initial training exercise experiments. These lessons were gleaned from LAFD feedback and initial training exercises. The lessons learned from the feedback from the LAFD include: system design, visualization, improving trainee situational awareness, adjusting training level of difficulty and situation scale. We have taken these lessons and used them to improve the DEFACTO system's training abilities. We have conducted initial training exercises to illustrate the utility of the system in terms of providing useful feedback to the trainee. Through DEFACTO, we hope to improve training tools for and consequently improve the preparedness of Incident Commanders.

7. ACKNOWLEDGMENTS

Thanks to CREATE center for their support. Also, thanks to Fire Captains of the LAFD: Ronald Roemer, David Perez, and Roland Sprewell for their time and invaluable input to this project.

ABSTRACT

This contribution presents a deployment exercise of multi-agent technology in the domain of deconflicted air-traffic control among several autonomous aerial vehicles (manned as well as unmanned). Negotiation based deconfliction algorithm have been developed and integrated in the agent-based model of the individual flight. Operation of the underlying multi-agent system has been integrated with freely available, geographical and tactical data sources in order to demonstrate openness of the technology. An additional, web client visualization and access component has been developed in order to facilitate a multi-user, platform independent use of the system. The features and application design is illustrated in the demonstration video clip[1].

1. INTRODUCTION

In the future warfare and humanitarian relief operations (especially in the surveillance and monitoring domains) there will be a strong potential for integration of the technologies and mechanisms supporting coordinated flight among the collective of autonomous manned and unmanned aerial vehicles. In this paper we argue that agent technology, relying on collective decision making among several autonomous intelligent agents, can provide solution for such a challenge. Even though this is not a fundamental research paper, this contribution provides good evidence of practical applicability of agent technology by reporting on a technology deployment exercise in this specific domain.

According to [11] the current air traffic control methods based on rigidly structured airspace have shown to be inefficient even for the future coordination of the piloted aircraft. This is true mainly due to: (i) inefficiency of airspace utilisation that is based on fixed predefined flight corridors, (ii) increased air traffic workload given by ever increasing air traffic density and (iii) use of obsolete technologies, that are in many cases 30 years old.

In the future these will be important for both UAVs and manned aircraft:

- requirements to increase flexibility of the vehicles operations,
- requirements to fly higher number of vehicles in substantially smaller airspace and
- requirements for higher precision of the flight plan and its accomplishment.

Due to the first two reasons of inefficiency listed above, the classical air traffic control methods are not very suitable for coordination of higher numbers of dynamically tasked aerial vehicles. In our work, we have built on top of the concept of *free flight* [9], [4] – an approach to autonomous routing of the aircraft and continuous self-optimization of the flight trajectory complemented by the peer-to-peer deconfliction mechanism.

The presented work resulted in a demonstration prototype (ATC) of a multi-agent system modeling deconflicted free-flight of collective of fully autonomous aircraft.

ATC has not been primarily designed as flight planner producing a set of deconflicted route plans for a number of aerial vehicles. There is a central planning component that provides (during the *planning phase*) the flight plans without consideration of possible operation of other aircraft. This planning process can be easily distributed among the individual aircraft and thus no central planner would be necessary. The plans are likely to contain possible collisions. Working with no-collisions makes planning considerably faster and much more flexible. This also results in substantial scalability improvement affording to operate higher number of aerial vehicles in condensed airspace (can be used e.g. in situation where a higher number of unmanned aerial vehicles carries out rapid surveillance tasks).

Following the planning phase, ATC performs the *simulation phase*, where the aircraft implement the provided flight plans in a free-flight fashion. In a danger of possible collisions, the embedded deconfliction mechanism makes sure that aircraft negotiate deconfliction maneuvers, while still optimizing their operation.

2. DECONFLICTION BY NEGOTIATION

ATC is designed to operate in distributed manner, which is why the deconfliction technology (while developed within the multi-agent ATC model) is ready for deployment on autonomous vehicles without any central point of control.

The aircraft are modeled by agent containers hosting several agents. In this contribution we will be referring to

agents representing an aircraft auto-pilot. This agent is a self-interested entity that is in charge of (i) preparing a detailed flight plan for the airplane respecting time-specific waypoints for the airplane's mission and (ii) executing the flight plan by performing the flight.

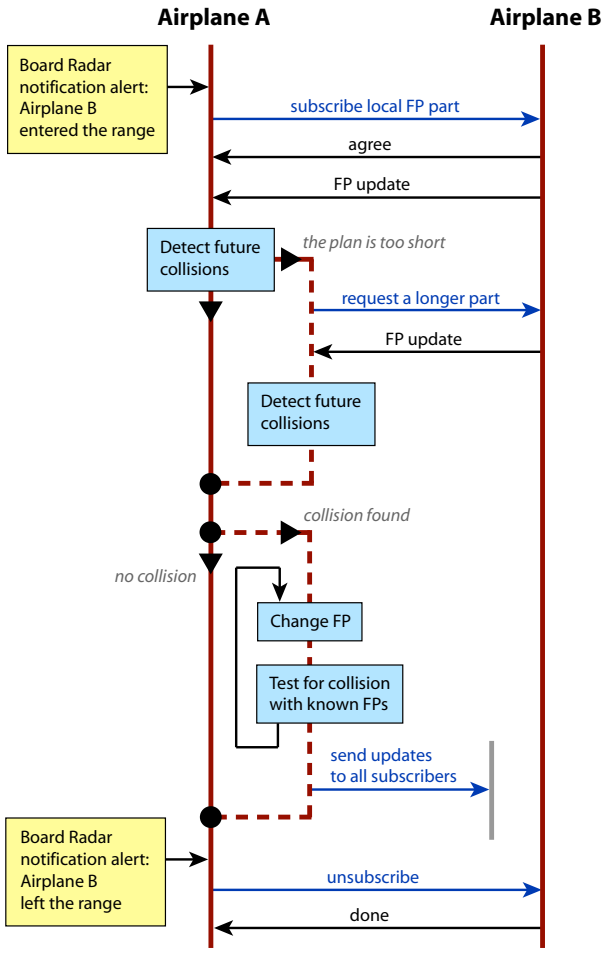

Figure 1: Negotiation protocol

Each simulated aircraft is surrounded by a number of concentric spherical zones: **Communication**, **Alert**, **Safety** and **Collision** zones. The **communication zone** is the outermost one. It represents the communication range of the data transmitter onboard the aircraft. Using this data, the aircraft can send data packets to other aircraft that are positioned within the specified spherical zone defined by its radius. The **alert zone** defines the operation range of the radar onboard the aircraft. If another aircraft is located within the alert zone, the aircraft are periodically notified about its relative position and its flight code. The **safety zone** encapsulates the area around an aircraft that other aircraft are not allowed to enter in order to minimize the mutual influence of the aircraft movements, e.g. airspace turbulence. If two aircraft do enter each other's safety range, they can still continue flying but their flight path may be influenced by e.g. turbulence. This is not the case when two or more airplanes fly together in a close formation. The **collision zone** is the innermost zone. It defines the critical contact area. When the mutual distance between two aircraft is smaller than the sum of their collision zone radiuses, the physical collision happens.

Cooperative deconfliction. In the simulation phase the ATC system solves collisions *cooperatively* by negotiation between the aircraft, see Figure 1. Let us suppose an aircraft `A` to fly along its planned optimal flight path through its mission waypoints. An airplane `B` enters the *alert zone* of the airplane `A`. The pilot agent of the aircraft `A` is notified about its position and flight code by the on board radar system. The pilot agent of the aircraft `A` tries to establish negotiation connection with the pilot agent of `B`. In the case when the connection cannot be established or the communication is not trusted, the pilot agents should use *non-cooperative approach*, described later in this section. If the connection was established successfully, the pilot agent `A` subscribes for a local area flight plan of the aircraft `B` (representation of the flight plan is described in Section 5.1). The pilot agent of aircraft `B` sends an update to the subscriber every time it changes its own flight plan. The update contains the part of the flight plan of the aircraft for the specified amount of time depending on the flight speed. The update is also sent when the time span of the previous update was not long enough and it needs to be updated again. When the pilot agent `A` receives an update from the pilot agent `B`, it executes the **collision detection process** on its own flight plan and the received one.

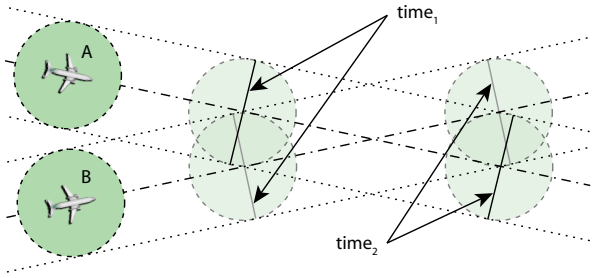

Figure 2: Flight plan collision interval

The collision detection process is a linear algorithm that analyses two flight paths and tests the condition of safe flights. If there is a specific point in time detected when the distance between the positions of the aircraft is smaller than the maximum of the safety ranges of the aircraft (see Figure 2), the detection process returns $time_1$ and $time_2$ which represent the first and the last collision point between the two flight plans. This information is needed by the pilot agent for better handling of the situation.

If the detection test is negative, both flight paths are safe for flying. If a collision is found, the airplanes `A` and `B` must modify their flight paths. The first prototype of the designed system uses a rule-based approach for modifying flight plans described in Section 2.1.

Non-cooperative deconfliction: The distributed deconfliction approach is open to be extended to *non-cooperative deconfliction*. The non-cooperative deconfliction is useful in situations when an airplane has a malfunctioning transmitter/receiver on its board or in the situation when there is an intruder/enemy airplane with adversarial behavior [7]

which intentionally sends incorrect future flight path parts to the others. The most suitable approach to the *non-cooperative deconfliction* is the game theory. In this case the pilot agent tries to change its own flight plan in a way that would guarantee a minimal collision risk for any future position of the other airplane. To determine all possible future positions of the other plane, information about its current position, direction and information about its type can be used. The monitored object's flight path is always continuous but there are also certain restrictions that depend on the airplane type – e.g. minimal/maximal flight speed, minimal radius of turning, etc. When the pilot agent wants to identify whether or not it should use the non-cooperative deconfliction for a particular airplane, it can integrate a special *detection module*. The detection module compares the notification received from the board radar with the known flight plan part of the aircraft in the radar range.

2.1 Collision Avoidance Mechanism

The specific collision type is determined based on the angle between the direction vectors of the concerned planes at $time_1$ projected to the ground plane (defined by X and Y axes), see Figure 3.

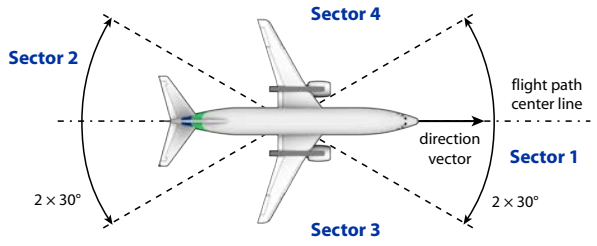

Figure 3: Identification of the collision type

Depending on the computed angle, the airplane `B` falls into one of four sectors surrounding the airplane `A`. Depending on that sector, one of the following rules is applied on the flight plan of the airplane `A` to avoid the collision:

- **Sector 1** – head-on collision, in this case the airplanes avoid each other by both of them turning to the right. The flight plan is changed as shown in Figure 4. The pilot agent shifts the plan points at $time_1$ and $time_2$ to the right, perpendicularly to the old direction vector. The length of the shift is equal to a minimum of safety ranges of both airplanes. Beyond $time_2$, the flight plan follows the shortest way to the next mission waypoint.
- **Sector 2** – rear collision, there are two subcases: i) the front aircraft is faster – airplanes do not change their current flight plans; ii) the rear airplane is faster – it has to change its flight plan so that it turns to the right and passes the front airplane without endangering it. The flight plan is similar to that in Figure 4. To achieve this, the rear airplane shifts its flight plan points at $time_1$ and $time_2$ to the right, perpendicularly to the old direction vector. The length of the shift is at least 1.1 times of the safety range.
- **Sector 3** – side collision, the airplane `B` has higher traffic priority. The aircraft `A` needs to slow down its speed so that it reaches the collision point at $time_1$ later than the airplane `B`. If this is not possible due to the minimal flight speed defined for each airplane type, the airplane `A` slows down as much as possible and shifts its flight plan point at $time_1$ to the right so that there is no collision between the two flight plans.
- **Sector 4** – side collision, the airplane `B` has lower traffic priority. The aircraft `A` changes its flight plan by increasing its flight speed so that it passes the collision point before the airplane `B`. The airplane `A` only accelerates as much as needed.

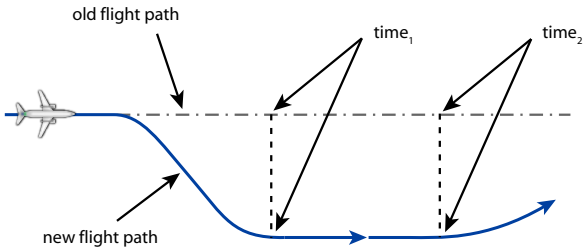

Figure 4: Change of the flight plan.

The above rule-based changes to the flight plan are carried out by both planes independently because each aircraft detects the possible collision with the other airplane from its own point of view. After applying the changes to the flight plan, the airplane sends an updated local flight plan part to all airplanes that subscribed for it. The change is also verified against all other known flight plans of all aircraft monitored by the board radar system. If another collision is detected, new changes are applied.

The pilot agent internally uses the *flight plan wrapper* interface for manipulation with its flight plan. The requests for each plan modification are handled as a special set of solver time-constrained waypoints. A special handling algorithm takes care of the execution of each modification that overrides the previous one.

3. A-GLOBE: MULTI-AGENT PLATFORM

The agent-based part of the designed prototype of the Air Traffic Control (ATC) system runs on the **$\mathcal{A}$-globe** Java multi-agent platform [10, 1]. **$\mathcal{A}$-globe** is a fast and lightweight platform with agent ***mobility*** and ***inaccessibility*** support. Besides the functions common to most of agent platforms it provides ***Geographical Information System***-like service to the user. Therefore, the platform is ideally suited for testing experimental scenarios featuring agents' position, position dependent environment simulation and communication inaccessibility. The platform provides support for permanent and mobile agents, such as communication infrastructure, storage, directory services, agent migration (including library migration with version handling), service deployment, etc.

$\mathcal{A}$-globe is optimized to consume just a limited amount of resources. **$\mathcal{A}$-globe** platform is not fully compliant with the FIPA [3] specifications, still it implements most protocols and respects the spirit of the specification. It does not support communication between different agent platforms (e.g. with JADE, JACK, etc.). For large scale scenarios, the problems with system performance that interoperability

brings (memory requirements, communication speed) outweigh any advantages, as heterogenous environment is of limited interest for simulations.

The $\mathcal{A}$-**globe** operation is based on several core components: The **Agent Platform** provides the basic components necessary to run one or more *agent containers*, the *container manager* and the *library manager*. The **Agent Container** is a skeleton entity that provides basic functions such as communication, storage and management for agents. The **services** provide common functions for all agents in a container. The agents have two means of communication with a service – either via standard messages or by using a service shell – a special proxy object that interfaces service function to a client so that they appear to be synchronous function calls, but the calls are actually handled in the service thread thereby preventing deadlocks and synchronization overhead.

The $\mathcal{A}$-**globe** platform is primarily aimed at large scale, real world simulations with fully fledged agents. To support this goal, it includes a special infrastructure for environmental simulation. *Actor agents* play roles in the simulated world, while *Environment Simulation (ES) agents* implement the simulated world itself. ES agents only rarely use messages to communicate with actor agents. Instead, they communicate via *topic messaging*.

Topic messaging implements container to container messaging reserved for easy environmental simulation. Topic messaging is built on top of standard messages and is managed by the Geographic Information System (GIS) Services – server and clients. GIS services provide distribution and subscription mechanism for the agents. ES agents can be responsible for nearly any simulation layer, depending on the wishes of the developers. Accessibility agent, which controls the availability of communication links between containers holding the actor agents, is one of the most important of ES agents. $\mathcal{A}$-**globe** messaging layers use the information provided by the accessibility agent to prevent sending messages between inaccessible nodes. Accessibility simulated by the system can depend on many factors, typically including the distance and simulated link reliability.

4. PROTOTYPE STRUCTURE OVERVIEW

Air Traffic Control (ATC) system is mainly written in Java except for the real-time visualization component which is written in C++. Agent-based part of the system runs on the $\mathcal{A}$-**globe** Java multi-agent platform. The system consists of several components, see Figure 5:

– **ATC core** is a mandatory component of the system responsible for aircraft simulation and airways planning. The component also provides interfaces for connecting a number of real-time visualization components and remote web clients. See Section 4 for details.

– **Real-time 2D/3D visualizer** is an optional component that provides the user with a real-time overview of the simulation state with all important information in a 3D/2D environment. See Section 7 for details.

– **Remote web client** is an optional component allowing a remote user to connect and interact with the ATC core system via a client application executed from an internet browser. If necessary, all communication data can be secured using asymmetric cryptography but it comes with higher processor load requirements. See Section 7 for details.

Agent-based core system encapsulates one *server component* (described in Section 4.1) and one or more *platform components*, Figure 5. The *platform component* is used as a registration unit for starting the simulated *aircraft container* (described in Section 4.2) inside Java Virtual Machine (JVM). When ATC system is used for planing/simulation of a huge number of aircraft, it is highly recommended to use several host computers with their own JVMs and *platform components*. The number of running aircraft is proportionally split between the registered platform components. This enables the ATC system to balance the overall load between all registered computers.

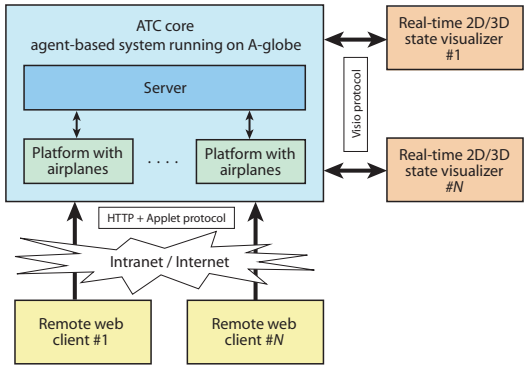

Figure 5: ATC System Structure Overview

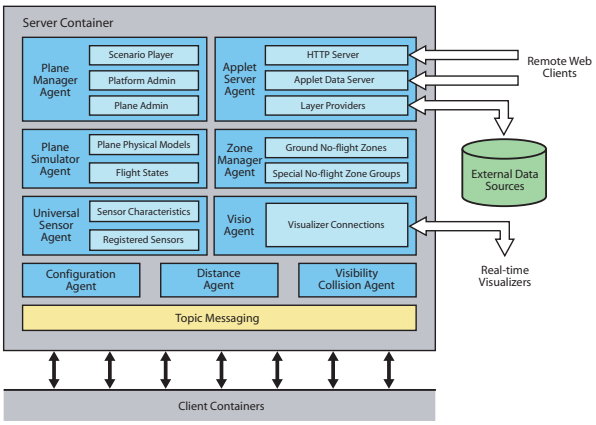

Figure 6: Server component of the ATC Core system

4.1 Server Component

The *server component* of the ATC core system is a sole central element of the system. It simulates positions of aircraft and other objects in the simulated world, aircraft hardware, weather conditions, communication ranges given by the ranges of board data transmitters, etc. It is also responsible for acquiring information about all airplanes and provides them to both types of visualizers. If the proposed distributed agent system for flying on deconflicted airways was used to control real aircraft, this *server component* could be removed from the system.

The *server component*, Figure 6, consists of several agents. **Configurator Agent** loads initial configurations from the specified configuration files and distributes them to other agents. **Plane Manager Agent** administrates connected

JVM platforms and running aircraft containers, it spawns new airplanes and removes the existing ones, and assigns initial flight missions to the airplanes. New airplanes can be started automatically as specified in the scenario script. The server also acts as a load balancer between connected platform components. **Plane Simulator Agent** computes the current position of the aircraft in the simulated world. It contains all physical models for all plane types and keeps all current flight plans and states of the running aircraft. When a plane *pilot agent* changes some part of the flight plan, the change is propagated via the *plane agent* to the *plane simulator agent* in the form of a difference flight plan update. The agent can be asked for the current airplane position by the *pilot agent*. **Distance Agent** calculates Euclidian distances between each pair of existing aircraft using their current positions. **Visibility Collision Agent** prepares **$\mathcal{A}$-globe** visibility updates [10] for controlling communication restrictions between airplanes. It also detects whether there has been a physical collision between flying aircraft. The airplanes that have collided with any other object are uncontrollable and they fall down to the ground. Falling aircraft can endanger any airplane that flies under it. **Universal Sensor Agent** represents all radar sensors on aircraft boards. **Zone Manager Agent** takes care of no-flight zones. It transforms any defined no-flight zones to a compressed octant tree. The ground surface is also represented as a special no-flight zone. This allows to use the planning mechanism even for generating flight plans that do not collide with the ground surface. No-flight zones can be dynamically changed during the planning/simulation. **Visio Agent** is an interface between the Core agent system and the C++ real-time visualizers. To ensure fast communication between them, a special binary communication protocol defined is used. **Applet Server Agent** runs the HTTP server, Applet Data server and all external data providers. It provides a communication interface between the agent system and the *remote web client* (described in Section 7).

All server agents communicate together using **$\mathcal{A}$-globe *topic messaging*** described in [10].

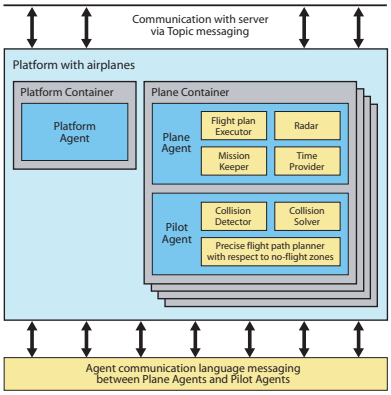

Figure 7: Platform Architecture

4.2 Platform Component

The *platform container* is used as a registration unit for starting containers with agents simulating aircraft behavior. Design of the platform component is shown in the Figure 7. The only agent running in the *platform container* is the *platform agent*. The agent acts as a control bridge between the *plane manager agent* and the local JVM on which it is running. Through this agent the *plane container* can be started or removed. Many *plane containers* can run in each *platform component* (inside one JVM) or there can be no *plane containers* at all.

Each running *plane container* hosts two agents. **Plane Agent** provides high-level airplane functions, such as flight plan execution in cooperation with the *plane simulator agent*, radar and detector readings, airplane configuration and time synchronization ticks. **Pilot Agent** is the main control unit of the simulated aircraft handling negotiation based deconfliction as described in Section 2. It processes notifications about every new visible objects on the radar and tries to communicate with the respective *pilot agent* if there is any. It generates a detailed flight plan based on the initial mission specification given by the *plane manager agent* with respect to the no-flight zones (Section 5), described in Section 5.2.

The airplane container agents communicate with the server container via **$\mathcal{A}$-globe *topic messaging***, while together they communicate using standard agent communication language (ACL) messages.

5. FLIGHT MODELING

The modeling of flights in our system proceeds in two main phases: the *planning* of the flight plans for each airplane and the *simulation* of these flight plans. In this section, we give a brief description of the planner component and other key concepts related to the flight modeling. We use a very simple physical model of the airplanes: they are modeled as mass points moving along a previously planned trajectories.

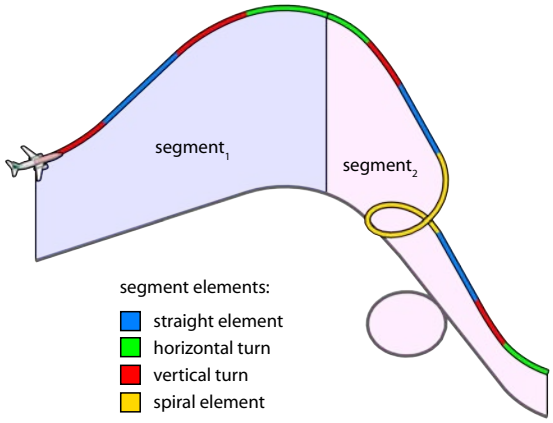

Figure 8: Flight plan, segments, elements

5.1 The Structure of Flight Plan

The flight plan describes a trajectory which the plane follows during its flight. Its principal building blocks are *waypoints*, *segments* and *elements*. A waypoint is an important navigational point used for rough definition of the flight route; it represents a certain location and also specifies the time interval when the airplane should fly through it. The waypoints serve as an input to the planner, which generates the precise flight path consisting of the segments and elements. A segment is a portion of a planned flight path

between two adjacent waypoints. The segments are composed of elements, which constitute the most basic parts of a flight plan with a simple geometry.

Our planner is able to generate flight paths from four types of elements: straight elements, turns (horizontal and vertical), spirals and a warp element. The warp element is a special kind of element allowing for an abrupt change of certain parameters of the flight route (e.g. position, direction or velocity). Without warp elements, the flight trajectory is always continuous and smooth and each element is connected smoothly to the adjacent ones. This is desirable in most cases; exceptions to this rule will be mentioned later. An example of a flight plan is shown in Figure 8.

5.2 Flight Path Planning

By the flight path planning we mean creating a smooth and continuous path passing through all input waypoints, which will also satisfy the time constraints associated to the waypoints. The planning proceeds in three phases: the computation of the actual path without regard to the time constraints, the adjustment of the flight plan to satisfy the time criteria and the replanning of the plan in the parts where it collides with no-flight zones (if defined).

During the **Path Planning**, the planner generates a detailed flight path which passes through all the waypoints. For each couple of successive waypoints, a segment is created, initially without any elements. A segment represents the smallest part of a flight plan which can be planned independently on the other parts of the plan. By planning, we mean filling of a segment with elements; the planned segment is typically composed of 2 to 8 elements.

After that, the **Time Planning** follows. For each segment, the actual flight plan is adjusted so that the time of flight through the segment matches the time intervals defined in the start and end waypoints belonging to the segment. The adjustment is done in two ways: through stretching the segment by altering some of its parameters (so that it becomes longer and thus the flight takes more time) and through setting the velocity of the plane at the beginning of the segment. For this reason, we place a warp element at the start of each segment, which allows for a step change of velocity at the segment boundaries. By using this simplification, our planning algorithm is very fast.

The flight path for an airplane can be planned with respect to predefined no-flight zones (such as areas around power plants, military facilities or natural terrain obstacles). **Avoiding the no-flight zones** is done as follows: the segments of the flight plan generated in previous phases are tested for collisions with the no-flight zones. If any segment intersects a no-flight zone, it is replaced with a flight path which bypasses the respective no-flight zone(s). This is accomplished through finding suitable "bypassing" waypoints, which roughly define the collision-free flight route, and through planning a flight path through them. The situation is shown in Figure 9.

The problem of finding the bypassing path is thus equivalent to finding suitable waypoints that define it. These waypoints have no time constraints. Our approach to finding these waypoints is based on a spatial subdivision of the area of interest by an octal tree to a set of cubic cells. The cells intersected by a no-flight zone are marked as full, while the rest of them is marked as empty. By using the well-known A^* algorithm we find a sequence of empty cells, connecting

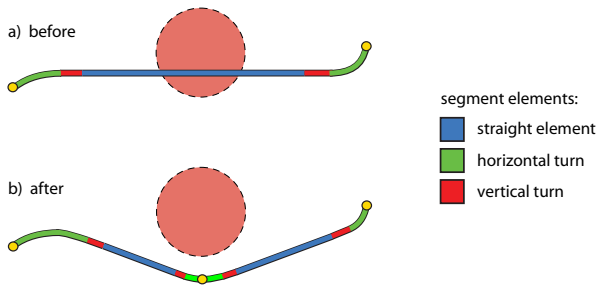

Figure 9: Avoiding the no-flight zone.

the cells containing the start and end waypoints of the replanned segment; this sequence forms a continuous "tunnel" which bypasses the no-flight zones. The waypoints are then placed in the "tunnel". . This approach is similar to that described in [6].

6. REAL DATA INTEGRATION

The designed ATC system integrates four data sources:

- **National Aeronautics and Space Administration (NASA)** – a mosaic of Landsat7 images[2] at the maximum resolution of approximately 50 meters per pixel was used as an underlying ortophoto map of the United States
- **U.S. Geological Survey (USGS)**[3] – detailed vector shapes of 50 U.S. state boundaries; a set of more than 650 U.S. airports, including their names, GPS coordinates with the corresponding average numbers of enplanements per year; a set of more than 26 thousand major U.S. highway segments
- **Geographic Names Information System (GNIS) database**[4] – a set of more than 24 thousand U.S. populated places, including their names, GPS coordinates with the corresponding population; a set of more than 80 U.S. powerplants, including their names with GPS coordinates to act as the no-flight zones
- **ATC flight data** – airplanes including position and direction; rough flight plans in the form of series of points in space through which the airplane is supposed to fly on its way; detailed flight plans

7. FLIGHT VISUALIZATION

The **real-time visio** allows the user to overview the entire simulation in a 2D/3D environment, to efficiently navigate through it, but also to provide the user with all the important data and information at the same time.

An open-source 3D game engine CrystalSpace [2] was used as a platform on top of which the visualization component is built. For efficiency and performance reasons, the entire visualizer is written in C++ and it internally utilizes the OpenGL graphics engine. A binary-coded network communication protocol has been defined and implemented to allow fast data exchange between the core system and the visualizer component.

[2] `http://onearth.jpl.nasa.gov`
[3] `http://seamless.usgs.gov`
[4] `http://geonames.usgs.gov`

The communication is duplex: by sending messages to the visualizer, the core system notifies the visio that an airplane has been spawned, destroyed, it has changed its position etc. On the other hand, the visualizer sends messages to the core system e.g. when it requests specific information about a certain airplane upon user's demand, such as its flight plans. In response to this request, the simulation system selectively sends the required data. This behavior was introduced to reduce the amount of data that need to be sent over the network – instead of sending all the data continuously even if they are not needed.

The visualizer provides two main display modes: a two-dimensional (2D) view (Figure 10) and a three-dimensional (3D) view (Figure 11). They both work with the same underlying data, only the way of depicting them differs.

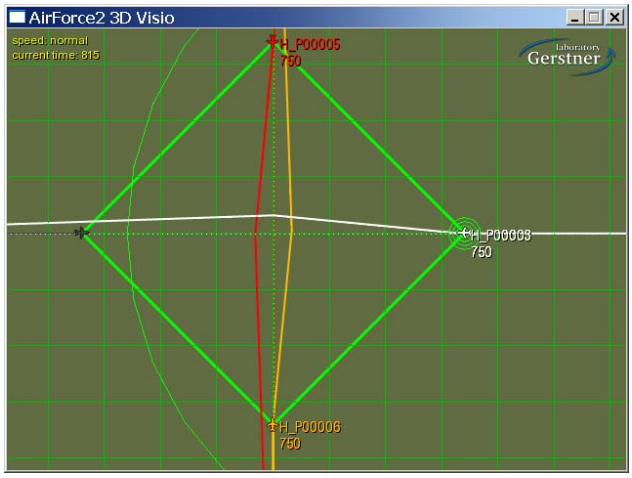

Figure 10: Real-time visualizer: 2D view

The **2D mode** provides a radar-like top view of the scene. Airplanes present in the system are displayed as 2D icons that visualize both current position and direction of each airplane. Once the airplane is selected, the camera starts following it so that it stays in focus. A set of zones is displayed around the selected airplane as a group of concentric circles. Most importantly, these refer to the collision range (innermost) and the visibility range (outermost) of each airplane. The current flight plan can be displayed for the selected airplane and/or for all airplanes that are visible to it. Flight plans in 2D view are represented by solid polylines that interpolate through the intended route.

The **3D mode** (see Figure 11) is useful for observing the entire simulation in a natural 3D environment that allows the user to get a better insight of the spatial relations between airplanes, the actual 3D shapes and possible collisions of flight plans, series of waypoints etc. In 3D, flight plans are displayed as three-dimensional semitransparent corridors of a rectangular profile. As the visio is required to cope with as many as hundreds of airplanes, massive optimizations of visualization of 3D space have been implemented. One of the key features in this respect is the incorporation of multiple levels of detail (LOD) for all 3D models.

Another important feature of real-time visualizer is the ability to interactively control the speed of the simulation. The visualizer displays the current speed of the simulation in the top left-hand corner of the screen, together with the current simulation time.

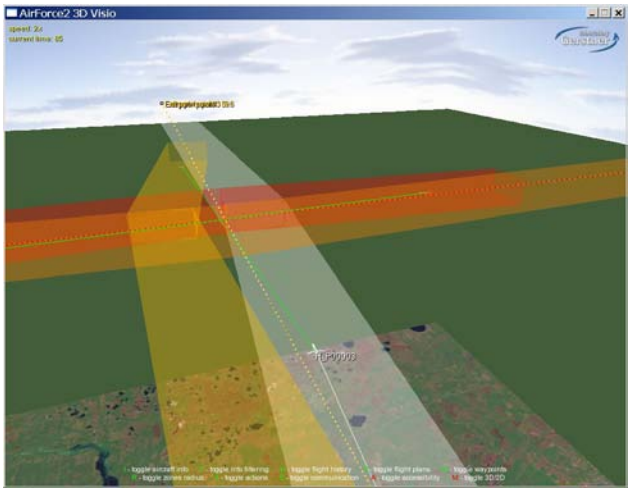

Figure 11: Real-time visualizer: 3D view

The simulation can also be accessed using a **remote web client**, a Java application (see Figures 12 and 13) that connects via network to the simulation system which acts as a server and provides all its clients with regular data updates. This way a number of users can concurrently observe and interact with the same simulation. Accessing the simulation system via network is as simple and straightforward as opening a web browser and entering the IP address of the computer on which the *core system* is currently running.

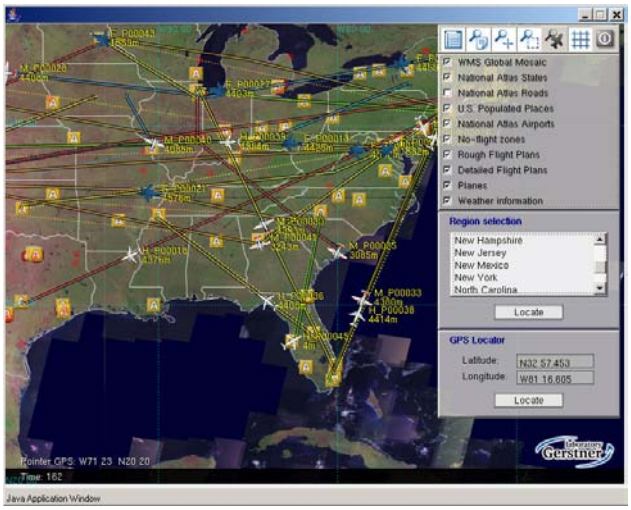

Figure 12: Remote client GUI overview

Before the user can access the simulation, he needs to log in the system by entering a valid combination of username and password. Remote client authentication procedure is secured using one-time hashes for password validation. To minimize network traffic between the remote client and the ATC core system, a combination of HTTP and a special binary protocol is used.

The ATC core system uses a Java Web Start application for loading and starting the client. The client is built on top of JOGL libraries (Java binding for OpenGL [5]) which are

used for accessing graphics 3D acceleration.

The icon palette located in the top right hand corner of the client window gives the user access to application controls, e.g. data layer menu, zooming to a named region, zooming to a selection, zooming to a particular airplane, GPS locator, coordinate grid control and the logout button.

As the user changes the view, the appropriate data segment of the virtual map is requested and downloaded from the server, and therefore at any moment the client needs to keep only a minimal amount of data, which results in its fast and efficient performance.

Figure 13: Flight plans avoiding no-flight zones

8. CONCLUSION

In the paper we present how agents can be used for the negotiation-based deconfliction in the Air-Traffic Control. We describe the prototype of the ATC system where we integrate our agent-based solution with several external data sources. The external online data sources provide necessary information about ground surface, airport locations, weather conditions, no-flight zones and area boundaries for the ATC system. We introduce two types of system visualization: real-time and remote using an internet browser.

The ATC prototype has only simple deconfliction rule-based mechanism for the flight plan changes which assumes that all airplanes use the same deconfliction rules. The system will be extended so that airplanes that detected future collisions would iterate through *monotonic concession protocol* (MCP) to find new flight plans that are collision free. The monotonic concession protocol is a simple protocol developed by Zlotkin and Resenschein for automated agent to agent negotiations [12, 8]. Both airplanes prepare a set of possible flight plan changes scored by the utility function. The utility function includes pilot's own intentions including flight priority, fuel restrictions, time restrictions, etc. From all collision free combinations of flight plan pairs, the possible solution set is created. The iteration protocol results in a commonly accepted solution of the collision. Then each airplane applies the respective flight plan changes. However, the iteration solution can lead to a situation when the solution is not found fast enough. The process has to be extended with an emergency solution that is used when the iteration process does not lead to any fast solution. As the emergency solution, the game theory approach can be used.

ABSTRACT

This paper presents a case study for the application of agent-mediated negotiation techniques in transportation logistics. More specifically, we consider the interaction between several logistics service providers negotiating over the allocation of transportation orders. In this context, we show that automated negotiation techniques (especially multi-issue or multi-item negotiation) can bring significant advantages, by allowing parties to discover jointly profitable bundles (allocations) of orders. The model, evaluations and results reported in this paper concern the business processes of Vos Logistics, one of the largest European transportation logistic providers.

1. INTRODUCTION

Negotiation represents a key form of interaction in agent-mediated electronic markets that transcend the sale of uniform goods. Through negotiation, suppliers and consumers can reach complex agreements in an iterative way, which better match the needs and capabilities of different parties. Recent research work has led to a variety of new, increasingly complex algorithms to deal with application of automated negotiation (especially multi-issue or multi-item negotiation) in a variety of settings [4, 9, 11].

Transportation logistics and supply chain management represents a challenging, but potentially very fruitful area for application of automated negotiation. In this setting, it is often possible for all parties in a supply chain to obtain joint savings through more efficient, fine-grained matching of their requirements and capabilities (i.e. orders and transport capacity). The increasing complexity of modern supply chains, as well as increasing competitive pressures in this market has led to an increasing demand and interest for such distributed optimization techniques.

The practical impact of improved allocation which can be achieved through such techniques can be significant. For example, in the Netherlands, the average transport performance is between 40% and 60%[1]. [2]. Improving this utilization rate is also the goal of the DEAL (Distributed Engine for Advanced Logistics) project, which groups together several universities and large logistics service providers in the Netherlands. The work reported here is also carried out in the framework of this project, involving the CWI and Vos Logistics.

The paper describes a case study application of automated negotiation to the logistics domain. It is important to stress that, in this paper, we do not aim to propose a new algorithm or analyze

[1] Defined a defined as the extent to which transportation units are utilized as percentage of total capacity, usually given in ton-kilometer. Thus, a truck that is driving with only half its capacity has a transport performance of 50%.

fundamental aspects of agent-mediated negotiation techniques as such (this has already been done elsewhere, in papers by the same authors at the research track of AAMAS and AMEC [4, 9, 6]. Our goal is to focus more on the specifics of the application domain and to describe our experience with agent-mediated negotiation techniques in the real-life case of the organizing branch of Vos Logistics. The paper is largely based on the Master Thesis work of the first author, performed jointly at Vos Logistics and CWI [13].

The remainder of the paper is organized as follows. In Section 2 we describe the logistics of the transportation domain and briefly outline the profile of Vos Logistics as well as the transportation market in which it operates. Section 3 goes more in depth, by providing a more detailed analysis on how the order allocation and negotiation processes are actually conducted at the Vos Logistics Organizing branch in Nijmegen. Section 4 briefly outlines the potential of existing techniques from agent-mediated negotiation and discusses to what degree and how they are relevant or applicable to this domain. Section 5 describes our proposed multi-issue negotiation solution and how it can be used to discover more efficient allocations (or bundles) of orders during trading. Section 6 presents an analysis of the gains which can be actually achieved by bundling of transportation orders, based on the real order set of Vos Logistics Organizing. Section 7 provides a discussion of how our approach compares to other approaches to this problem (both from the theoretical literature and industrial-grade solutions). We conclude the paper by pointing out some of the challenges which can be encountered in the application of a pilot project on automated negotiation at a company such as Vos Logistics.

2. THE TRANSPORTATION LOGISTICS DOMAIN

Several trends have recently produced a significant impact on the area of transportation logistics. One of these is an increase in competition, with the continual entry of new carriers in the market pushing down expected profit margins. Another one is the increasing complexity and sophistication of modern supply chains. In fact, due to increasing and shifting trade patterns, not only the complexity of transportation chains has increased, but also their variability and dynamics. These challenges require increasingly sophisticated optimization solutions, that exploit all the niches in the supply chains involving different companies.

We note that his optimization has to occur both intra-company (where a company optimizes its own activity), but increasingly also inter-company, between different actors that do not necessarily share the same goals. Inter-company optimization poses considerable extra challenges, since the parties forming the supply chain can be self-interested, so they may be unwilling to share private planning information and strategic concerns make the problem considerably harder than cooperative case. The solutions proposed in this paper specifically address this case of inter-company optimization of the logistic chain.

The transportation management literature [12] identifies two main types of orchestrator companies for transportation logistic chains:

- Third Party Logistics service providers (3PL), which orchestrate the logistic processes and assures they are well executed according to a current logistic concept
- Fourth Party Logistic service providers (4PL), which orchestrate the supply chain and are responsible for the design of the logistic concepts.

There is, however, considerable disagreement about the exact meaning of these terms, both in existing literature and in practice. In our approach (and the remainder of this paper) we use the term 3PL provider companies to denote those that have their own transport capacity (i.e. truck fleet) and plan (or orchestrate) their movement, based on a set of orders from shippers and other companies. Fourth Party Logistic companies (4PL) have recently emerged as a result of the increasing complexity of supply chains and mostly have a role of coordinating these chains. In this paper we denote as 4PL companies those that do not have their own transport capacity: they receive large transport orders from shippers and then distribute them among a set of 3PL companies or independent carriers. This process involves direct negotiation with 3PL companies and often entails breaking up large orders or bundling orders for partial loads, in order to increase efficiency. The remainder of this section describes in more detail the company which forms the object of our solution, as well as the market in which it operates.

2.1 Company profile

Founded in 1944 as a one-truck company, transporting loads between Oss and Nijmegen in The Netherlands, Vos Logistics has grown into one of the larger logistics service providers in Europe. It has over 3000 trucks, 10000 trailers and containers, 350000 square meters of warehousing sites, 325 storage silos and 2 rail service centers. Vos employs 5000 people working at more than 45 locations throughout Europe. Annual turnover is around 800 million euro.

The increasing complexity of transportation chains has determined Vos to offer new solutions to its large corporate customers (shippers), which can now outsource all of their transportation activities to Vos. This lets them avoid the problem of finding and negotiating with individual suppliers, billing, following up orders etc. Another advantage of using this outsourcing service for large shippers is that Vos Logistics has a much better knowledge of the transportation market, so it is better positioned to find suitable sub-contractors.

Vos Logistics Organizing from Nijmegen (henceforth abbreviated VLO in this paper) is a subsidiary of Vos Logistics B.V. that was set up in order to handle such complex supply chain orchestration activities. Based on the taxonomy above, VLO (the subsidiary) can be seen as a 4PL company, though its parent company, Vos Logistics performs mainly 3PL activities. Hence, VLO acts as an intermediary company that acquires large (sets of) orders from suppliers and negotiates the allocation of the orders, the terms of transportation (i.e. delivery deadlines, destination) as well as the price with which 3PL companies that subcontract these orders.

2.2 Market organization. Closed vs. open group negotiations

This section describes the operation of a 4PL logistic company, which simultaneously interacts with customers (shippers), a set of 3PL companies (with actual carrying capacity) and the open market. For the purpose of this paper we identify this 4PL company with Vos Organizing (VLO), but the model should be a general enough to be applied to other companies in the same field.

Figure 1 presents a graphical model of this interaction.As depicted in Figure 1, there are two main mechanisms for allocating orders received from shippers:

- **Closed group negotiation.** Most of the orders (i.e. around 80%) received by the 4PL company are currently not auctioned off to an outside market, but are allocated among a small group of trusted 3PL carriers. The size of this group is around 5-10 companies. The composition of this "closed group" of trusted companies is based on trust and a history of good business relationships – in fact for each shipper there may be a customer specific list of companies with which the negotiation takes place. In current practice, the protocol for conducting negotiations is usually bilateral and sequential.
- **Open market.** A small subsets of orders (around 20%) is offered on the "open market". Usually this means offering the loads through transportation matching sites such as Teleroute [15]. The important point here is that there are no barriers of entry or "admission rules" on these sites (i.e. any company or individual carrier in the Netherlands or in the whole of Europe can make offers by phone for these orders)

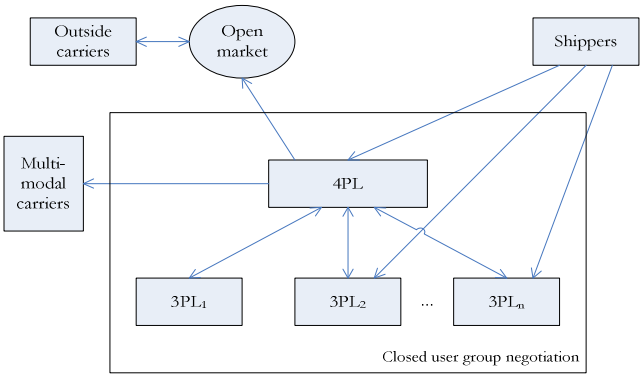

Figure 1: Interactions between parties in a multi-party logistics setting

We argue that both types of mechanisms can benefit from agent-based automation, though they may require different mechanisms. For the open group negotiation, auction protocols would probably be the most suitable, since here all agents are strictly competitive and there are no barriers of entry.

However, in our approach we concentrate more on the first set-up, the closed negotiation, chiefly because it is more applicable for our particular setting, i.e. it has a higher business impact and 80% of the orders are allocated in this way. For this set-up we considered two types of choices. The first one is automated negotiation, especially multi-issue and multi-item negotiation models that enable parties to reach mutually profitable (Pareto-efficient deals [8]) that go beyond strictly price competition. A second choice would be to have a combinatorial auction protocol, where the 4PL company would act as a "center".

In this paper we mainly explore the first option, since we feel it allows us more flexibility in dealing with side constraints and incomplete information. However, the auction option is also being considered, especially if the protocol could be adapted to quantify issues such as trust or other constraints. Further discussion of this issue is given in Section 5.

3. ORDER ALLOCATION AND NEGOTIATION PROCESSES AT VLO

This section aims to give a more in-depth look at how the order allocation and negotiation processes are currently performed at Vos Logistics. This is an important part of any industry analysis, in order to assure that the models considered can lead to usable pilot applications within the company and are not of merely theoretical interest. We focus here on the daily outsourcing (i.e. "spot orders"), which is the main area that could be automated through agent technologies, since it is unlikely that automated agents can be entrusted to take higher-level or strategic decisions.

3.1 Order set characteristics

There are several characteristics (parameters) that describe every transportation order. The following is a non-exhaustive list:

- The volume (or mass) to be transported
- The price (computed either per unit volume or unit mass)
- The time windows (in the form of time for picking up the goods and the deadline for delivery)
- Locations where the order is picked-up/delivered
- Extra transport conditions (e.g. refrigeration, liquids, fragile merchandise etc.)
- Arbitrary constraints that the shipper may impose (e.g. do not transport my goods at the same time as company X's)
- Flexibility of contractual terms (e.g. time ahead of the actual transport when a contract may be re-negotiated or cancelled)

Due to the time limitation of human planners, currently most of the parameters are not explicitly negotiated about every order. From the above set we identify two characteristics that are particularly important from the perspective of how orders are currently priced by carriers:

- The percentage a load takes from the total volume of a truck, commonly referred to in the field through the acronyms FTL (full truck load) and LTL (less than truck load)
- The "fruitfulness" of the region the order originates from or is to be delivered. Here by "fruitfulness" we mean the likelihood that there will be return freight from that region.

In the following sections we discuss these two dimensions in more detail and show their importance with respect to the different types of bundling.

3.2 Bundling of LTL shipments

Making bundles out of individual orders is a well known way to increase offer value [9, 4]. Two potential improvements have been found in the area of bundling; consolidating multiple part loads with overlap in route and the offering of return shipments or subsequent loads at the unloading destination.

VLO can gain considerable savings when multiple LTL or part loads, with overlap in (part of their) route, are offered as a bundle. To illustrate, a typical price table, using actual carrier data, is displayed in Figure 2 which depicts the price per pallet for the various loading percentages of a truck[2]. From Figure 2: Relationship between load and price per pallet, we can see that the pricing of LTL (less than truck load) orders follows a logarithmic–like pricing function. An order for a quarter of a truckload is roughly 50% of the FTL price for example whereas half of a truckload equals approximately 70% of the FTL price.

Currently, the process of bundling is executed by hand by VLO for the shippers that request it. A number of solutions exist, both agent-based and non agent-based, to automate and optimize the process of making efficient bundles out of a given set of orders.

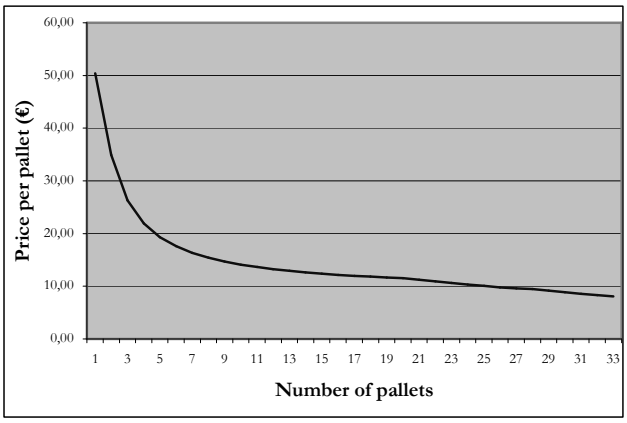

Figure 2: Relationship between load and price per pallet

3.3 Bundling of return or subsequent freight

For the bundling of a shipment with a corresponding subsequent or return shipment, the notion of fruitfulness plays a central role. In a fruitful region much freight is offered and a truck runs only a limited amount of empty kilometers, whereas in a fruitless region not much freights are offered and on average trucks run a significant amount of empty kilometers before pickup of the next freight. Depending on the fruitfulness of the unloading area and the quality of the carrier's own network and his own capabilities in matching demand and supply, a truck has to run a certain number of empty kilometers from the unloading point to the next pickup location. If VLO was to offer a new freight at or close to the unloading location, a significant discount might be obtained from the carrier as the truck is decreasing its empty kilometers. Savings depend on the area the new freight is offered in and the quality of the carrier's own network. If a lot of freight is offered in the region, the discount will be smaller. Similarly, if a carrier's own network is mature and the carriers are very capable of finding subsequent shipments, the discount will be smaller.

This concept can be seen in current business practice at VLO, in which a certain price/km value is used for a 'country of origin' to 'country of destination' combination. Different values are used for each combination, e.g. for a shipment from France to the Netherlands a lower value is used than for shipments from the Netherlands to France. This has to do with the amount of return freights generally available in the country of destination. If a truck coming from France has to deliver freight in the Netherlands, chances are high that there is a freight weighting to get from the Netherlands to France. It is different the other way round. If a truck is empty in France there is a much smaller chance that there are freights weighting to get from France to the Netherlands and as a result there is a higher chance that the truck has to return empty. To illustrate, rates from France to the Netherlands are about € 0,60 to € 0,80 per kilometer, whereas prices from the Netherlands to France range from € 1,25 to € 1,50 per kilometer.

4. AUTOMATED MULTI-ISSUE NEGOTIATION: MODELS & RELATION TO THE TRANSPORTATION DOMAIN

The concept of electronic negotiations or e-negotiations is a very broad one. As shown in [1], it covers a whole spectrum of negotiations ranging from the unstructured exchange of messages using email and chat systems, to partially structured e-negotiations supported by negotiation support systems, negotiating software agents or online auctioning platforms for selected tasks, to completely structured negotiations conducted autonomously by computer systems.

The scope of our approach is the automated case, where parties are represented by software agents. More specifically, we are interested in multi-issue or multi-item negotiation models, which allow agents to exploit so-called "win-win" opportunities. As shown by Rosenschein & Zlotkin [10], such negotiations represent non-zero sum games, where "as the values shift in multiple directions, it is possible for both parties to be better off". In our application domain, this means that negotiations between agents representing different transport providers (carrier companies) do not focus exclusively on price, but also allow the discovery of mutually beneficial bundles of orders, which are customized to accommodate for niches in their supply chains.

In the following we discuss some of the issues identified by our case study at VLO that could potentially form the object of automated negotiation techniques. Some of them (especially the question of time windows) is important because it influences the potential gains which can be achieved through the bundling of orders.

4.1 Negotiation over price

In current practice at VLO, price is the only issue negotiated. This negotiation currently is performed by humans and takes place over the phone. Even for this one issue there are some advantages to be gained from automation.

First, efficiency could be improved, since transaction costs would be reduced by automating the process. Furthermore, humans have

[2] A regular trailer (truck) has a volume of 33 euro pallets, while large-volume trailer can take 38 pallets. Note that a euro pallet is 1.20 meters wide and 0.80 meters long.

a cognitive limitation on how many parties they can negotiate with at the same time and how many counter-offers they can make in each negotiation. In current VLO practice this leads to rather large bid-offer spreads between offers and between negotiations for similar orders. If these negotiations could be automated, this would increase the effectiveness of the deals made as well.

However, we should point out that automated negotiations are however no panacea and should be treated with care. In human-controlled, traditional negotiations, the communication, formulation of offers and making of concessions is a vehicle for both a consensus and understanding [7]. In vaguely defined negotiation situations, a human-controlled negotiation process will probably be more efficient and effective than what would be possible with even the most sophisticated intelligent agents currently available. Therefore, having a clear protocol is crucial in automated negotiation models.

4.2 Negotiation over time windows

Currently, time windows (i.e. time interval when an order is to be delivered) are considered to be fixed, due to the complexity and high cost of negotiating a potentially exponential number of combinations of order bundles/time windows. It has however been indicated that VLO's customers would be willing to be more flexible if doing so would result in savings to them. Basically there are two ways to handle this option. VLO could give a discount if shippers would be willing to extend their time windows, e.g. a 5% discount if the time windows are increased from 1 to 3 days. This would require that VLO knows what savings can be achieved in the various situations, to make sure that the discount percentage given is a realistic one. The other option is to let the customer specify discounts or penalties in case of earlier or later delivery.

	Three days earlier	**Two days earlier**	**One day earlier**	**Original date**	**One day later**	**Two days Later**
Initial amount/ shipper	€ 650,00					
Penalty for date change	Not accept	- €150,00	- €50,00	€ 0,00	- €150,00	Not accept
Actual revenue	n/a	€ 500,00	€ 600,00	€ 650,00	€ 500,00	n/a
Best carrier's offer	n/a	€ 530,00	€ 530,00	€ 630,00	€ 490,00	n/a
Gross margin of VLO	n/a	- € 30,00	€ 70,00	€ 20,00	€ 10,00	n/a

Table 1: Example of margin fluctuations with flexible time windows

Table 1 illustrates this later concept through a fictional example (but which, nevertheless matches characteristics of real orders – as discussed with VLO planners), how VLO can benefit from deviating from the original date, e.g. because capacity on the original date is hard to find and prices are high.

There are several reasons why rates could fluctuate at different time periods:

a) Using extended time windows there is the possibility to better match freights with the location of a carrier's vehicles. For example, in the case of shipments from Germany to the Netherlands, a Dutch carrier will be cheaper as they are likely to have freight from the Netherlands to Germany and can pick it up on the way home. However, these carriers do not arrive in Germany until Tuesday, as trucks and drivers return to their home base during the weekend. If the time windows for a freight which is scheduled at Monday are extended by 1 day, a Dutch carrier is able to take on this shipment, whereas VLO otherwise would have to go with a more expensive German carrier.

b) Extended time windows might also lower specific costs. Again, a simple example helps illustrating this principle. Consider freight from the Netherlands to the North of France with an original pickup date of Wednesday and one from the North of France back to the Netherlands with an original pickup date of Thursday. If the time windows are extended, the carrier could load the freight to France very early Wednesday morning for example and drive to the North of France. If the carrier can pickup the return freight that same Wednesday right after unloading, he can drive back the same day. As a result, instead of chartering an international driver, a much cheaper so-called national driver can take care of these shipments, as there is no need to sleep over in the truck and wait to pickup the freight the next day.

Besides these effects, specific to certain carriers, there may be market-wide or industry-wide effects as well, such as the "end of the month" effect, when shippers want to transport the goods to remove them from their inventory lists, and one-time effects caused by disruptive events such as strikes etc., which cause a backlog of orders in certain periods. In this case, extending the time windows to help carriers better cope with such events may be desirable.

5. PROPOSED SOLUTIONS FOR MULTI-ISSUE NEGOTIATION AND BUNDLING

From the discussion in Sect. 2-4 above, we can see that there is a wide variety of issues that could, potentially, be considered in automating the negotiation processes al VLO.

Here we focus on one of them: automating the "closed group" negotiation (see Sect. 2) between the 4PL and 3PL companies over the distribution of transportation orders. We chose this setting because of its relation both with existing research lines at CWI and with current practice at VLO. In our models, we consider that orders can exhibit utility dependencies of two types:

- Complementarity dependencies, if the orders can be transported by the same truck (i.e. their pick-up/destination regions, delivery time windows and/or capacity fit)
- Incompatibility (or substitutability) dependencies, if orders cannot be bundled together, due to a mismatch between their delivery time windows and/or capacity.

In our model, dependencies are represented in the form of a utility graph, which encodes complementarity/substitutability relations between orders. In previous work (in part by the same authors) presented at the research track of AAMAS [9] a general framework was proposed to handle this type of dependencies, and this was successfully applied to the logistics setting. A software tool was built for this paper (a screen shot of the negotiation

phase is shown in Fig. 3). The tool should enable planners to compute (close to) optimal bundling of different sets orders and to explore different scenarios, by changing the constraints (e.g. time window constraints) and the information shared between parties.

This approach works by dividing the one-to-many negotiation between the 4PL and 3PL companies from the closed group in a series of one-to-one negotiation threads. This approach allows us to preserve the privacy of each party, since each company has to reveal their exact preferences and valuation only to its own automated agent. Furthermore, agents representing different companies do not have to reveal their preference information directly to other agents in the group, since approaches to automated negotiation such as those proposed in [9] allow agents to reach efficient agreements incrementally, with partial or incomplete information revelation.

There are, however, challenges when applying this model to a real-world setting. First, we assume all companies are represented by a proxy agent that does the bidding on their behalf. Second, we do not say much about how planning is performed, our approach concentrates only on optimizing the task allocation between a group of companies. Clearly for such approach to work well in practice, the planning of transportation within each company would need to be automated as well and connected to the negotiating agent. Alternatively, if planning is still done by humans, better mechanisms are needed to encode and elicit the preferences over the bundles - especially time and capacity preferences. An alternative to this automated one-many negotiation approach would be to use an auction-type of approach, instead of automated negotiation. For example, in other work, such as proposed by Sandholm and exemplified in the engine built by Combinenet [14], a similar problem is solved by means of a combinatorial auctions. This has other advantages (e.g. humans could also specify bids, so full automation from proxy agents is not needed), but also assumes that parties are willing to share truthfully their planning information and there is one trusted "center" to compute an optimal allocation.

In any case, it is realistic to assume that at any time, human planners or negotiators should be allowed to overrule the suggested agreements reached by their negotiation/auction proxies. As such, we envisage that the system would work more as a decision support tool which helps to explore various allocation scenarios, rather than a replacement for human negotiators.

A practical disadvantage of traditional auction mechanisms is that competition occurs entirely on price and the seller (in our case, the 4PL company allocating the orders) cannot discriminate between subcontractors based on other aspects, such as trust. This is a departure from real-life settings, where it may be possible that a party with a higher bid is offered the deal, if it is deemed more trustworthy (although this is difficult to quantify, since it is based on previous interactions and experience of the human planners).

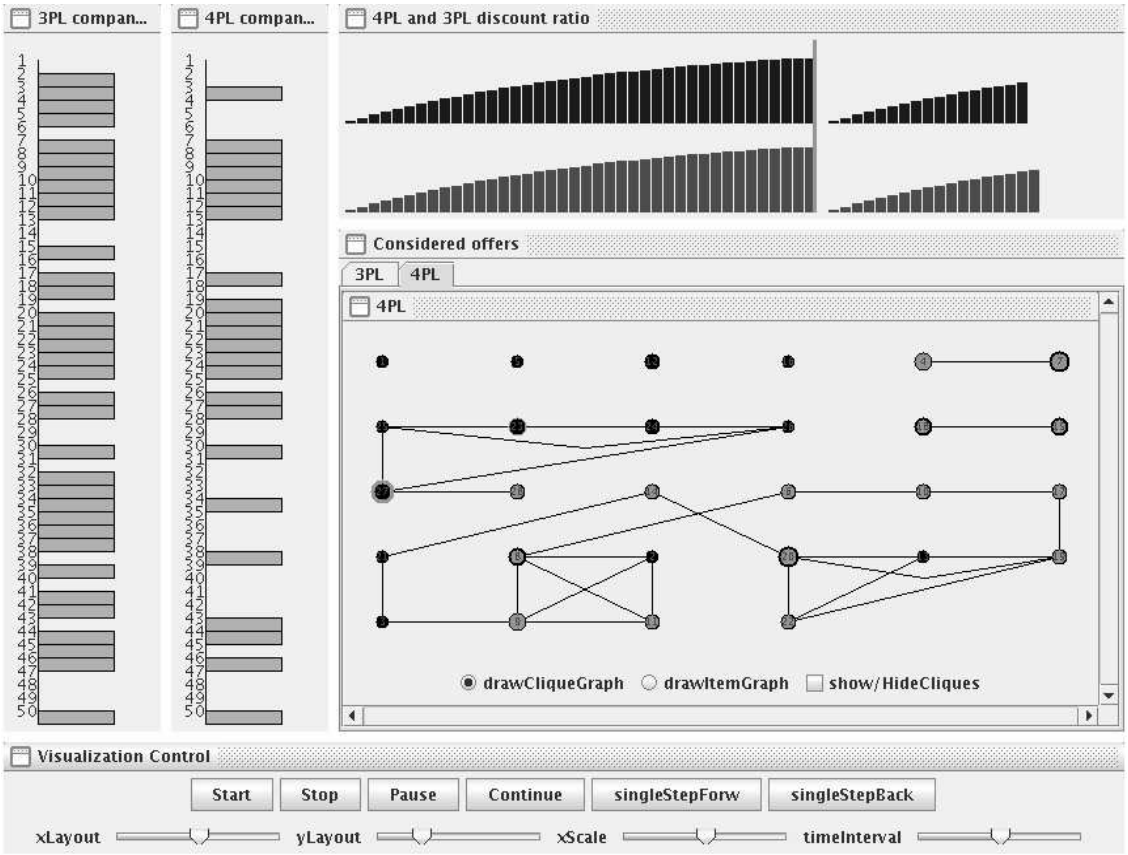

Figure 3: Screen shot of the negotiation tool built to visualize a closed group negotiation thread

By modeling the negotiation as a set of private one-one threads, asymmetric concessions to different parties (based on their trustworthiness) are possible. An alternative would be to modify the traditional open auction mechanism to take into account such considerations. Two alternatives have been proposed (c.f. [13]):

- Allocating closed-group orders through an auction with a pre-selection step, in which only certain companies are allowed (or invited) to submit bids. In this way, 3PL companies are already "screened" before accepting a potential offer.
- Modifying the winner determination mechanism of a traditional auction, such that not only price is minimized, but also a weighed element of trust is taken into account.

All the alternatives discussed above (concurrent, bilateral negotiation and modified auction mechanisms) will be considered as potential implementation options in the proposed pilot project.

6. ANALYSIS OF POTENTIAL GAINS ACHIEVED FROM BUNDLING ORDERS IN THE CASE STUDIED

From Section 5, we see that the way our negotiation model works is by finding more efficient "bundles" of transportation orders, which best exploit the niches in the supply chains of different market participants. The theoretical model presented above has been shown, through simulations, able to discover Pareto-efficient allocations, even in incomplete information settings [9]. However, for a practical setting, validating a model through simulation is clearly not sufficient and we need to explore what are the potential savings which can be achieved through such techniques in practice.

A thorough investigation of the potential savings which can be achieved through bundling of orders for Vos Logistics was performed using historic order data. The data consisted of the set of over 6000 transportation orders handled by the forwarding desk of Vos Logistics for the year 2004. We should mention, however, that in order to protect the competitive advantage of VLO as well as the privacy of their customers and associates, much of this analysis cannot be reported in this paper. For this reason we report here only the percentage improvements achieved through bundling, but without entering into details or monetary figures.

There are two main types of bundling considered with respect to transportation orders:

- Bundling of LTL shipments (i.e. bundling of orders that are less than one truck load)
- Bundling of subsequent/return orders for FTL shipments (full truck loads)

For the bundling of LTL shipments, we considered orders for which both the pick-up/delivery locations (computed based on the first 2 digit of the postal codes area) and the date matched. Additionally the sum of part loads in a combination should not exceed the maximum load capacity.

For the bundling of FTL shipments, the delivery location and delivery date of a first order had to match the delivery location and delivery date of a second order. In both cases, feasible allocations are considered, of course, only those in which an order belongs only to one bundle.

The results of the savings which can be achieved for a set of over 6216 orders handled in 2004 are shown in Table 2:

	Savings over the total over the total value of LTL orders	Savings over the value of all orders in the order set
Bundling of LTL shipments	19%	2-3%
Bundling of FTL shipments	-	12%

Table 2: Potential gains which can be achieved through bundling of orders using historic VLO order data for 2004

From the results in Table 2, two things stand out. First, we see that the potential gains which can be achieved from bundling partial loads seem rather modest, compared to that from bundling return or subsequent shipments. This can actually be explained by the fact that, overall, the percentage of partial (i.e LTL) loads in the order set was rather small. However, if one considers only the value of the subset of LTL orders, one can see that using more efficient bundling the average truck utilization (load) increases from 18% to 39%. Using actual carrier price data, this results in savings of 19% in terms of price per unit load. The result is significant, since it is estimated that in the future, the number of partial truck loads handled by VLO is likely to increase considerably. Finally, for the results above, we assume that only same-day orders can be matched, in order to be consistent with current practice. If more flexible time windows are allowed (through better negotiations), we estimate that the potential savings from bundling can increase considerably.

7. DISCUSSION

There are several other approaches which address similar problems to the ones discussed above, both in the literature on agent systems, but also implemented by commercial companies. Here we review them briefly and compare their functionality to our approach. The LS/ATN system developed by Whitestein Technologies and presented in Dorer and Calisti [3] is a multi-agent system for dynamic transport optimization. The system provides agent-based optimization and execution capabilities that automate order dispatching, a crucial phase of transportation planning. The chief difference from our work is that the system proposed by Dorer & Calisti is mostly concerned with distribution of orders in the planning phase between trucks of the same company, while our system is concerned with automating the negotiation over loads between different companies in a supply chain.

The system proposed by Magenta Technologies [5] uses a multi-agent system to provide intelligent support for transportation scheduling. At the core, the system also relies on a virtual market engine to distribute loads. One feature of the MAGENTA system not currently considered by us are the semantic representation capabilities, as provided in the Ontology Management Toolkit.

Another set of solutions which address problems very similar to the ones described in this paper are provided by Combinenet [14].

Combinenet aims also at capacity optimization, by allowing more expressive bidding and scenario generation. We assume most of their solutions are based on efficient algorithms developed, in fundamental research by Sandholm and collaborators (reported, for example, in [11]). The main difference with the approach discussed in this paper, these solutions rely mostly on combinatorial auction algorithms to compute efficient bundle allocations.

Finally we should point out that there are also several electronic freight exchange sites, such as Teleroute [15] and Transporeon [16]. Teleroute (which is also currently used by VLO for their open market operations) acts more as a platform on which carriers and shippers advertise their order and transport capacity, but any negotiation and matching is done by human through the phone. Transporeon is another platform that provides a slightly more advanced functionality, such as bidding and order matching, yet well short of what can be achieved through automated agent-based solutions. Nevertheless, Transporeon has been used in daily operations by other partners of VLO, with considerable savings.

In comparison to these approaches, we focus mostly on the order allocation between several companies, more specifically on the order allocation between a 4PL and several 3PL companies. Our approach allows parties to discover optimal allocations in an iterative way, without revealing private planning information except to their own negotiating proxy agents. We envisage our tool being used as a human decision support tool, which allows human negotiators to investigate different scenarios, by changing the constraints, information shared and negotiation parameters of their agents. Humans are then free to accept/reject the proposed allocations, or re-run the negotiation in a new scenario.

Finally, our paper would not be complete without outlining some of the challenges we face in getting a pilot project on automated negotiation actually working at a company such as Vos Logistics. In general, in order for such a system to be adopted in practice, we need to show that the profit margins which can be achieved from adopting the new technology must be sufficiently high to warrant the effort and costs. Also, in our case, due to the fact that the system automates the interaction between several companies ("actors") in the supply chain, each of these must be willing to use this technology. Finally, the integration of automated planning of orders for each company with the negotiation proxy agent would be desirable in order to fully exploit the capacity of our system. Even if it is true that some of the companies use automated planning systems, we cannot assume this is necessarily the case for all companies in the supply chain. An alternative would be to allow humans to specify bids and offers, such as in an auction like protocol.

Despite the above challenges, our results from the approach so far have been very well received and a full scale pilot project is under way to apply such techniques in the daily outsourcing processes at Vos Logistics Organizing.

Acknowledgments

The authors wish to thank Walter Kusters and Rob Wijdeveld of Vos Logistics Organizing in Nijmegen for their advice and support at earlier stages of this work and Willem-Jan van Schijndel for his support with the data set.

ABSTRACT
The paper describes main features of an Intelligent Scheduler for Road Transportation Applications based on Magenta agent technology and characterized by a number of unique, advanced features such as real-time, incremental, continuous scheduling and schedule improvement, scalability from small to very large enterprise networks, multi-criteria schedule analysis and rich decision support for the user, pro-active agent negotiations.

The scheduler is event driven, which means that it construct schedules taking into account the occurrence of all schedule affecting events (such as the arrival of a new order, order cancellation, truck failure, road unavailability and driver no-show). As an event occurs the scheduler rapidly re-schedules only the affected part of the schedule thus causing the minimum disruption to already allocated resources.

The Scheduler has been tested on real data supplied by several UK Road Logistics operators.

The Scheduler was developed using protected Magenta technology for agent negotiations in virtual environment and knowledge discovery.

1. INTRODUCTION
Road transportation logistics is amongst the most complex business problems. The complexity is caused by the exceedingly high variety of possible solutions (large solution space), which rules out traditional combinatorial search algorithms, and uncertainty due to high dynamics and volatility of the operational environment and openness of business networks, which makes optimisation impractical – a single optimisation run is typically an order of magnitude longer than a typical interval between two consecutive changes in operational conditions.

Resource allocation is an ongoing continuous decision making process in real time where criteria are changing "on the fly". Therefore the two key capabilities currently required from schedulers are supporting complex business networks and planning in continuous mode.

An effective road transportation scheduler must handle transportation instructions (TI) from many different loading points to many different destinations (e.g. customer locations and cross docks where cargoes are offloaded and consolidated) and many different routes by which orders can be delivered. Choosing the best route based on consolidation or other criteria is referred to as dynamic routing. The scheduler must also be able to allocate cargos of many different sizes and weights to many different types of trucks and trailers; take into account preferences of owners, operators and drivers and fit the schedule into numerous constraints imposed by warehouse working hours, driver work rules, safety regulations and enterprise policies, eg, on choosing between own fleet and third-party carriers. Different companies have different critical constraints, e.g. permission to override time or other constraints to achieve a more efficient schedule. The schedule created must be not only feasible but also efficient, i.e. possibilities for backhauls and consolidations should be found.

Complexity is also defined by the number and variety of orders (and other events that affect scheduling) per day and the number and variety of transportation resources such as trucks.

In addition, the scheduler is expected to rapidly reschedule orders and transportation resources affected by unexpected events such as: the arrival of new orders, cancellations, failures, bad weather conditions, road works and no-show of drivers or loading crews.

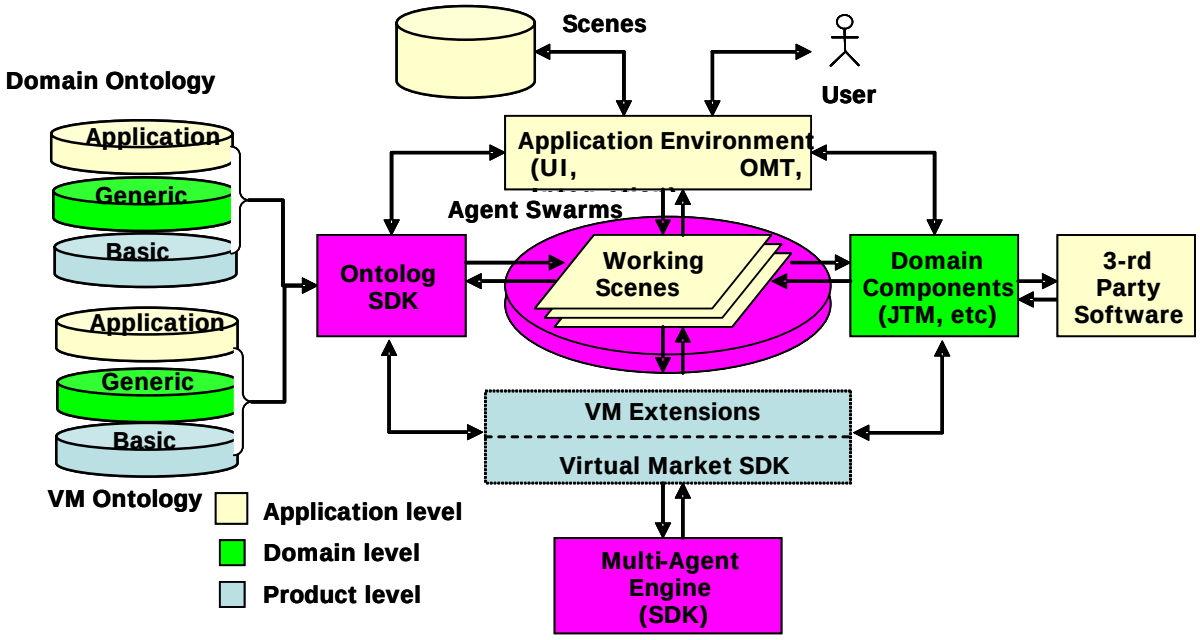

Fig.1.i-Scheduler Architecture

To enable enterprises to plan and re-plan continuously, reacting to events in real-time, schedulers must support "Planning / Commit / eXecute" (PCX) stages and plan across a multi-day planning horizon.

In the planning stage orders are assigned to a truck and its journey is constructed. During this stage orders can be added or removed and the route planned for the truck can be changed as a result of subsequent events

At some point the scheduler must commit the truck. This will trigger communications to warehouses, driver shift planners, truck servicing etc to make ready the truck for its journey. During this phase changes to the truck schedule are undesirable because there would be knock on effects for the warehouse, driver assignment, etc.

The execute stage starts with the driver performing his pre-journey checks and continues until his debriefing at the end of his shift is completed. During this phase a high level of sophistication would be needed to alter the truck schedule in transit.

Magenta i-Scheduler supports PCX by allowing commit of individual trucks from a rolling schedule.

To achieve competitive advantage schedulers must take into account real-time economy where decisions are based not on some average rule but on the detailed analysis of the current situation. For example, a truck loaded by only 10% with a special cargo may be very profitable whilst a rule-based scheduler would not allow a nearly empty truck to start a journey. The requirement is to assess the economy of each truck, each journey, etc., which implies using the activity-based cost model. The current generation of batch schedulers cannot satisfy these requirements; a fundamentally new approach to the task of allocating resources in real-time is therefore needed.

Designing a scheduler that can cope with such a variety of operating conditions, handle uncertainty related to the occurrence of events and at the same time continuously produce schedules that maximise the specified value (or minimise transportation costs) is a real intellectual challenge. To the best of our knowledge such schedulers have not been proposed in the literature or implemented in practice.

2. SOLUTION

A complex problem can be solved effectively only with a complex tool. The tool must be capable of providing the "requisite variety" of behaviours, as postulated many years ago by Ashby [1]. Only the tools based on distributed (rather than centralised) decision making fully satisfy this criterion.

The scheduling tool described in this paper handles complexity by balancing and resolving conflicts of interests of many active players rather than by following given rules and satisfying specified constraints.

This is achieved primarily by assigning an autonomous agent to every player in the transportation system and tasking agents to obtain the best possible deals for their clients. Players here include the transportation enterprise as a whole (represented by the Enterprise Agent) and all individual transportation demands and resources (including drivers and resource owners). Demands

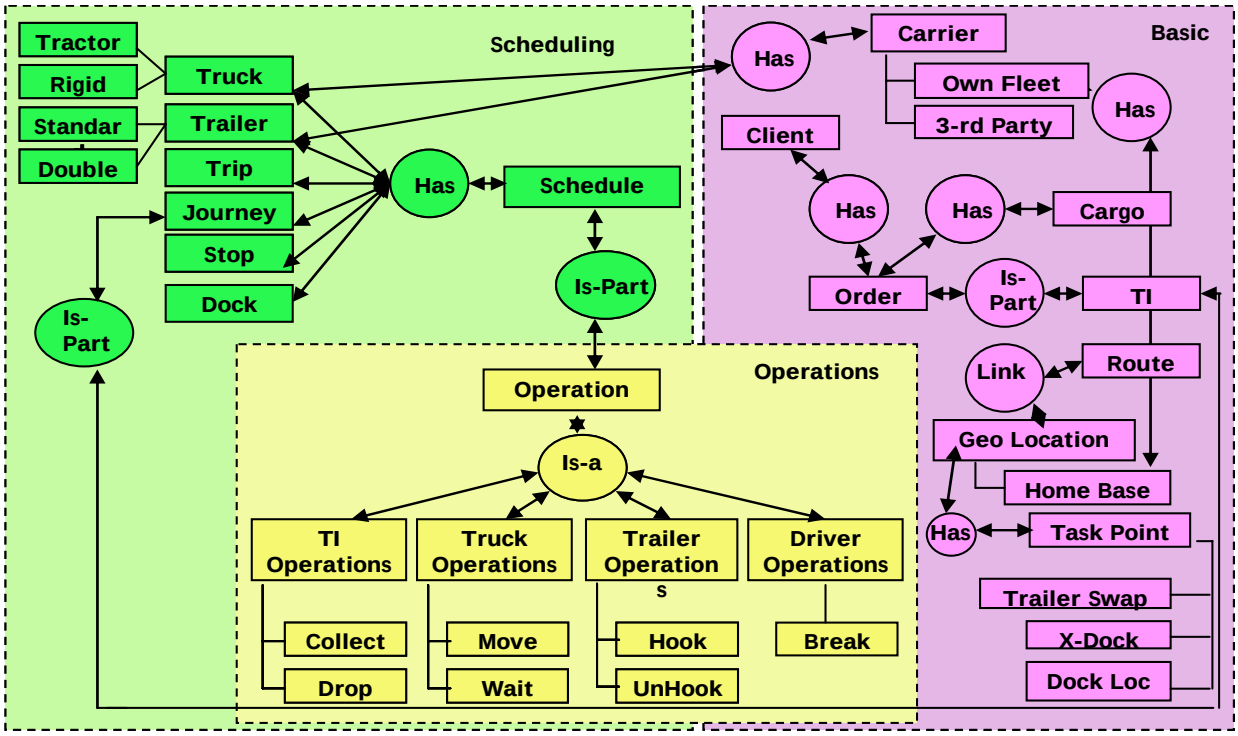

Fig.2. i-Scheduler Ontology Architecture

and resources that have common interests self-organise into groups represented by a single agent. Agents may decide to compete or co-operate depending on prevailing circumstances.

Human operators are provided with facilities for monitoring the scheduling process and overruling the decisions made by agents. Magenta i-Scheduler supports users in their interaction with the system by providing them with options and evaluating consequences of their decisions.

Conceptual knowledge on scheduling is separated from the resource allocation mechanism, which greatly simplifies updates and increases the reuse of code.

The process of formalising domain knowledge helps in refining it and closing the gaps left due to the empirical nature of knowledge collection.

To construct a schedule Magenta i-Scheduler uses a formal description of business domain knowledge (Ontology), formal description of particular situations (a Scene), formal description of agent goals (e.g. to increase profit, maximise service level, decrease risk, etc) and real-world events. Formal descriptions can be stored, changed and examined by decision maker at any time.

Agents working in the system are goal-driven. They do not perform combinatorial search and instead negotiate to achieve the goal, which allows overcoming the problem of the very large solution space. Each agent searches only for the solution which is the best for its client, for example, to occupy a particular time slot. If this option is already taken by another agent, the conflict of interest is identified and resolved by negotiation aimed at maximising the specified enterprise value or minimising transportation costs.

Agents are knowledge-driven. They use a Scene for analysis of the situation in the business network represented by the Scene with a view to improving quality and performance of the scheduling process. Scenes can be constructed and analysed dynamically by agents or human operators, forming the basis for Continuous Planning and Execution.

Scenes are the basis for a sophisticated interaction with users. The user is informed about the current situation by the current Scene and is given support for decision making. The fact that a Scene is a formalised description of a business situation helps to recognise patterns and identify gaps in the user knowledge and understanding.

Finally, the Road Transportation i-Scheduler can work in conjunction with Magenta knowledge discovery tools, with a view to discovering useful patterns of behaviour by means of clustering (finding groups of records with similar properties) which amounts to learning from experience.

3. ARCHITECTURE

The Road Transportation i-Scheduler is based on the standard Magenta software architecture as depicted in Figure 1 and described in [2] and [3]. The key features of Magenta technology are protected [4] and [5]. The earlier version was reported in [6].

The software is powered by a Multi-Agent Engine which contains all runtime tools necessary for the agent operation. Formalised knowledge is in Ontology supported by a powerful ontology

editor. Agents negotiate scheduling decisions in the Virtual Market.

The Logistics i-Scheduler is implemented on a J2EE platform.

4. ONTOLOGY

Ontology is constructed as a network whose nodes are objects (order, transportation instruction, cargo, truck, etc) and links are relations (Journey consist of TI, etc). It contains also attributes of objects like truck capacity, etc.

As depicted in Figure 2, Ontology is divided into three main parts. Basic part of ontology includes main logistics concepts. Schedule Ontology consists of schedule owners and schedules and contains references to the operations which constitute schedules, described in operation ontology. This structure allows the introduction of any type of operations into schedules.

A typical Scene is shown in Figure 3. The scene representation is design to help the user to understand the network situation. Looking at "Client" it is possible to find out where all TIs are at any given moment. Looking at "Location" it is possible to see all Journeys that are planned to go through this location.

Scenes also make decision making logic more visual and understandable to the end-users.

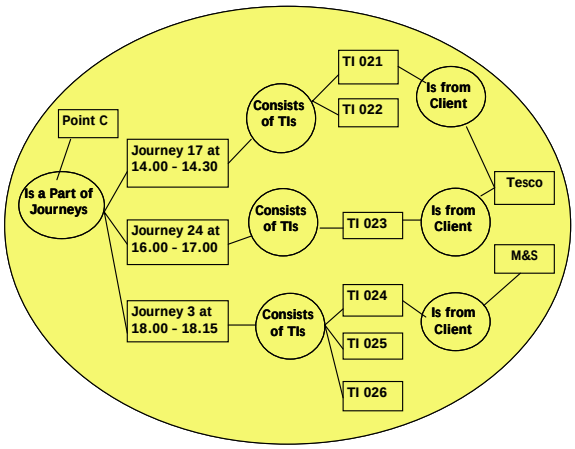

Fig.3. An Example of Scene

5. VIRTUAL MARKET

Virtual Market is a virtual environment in which agents negotiate the allocation of transportation resources to orders.

5.1 Agent Types

The Logistics i-Scheduler has several key types of Agents, including:

- Customer Agent – looks after the required Customer Service Level
- Order Agent – splits orders into transportation instructions and monitors its Key Performance Indicators (KPIs). If the allocation of a Transportation Instruction (TI) is unsatisfactory the Agent will try to improve it by searching for the most appropriate journey
- Transportation Instruction Agent – searches for the best journeys
- Journey Agent – looks for the best TIs, devises good consolidation, looks for the best routes with minimal mileage
- Cross-dock Agent – supports the schedule for cross-docking and allocates Journeys to time slots
- Group Agent – keeps similar TIs together
- Enterprise Agent – minimises fixed costs by decreasing number of trucks used; switches company strategies; monitors schedules and causes disturbances to destroy 'bad' journeys

Each type can act as a Demand Agent or a Resource Agent depending on the situation.

5.2 Generic Virtual Market Architecture (Agent Communities)

Magenta i-Scheduler has a generic virtual market architecture, which enables agents to form natural coalitions, e.g. TIs on a Journey or Journeys which together constitute a Driver Shift (all journeys made by a driver during his working day). This means that virtual market is organised in many levels, with nested groups formed by common interests where each group has an agent representative (Group Agent) who monitors what is happening in the group. Agents can join the group and leave it. The whole group can move (e.g. Journey goes to another Driver Shift).

This architecture provides flexibility in developing communities of different types of agents which can work as coalitions. Such approach also gives more options to find a right balance between interests of individual egoistic agents (TI, journey, etc) and interests of communities of agents (fleet, journey, etc). Also, this balance can be changed dynamically in reaction to events (X-Dock under terrorist attack). Finally, this architecture forms the basis for ongoing self-improvement of schedules.

The generic architecture provides stable, well-designed and elegant basis for rapid development of new applications in a wide range of new domains (supply chain, factories, containers, projects, finance, nurses, conference boxes, etc).

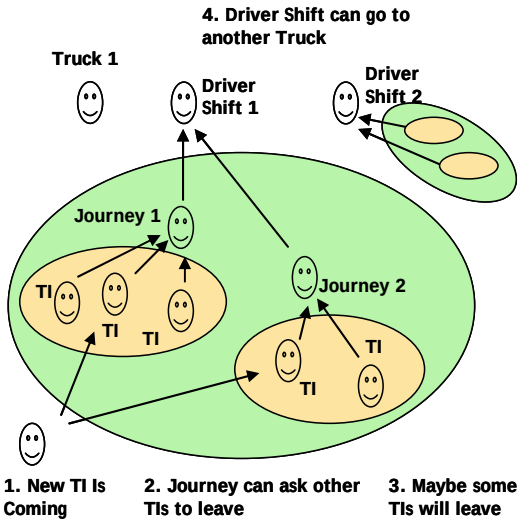

Fig.4. Multi-Level Virtual Market Architecture

5.3 Agent Negotiation Strategies and Protocols

Every agent is given the task of obtaining the best possible match for its client and a right to drop a previously agreed match if a better opportunity presents itself as events continue occurring. The abandoned partner pro-actively seeks a new match.

Agents on the Virtual Market use enhanced Contract Net negotiations protocol. Within Contract Net protocol agents pass the following iterations:

- Ask for pre-matching (rough) estimation
- Ask for plan, if possible to allocate without drop
- Ask for complete plan (drop is possible)
- Accept proposal
- Receive notification that plan is applied/failed

At each stage agents can cut or prioritize negotiation branches, thus detecting uninteresting options with fewer calculations.

If a plan fails, the agent can re-send a corrected proposal.

If an agent has two equal options, one of which involves drop and another is without drop – it will prefer the option without drop, as it saves time.

The protocol is decomposed into two parts: the contractor role and coordinator role. The contractor role is responsible for (and fully encapsulates) message exchanges between a particular pair of agents representing demand and resource.

Coordinator role contains decision-making logic of an agent at the protocol level and allows the demand agent to interact with several resources simultaneously (demand agent's coordinator role) and resource agent – with several demands (resource agent's coordinator role).

Magenta agents have multiple objectives, or criteria (quality, price, time, risk) each with a weight coefficient. This can be changed by the user for each individual agent. At any moment of time the user can increase the relative importance of the service level or maximise profit criterion. If for example orders from VIP customers are allocated and a new order comes from an even more important customer with tighter conditions, this may result in decreasing the service level for already allocated orders within the allowable interval. Changes in weight coefficients represent the change of agent strategy of working in the virtual market.

5.4 Microeconomics

The aim of microeconomics in Magenta multi-agent systems is to ensure that at any moment of time each agent knows which journeys are profitable for the company and which are not. There is a possibility to take into account not only "physical costs" but also the cost of planning. For this, the following principles are introduced. Each order finds out the cost of its transportation using price list and finds the most profitable journey. The profit received from transportation is shared between TI, Journey and Truck Agents. The microeconomics includes a system of taxation aimed to further improve scheduling efficiency. It does this by applying a penalty (tax) for making changes to the schedule close to Commit time. This ensures that only changes giving significant benefits are made as planning time runs out.

6. HOW THE SCHEDULING WORKS

The Initial Scene, which is a model of the transportation system at the beginning of scheduling, is constructed by an operator using a user-friendly editor or imported from an XML file. The Scene depicts all transportation resources (trucks, trailers, depots, warehouses, loading points, delivery points) and their locations on the transportation network. Goals, criteria, objectives (KPI), strategies and preferences are specified.

As the first order arrives, agents split the order into transportation instructions and allocate transportation resources to each TI. The Initial Scene is thus modified into the Current Scene, which is being updated after every event. The Current Schedule is extracted from the Current Scene and can take the form of a table or a diagram.

New events are added to the current schedule. They can be imported from third-party systems, from XML-files or added manually. Events are assigned individual objectives and strategies. When new events are entered into the system, the system stops other activities (or delays the incoming event) and starts TI allocation.

If events are entered in a batch, prioritization is carried out. Outstanding TIs can be prioritized with the help of prioritization logic defined in ontology or manually.

Next, new TIs are planned incrementally. TI agents pre-match by making rough option estimation and checking constraints. Next, they start negotiation with Journeys telling them the amount they are ready to pay for allocation. If TI is interesting for the Journey, it tries to allocate this TI using Open Slot, Shift or Drop algorithms. If an option is found, Journey makes the final option estimation and checks constraints. Journey sends message to TI to confirm allocation and informs other TIs belonging to it that new TI was allocated and they can re-calculate their values and costs.

If there are no new events, unsatisfied TIs, Journeys, Driver Shifts and Trucks could start pro-active improvement of their allocation. An important advantage of Magenta software is that this pro-

active improvement takes place in the system perpetually – i-Scheduler continuously works towards the best possible schedule. Any type of agent can be pro-active and agents who are unsatisfied with their current allocation are most likely to get pro-active.

User can review results using a Gantt chart or a map and analyse reports. There is a possibility to manually adjust the schedule asking the system to suggest alternatives. The system can also highlight parts of the schedule that needs improving.

Each Journey has its individual commit time. As commit time approaches, the agents get more and more active to utilise the last chance to find a better option. After the commit time of a Journey (e.g. 3 hours before the driver sets off) no further changes are made to this Journey schedule – Journey is passed to commit stage. In future versions, in order to improve versatility of the system, it will be possible to carry out additional scheduling at commit stage.

The incremental nature of Magenta scheduling and the use of different planning strategies means that the i-Scheduler will always produce a plan for an order, even if it is entered into the system very shortly before its commit time.

7. USER INTERFACES

The main window of the Logistics i-Scheduler, as shown in Figure 5, allows importing orders and placing them in the queue, starting planning and reviewing the schedule using a Gantt chart (Figure 6) and map, including detailed information about journeys and KPIs. Different parts of the window can be easily configured and re-arranged.

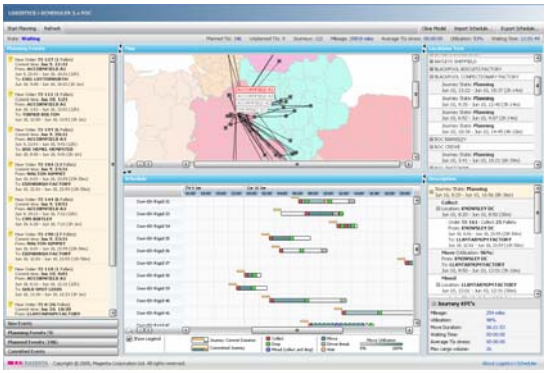

Fig. 5: Desktop Interface with Easily Configured Dashboard

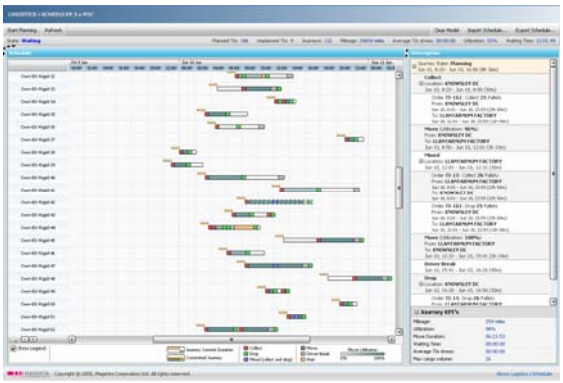

Fig. 6: Schedule Gantt Chart

At any moment user can view agent inspector (Figure 7) showing which agents are currently working in the system and analyse a negotiations log (Figure 8).

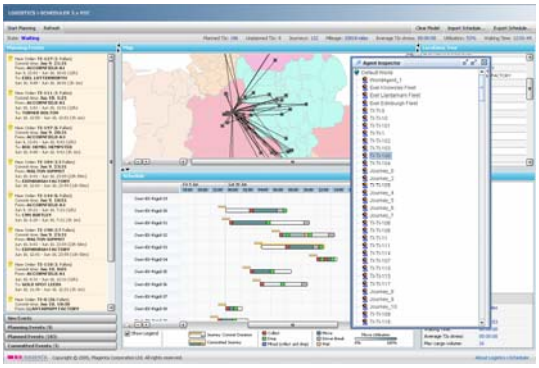

Fig. 7: Agent Inspector

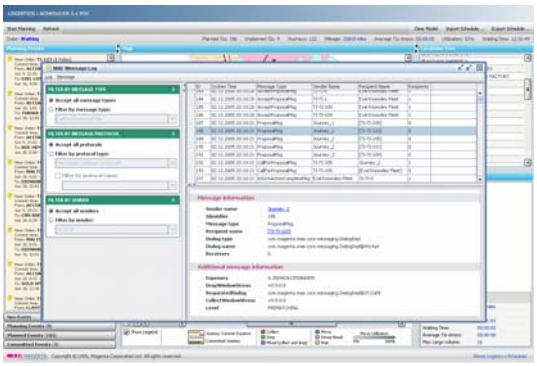

Fig. 8: Agent Negotiation Log

8. TESTS WITH CLIENT DATA

The first version of the Road Transportation i-Scheduler was tested on two sets of real-time data obtained from Client A, a 3rd Party Logistics Provider, and Client B, a provider of logistics and freight management services.

8.1 Client A Test Results

Client A requirements were to create transportation schedules in real time for 200 transportation instructions and 50 trucks (36 own fleet trucks plus 15 third-party carriers) operating on the UK Business Network. The network included 9 Distribution Centres/factories, cross-dock points for primary/secondary moves consolidation, 3 truck bases doing shared operations. Additional requirements were handling transportation instruction availability windows, backhaul, consolidation, vehicle capacity availability windows and constraint stressing.

The Client A currently employs two operators who require four to five hours to produce the schedule. Because of the current slow scheduling process, the Client plans two days in advance of execution. The Client also experimented with conventional batch schedulers and found that they could schedule only 70% of journeys correctly. The 30% of journeys had to be re-scheduled manually.

The Magenta i-Scheduler has completed scheduling of 200 transportation instructions in 8 minutes, planning 116 journeys of a total of 20790 miles. The result exceeded expectations with 95% of journeys scheduled correctly without any manual rework. The remaining 5% could not be scheduled during the tests because of incomplete information. Using Magenta scheduler Client A could complete planning and execution in the same day.

8.2 Client B Test Results

Client B requirements were to create transportation schedules for 4000 transportation instructions and 200 trucks operating on the UK business network. The network included primary and secondary deliveries between about 600 locations, 3 cross docks, 4 secure trailer swap locations and other types of locations. The network was also characterized by considerable number of very small orders. Special requirements included dynamic routing, cross-docking, handling location availability windows and driver breaks.

It took Magenta i-Scheduler about 4 hours to build a schedule for 4000 orders and 200 trucks with dynamical routing through 3 cross docks. This schedule showed an effective consolidation of small orders onto trucks. It was capable of incrementally planning new orders in near real time (a few seconds was required for each new order). As far as we know, this has not been achieved by any other transportation scheduling system. Before testing Magenta software the Client has spent considerable resources searching for a scheduler capable of handling their requirements and found none.

8.3 Performance Tests

During the tests on client data Magenta conducted an investigation into the effect of the number of orders on scheduler performance. As Fig. 9 shows, in situations in which a new order arrived when previous orders have been allocated, the time required to complete the schedule is, approximately, linearly dependent on the number of orders.

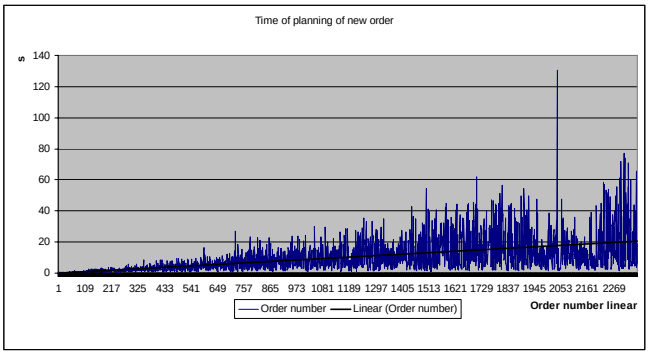

Fig. 9: The Effect of the Number of Previously Planned Orders on Scheduling Time for a New Order

This result is highly significant. It shows that Magenta schedulers can be easily scaled up to handle any size of order allocation.

A close inspection of the diagram shows that although the average increase in time is linearly dependent on the number of orders there exist significant number of low points and picks. Low points signify a situation where the new order was allocated with a minimum of re-scheduling, and picks are present where the arrival of a new order required a considerable re-allocation of previously assigned resources.

A very strong advantage of Magenta i-Scheduler is that planning is very fast and therefore can be done in real time. The rapid scheduling is achieved by the use of the incremental scheduling process, as opposed to the batch mode. Incremental planning gives an additional benefit of re-scheduling only those parts of the schedule that are affected by the occurrence of a new event, without having to completely destroy the schedule and re-build it "from scratch".

9. CONCLUSIONS

The test results described in Section 8 of this paper show that Magenta multi-agent technology, in general, and Magenta Road Transportation i-Scheduler, in particular, are capable of significantly improving scheduling effectiveness in comparison with conventional rule-based centralised schedulers. The difference is particularly visible in cases where there is a need to match a very large number and wide variety of orders and resources in real time.

The key features that contributed to the effectiveness of scheduling are summarised below:

- The distributed nature of decision making, which enables the swarm of agents to achieve a common goal whilst each agent member of the swarm is allowed to pursue the achievement of its own goal and yet be ready to negotiate when a conflict of interests is discovered.
- The ability to incrementally react to the occurrence of a new event, such as the arrival of a new order, by re-scheduling only affected parts of the previously agreed schedule.
- Pro-activity of agents, which drives them to improve the previously agreed allocations whenever practical.

ABSTRACT
In this paper, we describe our effort and lessons learned in commercializing an innovative infrastructure to support student participation and collaboration and help the instructor manage large or distance classrooms using multiagent system intelligence. The system, called I-MINDS, has a host of intelligent agents for each classroom: a teacher agent ranks and categorizes real-time questions from the students and collects statistics on student participation, a number of group agents that each maintains a collaborative group and facilitate student discussions, and a student agent for each student that profiles a student and finds compatible students to form the student's "buddy group". Our commercialization plan is three-fold: (1) to strengthen our understanding of potential customers, (2) to understand our competitors and alternative products, and (3) to examine and estimate the market potential for I-MINDS. To accomplish the above, we have conducted experiments to further investigate the impact of I-MINDS in actual use, comprehensive research on existing products and technologies, secure legal protection of our technology, plug-and-play I-MINDS for various demonstrations to companies for joint research and development.

1. INTRODUCTION
In December 2005, we founded a start-up company called I-MINDS, LLC, with the intention of commercializing a multiagent system called I-MINDS. Subsequently, we received funding from the National Science Foundation's Small Business and Innovative Research (SBIR) program to further improve the system technically and commercially. This paper describes our effort this past year and the lessons learned.

I-MINDS is a computer-supported cooperative learning (CSCL) system. There is need for CSCL systems especially in large or distance classrooms. Students in large or distance classrooms often do not enjoy the same level and quality of student-to-student and student-to-instructor interactions during the class (synchronously) or after the class (asynchronously) as in smaller classrooms. Such interactions are, however, important to foster group-based learning and student affinity in a class. To improve such interactions, educators have turned to technology such as personal response systems, online chat rooms, teleconferencing tools, and computer-supported cooperative learning (CSCL) environments. However, these systems do not adapt to diverse student and instructor needs and behaviors. These systems are passive participants in the process and students and instructors often resort to other modes of interactions (e-mail, phone, or face-to-face meetings) in order to address individual problems. Further, the advent of Internet and multimedia technology has meant potentially drastic changes in the teaching and learning process from the traditional classroom setting to a more geographically distributed, virtual but still interactive one. Hence, there are both motivation and opportunity to develop intelligent CSCL systems.

The long-term goal of our technical and commercial effort is to ultimately build systems to support intelligent virtual classrooms where students enjoy peer interactions as well as on-site, small classroom students, and where students enjoy student-instructor instructions as well as on-site, small classroom students. A secondary goal is to extend the virtual classrooms concept to other group-based applications such as decision support, focus group studies, and corporate training, and other cooperative work where agents might play a role [14], since the technologies and features of a CSCL system could be of significant use in these applications. For example, agents that support collaboration between two students can be used to mediate the discussions between two focus group participants.

Our commercialization effort for started with three main objectives to study the commercial feasibility of the I-MINDS technology.

Objective 1. To strengthen our understanding of potential customers. To assure that the technical design of the I-MINDS system meets education needs of teachers and students and successfully reach customers in the later-phase commercialization, we have researched to gain an in-depth understanding of potential customers from the following perspectives: (a) needs of teachers and students in real-time virtual classroom environment, (b) the current market offerings and how I-MINDS can fill the gap to fulfill unsatisfied customer needs, and (c) the decision-making processes of purchasing and implementing technology improvement in post-secondary schools in both academia and industry.

Objective 2. To understand competitors and alternative products. An effective evaluation of our competitors and alternative solutions will help us understand the online educational market. With this evaluation, we will be able to identify important issues during the commercialization phase, such as the I-MINDS business model, pricing strategy, competitive advantages and potential entry barriers.

Objective 3. To examine and estimate the market potential for I-MINDS. Further, we have investigated the current situation for overall education and training industry and our specific targeted market. Based on our analysis of the information collected about customer, market and competitors, we will be able to identify the key success factors in the industry which will help commercialize I-MINDS more effectively.

In the following, we first describe I-MINDS and its capabilities in Section 2. Section 3 discusses specific steps that we have taken towards achieving our three aforementioned objectives and more. Section 4 presents the lessons learned. Finally, we conclude.

2. I-MINDS

Our innovation is an infrastructure called the Intelligent Multi-agent Infrastructure for Distributed Systems in Education (or I-MINDS). I-MINDS consists of different intelligent agents working together to actively support student-student and student-instructor interactions. Specifically, there are agents that rank and categorize questions, and profile students to help the instructor manage a classroom in real-time; agents that find compatible agents to form "buddy groups" for students; and agents that form and maintain structured cooperative learning groups.

We have pilot tested I-MINDS and further deployed the software in the laboratory of an introductory computer science course at the Computer Science and Engineering Department of the University of Nebraska. Tests based on student assessments and control-treatment groups showed that I-MINDS, though still needing better graphical user interfaces and further development, could support and improve student performance and instruction in several pedagogical aspects.

2.1 Architecture

I-MINDS is built using a loosely-coupled layered architecture [7], which makes I-MINDS flexible and usable in heterogeneous environments.

The bottom layer (i.e., the network layer) in I-MINDS provides the basic communication functionalities by using sockets. Since sockets are available in a variety of platforms across the network, this layer allows I-MINDS to communicate in heterogeneous situations.

The second layer provides system-level protocols and encapsulations with necessary abstraction to provide convenient communication and deployment functions to the upper layers. This level includes a Relational Database Management System (RDBMS)-type database (MySQL) and an audio/video server (Macromedia Flash© Communication Server). The database is used by the agents for fast storage and retrieval of information and the audio/video server helps establish audible and visual communication between the teacher and the students.

Finally the topmost two layers of I-MINDS contain the intelligent agents i.e., teacher agents, student agents, and group agents. Each intelligent agent has two sets of modules: content dependent and content independent. The content independent set provides the definitions and processes for general education-related services, while the content–dependent module handles specific course-related information and knowledge base, providing the required data and the heuristics used to gather, analyze, disseminate and process the generated data.

2.2 AGENTS and TOPOLOGY

Figure 1 shows an example of the topological infrastructure of I-MINDS [8]. The manager manages the ongoing classroom sessions. It manages system level information such as the list of ongoing classes, list of courses and teachers, the login names and passwords for the students for each of the classrooms, etc. I-MINDS is capable of holding multiple concurrent classroom sessions. In each I-MINDS classroom session, the teacher, students and student groups are assigned the teacher agent, student agents and group agents, respectively. These agents support the person/group that they serve.

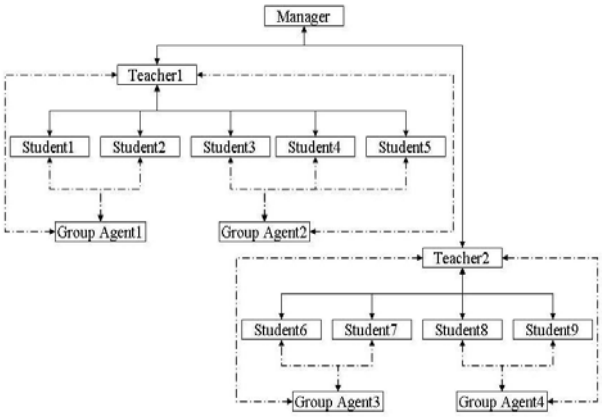

Figure 1: I-MINDS Agents and Topology

Intelligent agents are autonomous and can operate robustly in rapidly changing, unpredictable, or open environments. With these intelligent agents serving and catering to students' unique needs and behaviors, students will be able to participate in a computer-supported cooperative learning (CSCL) environment actively rather than listening to the lectures passively as in a traditional large or distance classroom. Currently, I-MINDS has three

types of intelligent agents: (1) teacher agents, (2) student agents, and (3) group agents.

2.2.1 Teacher Agent

A teacher agent, interacting with a teacher, is responsible for disseminating information streams to student agents, maintaining profiles for all students, assessing the progress and participation of different students, ranking and filtering of the questions asked by the students, and managing the progress of a classroom session. A teacher agent mainly interacts with an instructor. It also sends instructions to the group and student agents.

Question ranking is a key feature that allows the teacher agent to manage large or distance classrooms for the instructor. When questions are asked, the teacher agent scores each question based on a set of keywords and heuristics. Keywords are subject-topic specific and weighted. Heuristics are course-specific. For example, a question asked by a student with a high-score profile will be given a high score; a question asked by a student who has never asked a question before will also be given a high score to encourage the student to ask more questions in the future; and a "why?" question is scored higher than a "what?" question. After scoring, the questions are ranked and displayed to the instructor. The instructor may choose to answer or discard a question. This is how the instructor's actions trigger the reinforcement learning mechanism of the module. When the instructor chooses a lowly-ranked question over a highly-ranked question to answer, the teacher agent takes this as an indication that it has ranked the question incorrectly. It thus traces back to the heuristics and keywords that have contributed to the high score of the question and lower their weights; likewise, it increases the weights of the heuristics and keywords that have scored the question low in the first place. Thus, by answering and discarding ranked questions, the instructor implicitly teaches the teacher agent how to better score and rank the questions. Details of this module can be found in [9].

Question grouping is another feature that allows the teacher agent to address multiple similar questions together and profile students who ask similar questions. Future applications of this feature include automatically generated and answered Frequently Asked Questions (FAQs). Question grouping is based on question classification and keyword matching. To achieve question classification, we adopt the *utterance classification* approach in the AutoTutor [3]. We use the ApplePie parser [11] and the utterance classifier program of AutoTutor [10] to classify a question into one of twelve classes such as Contribution, Discovery, and so on. This classification feature also allows the group agent to monitor the roles of group members in group discussions. Two questions are also considered similar if they share a high percentage of keywords. Details of this module can be found in [6].

A student is profiled by I-MINDS' agents in several ways. First, student-instructor interactions are profiled mainly based on the quality of questions that a student asks. Based on the grouping of these questions, students can also be profiled relative to others in terms of compatibility.

2.2.2 Student Agent

In an I-MINDS supported classroom, a student agent serves a unique student, and, similar to a teacher agent, it also has a GUI front-end. A student agent primarily interacts with a student. It also exchanges information with the teacher agent and the group agents.

The student agent first allows for student login and course registration through communicating with the manager and the teacher agent, respectively. The student agent then acts as a medium: displaying the instructional materials received from the teacher agent to the student and relaying information from the student to the teacher agent.

When a student asks a question or performs some kind of collaborative activities (e.g., initiates a forum discussion or participates in sketching out ideas), his or her profile is changed and subsequently updated with the teacher agent and other student agents. The change might trigger other student agents to recruit the student to join their buddy groups. Thus, a buddy group is dynamic. Further, if a student is not responsive to a buddy group that he or she is a member of, he or she can be dropped from the group. Hence, more responsive students will be approached more frequently than the others. The student agent also adjusts its heuristic rules according to the current classroom environment. For example, in a course in which students are very active in collaborative learning in every classroom session, a buddy who has not been active for the entire session may be dropped. Thus, the student agent keeps a profile of its student's buddies in terms of their responsiveness in collaborative activities (forums and digital whiteboard). These include the number of messages sent, type of messages, frequency of messages being sent, time spent on "idea sketching", the number of times a student is dropped from a buddy group, and so on.

2.2.3 Group Agent

In I-MINDS, a group agent is activated when there are structured cooperative learning activities. Structured cooperative learning involves specified activities that explicitly require students to cooperate. Since a group agent works behind the scene, it does not have a GUI front-end.

To support structured cooperative learning, the content-independent module set is capable of forming groups (or coalitions) of students based on their profiles, evaluating student perception of teamwork and other members through online surveys, tracking student participation, and improving its heuristics in monitoring and forming better groups.

To support the Jigsaw learning model [1, 2, 4], we have designed an auction-based learning-enabled coalition formation algorithm called VALCAM that combines automatically tracked collaboration activities with subjective peer-based evaluations of a student's performance in structured cooperative learning.

In VALCAM, the teacher agent acts as a coordinator or the coalition formation process and makes global decisions, such as, what should the least number of members in a coalition be, how long should the coalitions last, how the performance of each coalition should be evaluated, etc. The group agents then manage the coalitions. Each group agent monitors the performance and activities of the members of its assigned group. After the coalition has completed their tasks, the group agent also evaluates the performance of each student agent as a group member.

VALCAM algorithm is based on reinforcement learning of the student agents. In the beginning of every session the teacher agent chooses a few students and then initiates the group formation.

During the group formation process, each student agent bids—an iterative Vickrey auction—to join its favorite group based on virtual currency earned from previous Jigsaw activities. Once the groups are formed, the student agents work with their group members to complete tasks assigned by the instructor. Finally, when the assigned task is completed, the student agents are rewarded with virtual currency based on their individual performance and their performance as a group member through surveys of their peers' evaluation of the student. Students who performed well will receive more virtual currency, allowing them to more successfully bid for their favorite groups in future sessions. Details of this algorithm can be found in [5].

3. COMMERCIALIZATION EFFORT

During the past year, we have taken several steps towards commercializing the I-MINDS system and its technology, in accordance to our three feasibility objectives. Specifically, we have conducted the following.

First, we have worked with our university to protect the intellectual property of our technology. This has involved identifying what we want to market as our product since we want to protect the product as well.

Second, we have continued to improve the I-MINDS technology and product. Based on our deployment of I-MINDS in actual classrooms, we have identified features that would improve I-MINDS' user-friendliness and also identified agent-based technologies to better utilize agent intelligence to support a virtual classroom.

Third, we have continued to deploy I-MINDS and collect more data to evaluate I-MINDS' impact on student learning.

Fourth, we have continued to solicit additional funding and sponsorships. We succeeded in obtaining funding from Microsoft to port I-MINDS to the Conference XP Platform.

Fifth, we have worked with a consultant company to research the potential markets for I-MINDS. Under their guidance, we have conducted two comprehensive studies into the e-learning market and the focus group market.

Sixth, we have contacted several companies and demonstrated I-MINDS. For each demonstration, we have customized I-MINDS to fit the individual company's application needs.

3.1 Intellectual Property

Protecting the intellectual property of our technology is of paramount importance. Identifying what to protect is also critical. Since the company executives are all associated with the University of Nebraska, and since the I-MINDS was developed using university resources and on university properties, our agreement with the university is as follows. The university has the rights to the technology. However, the university gives us the exclusive rights to commercialize the I-MINDS technology developed thus far. Further I-MINDS technologies developed using non-university funds and off the university properties, as a result, will belong to our company.

3.1.1 What Is Our Product?

Identifying the specific innovation to protect and the type of protection is critical. After numerous discussions with the University's technology transfer office and legal experts, there are several choices: (1) the entire I-MINDS as a software product, (2) the I-MINDS technology as an enabling technology, and (3) the I-MINDS technology as a data collection service. The first choice basically sells I-MINDS as a standalone, packaged software product. Choosing this option implies that our business plan would be to create different versions of end-to-end, full-feature I-MINDS to suit different needs such that I-MINDS can be used with plugging it into other existing software modules that our customers might already have. This choice is less desirable as it would impose a heavy product development cost on our startup company, which we cannot afford.

The second choice is to provide technical expertise to companies that would like to incorporate I-MINDS technologies into their existing software modules. Here, the unique I-MINDS technologies are the three groups of agents, equipped with machine learning capabilities, and the multiagent system technology. Choosing this option implies that our business plan would be to embed intelligent agent and multiagent technologies into our customer' existing software and to enable computer-supported collaborative environments. This choice is more attractive to us as it would allow our company to grow in steps that are more manageable.

The third choice is to help our customers build agents to support virtual collaborative environments to collect, analyze, and report data for them. Choosing this option implies that our business plan would be to promote the autonomous capability of these agents in observing their environments, making decisions, actuating those decisions, and tracking every action and outcome, and how one could gain insights from looking at how users interact in a collaborative environment. This choice is less attractive than the second choice as it would probably detract our company from what we initially set out to do. That is, our long-term goal is to research and develop intelligent computer-supported collaborative systems. However, we recognize that this third choice might be a feasible as an intermediary one to make our first baby step into the commercial world.

3.1.2 What Kind of Protection?

There are several types of protection. We are concerned with formal patent protections and various software license agreements. Filing a formal patent protection has its pros and cons. In terms of advantages, it protects the product or technology (as described in the first two choices as described in Section 3.1.1) strongly. It also gives us the satisfaction of being recognized as inventors. However, the patent application process is expensive and lengthy. While the process is taking place, it would also be not convenient for us to publish related research papers on the technology. On the other hand, software license agreements are more flexible and can be structured at a per customer basis. Other contractual agreements can also come into play. As a result, as we develop more and more features and technologies, we do not have to keep filing for patent protections.

Presently, we have duly filed for a provisional patent with the United States' Patent and Trademark Office. Meanwhile, when we demonstrate our products to other companies, we require both parts to sign a non-disclosure agreement.

3.2 Technical Improvement

Building a research prototype and developing a marketable product is different. For the latter, the product needs to be reliable, user-friendly, well-designed and well-suited for the customers. A reliable product does not crash and, if it does crash, should be

easily re-started without loss of data or incurring additional costs on the users, for example. Towards this end, we have continued to simplify how our product can be downloaded, installed, and executed, and to improve the look-and-feel of the graphical user interface. Some examples of improvement are as follows. Currently, our I-MINDS tool supports the Jigsaw cooperative learning model and also provides visual analysis of classroom data.

3.3 Deployment and Evaluation

Actual deployments and evaluations are important to our commercialization effort as we can (1) study how I-MINDS impact the users—in our particular situation, how students learn, and (2) study how to improve I-MINDS' look-and-feel to be a more polished product ready for the commercial market. Encouraging results have allowed us to pitch I-MINDS more convincingly to companies as we try to seek commercial partnerships in the past year.

3.3.1 Pilot Study

To determine the potential impact of I-MINDS on student learning, a pilot study [12] was conducted in May 2003 where the tool was used by subjects in a controlled experiment to assess what impact it had on student learning of Global Information Systems (GIS) content.

In the pilot study, the *control* group was conducted like a traditional classroom, with the instructor and the students in the same room. The *treatment* group was conducted as a distance classroom where the instructor and the students were in separate rooms and their only communication channel was through I-MINDS. Results from the two testing sessions were encouraging. Here we outline the results as reported previously in [12].

Although there was a slight difference in the means of the experiment and control groups for Test 2, this difference was not statistically significant ($p > .05$), and *the amount that the treatment group improved from the pretest to the posttest was nearly twice that of the control group.*

Comments from the university professor who used I-MINDS in teaching both of the content lessons were also encouraging. He indicated that the teaching tool was very easy to learn and use. He also said that the tool could enhance distance learning, especially by making it possible for building an archive of information that could be accessed "on-demand" by students. The instructor also noted that questions asked of him via I-MINDS tended to have higher quality, reflecting a deeper understanding, and demand a richer response than those questions posed during the control sessions.

3.3.2 Deployment in Actual Classrooms

In Spring 2005, we deployed I-MINDS in the laboratory of an introductory computer science course at the University of Nebraska. The course is CS1, the first core course for computer science and computer engineering majors in the Computer Science and Engineering Department. The course had three 1-hour weekly lectures and one 2-hour weekly laboratory sessions. In each lab session, students were given specific lab activities to experiment with Java and practice hands-on to solve CS problems. In Spring 2005, there were three different lab sections, each with about 20 students.

Our study utilized two sections. In the control section, students worked in Jigsaw cooperative learning groups without using I-MINDS. Students were allowed to move around in the room to join their Jigsaw groups to carry out face-to-face discussions. In the treatment section, students worked in Jigsaw cooperative learning groups using I-MINDS. Students were told to stay at their computers and were only allowed to communicate via I-MINDS. With this setup, we essentially simulated a distance classroom environment.

For each lab, the students were given a lab handout with a list of activities—thus, a lab is a task and its activities are the subtasks. We conducted the study for three weeks, covering topics in debugging and testing, Unified Modeling Language (UML), and recursion.

Table 1 shows the post-test scores of the three sessions for the "Control" (i.e., Jigsaw without I-MINDS) and "Treatment" (i.e., Jigsaw with I-MINDS) sections. The results indicate that students using I-MINDS for the Jigsaw activities were able to obtain comparable and even better post-test scores. We had initially hypothesized that the students in the control section would perform better than the students in the treatment section simply because the students in the former would have a chance to discuss face-to-face and were able to use paper and pencil to draw and share the same computer screen during the stages 2 and 3 of the Jigsaw process. On the other hand, I-MINDS, still lacking user-friendly GUI, had been expected to hinder such free, natural interactions among students, leading to ineffective collaborations. Thus, the result had not been expected. Students in the Treatment section performed better than the students in the Control section in the later two sessions. Further, students in the Treatment section also achieved better standard deviation—meaning that these students' post-test scores were more tightly clustered than those of the Control section. Upon closer analysis, we suspect that the act of typing and communicating through the forum and digital whiteboard of I-MINDS forced the students to articulate explicitly their thoughts and focused their attention to the tasks at hand. This in turn improved student understanding of the subject matter.

Table 1: Student performance for the Control (Jigsaw only) and Treatment (Jigsaw w. I-MINDS) sections

Peer Rating Questionnaire Results				
Week	**Control Section**		**Treatment Section**	
	Mean	**Std. Dev**	**Mean**	**Std. Dev**
1	42.02	2.68	35.60	5.97
2	39.06	7.05	33.30	8.65
3	39.90	4.80	38.59	6.34

The results were very encouraging: without face-to-face interactions, students carried out their I-MINDS-supported Jigsaw tasks and performed relatively well in individual post-tests.

Details of the results can be found in [13].

3.4 Other Sponsorships

We have also submitted proposals for additional funding and have received a grant from Microsoft Research to port I-MINDS technology into the Microsoft Conference XP Platform. This partner-

ship allows us to develop an I-MINDS product enabled by a far more reliable infrastructure in the Conference XP Platform than we could ever build on our own in the short term.

3.5 Market Research and Consultants

The National Science Foundation's Small Business and Innovative Research (SBIR) Program has retained Foresight Science and Technology, a high-tech consulting firm specializing in "moving technology out of people's minds and into practical applications," to help SBIR grantees devise a business plan (or commercialization plan). Working with Foresight, we have conducted two comprehensive market studies: (1) e-learning, and (2) focus groups. Here we report briefly on the market research studies.

3.5.1 E-Learning

Here, our *market drivers* (economic, social, or political) are (1) the consolidation of the e-learning market, (2) increased reliance on technology, particular the Internet, (3) increased number of online universities, and (4) decrease in funding in traditional post-secondary education. In terms of the *market size*, according to a report by Eduventures, the market for fully online distance learning will grow 38 percent over 2004, reaching revenues of more than $5 billion. According to a report from Frost & Sullivan, by 2010 the total market size for e-learning is estimated to be $12.18 billion. The education segment of that market is anticipated to be 28.5%, giving us a market for educational e-Learning that is roughly $3.5 billion. The corporate segment is anticipated to be 67%, giving us a market of approximately $8 billion. The government segment is anticipated to be 4.5%, giving us a market of approximately $500,000. In terms of *competitors*, there are numerous commercial, popular products such as eClassroom, Blackboard, Desier2Learn Suite, Centra, and so on, that support e-learning. Some also support cooperative learning, but none uses agent or multiagent intelligence. In terms of *potential patent infringements*, we searched the US Patent Office (USPTO) for both issued patents and patent applications with a set of relevant terms. We have identified several similar patents but are able to distinguish our technologies clearly from these patents. We have also looked into recent and *ongoing research and development* and identified a host of projects on e-learning software. For example, the University of Illinois at Urbana-Champaign presented a framework for mutual online concept learning for multiple agents in 2002, the University of South Carolina at Columbia has an NSF-funded project to develop multiagent technology for e-commerce and other applications which could have implications for the educational and training markets, and so on. In terms of *customers*, we look into both competitors and users. Competitors could be potential customers for joint research and development. Potential users are universities that provide online education. In terms of *promotion*, participating in conferences, workshops, and trade shows is one way. Further, having a good website (homepage) for our company, posting the results of our studies, and contacting educational organizations such as the Association for Educational Communications and Technology and the United States Distance Learning Association are also worthwhile promotion approaches.

3.5.2 Focus Groups

Here, our *market drivers* are (1) consumer behavior becoming much more difficult to understand using traditional focus group survey methods, (2) lack of training on how to conduct such surveys and to analyze such survey data, and (3) online focus groups save time and money. In terms of the market size, it was roughly $300 million in 2001. According to Gantry Group Newsletter (issue no. 3, October 2001), "the movement to online research is considered to be the largest paradigm shift in market research since the high penetration of telephones in the late '50s. Marketing research is currently a $6 - 7 billion dollar industry in the U.S., with online research making up just under $300 million. Larry Gold, editor of Inside Research, has predicted that this figure will double in each of the next several years." In terms of *competitors*, there are several products such as WebSurveyor, QualBoard, and SnapSurveys suite of survey software. In terms of *potential patent infringements*, we once again searched the US Patent Office (USPTO) for both issued patents and patent applications with a set of relevant terms. We have identified several similar patents but are able to distinguish our technologies clearly from these patents. We have also looked into recent and *ongoing research and development* and have not found specific projects that are related to supporting online focus groups. One relevant project is the Group Support Systems at the University of Western Australia. In terms of *customers*, once again, both competitors and users are our potential customers. In terms of *promotion*, associations of interest are the Council of American Survey Research Organizations, the Market Research Society, the American Marketing Association, etc.

3.6 Customized Demonstrations

In the past year, we have also demonstrated our product to three potential customers—three companies who could partner with us for joint research and development of the I-MINDS technology. For each demonstration, we first investigated about what the company wanted and what their application needs were, then we added customized features to I-MINDS, and finally tailored our demonstrations to the company's domain application. One example of such customizations is the use of vocabulary pertinent to each company on our software and in our presentation. Other customizations have included building special visual displays, adding new functionalities to I-MINDS, and setting up specific test scenarios for the demonstration. These have been time-consuming activities.

4. LESSONS LEARNED

In this section, we report on the lessons learned in our year-long commercialization effort of I-MINDS. In Section 3, we have outlined and described activities such as identifying our product and intellectual property protection, improving the technology, deploying and collecting results on the technology, soliciting additional funding, studying the markets, and presenting the technology with customized demonstrations.

Overall, the process has been educational and time-consuming. We have learned about the legal issues, market studies, promotion, and how to build a startup company from the ground up. Here we specifically talk about our experience in five aspects: (1) how to distinguish our technology or product and the notion of agents, (2) being innovative or "cutting edge" does not always translate into marketability, (3) how deciding on the intellectual property protection strategy help shape our focus, (4) the costs and benefits of customized demonstrations, and (5) the market research studies.

4.1 The Notion of "Agents"

Based on our market research studies, we identify the intelligent agents and the multiagent infrastructure as the distinguishing technology that I-MINDS has in the commercial world for online collaborative applications and systems. However, the use of agents is still not commercially mainstream in our e-learning and focus group domains. The awareness of agents or the appreciation of what agents and a multiagent system can do is still not widely apparent. Thus, in our contacts with potential companies, we have had to explain the notion of intelligent agents: what they can do individually, and what they can do as a team, and what they can learn to do overtime to adapt to their environments. We have also learned that the notion of intelligent agents is not practical without a context—specifically a context that the potential customers are familiar with, preferably a context that is tailored to their applications or domains. We have also learned that promoting intelligent agents is not always the right thing to do as how "these modules" can offer the potential customers what they need but do not have is more important.

Also, explaining the notion of intelligent agents and multiagent systems in layman's term is very important. We have learned that situating agents in a big picture, within the context of the potential customers' needs and applications, is key in cases where they appreciate the advantages of agent technology.

4.2 Curse of Cutting Edge

Due to the economic downturn, at least in the U.S., for the past few years, companies might not be willing to invest as much in the "research" portion of their research and development (R&D). Some companies look for applications that are almost ready to be plugged into their mainstay of software products; some companies look for applications that can be used off-the-shelf. We have had difficulty in locating companies that are willing to invest in joint R&D effort. Partly this is due to the nature of our technology and product. Being a software product, companies do think that if one can build such as product, then they can also build it. Thus, there is no point in joint R&D.

More importantly, if the technology is "cutting edge", then companies might not be willing to invest in joint R&D and wait for a few years for the technology to transfer into matured applications.

In a sense, we tend to believe that we are visionistic and see the potential impact of our technology and product in changing how people collaborate online. And we have not succeeded in convincing our potential customers of that vision.

4.3 Intellectual Property

Securing an intellectual property protection is of paramount importance in terms of protecting the revenue of the company. However, we have also learned that the process of identifying the product or technology that we want to protect and types of protection suitable could help shape what we really want to market. Thus, this discussion should take place early and reach a decision as soon as possible.

Based on our experience, initially, we had a vague idea of marketing I-MINDS as a standalone, packaged system. However, as we clarified on what we wanted to protect through our discussions with our technology transfer office and legal experts, we have come to realize that it is also the use of agents and the multiagent system framework that could be marketed as well as the expertise and experience that we have accumulated during the R&D of I-MINDS. These could be translated into enabling technologies or services, which might not be easy to patent but could be contracted or protected through other agreements.

4.4 Customized Demonstrations

Customized demonstrations have their pros and cons. The pros include (1) better, more application-specific demonstrations to our potential customers, and (2) continuous technical improvement of our product and added application of our technology. However, as alluded to earlier in Section 3.6, customizations are time consuming. Particularly, half-baked customizations do not help while genuine customizations require us to (1) interact and communicate with our potential customers to find out what they want to see, (2) find a midway point between what we currently have and what they want to see where it is feasible for us to build before the demonstration, and (3) customize the software product. During the customization, we also need to design the use cases or test scenarios so that we can, in a short demo, clearly highlight what our software can do.

A demonstration should also be captivating and pertinent to the potential customers right from the start. Unlike a presentation or demonstration at a research conference or workshop, these demonstrations are usually to company executives who might not understand or might prefer to not be concerned with the underlying technology (e.g., the agent technology in our case) but who might appreciate what they could see and point-and-click in real-time. Thus, it is important to show what the bottom line is right from the start of the demo: what and how can the technology or product benefits them in the short term in particular, and in the long run in general.

4.5 Market Research Studies

Based on our experience, we realize how valuable it is to have the opportunity to work with a consulting company for those who are not experienced in commercializing an innovation. Our first market study was about e-learning. Initially, we supplied the consulting company a set of documents describing our product and technology. The consulting company then did the research and gave us the outcome, which is summarized in Section 3.5.1. Given this document and experience, we conducted our second market study about focus groups on our own. From the first study, we learned about the online resources to obtain necessary information and the strategies and approaches to such a study. Key components to research include market drivers, potential patent infringements, ongoing projects, competitors, customers, and promotion. Strategies include investigating the above components with a keen eye on distinguishing the uniqueness of our product or technology.

A market research study is time consuming and may require exhaustive, investigative searches online as well as in the libraries. For our second market study, it took more than 40 person-hours.

5. CONCLUSION

We have described our effort and lessons learned in commercializing an innovative infrastructure to support student participation and collaboration and help the instructor manage large or distance classrooms using multiagent system intelligence. The system, called I-MINDS, uses a multiagent framework to support teachers

and students. Our commercialization plan has three objectives: (1) to strengthen our understanding of potential customers, (2) to understand our competitors and alternative products, and (3) to examine and estimate the market potential for I-MINDS. Guided by these three objectives, we have methodically carried out six primary sets of activities: (1) identifying the intellectual property protection and the product to be protected, (2) improving the I-MINDS product and technology, (3) deploying and evaluating I-MINDS, (4) securing other sponsorships, (5) conducting comprehensive market research studies, and (6) giving customized demonstrations. Based on our year-long effort, we have had some lessons learned. We have found out that the one thing—the intelligent agent technology—that distinguishes our product is also the one thing that is difficult to "sell". We have also found that a product that is cutting edge is not always commercially marketable. We have also learned that securing intellectual property protection should be done early, not only to protect our product and technology, but also to help shape the very "thing" that we want to market, that demonstrations to solicit joint R&D differ significantly from demonstrations in academia, and that for inexperienced people like us in devising a business plan, having a consulting company to work with is invaluably important.

6. ACKNOWLEDGMENTS

The I-MINDS project was first developed with a seed grant from the National Center for Information Technology in Education (NCITE). It was later sponsored partially through an NSF SBIR grant DMI-044129. The authors would like to thank Foresight Science and Technology in their help in market research. The authors also would like to acknowledge Art Zygielbaum, a vice president of I-MINDS, LLC, and our software developers and research students Xuli Liu, Nobel Khandaker, L.D. Miller, Xuesong Zhang, Phivas Vemuri, and Suresh Namala.

ABSTRACT

The size and complexity of enterprise computer systems are growing rapidly. As a result, system management has become increasingly difficult and expensive. In fact, management costs are typically estimated at 50%-70% of the total cost of ownership. Despite large investments in management software and personnel, enterprise computer systems are usually managed sub-optimally. This situation calls for a fundamental change in the way systems are managed.

Recent studies suggest that systems manage themselves autonomously. Initial studies towards that goal reside in the fields of Autonomic Computing and Self* Systems. Many of those studies devise mechanisms for system monitoring, data filtering, problem determination, problem fixing and system adjustment and reconfiguration. The mechanisms are based, in large part, on methods from Artificial Intelligence, Statistics, Operations Research and Software Engineering.

Current enterprise system management solutions – theoretical and practical – are centralized. However, the typical enterprise system is distributed. We claim that a centralized solution presents several risks. For instance, it introduces a management bottleneck, it incurs communication overheads, etc. We hence advocate that enterprise system management should be addressed in a distributed manner. Combining distribution and AI, we believe that an agent-based solution is appropriate. In this paper we present in more detail the suggested approach.

1. INTRODUCTION

The size and complexity of enterprise computer systems are growing rapidly. Contemporary enterprise systems typically include thousands of hardware and software components distributed across networks and geographies. These components are heterogeneous in their functionality, their interface with other components and with human users, and their manufacturers. Additionally, management practices and tools, when provided with the components, vary considerably in their capabilities. For instance, some tools merely monitor a small set of operational parameters and provide a report on their values, whereas others may be collecting a large and diverse set of parameters and provide complex analysis such as trending, prediction and bottleneck analysis. Note however that, even had all of the components been provided with the best management tool each, the management of the entire enterprise system will not instantaneously be resolved.

In managing an enterprise computer system, one needs to manage not only its components, but the relationships between them as well. Theoretically, this introduces a combinatorial problem, as any combination of components should be considered in the solution. Indeed, in recent years system management has become increasingly difficult and expensive. The costs of management are typically estimated at 50%-70% of the total cost of ownership, as can be inferred from multiple market studies (see e.g. [12]). Large investments in management software have not yet produced good solutions. Apparently, as many system administrators admit, enterprise computer systems are usually managed sub-optimally. This situation calls for a fundamental change in the way systems are managed. We advocate that this change will require a combination of Distributed Systems [9] and Artificial Intelligence techniques. The discipline that combines such techniques is Distributed AI—the parent discipline of agents and multi-agent systems.

Recent studies suggest that systems manage themselves autonomously [5]. Initial studies towards that goal reside in the fields of Autonomic Computing [3][6] and Self-* Systems [8]. The idea of systems that manage themselves is not new, though. Computer scientists have envisioned such systems since the era of Turing and von-Neumann [10][11]. Attention to these ideas has returned only in the last few years. Research in the area studies, among others, self-diagnosis, self-organization, self-configuration, self-awareness, self-management, etc. Many of these studies

devise mechanisms for system monitoring, data filtering, problem determination, problem fixing and system adjustment and reconfiguration (e.g., [2]). The mechanisms are based, in large part, on methods from Artificial Intelligence, Statistics, Operations Research and Software Engineering. Notably however, techniques for addressing distribution-related other than networking aspects of self-management are rarely employed. Further, the extent to which solutions address heterogeneity is limited.

Current enterprise system management solutions – theoretical and practical – are mostly centralized, although the typical enterprise system is distributed. Management solutions require human intervention and they are far from being autonomous. We argue that a centralized solution presents several limitations and risks. For instance, it introduces a management bottleneck, it incurs communication overheads, etc. We hence advocate that enterprise system management should be addressed in a distributed manner. We also argue that increased autonomy of the management system should reduce its TCO. As suggested above, we believe that an agent-based solution is appropriate. In this paper we present in more detail the suggested approach.

2. CURRENT SOLUTIONS

The goal of an enterprise computer system is to provide the enterprise with services of data processing, data communication and data storage. These services should be provided at a certain quality, to support the business operations and goals of the organization. The goal of system management is to assure that the system indeed provides the services expected, at the quality expected.

For instance, consider an organization whose business is graphical design. One goal of the system may be the retrieval of graphical files at a maximum delay of one second, regardless of the location of the file and its requestor. Of course, one should expect the initial system configuration to support this requirement. However, since data volumes and usage patterns change over time, and since system components may fail or degrade, the system might, in times, fail to address the required retrieval time. The major means for reducing the rate of occurrence of such problems is high-quality system management.

As stated above, the ultimate goal of system management is to assure service provision at a certain quality. Had management solutions fully addressed this goal, there would be no other requirement from these solutions. However, since no solution fully addresses the management goal, other requirements are typically set. These include the following:

- Reports on the system status: are the goals set for the system satisfied? What are the deviations from these goals?
- Trending and prediction: what are the system's patterns of operation? What system status would they lead to?
- System analysis, e.g.:
    - Dependency analysis: which application or component depends on which, and in what ways?
    - Root-cause analysis: what is the root-cause of a reported problem?
    - Bottleneck analysis: which components in the system experience the highest load, and which ones will fail first as a result of a high load?
- Remediation: what can be reconfigured or fixed, and how, to resolve reported problems, and to avoid problem build-up?

The requirements listed above are addressed to a limited extent by existing solutions. Fielded solutions, and in particular enterprise system management tools, mainly address the reporting and trending requirements. That is, such tools perform the following:

- Monitor the system – its components and applications – and store the collected data (possibly after some filtering and processing).
- Generate reports from the stored data
- Detect abnormal system and component status
- Compute simple trends
- Support a restricted set of component and system reconfiguration actions, including automated component replacement

The management functions listed above are not supported by all of the management tools. In practice, many tools offer a rather limited management function: they usually monitor the system and report on system status and trends, detect some types of abnormal behaviour, and, in some cases, they allow for (partial) automated reconfiguration of the system to address detected problems, commonly in a human-in-the-loop manner.

Solutions to the system management problem performed in research labs and published in the literature provide a variety of functions which are not yet part of fielded solutions. In particular, analyses such as dependency analysis, root-cause analysis, bottleneck analysis and prediction are addressed (e.g., [1][4][7]). Additionally, system re-configuration and a few self-healing functions are also resolved. However, research-grade solutions have several limitations, as follows:

- They usually solve a single, isolated problem, and do not provide a comprehensive solution as a management tool should.
- They tend to be theoretical, in the sense that they typically make assumptions that do not hold in the field.
- Commonly, they do not attempt to reduce the computational complexity of the suggested solution

Despite these limitations, it is expected that research solutions will eventually move into fielded tools. Note however that research solutions, although more advanced than tools, are far from addressing all of the requirements listed above. This invites additional research, and as stated above, agents and multi-agent systems could be the right discipline for this research.

3. TYPICAL ARCHITECTURES

In this section we describe the common architectural properties of enterprise system management tools. Although typical enterprise systems are distributed systems, both the fielded and the research solutions to the management problem are mostly centralized.

A management tool consists of five major layers: monitoring infrastructure, a database, an analysis layer, an activation layer and a user interface. An illustration of a typical architecture is depicted in Figure 1, where the management tool appears in grey. Typically, the monitoring infrastructure is not monolithic. Rather, it is comprised from multiple monitoring elements. Each such element (in times referred to as an agent) may be located on, or near, the component(s) it monitors. It collects data from the components it is assigned to using standard protocols such as SNMP and CIM/WEBM. The monitoring elements send the collected data, in some cases after some simple filtering, to a *central* management point to be stored in the database and analyzed as found appropriate.

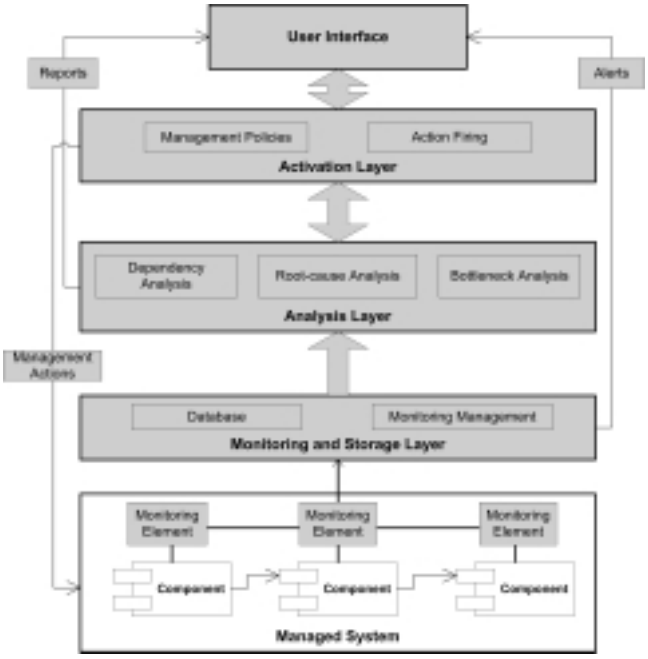

Figure 1. Management tools: a typical architecture

The analysis layer is typically located at the central management point. It may be implemented as a single monolithic software component, or as a collection of such components each specialized in a specific type of analysis. The analysis layer retrieves from the database data collected and filtered by the monitoring layer. The results of the analysis are sent either to the user interface as reports, or to the activation layer, for policy updates, planning and action firing.

The activation layer, located at the central management point as well, consists of an action firing component. It usually consists of means for representing management policies and activation rules too. Action firing is performed either by the user, or automatically via activation rules, following management policies. Actions are performed directly on system components and may include parameter setting, component and system reconfiguration, component replacement, and others.

The user interface usually runs at the central management point, however web access to the user interface is becoming increasingly common. The user interface provides the user with access to an array of management functions. These include systems visualization, reporting and trending, analysis activation and results, action firing (see details above), and management of the management tool itself.

The architecture described here does not cover all types of management tools, however it represents well many of them. One of the prominent common properties of these tools is their centralization. Typically, such tools will be running on a server dedicated to system management. The advantages of this approach are the computational efficiency of data retrieval and analysis, and the high reliability of the servers on which the management software runs. However, the centralized solution has several weaknesses, as follows:

- **Communication overloads**: Frequent monitoring of multiple components across the managed system generates large data streams. These are sent to the central management server, possibly overloading the server and the network. Contemporary centralized management tools address this problem by reducing the frequency of their monitoring. As a result, the quality of management may be compromised.
- **Computation overloads**: When multiple analysis methods are activated concurrently to analyze a large number of components and their operational parameters, a central server might exhibit computation overloads, which will in turn result in slow analysis and delayed response to problems detected in the managed system.
- **Single point of failure**: A widely known problem of centralized solutions is them being a single point of failure. In this respect, system management tools are not an exception. A failure of the management tool may result in degradation in the quality of services provided by the managed system, and may lead to its failure.

The weaknesses discussed above call for a change in the way management tools are designed and deployed. In particular, distribution could provide some remedy to all issues raised. However, distribution may introduce new problems, as follows:

- **Synchronization and consistency**: Once the management of a system is distributed, the widely known clock synchronization problem arises. Additionally, when data is distributed across multiple management points, inconsistency among them may arise. These problems may in turn result in errors in data analysis and reporting, and in action firing.
- **Communication overhead**: The distribution of management across the managed system requires coordination among the managing points. This in turn results in increased levels of communication traffic and may impose a communication overload. Careful design of the coordination can minimize this risk.

It appears that, although distribution could provide significant advantages to system management tools, there is a need for a careful design to reduce the risks introduced by distribution. In the following we propose a possible approach to the distributed design of enterprise system management tools.

4. AN AGENT-BASED APPROACH

Given the requirements for data collection, filtering and analysis, and for action firing, across a distributed heterogeneous system,

we believe that an agent-based solution is adequate. Our proposed solution approach is as follows:

- **Data collection**: In current solutions, data is collected and sent to a central management point. We suggest that collection will be performed by agents that implement some intelligence. In particular, they should intelligently filter the data collected, and transmit, either to a central point or to other management entities, a small subset of the collected raw data. This should resolve the communication overhead present in current solutions.
- **Data analysis**: In current solutions, analysis is performed at a single central point. We suggest that each type of analysis be performed by a specialized component or agent, possibly located on a separate machine. This should resolve the computation overhead present in current solutions.
- **Action firing**: In current solutions, management policies are maintained at, and actions are fired from, a single central point. We suggest that some policy maintenance and action firing will be moved to the agents residing next to the managed components. In particular, some policies and actions are relevant only to a small subset of the system, and it should be efficient to maintain the former, and fire the latter, in vicinity to their target components. By this, communication overhead will be reduced and timeliness of management actions will be improved.
- **Coordination and collaboration**: In current solutions, due to their central approach, no coordination or collaboration are implemented. In a distributed solution where data collection, filtering and analysis, and action firing, are performed locally by agents, there is a need to coordinate among them to avoid inconsistencies and prevent conflicting and redundant actions. Collaboration could further enhance the capabilities of the management tool. We suggest leveraging multi-agent coordination and collaboration methods to address this goal.

5. CONCLUSION

The solution approach suggested in this paper is described at a conceptual level. The main aim of this description is not to provide guidelines for developing agent-based management systems. Rather, we want to raise community awareness to a problem domain in which, to date, little was studied, and where agent-based solutions appear as a promising solution approach. As we demonstrate, distribution, local autonomy, intelligence and coordination could provide significant improvements to the quality of enterprise system management solutions. Since agent-based systems inherently realize these properties, we believe that agents and multi-agent systems should be studied and utilized in this context. We are confident that the results of such research will span far beyond this specific application domain, influencing the disciplines of system management, self-*, autonomic computing and, of course, agents and multi-agent systems.

ABSTRACT

The consideration of medical implants as an increasingly important population of isolated agents is a valuable perspective that should not be ignored by the agent community. Implanted Medical Device (IMD) applications are complex, naturally distributed, and could benefit from such attention. This paper explores implantable medical devices and their attributes in an agent context and terminology. It submits that an increasing body of IMDs should be considered agents and that there are opportunities for incorporating these implantable agents into multiagent systems (MAS). This will include: (i) Discussion of several IMDs in traditional agent terms. (ii) Discussion of trends and issues in IMDs related to their potential role in MAS. (iii) Experimental exploration of some potential MAS applications in the problem of medical monitoring. (iv) Broader discussion of the value of framing IMDs and applications involving them in the agent paradigm.

General Terms

Medical Monitoring, Implant, Medical Device, Agent, Multiagent System, Implantable Agent

1. INTRODUCTION

Currently there is a wide range of different implantable medical devices (IMDs). Although the importance of stents, bio-implants, valves, joint replacements and other "passive" IMDs is clear, this paper focuses largely on those which contain more sophisticated processing capability (sometimes called 'active' IMDs in industry). Still, in this category there are quite a number of IMDs made by a range of companies. A variety of pacemakers, Implantable Cardioverter Defibrillators (ICDs), neurostimulators, programmable drug pumps, and other devices are currently being used by patients around the world. These devices are created by companies including Medtronic[1], Guidant, St. Jude Medical, Boston Scientific, NeuroPace, and many others.

1.1 Implants and the Agent Literature

There is already discussion in the literature of both medical monitoring and systems interacting with implantable devices [2, 6, 9, 10, 15, 19, 24]. As part of this there has even been the limited suggestion that IMDs responsible for monitoring patients "might also benefit from natural language and artificial agent technologies" [6]. To the knowledge of the authors, however, no one has discussed implants as agents or explored them as participants in agent-based systems. The broader discussion of what is and what is not an *agent* is already present in the literature and provides an important context in which we consider this material in Section 2.

1.2 Brief History of Pacemakers

About a decade after the first external pacemakers were designed and built, Medtronic began to produce early implantable pacemakers[2] and continues to manufacture their complicated descendants today. The earliest pacemakers were fairly simplistic as they supported no real sensing, processing, or communication capabilities. After a few years pacemakers could be recharged and switched to different rates of pacing. Development of wireless techniques for communication emerged. Pacemakers were eventually made to be "responsive" to their environment in a closed loop fashion so that they could, for example, sense the level of activity of their host and change the pacing rate. Many modern devices involve significant processing to facilitate sensing, monitoring, detecting, responding, communicating, and other activities. Several of these support so called "downloadable firmware" in which at least some software code can be sent to the device for it to run in addition to or as a replacement

[1]This company employs the primary author of this paper, is the largest IMD maker with a broad range of cardiovascular, neurological, and other devices.
[2]The earliest work was done by a Swedish team on a patient who ultimately went through 22 pacemakers and 5 lead systems over about 43 years until he died in 2001 from a problem not related to his pacemaker systems [11].

for existing code.[3] [4]

2. IMPLANTS ARE AGENTS?

We submit that some IMDs might be considered to meet many of the criteria and completely satisfy some of the notions set for agency in AI tradition and literature. By reviewing specific IMDs and agent concepts we hope to explore and help elucidate the place of implants in the spectrum and taxonomy of agents. In a longer version of this paper [4] we address these questions in greater detail, including agent properties such as persistence, action-perception relationship, autonomy, social ability, mobility, benevolence and veracity, etc. Here we will discuss environments, sensors, and effectors as key aspects of agents which are "anything that can be viewed as perceiving its environment through sensors and acting upon that environment through effectors." [23]

2.1 Implants' Environments

IMDs transition through a few environments (e.g. in the sequence Manufacturing, Implant(ed), and finally Explant(ed) with the majority of device life in an implanted environment). Consider the SynchroMed II^{TM}(S2) implantable drug pump as an example. It may be useful to think of an implant as a very high reliability robot, but one which is never turned off and is almost always capable of wireless communication. Generally, within a minute of power a S2 has completed some initialization, diagnostics and logging; enabled wireless communications; sounded an audible alarm, and depending on its configuration (or lack there-of) begun to pump drug and sense its capability to do so. After it is completely assembled, a S2 is communicated with wirelessly to ask it to configure itself and perform diagnostics. Eventually, a clean-room worker would put the implant into a sterile package where it would remain until taken out in the operating room. Eventually the device would be put into its implant(ed) environment. At this time, a doctor uses the physician's programmer to inform the implant of this change. The device will do some processing and make some changes to its behavior. As time passes and different events occur the device eventually will indicate that the physician should consider replacing it (Elective Replacement Indicator or ERI) and may change its behavior (especially if allowed to reach End Of Service or EOS). At some point, the device will be removed from the patient (explanted) and discarded or returned to Medtronic for analysis.

2.2 How Implants Sense Their Environment

There is a great variety of sensors employed in IMDs to allow them to better and more appropriately sense their environment. The S2 device, for example, senses its electromagnetic environment for the presence of wireless telemetry communications. The S2 also monitors itself, checking for stall, measuring its battery voltage, tracking the passage of time, self-diagnosing numerous other issues that might arise and responding appropriately based on its understanding of its environment, capabilities, status, history, and configuration. During testing each S2 pump expels fluid while monitoring itself. If the pump were to stall (e.g in the presence of a strong magnet or damaged part) the S2 would detect this and indicate it by audible alarm and indication in a following telemetry session. For a more subtle example consider that the S2 tracks how much volume it has pumped and if it believes it is implanted when this exceeds some threshold it will trigger an audible alarm and consider itself in an ERI or EOS state. Furthermore, if at that time a physician asks the S2 to return to its "implant behavior" it will not (even where the condition causing it to leave its implant behavior was transient such as recognition of a temporary dip in battery voltage). Even so, relative to many other IMDs the S2 is relatively sensor poor.

In the broader pool of IMDs more sensors have been proposed and put to use. We mentioned earlier that cardiac pacemakers make use of sensors to determine patient activity. The determination of activity, posture, etc is accomplished for example using 1, 2, or 3 axis accelerometers in a range of devices like the Medtronic Kappa 900^{TM}. For the most part, cardiac devices also monitor the electrical activity of the heart (ECG) using leads to propagate the signals. Recently some devices including Medtronic's Reveal^{TM}Insertable Loop Recorder and Reveal Plus have enabled "leadless" or subcutaneous sensing of the ECG. Yet other cardiac devices are sensing oxygen, pressure, or other[5] levels [20].

Furthermore, though traditionally limited in their sensing capabilities, neurostimulators and other IMDs are bringing traditional and novel sensing modalities to new areas of the body; for example the NeuroPace Responsive NeuroStimulator^{TM}(RNS) which measures the electrical activity of the brain (EEG) to detect epileptic seizures [18]. Temperature sensors have also been used (e.g. to address tissue heating with recharge). Some devices utilize sensors to simplify patient communication (e.g. using accelerometers to detect a patient tapping on the implant or respond to the presence of a simple magnet). In the future, research may lead to direct "Brain Computer Interfaces" [13]. For shorter life IMDs, a number of other sensors, including notably pH sensors, like those in Medtronic's Bravo^{TM}, can be used. In the near future, IMD sensors may sense a range of new things including chemicals like "hormone levels, anesthetic agents and other factors within the human body such as ... drugs" [16].

2.3 How Implants Affect Their Environment

The S2 devices, used as an example previously, affect their environment by delivering drug to it. With the ability to kill or incapacitate a patient by delivering drug too quickly (overdose; e.g with morphine in pain therapy) or too slowly (under-dose; e.g. with Baclofen in spasticity therapy), the significance of this effector can hardly be understated. Although more rarely utilized, another effector is the S2's built in audible alarm which can generate a range of tones and patterns to alert the patient, caregivers, or other user of different conditions. Also of great importance, but more subtle is the device's ability to generate wireless fields (for the purpose of communicating).

While also able to communicate wirelessly, cardiac devices have slightly different effectors that often include the ability to electrically stimulate the heart. In the future

[3]This is presumably valuable for confronting issues related to software/firmware which occur in the field but more fundamentally illustrates the flexibility of the devices.

[4]The capability of IMDs varies; typical clock speeds 32kHz to 3MHz, memory (RAM,ROM,EEPROM,Flash,...) 8kB to 2MB, and miscellaneous custom circuitry.

[5]For example respiration or lung fluid levels via impedance measures.

cardiac and other devices may include both electricity and drug delivering effectors [8]. Furthermore, stimulation is not targeted only to the heart, for example, neurostimulators like Medtronic's Activia™ device for Parkinson's therapy and NeuroPace's RNS for epilepsy both use stimulation targeted to the brain, and those like the Cyberonics device deliver stimulation through cuff electrodes to the vagal nerve. Cochlear implants, various sight related implants (including direct interface to the visual cortex, subretinal implant, etc.) [26], diaphragm stimulation [3], and a number of other devices and therapies reflect the diversity of stimulation targets. Even beyond electrical stimulation, drug delivery, wireless communication and audible alarm there are some "other" and emerging technologies for implantable effectors. Certainly an exhaustive list of sensors or effectors is beyond the scope of this paper, but consider for example potential implantable thermoelectric devices, to be used for example in cooling the brains of epilepsy patients [12].

3. IMPLANT TRENDS AND POTENTIAL ROLES IN MULTIAGENT SYSTEMS

The IMD industry is large, competitive and growing quickly as it reflects the developing market for the devices it produces. IMDs themselves are becoming smaller, longer lasting, more broadly applicable and better reimbursed both in response to and as a fuel for their growing industry. As medical devices and other technologies keep patients alive longer the aging population further supports the industry with replacement and combination therapy needs[6]. Important results of these positive feedback systems are that IMD systems are becoming more prevalent, flexible, complex, capable and accessible to potential customers and users. As this continues, we submit that the potential role and importance of IMDs in multiagent systems and as implantable agents themselves is also growing.

While there is strong pressure to add intelligence, capability and flexibility to implants, these things often bring complexity. Even more so than in other systems, there is also pressure to keep implantable components as simple as possible so as to increase their longevity[7], simplify testing, reduce the likelihood of error, reduce device cost[8], and speed time to market. With these forces there is pressure to move some system capability outside of the implantable device and into instruments which communicate with it from outside of the body. In practice there has been an increase in communication capabilities, range and complexity in instruments like the patient and physician programmer devices that are designed to communicate with implantable devices.

This growing role of instruments can be seen not only with traditional, life-sustaining uses of implants (e.g. pacemakers), but also as IMDs are increasingly used for non-life-sustaining therapy, combined therapy and monitoring, exclusive-monitoring and other applications. As this trend continues, the volume and complexity of the data available from these devices also grows, presenting the primary problems of medical monitoring with implantable devices. This results in further pressure for increasing memory, automation, decentralization, and prominence in the role of external instruments and in many cases has affected a shift to a more patient centric system involving patient programmers, telemedicine, and transferable electronic medical records. Despite the complexity more patients, physicians and caregivers are using instruments which interact with medical devices and the data they gather and as this continues the role of human computer interaction and "human factors" becomes increasingly important [14].

3.1 Implantable Agent Interaction

Traditionally IMDs have been fairly solitary agents, for the most part interacting only with their environment and the humans that communicate with them almost directly (through simple programmers and the applications that run on them). Consider that in the future this could change, and implants may begin to interact with other agents to a greater extent. This could take the form of implant to implant communications, implant to wearable agent communications, or implants communicating with agents that are transiently (or ubiquitously) available in the environment.

3.2 Implanted Networks

As some of the trends like increasing device prevalence continue, the likelihood of finding multiple implantable devices within communication range increases. This enables implant to implant communication in the field. Although the idea of the IMDs in two acquaintances or even strangers utilizing their transient link is fascinating, the simplest and most tangible cases to consider might be between implants concurrently implanted in the same person. There is some precedent for this, concern, and even design relating to this in existing IMDs. Despite this concern and ongoing work, there is significant potential for and interest in implant-to-implant communication within a patient's body [1, 7]. Some of the motivations for this might include surgical implantation issues, device coordination issues, robustness[9], as well as resource and capability sharing[10].

3.3 Implantable-Wearable Systems

One of the simplest and most obvious uses of implantable-wearable systems is one in which a single wearable component regularly interacts with a single implantable compo-

[6]It has been well documented in agent literature that the aging population presents a significant target for agent applications [21].

[7]Implants often do as little processing as feasible to reduce the power consumed by the microprocessor and other circuitry. By reducing power, the device can last much longer with the same size battery.

[8]As with any highly regulated, mass produced, embedded system where space and power is at a premium, the cost of memory and other miniature electronic components, even read only memory, can be high and have an effect on production cost.

[9]In the simplest case, the implants could regularly check on each other, and if for some reason one consistently does not respond appropriately, the other could respond (e.g. alert the patient, log troubleshooting information, etc.). More practically implants could propagate messages to each other increasing both the reliability and size of their telemetry cloud.

[10]For example, only one device need have an audible, vibratory or other means of alerting the patient and other devices could use it. In another embodiment, a primary closed loop therapy (e.g. neurostimulation for epilepsy) may recognize that it is being unsuccessful in suppressing a life threatening event and call in the services of a secondary device (e.g. implantable drug pump delivering a potent anti-epileptic drug).

nent. The most fundamental uses of such systems are valuable for supplementing basic implantable capabilities (like processing, sensing, and memory). Consider for example that modern cochlear implants generally include an external device which senses and processes audible inputs and an implanted device which stimulates the auditory nerve. Conversely, as an example, implantable memory is not sufficient to store the large amounts of data modern cardiac (and other) devices monitor and so these devices can be used with an external holter monitor like device to record much greater amounts of data (which may be particularly useful in tuning therapy). For the Medtronic Restore^{TM}Neurostimulator system, there is currently a wearable system for recharging the implantable. Over a period of time the Restore recharger provides a strong field in short bursts enabling inductive recharge. In between bursts, the recharger measures and models the temperature and then decides if and how long to wait before continuing the recharge (to avoid implant heating issues). Another potential embodiment for such a system, and one perhaps more in line with the tradition of telemedicine, might be one where wearable devices are not the primary link between implantable agents and the rest of the system. Instead, implantable agents may interact directly with agents which are only transiently available (e.g. not worn or implanted in the same body-area network).

3.4 Implantable Communication with Transiently Accessible Devices

Telemedicine systems which occasionally interact with implantable devices are already achievable and in place. Consider for example that a relatively small, privately held company NeuroPace has developed and tested the NeuroPace Data Transmitter (DTR) system. A recent abstract on this system for "on demand monitoring in the Outpatient Environment" explains: "On an intermittent basis, the DTR is connected to a phone line and data is transmitted to the secure server where it can be viewed by the treating physician over any Internet connected computer." [22] To the knowledge of the authors, it is not yet discussed in the literature whether findings in more traditional cardiac centered telemedicine systems can be generalized to systems and therapies like the NeuroPace DTR. With this caveat in mind, there is evidence that such systems are practical to implement and provide clear potential for cost savings [5]. These systems are not perfect with respect to usability, patient compliance, data loss and other concerns, but Medtronic's CareLink^{TM}system, with over 50,000 patients, is an example of their viability at a fairly large scale. These traditional telemedicine systems involving implants require the patient to consciously interact with the system on a regular basis. We submit that the interaction between a transiently available telemedicine system and implants could be further automated and its users better served using a multiagent approach as we will discuss in Section 5.

Beyond traditional telemedicine motivations, there are other applications and embodiments of implantable communication with transiently accessible devices some of which might benefit from agent technologies. We leave these for future work, but will suggest that these may involve distributed clinical research, anonymization, authentication and identification, patient based electronic medical records, device update, maintenance and support, data integration and summarization, emergency response and localization, trauma and triage, automatic fleet management, improved software platforms for interacting with medical devices, auditing, reporting, novel physiologic computer interfaces, etc.

4. IMPEDIMENTS TO IMPLANTABLE AGENT APPLICATIONS

4.1 Business Case

Although it is fairly clear that IMDs could technically be used as part of a multiagent system, the business need and benefits of such a system are, perhaps, less obvious. As discussed elsewhere in this paper, the use of a MAS approach could improve data management, instrument usability and possibly other aspects of IMD systems, but the cost of their implementation, validation, deployment, is a significant business hurdle. Even a relatively large telemedicine system like CareLink^{TM}would have a hard time overcoming these costs in the sale of its services. Consider, however, that this is not the business model that really matters. Revenue from telemedicine systems like this is very small in comparison to that from device sales. When viewed as a feature that could differentiate a product or company and potentially grow market share and increase implant sales the business case and potential is much more apparent. Potential future uses in distributed clinical and device research as well as new device applications (e.g. requiring collaboration or improved adaptability) may also become business drivers.

4.2 Technical Stability and Complexity

It is certainly true that some implants are already complex, real-time systems, difficult to upgrade or fix without replacement, performing critical functions, and need to function reliably for many years. For these and other reasons, keeping the implants simple is important because in may ways, simpler is safer. On the other hand, as an underlying premise of this paper we submit that some active implants are already capable of acting as agents there would be little or no added complexity *in the implant*. Interestingly and although not widely discussed in agent terms, this existing design is in large part due to the desire to provide flexible but robust and autonomous systems and is part of what makes it transparent to the implant whether it is communicating with another agent or simply a program.

As a broader MAS including non-implantable agents, there would also be added complexity and thus cost, perhaps especially in testing. The related issues would almost certainly mean slow adoption and limits to functionality initially. It is almost certain in the near future that the connection of IMDs with all other agents and resources of a MAS will be limited. Throughout this paper it is assumed that implants would play a limited, intermittent role in MAS's but could still have significant potential benefits and in some part it is this very requirement for some independence and automation that makes IMDs and the components that interact with them natural candidates for AS and, we submit, MAS applications.

One interesting subtlety worth noting is that instrument software which communicates with implants currently has an extremely long life cycle as it is expected to be used and maintained or replaced from launch date until the last date at which any device of the supported type is still implanted (which could be more than a decade after its implant) or

on the order of 15 years. Over this time tens of millions of dollars are spent on migrating applications to new platforms as operating systems and other once plentiful and well supported things become obsolete. For this reason portability, extensibility, testability and longevity are especially important. To address some of these and other concerns, some have proposed that applications interact with a single set of autonomous, persistent agents (e.g. for telemetry or data management) which are discovered and interacted with at run-time using appropriately flexible languages.

4.3 Legal, Regulatory, and Security

Though the specifics of these and other important concerns are well beyond the expertise of the authors, it is worth mentioning explicitly their existance and some initial opinions. First of all whether certain IMDs are viewed through the agent lens or discussed with agent terminology or even designed with certain agent properties in mind is not of direct importance to regulatory agencies like the FDA. Instead, the clear and potential risks, mitigations and benefits of such designs are of primary importance. Furthermore, we submit that certain products already approved by such agencies are already reasonably considered agents and in agent terminology by ourselves and some of our peers. On the other hand, this clearly does not change the fact that solid verification, validation, and consideration of risks and alternatives needs to happen for any medical product, especially IMDs. Privacy (e.g. in HIPAA compliance), robustness in the face of misuse, intellectual property clearance, and potential liability issues are at least in large part the responsibility of the manufacturer and essential items to address in potential products (AS, MAS, or not).

5. MAS IN MEDICAL MONITORING WITH IMPLANTS

There are significant motivations for medical monitoring. The most basic approaches to medical monitoring with implantable monitors center on having the patient periodically come in to a clinic where a caregiver manually uses an external tool (e.g. programmer) to off-load data from the IMDs. Telemedicine systems are becoming another important approach, but one which requires patients to manually use a device in their home to send data to physicians electronically (e.g. indirectly through the CareLink^{TM}system or on electronic medium recorded by a patient programmer). Both of these approaches have positive and negative aspects. For example, a traditional clinical visit may be more easily reimbursed, does not require a patient-device interaction (e.g. CareLink^{TM}base-station upload session or patient programmer downloading session) and might better facilitate a verbal dialog or other complex, high-fidelity interaction (e.g. visual inspection) which may have positive effects on patient perception as well as outcome. On the other hand, telemedicine approaches may reduce travel costs, increase the speed and ease with which data can be accessed and reviewed, automate electronic documentation, and allow both the patient and physician to participate asynchronously and outside of the clinic. These are generalizations, but we believe that there may be advantages to a medical monitoring system based on a multiagent framework in which an implantable agent interacts with at least one external agent. Some of these benefits could be realized by a MAS as simple as a basic telemedicine system in which the traditional base-station software has been changed to accommodate an agent which autonomously propagates information from an implantable agent to the physician (or other part of the system).

It is difficult to assess a MAS approach to medical monitoring because such a system did not exist at the start of this project and to test it appropriately would require a clinical study. Furthermore, to generalize the results of such a study the patient population would have to be sufficiently sizable and reflective of the many different device technologies, patient types, and other factors over a sufficient period of time. However, as a small first step on the theoretical, confidence-building journey to this end we provide the results of some simple simulations to explore some of the issues discussed.

5.1 Methods

Using the Swarm agent based simulation framework simulations were created to explore the medical monitoring domain and especially the data loss problem. The simulation was parameterized to allow easy configuration of settings related to simulation type (traditional, telemedicine, or MAS), range over which the rate of data accumulation is set for the population, range over which time elapses between office visits, frequency with which data-offloading is attempted (by the patient in the telemedicine style simulation or by the external agent in the MAS style simulation), etc. Experiments were defined by giving values to these parameters. The amount of data lost and amount of data off-loaded was calculated for each of the experiments described later to achieve the average of 10,000 agent-runs with each agent being simulated for 500 days.

5.2 Experiments

The most basic experiment explored simulation of the traditional approach to medical monitoring with IMDs in which data is accumulated (at a rate randomly distributed between 0 and 30% of capacity each day) until the implant's memory is full and from that point continually lost until the next office visit (set 180 days apart). To explore simulation of the modern telemedicine approach a second simulation alters this such that users attempt (with between 80 and 100% success) to off-load their IMD's data regularly (every 14 days) at home as well as during office visits. We also explored potential implementations of multiagent approaches to medical monitoring including one aimed exclusively at improving the success rate of home off-loading sessions (resulting in between 90 and 100% success).

Finally we explored a more realistic, though at the time not yet realized, multiagent approach to medical monitoring with IMDs that is aimed at approaching continuous monitoring. That is, it simulates agents which not only off-load their data during office visits but also interact with external agents to off-load their data at home. The key difference in this approach is that because the external agents and IMD agents autonomously off-load the data, they can attempt to do this at least daily and keep trying until they are successful (perhaps more than a day later) or determine no data need be off-loaded[11].

[11]In some respects, the interactive communications to determine the need to download data or to avoid downloading could be the most interesting. Telemetry with implantable devices affects their longevity through power drain to carry

Parameter Selection

In real clinical settings, the frequency of office visits, success rate of data-offloading attempts and particularly range of data accumulation rates vary significantly. The choice of 180 days between follow-ups reflects the conservative end of common practice with pacemakers (about every 6 - 12 months) and many other devices. The success rate of telemedicine offloading is also at the conservative end of that reported for CareLink [24]. Though many IMDs sense and process continuous real-time physiological signals and this data would be valuable for various retrospective uses, to our knowledge, there is currently no IMD which is capable of storing all of this for more than a short period. Instead IMDs tend to use tricks including lossy compression, saving only short data snippets surrounding detected events, and using priority schemes so the lowest priority data is overwritten first. The application of these approaches and interpretation of how much of the data is actually valuable varies widely, but we submit that our choice is conservative and would be so conservative for an external device recording the same signals that it would be laughable. It is also worth noting that in our experience the simulation results were not highly sensitive to relatively small changes in these choices.

LATITUDE and CONEXUS

The practical use and implementation of such a MAS may be hard to recognize, but could improve patient care in many ways. The industry is just now taking the first steps in this direction; consider that since the start of this work, Guidant has released the LATITUDE^{TM}Communicator system. This allows automated daily monitoring via a bedside device that operates in a manner largely transparent to the patient and is part of what Biotronic, Inc. spokesmen are saying is "definitely the wave of the future." [25] This system also includes an agent scale component which weighs the pateint and gives them spoken feedback and adaptive instructions. Further, since the first submission of this paper Medtronic issued a press release for the first clinical trial of its new line of IMDs with 2 to 5 meter range "Conexus Wireless Telemetry" which "will enhance efficiencies at device implant and during in-office follow-up visits, as well as enable *automatic*, wireless data transmission from the patients device to a home monitor." [17]

5.3 Results

Indicator Functions and Metrics

In the experimental scenarios described previously in this paper, only data which has been off-loaded is retained to be accessed outside of the implant. With this in mind, the amount of data that has been off-loaded is a valuable metric in determining success. Furthermore, the loss of data in medical monitoring is generally undesirable. The value of absolute data retention, or minimal to moderate levels of data loss depends on the intended applications, but may well not be linear. For example, some cases, like the retrospective analysis of continual real-time algorithms on the gathered data, may require continuous or near continuous data for very long periods to accurately reflect performance. In the experimental scenarios described in this paper, any data which is gathered by an implant full of not-yet-off-loaded data is lost. In volume this is equivalent to the loss of the oldest data not yet off-loaded in a full implant and can alternately be thought of this way if desirable.

out a full off-load. Interactions between IMD and external device could limit or terminate an off-load if the IMDs power reserves are low or if the data buffer is not yet sufficiently full to warrant data collection. In principle, this type of MAS-like interaction could optimize IMD performance across several parameters.

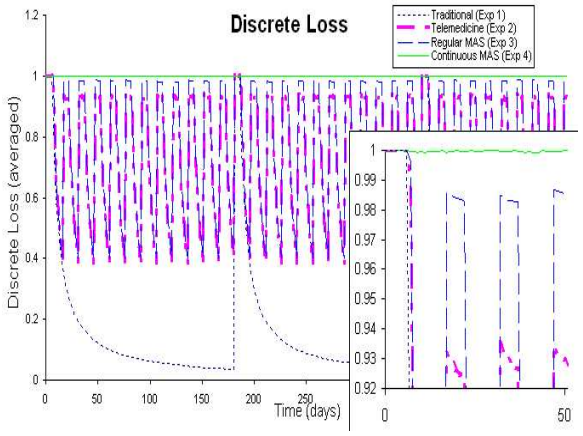

Figure 1: Discrete Loss: Experiments 1 - 4.

The mathematical relationship between the data lost by an agent pair (IMD and external home monitoring agent) is equal to the difference between the data on the device and the sum of the data off-loaded and the total data acquired by the IMD(see equation 1).

$$\begin{aligned}\text{dataLostFrom(agent)} \quad = \quad & \text{totalDataAcquiredFrom(agent)} - \\ & [\text{dataOffloadedFrom(agent)} \\ & + \text{dataOnDeviceOf(agent)}] \end{aligned} \tag{1}$$

We created a metric allowing better understanding of the data in graphical analysis called *discrete loss* or dloss. In this context, dloss is defined for each agent as 1 if the agent has not lost data since the last off-loading and 0 if it has (see equation 3). The discrete loss of the agent population is thus the average across agents (see equation 2) and reflects the portion of the population that has not lost data since their last off-loading. Thus for n agents data loss is defined as:

$$\text{dloss} = \frac{\sum_{agent=1}^{n} \text{dloss(agent)}}{n} \tag{2}$$

where for each agent

$$\text{dloss (agent)} = \left.\begin{array}{ll} 1 & \text{for : dataLostSinceOffload} = 0 \\ 0 & \text{for : dataLostSinceOffload} > 0 \end{array}\right\} \tag{3}$$

This indicator is useful in recognizing and understanding cases in which only a fraction of the agents are responsible for all of the data loss.

5.4 Discussion

Comparing the results of the simulations, it is clear that, given our assumptions, there are some potential advantages to be had with the application of multiagent techniques over traditional and telemedicine approaches in terms of data loss and data off-loading.

The simulations clearly reflect the data loss relationship (equation 1) and the parameters chosen relating to device memory capacity, data acquisition rate and device off-loading rate. As discussed, the parameters chosen reflect our subjective experience with medical monitoring implants but underly key assumptions which might be further explored in clinical studies and other future work. In speaking with medical and other experts who work with data and electronics, the diminutive amount of memory available in long-term implantable devices is often surprising.[12] In contrast consider that a single channel of EEG or ECG signal sampled at 256Hz with 2-byte precision might generate about 30kBytes per minute, filling all of memory for even extreme IMDs in only 1 or 2 hours.

The intuitive benefits of telemedicine over traditional approaches was apparent in our results with more than an order of magnitude improvement over the simulated traditional approach (Experiment 1) in terms of data off-loaded (and a factor of about 2.3 reduction in data lost). This improvement is due to the additional data-offloading opportunities afforded by the supplementary telemedicine approach.

Also as one might expect, the multiagent system (MAS) simulation aimed only at improving the off-loading success rate showed a small improvement over the simulated telemedicine approach as a result of the increase in off-loading success rate (gains in data off-loading and data loss rates of about 7 and 10% respectively). Considering only these differences, this rudimentary approach provides only incremental improvement that would likely not justify the cost of designing, implementing and validating it. On the other hand, it may be worth noting that this approach allows the patient to not worry about the process or their implant and perhaps even forget that it exists. This may be highly beneficial for patient usability and compliance (especially hard with elderly, cognitively imparied, or non-tech savvy), and perhaps in other ways as well. For example, it has been noted that patients who feel that their role is to recharge or otherwise service an implantable device may do so too frequently. This can negatively affect the device (e.g. depleting the battery) and reflect lost time and increased anxiety. Similarly, patient confusion and misuse of telemedicine equipment can result in costs to their healthcare and service providers by burdening call centers and technical service providers.

The final experiment, aimed at exploring a more realistic MAS approach demonstrated an improvement of almost 60% in data off-loaded and about 600% reduction in data loss (over the rudimentary MAS approach aimed only and increasing off-loading success rate). At the same time benefits in usability and transparency of the rudimentary MAS approach are still present. This simulation reflects a significant potential advantage of thinking of the medical monitoring system as a MAS. Though the findings may be intuitive, this is key evidence that suggests a MAS approach is appropriate because it hinges on autonomy and avoids patient compliance as a major issue. In other words, as a more complete paradigm shift it approaches a level of autonomous communication and cooperation between implant and telemedicine agent that is not practical in traditional approaches where asking the patient to constantly measure the contents of their implant, make off-loading decisions and initiate appropriate off-loads would be unreasonably burdensome and far from transparent.

[12]Implantable memory takes up valuable space and current in an IMD. In contrast to commercial memory, implantable memory is specially designed and validated to be highly reliable and draw minuscule amounts of power.

Implantable Agents in Multiagent Systems

Traditionally the implantable medical device market has been focused very heavily on physical implantable technologies and products (as these drive revenue for companies like Medtronic). Telemedicine, however, underscores the increasingly important role of instruments and software. Furthermore, as IMD-based systems and software continue to develop, the need for them to be distributed as highly robust, portable and increasingly automated systems is clear. We submit that agent based approaches can be applied to address this need. The first step may be thinking of implants as agents. IMD-wearable, implanted network, and transient IMD interaction with agents in the environment are emerging interaction patterns that can be used as lenses through which opportunities for IMD systems to benefit from the agent paradigm can identified and developed.

The experimental work in this paper is meant only as an example, not as a conclusive prescription for implementation. Taking the paradigm shift to agency and thinking of implants as potential parts of MAS allows for other, and perhaps better, solutions to this and many other problems. For example, we recognize that the implantable-wearable solution to medical monitoring discussed previously has not been considered adequately in our simulations.

One potential use of implantable-wearable systems is in providing access between IMDs and other external entities. Currently the external components of such systems are primarily simple tools to enable patient interaction with implantables (e.g. a patient programmer device which can be worn on the belt). In the future, however, small wearable telemetry booster devices could act to connect the short-range, proprietary wireless systems in modern implants to remote systems via longer distance wireless schemes. Were such a system to come into place it could create potential for a very large system in which implantable agents, hospital systems, emergency systems, company systems, and perhaps even patients' personal systems are intertwined. The role of agents in this system is not certain, but their advantages in automation, etc. could well shape this potential into what may become a huge and heterogeneous multiagent system with an important fraction of its constituents taking on an implantable form. This type of approach could open up new opportunities for a richer, more reliable medical monitoring systems addressing not only continuity of data issues, but also reporting, data priority, caching, analysis automation, data integration, distributed anonymous clinical research, and other important areas. Although some of the applications of these systems could well address these various goals and concerns, we leave this for future work but examine some examples in the longer version of this paper [4].

6. CONCLUSIONS AND FUTURE WORK

The use of IMDs is a large, complex, and growing domain which naturally lends itself to applications of distributed artificial intelligence. This field is particularly appropriate for autonomous agent and multiagent system consideration as a result of its vast base of existing autonomous, distributed, largely solitary agents and emerging needs and

capabilities for these agents to work as part of multiagent systems in medical monitoring and therapy. Though work in this nascent area of overlap between AAMAS and IMDs has already begun[13] it is not thought of in these terms and could benefit significantly from more explicit consideration.

ABSTRACT

This paper reports on our progress towards a framework for enabling Intelligent Organizations with agent technologies. We have built and deployed the part of the framework consisting of organizational middleware and domain agents. The organizational middleware reads workflow scripts at run time and interprets them delegating to specialized server agents access to business rules and data bases. Those server agents, in turn, communicate with specialized user agents that facilitate human interactions through traditional plain and grid forms. We have used these ideas to transform a conventional Hotel Information System into a multi layered, agent supported information system. Our MAS-ified hotel information system is already in operation in 10 hotels with a total of 2040 rooms.

1. MOTIVATION

Grupo TCA is a medium-size privately owned information systems company. It has been active in the design and development of integral information systems for the Latin American market, since 1982. Its main business comes from integral systems for vertical industries such as hotels, hospitals and retailers.

Ten years ago, TCA became aware that the vertical industry market was being sensitive to the *Business Intelligence* buzzword and TCA realized that, in the years to come, its use would provide competitive advantages in spite of the exaggerated claims being made at that time. TCA decided then to anticipate this threat and started *re-engineering* its integral information systems in order to facilitate reusability of the components and making artificial intelligence resources available in the systems. The strategy was to build a business rules repository that would become readily available to user applications that were subject to a predefined workflow and could also profit from different artificial intelligence techniques. Along the way it became evident that agent technologies were a core element in that effort. Over the last 5 years, TCA implemented its Hotel Information System (HIS) as a consolidated set of business rules available to a middleware workflow engine that reads workflow definitions and delegates concrete tasks and procedures to participating user and server agents. This modestly *MAS-ified* HIS whose architecture is reported in this paper is already operational in 10 hotels with a total of 2040 rooms. It is also the boot-strapping version of an agent-pervasive HIS that we are in the process of designing.

The paper gives a quick sketch of the conceptual background of the hotel information system and a brief description of its architecture. In section 3 we outline the implemented architecture, in section 4 we discuss some relevant results and in section 5 we mention the framework that generalizes the approach we report in this paper.

2. BACKGROUND

2.1 Organizations and Corporate Information Systems

An organization, a firm, is in essence a group of individuals that pursue their collective or shared goals by interacting in accordance with some shared conventions and using their

available resources as best they can [4, 5, 2]. Hotels, or other types of organizations, have conventions that "organize" their activity in consistent ways so that employees and clients have some certainty about what is expected of them or what to expect from interacting with members of the organization. These organizing conventions usually take the form of canonical documents, standard procedures, rules of conduct or records that participants adhere to in a more or less strict way. Corporate information systems (*CIS*s) provide organizations with powerful means to capture the way the organization works by implementing, somehow, those procedures, rules, documents and records. A *CIS* controls the processes that the organization follows, stores its experience and keeps track of the interactions that the members of the organization have with other staff members and also with suppliers, clients and other individuals who are not part of the organization.

Traditionally, *CIS*s are developed around the main business processes of the organization which are usually organized in a hierarchical system whose components —as is notoriously the case among vertical industry organizations— are tightly interrelated. Consequently, building a *CIS* usually starts by making explicit the system components, that is, the business processes of the organization and their main functionalities. Once there is complete business process definition for an organization, the current practice is to address the design and development of a *CIS* by performing three types of activity: *forms designing*, *work–flow modelling* and *business rules programming*. Although there are different ways of organizing these *CIS* development activities, the following two alternative approaches are prevalent:

- *Form centered programming.* The flow of activities is governed by the design of forms. That is, the intervening business rules are invoked by fields of a form where they read or write data, in a sequence that is determined by the form design. This approach has the advantage of easy programming, but provides no facilities to implement work–flow control on the intervening processes and there is no room for capture declarative conventions that could govern the interactions between the intervening components.

- *Work-flow centered programming.* The sequence of business rule applications is specified from a work–flow perspective: the intervening business rules are invoked by states of the the specified work–flow. This approach has the advantage of having all processes in the right sequence and with the proper follow-up. However, all links between the states and also the links with both business rules and forms have to be specified and programmed at design time, resulting into inflexible implementation of processes.

We propose a third approach that is guided by a high–level specification of how the organization is supposed to function. Such *prescriptive approach* makes explicit the *institutional* aspects of the organization and makes them operational through agents that mediate the organizational interactions that constitute the *CIS* (see Sec. 5 below). By relying on agent technologies we are able to address, separately, interaction or procedural conventions, declarative or decisional conventions, and the actual operation of the IT components of the *CIS*. The intended outcome is that , in addition to the obvious modularity and reusability advantages, such separation allows the fine-tuning of the *CIS* at different levels and at different times and therefore brings larger flexibility in the design and update of the *CIS*.

As the initial motivation could suggest, our goal is to develop the type of information systems that support the so-called Intelligent Organizations with their inherent focus on knowledge management and their need to adapt to a dynamic business environment. [1] Crudely put, with this approach we mean to enable Intelligent Organizations with agent technologies by building *CIS*s that capture corporate knowledge in an effective manner in order to support the work of people (and agents) that make use of IT resources in a distributed and dynamic environment. We intend to capture the established procedures and practices that organize *CIS* user interactions through the *performative* representation of the organization as an electronic institution. We will further encapsulate organizational guidelines, policies and decision criteria into the deliberative component of staff agents that support —or take over— tasks that are currently performed by employees of the organization. Finally, keeping in mind that we want to develop *CIS*s for vertical industries and that companies in those industries have many similarities, we will take advantage of agent technologies to deal with standard process components (like forms and business rules) and conventional IT resources (e.g. databases or display devices).

2.2 The Hotel Information System

Grupo TCA deployed its first hotel information system —*INNSIST*— in 1986. Its successors have evolved over the years and are now supporting the integral operation of more than 200 hotels in Latin America. The *INNSIST* Hotel Information System (HIS) supports the management and operation for the Front and Back-office of a hotel or hotel chain. Those management and operational functionalities are implemented as twelve modules, whose specific procedures were programmed to become the content of a *business rules repository*. The following is a list of these modules and the "business context that organize their operations":

Reservations. Individual reservation, group reservations, airline crew management, rooming list, availability control, availability forecasting.

Front Desk. Guest check-in, group check-in, hotel status, credit management, guest folios, client's account statements, guest checkout.

Housekeeping. Room status, room blockade, guest requirements service, maid work orders.

Telephone control. Tariffs catalog, schedule discounts, service costs, receipt printing, telephone switch control, maid status, line management, call accounting.

Night audit. Daily room update, automatic posting, cashiers shift review, audit sheet.

[1] An *Intelligent Organization*, as Liebowitz characterizes them [3], is a "knowledge–based organization whose business operations and internal processes are founded on knowledge competencies and the value of its products and services is given by the know–how, the intellectual capital and the technological advantage of the organization".

Sales. Sale statistics, packages and plans, travel agencies, allotments control, groups, sale forecasting.

Guest History. Guest stays history, promotional plans, guest preferences.

Club Management. Resort club services: Spa, boutique, snack bar, therapies control, special plans, tennis, golf.

Accounting. Forecasting, departmental accounting, transactions, uniform system of accounts, financial models, executive financial information.

Accounts Receivables. Statements, AR projection, balance due.

Accounts Payable. Buy conditions, payments suggestion, discount advantages, partial payments, multiple payments, payments projection.

Inventory Control. Physical inventory, item location, inventory value, inventory cost, inventory level.

Purchase Orders. Order quote, authorization levels, automatic purchase order generation, automatic orders, merchandise reception.

3. ARCHITECTURE OUTLINE

The hotel information system is implemented in a two-layer framework as shown in Figure 1. The bottom layer contains the actual domain components for the hotel *CIS*: data and business rule repositories, forms and display devices, and the corresponding server agents (for domain components) and user agents (for staff and clients that interact with the *CIS*). The top layer is formed by a work-flow engine that guides the actual execution of the *CIS*, and an organizational middleware that, directed by the specified workflow, articulates users and domain components.

3.1 The middleware and workflow engine layer

The organizational middleware runs the *CIS* by putting *business domain* elements and users in contact subject to the workflow specifications. Hence, the basic functions of this middleware are:

- to log users into the organization, controlling user roles, agent resources and security issues.
- to monitor user interaction,
- to load and interpret the *workflow specification.*

The workflow engine has two components: the workflow specification language and the workflow interpreter.

3.1.1 Workflow specification language

The commands available for workflow specification are the following:

- define TAG
- define business-rule-< *id* >
- define data-base-access-definition-< *id* >
- define report-definition-< *id* >
- conditional command execute on TAG
- conditional command execute on EVENT
- form handling.
  - activate function keys
  - define plain form
  - define grid
  - plain form
    - deactivate fields
    - input fields
    - display fields
    - goto field
  - grid form
    - deactivate fields
    - input fields
    - display fields
    - goto field
- call business rule (business-rule-< *id* >)
- call data base access (data-base-access-definition-< *id* >)
- call report (report-definition-< *id* >)

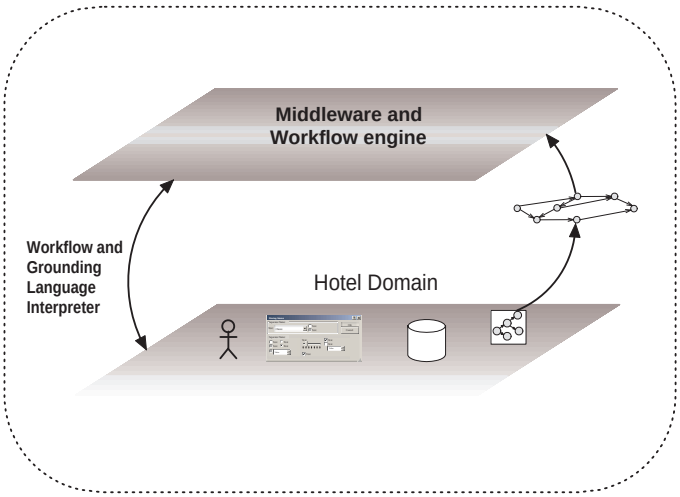

Figure 1: The workflow engine of the organizational middleware loads and interprets workflow specifications and monitors agent interactions

3.1.2 Workflow interpreter

The commands available for workflow execution are the following:

- read work flow specification
- load defaults
- initialize variables
- execute command
  - on TAG
  - on EVENT

3.2 The hotel domain layer

This layer contains the following components:

Hotel Domain Agents. We consider two types of agents:

- *User agents* (human or software) that are external users (clients, service providers and staff members of the organization) of the *CIS*, and
- *Server agents* that act as front ends for all the repositories and devices of the hotel domain and thus handle the interactions with other domain agents.

Interaction forms. These forms implement interfacing capabilities between user agents and other domain elements, e.g. form handling, data base calls, business rules triggering.

Workflow specification. Interpretable *workflow* specification that defines procedural behaviour for the organization.

Repositories. Business rules and data base repositories accessible to agents.

4. SOME COMMENTS ABOUT AGENT INTERACTIONS AND WORKFLOW EXECUTION

As indicated above, the hotel *CIS* we have implemented is run by the middleware and worfk-low engine that interacts with the hotel domain components and *CIS* users. Figure 2 illustrates how the middleware supervises the agents that handle the specialized domain components, such as data bases or business rule applications —a specialized *business rule* server agent (Bag) fetches business rules from a central repository that use data provided by another specialized *data base* server agent (Dag), to provide input to a *user agent* (Uag) that displays it in a user form.

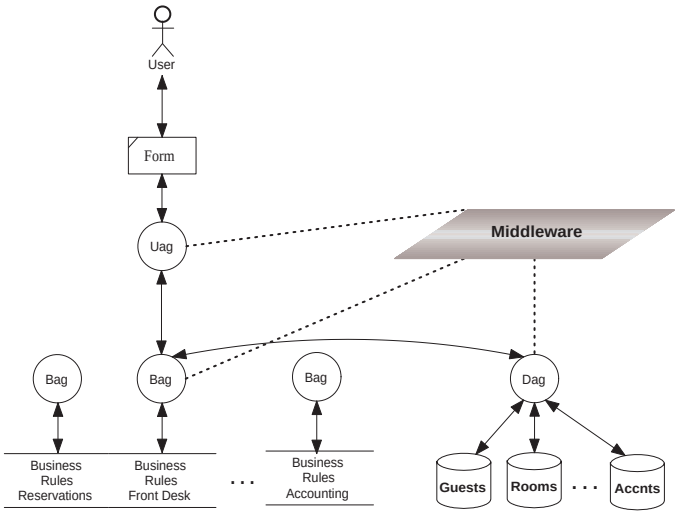

Figure 2: The middleware supervises business rules (Bag) and data base (Dag) *Server Agents* that handle all specialized tasks to serve the requirements of *User Agents* (Uag)

The middleware acts as a link between the user interface and the data base and business rule repositories, but all interactions are mediated by ad-hoc agents. The user interface is mediated by a user agent that is regarded as a client for the business rule and data base server agents. The main function of the specialized server agents is to act as a business domain components (including business rule repositories and data bases) facilitators for all user agents that may be logged-in at several client sessions. User agents can be located anywhere and in any platform; they may be implemented as independent applications, even as applications that require browsers for operation. All the communication with the middleware is made using a Tag-Value encoding via a XML protocol.

Once the interaction between the *user agent* and the *server agent* is established, the infrastructure does nothing but assuring that the communication between both agents is persistent until one of the agents decides to terminate. This is a very important point, because it is the responsibility of the agent programmer to consider all the communication contexts and to include a piece of code to deal with all the information interchange requirements. For example, in the workflow definition shown in Appendix A, once the F4 event is true and the workflow interpreter issues the command
`Interact(DataBaseSvrAg(DB_SUPPLIERS,NEW))`
it is the responsibility of the programmer to send all relevant information from the user form to the data base server agent in order to have the data base properly updated.
In a similar way, once the `SELECT_SUPPLIER` event becomes true, the workflow interpreted issues the command
`Interact(BusinessRuleSvrAg(BR_SELECT_SUPPLIER))`
and it is also the programmer's responsibility to trap the result of the business rule execution setting the value for some data or status variables. The programmer is responsible for maintaining the context of all agent interactions because as agent interaction evolves, they modify the context of the world, updating data and status variables as required. All the global variables are available in the scope of the workflow definition, that is, in the workflow specification the programmer can test for the value of variables defined as global by any *Server Agent*.

The workflow interpreter and the middleware environment impose no control over variables, neither global or local. That is, it is the programmer's responsibility to define and maintain the proper scope for the required variables. The middleware assumes that all agent interactions are between the User Agent and either the business rules server agent or the data base server agent.

Regarding workflow execution, tag and/or event value verification takes precedence over sequential process execution; that is, in the middle of a conditional execution of a TAG value, it is possible to break the sequential flow and skip directly to the first command of another conditional clause.

Regarding scope of workflow execution, once a flat form or grid is addressed, all subsequent workflow commands will be made in the scope of that specific flat form or grid, until another flat form or grid is addressed.

This system developed so far, however, has one major limitation: the workflow engine has no control over what is said between agents, as it deals only with specific conditional commands that test for contextual changes represented by changes in data and status variables. If we want to deal with complex interactions, this is an important limitation

because (up to now) we are forced to "hardwire" the control code for the execution of alternative procedures depending on what is said between agents.

In the implementations described in this paper, we only use *reactive* agents. Such a primitive implementation is enough for our current needs but we may readily change their specification to involve more sophisticated behavior. The benefits provided by the fact that they may potentially negotiate their information interchanges in a flexible way are evident. We should also note that our implementation of agents already assumes that they interact with other agents exclusively through speech acts. Such design decision will enable us to make them functional in the electronic institution environments that are under construction for the extended framework.

The middleware language outlined in this paper is being refined and extended to deal with new functionalities. We also want to go one step further and implement the concept of commitments between agents in order to provide the framework with the flexibility needed to deal with temporal constraints, that is, the effect of some interaction between agent A and agent B at time i, might commit agent B to do something at time $i + 3$, say.

The system described in this paper is currently operational in the following hotels:
– Avalon Grand de Cancún (154 rooms)
– Avalon Reef –Isla Mujeres (137 rooms)
– Blue Bay Cancún Club (310 rooms)
– Blue Bay Cancún Getaway (290 rooms)
– Blue Bay Desire Resort (110 rooms)
– Coco Beach Cancún (202 rooms)
– Karmina Palace Manzanillo (322 rooms)
– Mayan Palace Mazatlán (280 rooms)
– Radisson Casa Grande Chihuahua (115 rooms)
– Reef Club Isla Cozumel (120 rooms)

5. CLOSING REMARKS

In this paper we describe an agent-enabled information system that is being used to manage and operate medium sized hotels. In this system, agents are used as mediators between *CIS* components and system users under the control of a workflow engine.

We claim that the example indicates how current *CIS* development practices may be improved with:

- An Intelligent Organization environment that enables available information technologies resources (such as data bases, business rule repositories, data mining tools and automated decision making devices) with *MAS* technology.
- An agent oriented methodology for building complex information systems.
- Facilitating the separation of form design, workflow specification, and the programming of business rules and agent behaviour.

We are developing a framework that generalizes this example. More specifically, in order to deal with complex interactions, we want to use the theory and notions of organizations and institutions to implement prescriptive specifications that may be properly enacted. We are working with the notion of Electronic Institutions and extending the current IIIA EIDE environment to allow teleological and normative specification of agent interactions [1]. The purpose of the framework is to facilitate the building of *CIS*s that implement a high-level prescriptive specification of an organization by encapsulating the institutional elements of the organization through standard procedures and corporate decision-making criteria encapsulated in (corporate) user agents. We intend our framework to allow for the construction of *CIS*s that are flexible enough to adapt to changing requirements and business conditions. The system discussed in this paper will allow the boot-strapping of the proposed framework because, on one side, the the middleware layer developed so far is being extended to deal with richer electronic institutions and, on the other side, the workflow language and interpreter, as well as the user and server agents developed so far are being extended to provide more general *grounding language* and domain agents.

Figure 3 shows our proposed extended framework. The diagram shows how our present middleware layer is to become an organizational engine that implements an electronic institution —not just a workflow engine— that controls the business domain objects. That electronic institution engine, in turn, is the implementation of a declarative description of how agents should interact or, more precisely, of the institutional conventions that will govern the business domain interactions. These developments have been partially reported already. We have reported the implementation of a *Bayesian reasoning engine* [6] and the use of this architecture in our work on *Problem Solving Plans* [8]. Finally, in [7] we have discussed a conceptual framework and outlined an architecture and its integrative elements to enact an Intelligent Organizations using the Electronic Institutions approach.

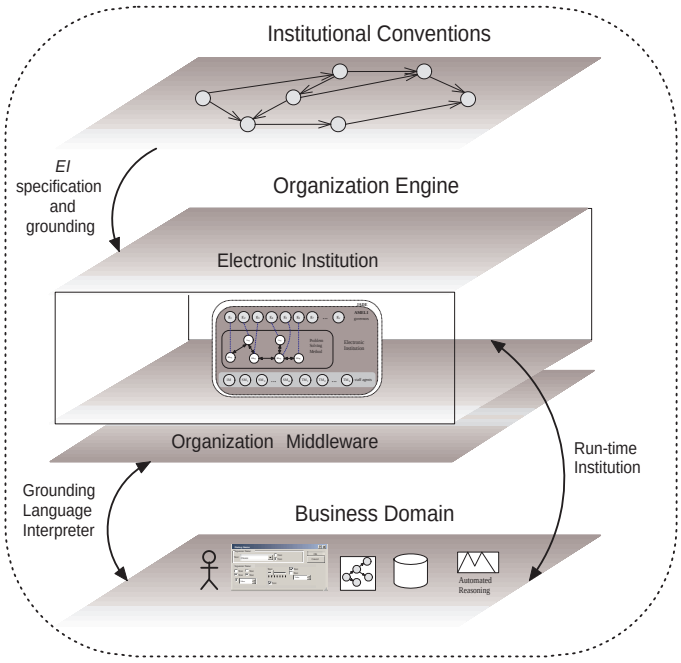

Figure 3: General Architecture using the concept of Electronic Institutions as part of the organization engine

1. INTRODUCTION

As has been argued very eloquently and effectively, there is a *chasm* that needs to be crossed in the adoption of any new technology [8], and the marketing of such technologies must somehow try to bridge the gap that arises. Many currently see agent technologies in the middle of that chasm period of adoption, where addressing the visionaries as well as the pragmatists (or early adopters) who avoid risks but readily see the advantages of tested technologies [11], is necessary. As part of the needed marketing exercise, we believe that a catalogue of case studies of deployed applications with real quantified business benefit, can help convince those wavering pragmatists. Perhaps more importantly, the lessons that can be drawn from such case studies may also be used to guide the efforts of new commercial agent technology providers, both in developing the technology itself, and in understanding the concerns and constraints of early adopters.

As part of its industrial activity programme, AgentLink III[1] has been developing such a catalogue of case studies for exactly this purpose, working in collaboration with a range of companies to provide a selection of example applications, and draw out important issues arising from their development. In this paper, we summarise some of these case studies, and review the lessons learned, with the aim of identifying key problems. Due to space constraints, only very brief descriptions are provided in each case, but they serve to illustrate the nature of the application and the range of sectors and solutions; the full set of case studies is available from www.agentlink.org.

2. COMMERCIAL AGENT APPLICATIONS

To date, deployed applications of agent technologies have been concentrated in a small number of industrial sectors, and for particular, focused, applications. These have included: automated trading in online marketplaces, such as for financial products and commodities; simulation and training applications in defence domains; network management in utilities networks; user interface and local interaction management in telecommunication networks; schedule planning and optimisation in logistics and supply-chain management; control system management in industrial plants, such as steel works; and, simulation modelling to guide decision-makers in public policy domains, such as transport and medicine [5].

While some of these applications may be implemented as closed systems inside a single company or organisation (for example, agent-based simulation for delivery schedule decision-making), the domains to which agent technologies are most suited are those involving interaction between entities from more than one organisation. For example, automated purchase decisions along a supply-chain, require the participation of the companies active along that chain, so that implementing a successful agent-based application requires agreement and coordination from multiple companies. Moreover, to fully exploit the benefits of agent technology, other suitable domains are those involving a multitude of variables, with complex interdependencies, which change dynamically and thus cannot all be known at design time. This requires agent solutions because of their ability to dynamically adapt to changes in the environment and thus to offer real-time optimisation. For example, agent-based solutions successfully replaced conventional systems for network planning and transportation optimisation, because these were limited in their ability to cope with the increasing complexity, and especially with the dynamics, of a noticeably globalised transportation business [3].

In this section we describe a suite of agent applications provided by agent technology vendors for several commercial clients. In particular we describe the work of the following companies.

- Agent Oriented Software and their system used to aid

the Ministry of Defence in military training.

- Eurobios and the simulation model they developed to improve production schedules for a cardboard box manufacturer.
- Magenta and their approach to helping a shipping company improve their oil distribution shipping network.
- Whitestein's system for logistics management.
- Nutech and the solution they developed for an energy production and distribution company.
- Acklin's approach to solving information exchange problems for insurance companies.
- Rockwell Automation and their use of intelligent agents for chilled water systems for the US Navy.

2.1 Agent Oriented Software and Military Training

Simulation and modelling are extensively used in a wide range of military applications, from development, testing and acquisition of new systems and technologies to operation analysis and provision of training and mission rehearsal for combat situations. In particular, distributed simulation environments for use in training and analysis drive much of this work. For example, simulation exercises involve a few dozen real people with the remaining hundreds or even thousands of other battlefield entities being computer simulations. As the human element is a key success factor in combat situations, the value of computer models of combat are greatly affected by their ability to accurately represent the range and variability of expected human behaviour.

The Human Variability in Computer Generated Forces (HV-CGF) project, undertaken by Agent Oriented Software on behalf of the UK's Ministry of Defence (MoD), developed a framework for simulating behavioural changes of individuals and groups of military personnel when subjected to moderating influences such as caffeine and fatigue. The project built on the JACK Intelligent Agents toolkit, a commercial Java-based environment for developing and running multi-agent applications.

JACK was particularly appropriate for several reasons. It incorporates the Belief-Desire-Intention (BDI) reasoning model, proven to effectively model certain types of behaviour, like the application of standard operational procedures by trained staff. JACK also includes facilities for the creation of intelligent team behaviour through the advanced JACK Teams model, while the JACK Agent Language extends Java with constructs for agent characteristics, such as plans and events.

For the project, Agent Oriented Software built a layer on top of Jack, called the JACK Cognitive Architecture (CoJack), that provides cognitive modelling capabilities for enhancing agent functionality with psychological attributes. Using these attributes, cognitively-plausible agents can be developed to simulate human psychological parameters, such as the capacity of human memory to handle multiple concurrent tasks, the perception and speed of reaction to events from the battle-space, and the ability to choose from different problem-solving tactics. This layer can thus be used to develop various cognitive models.

The influence of internal and external moderators are modelled as an independent layer, through a set of *behaviour moderators*, one for each influencing factor that modifies the agent's psychological attributes. These were plugged directly into the JACK Cognitive Architecture.

Also part of the core architecture is the JACK Intelligent Agents Team-based Platform, which was implemented using JACK's team based agent capability, to model human variability at team level. It facilitates the design, configuration and execution of a collection of agents organised in military structures realistic to the UK army. Each team member is a rational agent able to execute actions such as doctrinal and non-doctrinal behaviour tactics, which are encoded as JACK agent graphical plans.

2.2 Eurobios and Manufacturing Management and Optimisation

SCA Packaging, a leading international manufacturer in the corrugated-box market, turned to Eurobios to provide an agent-based simulation model to explore different strategies for reducing stock levels without compromising delivery times, as well as evaluating the consequences of changes in its customer base. In order to operate successfully in a highly competitive market, the manufacturing company found itself under growing pressure to maintain a high quality of customer service and decrease delivery times, as well as increasing plant efficiency and reducing inventories of finished goods

Eurobios developed a solution for the management and optimisation of the company's manufacturing plant. In the plant, customer orders arrive simultaneously for a large variety of boxes, each with its own colour scheme and specific printing, and often to be delivered at very short notice. Plant managers have to deal with varying lead-times, varying seasonality and overlapping production pathways, while trying to avoid weekend shifts and overtime, keeping the warehouse stock levels down, and ensuring *on-time and in full delivery* [2]. In addition, the complexity of plant processes, combined with the difficulty of predicting customer behaviour and machine failure, makes managerial decisions difficult. Thus, the problems and the trade-offs arising in the management of the plant require a detailed understanding of the relationships between customer order patterns, factory capacity, machine speeds, order batching and warehouse size (to mention just a few of the relevant variables), which can only be achieved through the use of sophisticated simulation technology.

The simulation model developed by Eurobios combined agent technology with discrete event simulation [2]; agents represented interacting entities with behaviour rules and decision capabilities attached, while the simulation of the processes was achieved using events, occurring concurrently or consecutively.

2.3 Magenta and Vessel Scheduling

As in many other transportation domains, in the domain of shipping, a major problem is efficient cargo allocation and vessel scheduling. Commonly, such tasks are performed manually by human schedulers with no automated support. However, this causes two major problems, as follows.

1. The vast amount of information that must be considered to schedule large fleets of vessels in a dynamic

environment means that the complexity is high, potentially leading to costly mistakes. Reducing the frequency of such mistakes improves fleet utilisation, allowing increased profits while using the same resources.

2. There are many domain-specific constraints that impact on the scheduling process and, each time an employee involved in scheduling leaves the company, their expertise in relation to these domain-specific constraints leaves with them; reliance on human schedulers alone brings great dependencies causing the company to become inefficient, and requiring new employees to start building up expertise from scratch.

In the scheduling of ships, many factors must be taken into account. First, each vessel, cargo, and port has different constraints that may prevent certain schedules (for example, a vessel may be too big for a port, or a cargo too big for a vessel). Such constraints are *hard* in that they cannot be broken during the scheduling process. However, other *soft* constraints must also be considered. These are constraints that the scheduler can break only if there are no other reasonable solutions available such as, for example, reducing the amount of time that a vessel travels without cargo. In addition, the environment is dynamic, in that the cargo is changing constantly, and the vessels may fail, rendering them out of service for a period, and requiring a reschedule for their cargo over that time.

In addressing these concerns for a large shipping company, Magenta Technology developed the *Ocean i-Scheduler* vessel scheduling tool [4], which was built on top of Magenta's agent technology, using the multi-agent paradigm. The shipping company's original requirement for their application was simply an online system to allow direct booking of cargo to be transported. However, after discussions with Magenta and demonstrations of their agent technology, it was clear to the company that agents might enable the development of a much more useful system. A proof of concept application developed by Magenta convinced the customer to invest in the development of a full scale system. The customer was first impressed by the way that, using agent technology, the system's behaviour could be changed without having to shut it down or introduce new code. Second, they recognised how well the agent system itself could handle changes to cargo, vessels, and ports. Overall, the customer envisaged two benefits to implementing their system in this way.

1. The system would provide support to employees in the scheduling task, therefore reducing the possibility of costly mistakes.

2. The system would provide a formal model of the business knowledge needed to schedule shipping fleets, so that much less knowledge might be lost when scheduling employees leave the company.

In the development of the system, the client, together with Magenta Technology developers, used the agent paradigm also as a design tool. Each cargo, vessel, port, etc., was modelled as a real-world role. For example, the role of vessel was designed, taking into account the responsibilities and rights of such a vessel. Then, for each vessel in the client's fleet, a vessel agent was created. The developers claim that this led to a simplified design when compared to what might have been developed using traditional software engineering techniques.

2.4 Whitestein and Transportation Networks

In transportation, one of the keys factors affecting efficient operation is the optimisation of the use of available capacity. Strategic network planning and short-term route optimisation are used to allocate despatching plans but are normally performed manually, causing difficulties when plan deviations become necessary due to the occurrence of unexpected events.

The Living Systems Adaptive Transportation Networks (LS/ATN) application is a cost-based optimisation system for transport logistics [3]. Developed by Whitestein Technologies, LS/ATN is designed to provide automatic optimisation for large-scale transport companies, taking into account the many constraints on their vehicle fleets, cargo, and drivers. Although the agent solution accounts for only 20% of the entire system, agent technology plays a central role in the optimisation. Vehicle drivers send information specifying their location and proposed route, and the system determines if that vehicle can collect an additional load, or swap future loads with another vehicle in order to reduce cost. A negotiation is performed automatically by agents, with each agent representing one vehicle, using an auction-like protocol. The vehicle that can provide the cheapest delivery wins the auction, reducing the overall cost of cargo delivery and, in most cases, the combined distance travelled for all vehicles. The aim is to find a local optimum (that is, not European-wide), so that only vehicles travelling in close proximity to each other will be involved in negotiations.

2.5 NuTech Solutions and Plant Optimisation

Recent years have seen substantial change in the energy transformation market caused by deregulation, fluctuating energy prices, changes in customer demand and changes in production and delivery costs. In this context, a large energy supply company sought out NuTech Solutions to develop a system that would enable them to address a number of key concerns. Essentially, the company needed to optimise its operations so that it could schedule the production and distribution of liquid oxygen and liquid nitrogen from more than 40 plants to 10,000 customer sites.

The Supply Chain Production Optimiser system developed by NuTech combined the power of ant system optimisation and genetic algorithm search techniques, and is one of the largest and most successful applications of these techniques used in industry to date. The system takes into account the production schedules of all of the company's oil production plants and adapts them to projected energy prices, weather changes, client demand and desired inventory levels. Utilising data representing seven day power prices, customer demand projections, daily power costs and efficiency measures from every plant in the network, the system evaluates production costs based on forecast demand to determine which plants should produce which products. In addition, the system can model and take into consideration potential plant production capability, maintenance needs and power issues that may impact upon the generated schedules. All of this information can then be fed into the energy company's *operations control centre* to enable adjustments to be made to the operation of the plants to meet production requirements across the whole network.

2.6 Acklin and Information Management for Insurance

The process of handling transnational insurance claims is heavily bureaucratic, with most of the information processing done by humans, resulting in long times for settlement. European insurance companies use heterogeneous information systems, with different means of storing and using data, so that the data must be exchanged manually between companies when dealing with claims, which involve motor vehicle accidents in one country by drivers from another. Acklin, B.V. developed an agent-based system to automate the exchange of insurance information between human operators in the claim handling process [10] concerning trans-national vehicle accident claims. The main customer was a major Dutch insurance company, but other insurance companies involved in the claim handling process with this customer needed also to implement this system for interoperability reasons.

The KIR system developed by Acklin consists of a network of communicating agents to which the back-office of every insurance company can connect in order to exchange information. The communication between agents is done by email, as a means of message transport, because it was the only technology that was supported by all the insurance companies implementing this automation solution.

The agents were designed and implemented using the Five Capabilities model, also known as conceptual separation of concerns, which is composed of the following models:

The communication model handles all the interactions between agents and other systems, and it has methods for message transportation, representation and interpretation.

The competence model contains methods for the execution of the tasks for which the agent is designed.

The self model represents the knowledge that an agent has about its own capabilities (i.e. goals, tasks, jobs, states and competencies).

The planner model contains planning strategies that can be used to achieve the goals.

The environment model gives the agent a view on the world in which it operates (i.e. the other agents) and with which it interacts.

The advantage of this approach was that each model could be implemented independently, to reflect the type of agent; for example, for agent roles like payer and handler, the differences in capabilities were implemented only in the competence and self models.

The introduction of the KIR system resulted in a work pressure release of three people at the customer site and reduced the process of identification of client and claim information from 6 months to 2 minutes. The success of this system led the customer to request its implementation at European level.

2.7 Rockwell Automation and Chilled Water System

For many years now, Rockwell Automation has been investigating the use of multi-agent systems in manufacturing and various control and diagnostics applications [7]. Based on the Autonomous Cooperative System (ACS) proprietary agent platform [6], Rockwell Automation developed an intelligent application for distributed control of a shipboard Chilled Water System (CWS) for vessels of the US Navy [9].

In the CWS application, intelligent agents are deployed within commercial off-the-shelf (COTS) Programmable Logical Controllers (PLCs). Specifically, the set of functionalities of the standard Rockwell Automation ControlLogix and FlexLogix controllers was extended so that they can host a collection of various intelligent agents. The deployed agents carry out negotiations and collective decision-making aimed at dynamic reconfiguration of the Chilled Water System and fluid rerouting as a result of possible failures in the system.

The CWS application has been demonstrated on the Reduced Scale Advanced Demonstrator (RSAD) model, a Rockwell Automation developed reconfigurable fluid system test platform, which is a scaled-down version of a real ship. It features two chilling plants with 16 chilling targets on board the ship (for example, combat systems, communication systems, and radar and sonar equipment). Each water cooling plant is represented by an agent, as well as each chilling target(heat source), each valve, and some parts of the piping system.

3. LESSONS LEARNED

Having presented an overview of these agent-based applications, we now turn to discuss the main lessons learned from their development and deployment, and from the successful collaborations between the software companies and their industry clients. In this section, we present some of the challenges encountered and the ways in which they were overcome, in terms of selling the technology to the customer, knowledge acquisition and knowledge engineering, integration with legacy systems, validation, usability and operationalisation, and standards.

3.1 Selling Agent Technology

One of the important factors in securing a contract for an agent-based application was selling the agent technology to the right customer in the right industry sector. To achieve this, it was generally necessary to focus on industries who were forced to transform under competitive pressures and on companies who were looking to streamline some of their processes in order to reduce costs and become more efficient. Not only did agent technology need to address these demands, but it had also to deliver visible business or commercial value to the customer and sometimes even to their cooperating partners. In particular, success in securing such contracts often required helping companies to achieve a more profound transformation of how they operate and not just an incremental improvement.

Because of the disruptive nature of agent technology, a good relationship with customers was also important, as was having a history of successful implementations of agent-based systems, and experience of modelling of the particular problem domain. For example, the extensive experience of Eurobios with supply chain optimisation using agents was valuable in convincing managers at SCA Packaging of the feasibility of an agent-based solution. The alternative model was to find *pioneering* customers, or *early adopters* who understood the potential business value of the agent-based application and were willing to invest in it (such as the insurance company in the Acklin case study and the MoD),

even if they did not have competence in the specifics of the technology itself.

The agent metaphor itself was also useful in attracting customer interest, as it was found to be an intuitive way of modelling some business domains (for example, in the insurance case and the packaging plant) and easier to understand than analytical or mathematical models typically used for optimisation. With concepts such as roles and responsibilities, agent-oriented approaches to problem and system description are much closer to the ways in which managers conceive of business domains than are traditional software engineering descriptions. By mapping organisational functions onto agents using roles and capabilities, and by mapping business logic and process flows onto message exchange patterns between agents, it was easy to reason about and better understand company processes, especially when visualisation was used in early model-building stages. This aspect particularly appealed to senior management and process engineers, and made it easier to convince them to invest in the agent-based solution, even when the customer had no prior exposure to agents. The same cannot be said about using agents for cognitive modelling for the first time in a defence application, where building cognitive science concepts on top of agent concepts, and then linking back and interpreting simulation results according to cognitive principles was problematic. However, by successfully completing the project and demonstrating the feasibility of agent technology in modelling moderated behaviour in distributed simulations, further interest was raised within the defence community in applying agents to other types of simulations, thus pushing agent technology towards exploitation and development of new areas.

3.2 Knowledge Acquisition and Knowledge Engineering

In modelling and simulation applications for planning, such as the corrugated-box factory modelling of Eurobios, the cargo fleet scheduling of Magenta, or the production planning and routing optimisation of NuTech, knowledge acquisition and model building are often performed simultaneously and iteratively. To build a model that matches reality as accurately as possible requires gathering information about different operations and processes from documents and company databases, as well as eliciting and formalising knowledge from domain experts. For large scale and complex problems, the model is built incrementally, in several steps, from a simple basic model through to a detailed and complex one that approaches reality. The model and underlying knowledge are then validated by experts, after which more knowledge acquisition is undertaken to refine or correct the rules where necessary.

These tasks pose particular challenges but also offer substantial benefits both to software developers and customers. For business performance optimisation systems, for example, data acquisition often requires significant effort in companies where data is spread between different enterprise applications. This effort is even higher when there are no existing integration applications (such as enterprise resource planning, or ERP) in a company, and where the enterprise applications do not automatically generate the information necessary for optimisation. Such is the case of transaction-based applications, (as experienced by Eurobios at SCA Packaging, for example), which are not designed for storing intermediate states of information between transactions or for storing the events that model the business processes; neither are they able to store other types of information like the time of generating the data, or what-if analysis information, typically used in the modelling and optimisation task.

In terms of eliciting domain knowledge, specific challenges were encountered.

- First, the process of making explicit that knowledge which is complex, unformalised and developed through years of experience by people working in the field was one of the most challenging and time-consuming aspects of the acquisition task in some of the cases we considered.
- Second, clarifying domain terminology to the software developers was often necessary and was clearly very important, especially in the early stages.
- Third, the effort to obtain data of sufficient quality and detail was sometimes underestimated, and several iterations were necessary because the software engineers and business managers often had a different appreciation of what it is that constitutes good data.
- Additional problems came from the fact that domain experts often had little understanding of, or interest in, agent technology, and had limited time available for discussion (as in the case of the defence application).

Sometimes minor alterations to the documented processes were introduced on an *ad hoc* basis at an operational level without informing management. For example, changes to delivery dates for a particular customer were introduced by plant operators at SCA Packaging, based on their everyday understanding of customer order fluctuations. Consequently, there were often discrepancies between the results of simulations and real data from the domain (such as the warehouse stock levels in the case of the cardboard-box factory), which had to be corrected.

However, discovering such discrepancies was one of the benefits of the knowledge acquisition and engineering activities. Indeed, the impact was broader than just the software model, and reached beyond the realm of software development. Not only did different departments gain an insight into each other's work practices, but by encouraging them to talk to each other in the process of eliciting knowledge, some of the communication barriers between functional departments and between different management roles in the company were eliminated.

3.3 Integration with Legacy Systems

A key concern of many companies when deploying and integrating new IT systems is data security and the stability of the systems already in place (or legacy systems). For these reasons and because of the current early stage of agent technology adoption, agent-based applications for simulation and optimisation were used as tools to assist human decision-making and not operationally to control or automate processes. The only integration with legacy systems was therefore at a database level and not with any planning or scheduling applications in use at client companies. The only example of process automation with agents was the exchange of information in insurance claim handling, but no actual integration with insurance systems was present here

either. A contrasting case is the Co-JACK system developed by AOS, where the agent-based system was integrated with other simulation environments in order to take advantage of well developed user interfaces and high-fidelity graphical modelling of various geographical environments. Two main integration approaches were identified, as follows.

- The vertical approach, used by AOS, by which the Co-JACK agent system was built using a layered architecture, and the bottom layer of the architecture (the CGF Interconnection Layer) was used for integration with existing defence CGF systems (such as the OneSAF Test Bed).
- The horizontal integration approach, by which every agent interfaces with company databases, was used by Acklin. In order to minimise the interference between agents and the back-office of the insurance company, Acklin developed an interfacing component that maps execution commands from an agent to the back-office, and returned results from the back-office to the agent. Transferring data between agents and the interfacing component was done through a buffer where instructions and reports are read and written by agents. This solution enabled agents to have controlled, but not direct, access to the required functionality and data from the legacy system. The interfacing component was developed by the IT department of the insurance company, thus sharing the risk with the client and allowing the client to retain control over company systems and data.

3.4 Validation

Validation is crucial to ensure the accuracy, correctness and realism of any model and of its outputs. Due to the complexity of the processes being modelled, extensive tests are usually necessary for diagnosing problems and tracking system behaviour, not only for validation purposes but also to help the customer understand how the system works. However, the task is challenging, not least because agent-based systems may explore realms of behaviour which go beyond people's intuition and expectations and therefore results often seem surprising [1]. Testing and validation are even more problematic when the system must access company databases for data input in real-time and when this interaction occurs over multiple steps (for example, in the Eurobios case), because simulations become irreproducible, making diagnosis and debugging more difficult.

In addition, questions of how much time and effort to spend in system design and model building, as opposed to implementation and validation are common difficulties, and were experienced by Eurobios. On the one hand, spending considerable time in advance to ensure sufficient data accuracy, and designing the application to ensure reusability, quality and robustness was important. However, it was also found that only through simulations during the model calibration and validation stages did certain issues surface that would not have been discovered at design time. For reasons of complexity, there was a point after which spending more time in design brought no further value to the final system because there was a chance that what was being designed would later be invalidated.

In contrast, in the case of the Co-JACK system, experiences with model validation and overall system testing were different and more challenging, firstly because they had to address the problem of integration with the CGF system, and secondly because the realism of human behaviour modelling had to be proven without being able to test the system in an actual combat situation. Testing was therefore achieved by showing how changes in psychological variables within Co-JACK determine changes in the behaviour of the entities in the OneSAF system, thus testing the link with the CGF system. The agent-based model was validated by comparing the results of the simulation with those produced by other cognitive architectures that had previously been validated through experiments with humans.

3.5 Usability and operationalisation

Training and familiarisation play a vital role in the adoption of any new technology; this is true for agent technology, too. When an agent-based system is used to assist decision-makers (as with human schedulers in the Whitestein and Magenta applications), trusting the results of an optimisation or a simulation is essential, especially since decision-makers have a great deal of experience in their area. A period of familiarisation and day-to-day interaction with the system is therefore necessary for users to accept and have confidence in the recommendations of the software, and to rely on it when making critical decisions.

At this user-oriented level, usability was also an important aspect of operationalisation. To encourage day-to-day use in a seamless manner, customers may require that user interfaces are designed in a similar way to, or share some features with, standard software packages used in that particular industry. For example, the experience of Whitestein was that transportation management systems have specific interface designs and functionality, which the agent-based system for transport route optimisation had to provide.

In the Co-JACK application, demonstrations with non-expert users initially showed a fair amount of difficulty in the use of the system both in terms of writing accurate tactics for the model and tracing and understanding overall system behaviour. This was due to the complexity of inferences at the agent level, and of the interactions between agents. Thus, dealing with the combinatorial explosion of different outcomes in the battle-space, and how this explosion could most usefully be presented for decision support or training, were two of the objectives identified for further development during a subsequent project phase.

3.6 Agent Standards

While agent standards, such as FIPA[2], are developing and becoming more mature, it is interesting to note that in many of the projects outlined in this article, the developers did not use current agent standards for such elements as agent communication, and have developed their own languages and protocols. These design decisions reflect the closed nature of many of the systems. Where systems are open, in that they involve different organisations, they are not open in the sense that agents developed outside of these organisations can participate in the system. Even so, with these organisations developing their own interaction languages and protocols, this is a sign that the state-of-the-art in this area does not appeal to industry partners as much as many would hope, and that perhaps work is required in this field to make it more relevant and applicable to industry.

4. CONCLUSIONS

This paper has reviewed and discussed some of the most important lessons and experiences of developing agent-based applications for niche markets, in the logistics, production, defence and insurance sectors. The experiences and challenges faced are largely determined by the nature of the business operations in the industry domain, the characteristics of the problem to be solved and the issues related to the organisational and technical infrastructure of the client company. Nevertheless, commonalities were observed across these applications, which led us to believe that sharing these lessons may also be useful to other companies considering agent-based implementations in the future. The common aspects can be summarised as follows.

- From a business perspective, technology adoption decisions should be strategic, based on long term benefits and supported by a clear business evaluation. A software developer wishing to sell agent technology to a new company must put forward a strong business case, identifying the commercial and technical value of an agent solution for that company, and the advantages of agent technology over other technologies already in use in the relevant industry, but without underestimating them.

- From a technical perspective, while the specific agent solutions considered here address specific performance requirements like dynamic adaptivity and real-time response, they also had to satisfy requirements common to any software implementation for industrial applications, such as accuracy of results, interoperability, robustness and user-friendliness. It is thus important that development and deployment is approached with traditional software engineering methods and standards, and traditional project and risk management techniques used for IT implementations.

More generally, it can be concluded that successful adoption of agent technology depends on identifying the specific key conceptual and technical aspects related to agents that can address real world problems, even if these problems require unsophisticated solutions, and introducing innovation only where necessary.

Acknowledgements

This paper is a personal view based on interviews conducted with relevant experts from each of the companies mentioned: Tony Delaney and Martyn Fletcher from Agent Oriented Software; Vince Darley from Eurobios; Nadezhda Yakounina of Magenta Technology; Christian Danneger and Klaus Dorer from Whitestein Technologies; Bryan Woody and David Davis from NuTech; Chris van Aart from Acklin and Y'All. The interviews were undertaken as part of the case study effort of AgentLink III, the European Commission's Coordination Action on Agent-Based Computing. We are grateful to all those who contributed. The full set of case studies is available from www.agentlink.org where more complete presentations are also given.

ABSTRACT

In this paper, we describe an innovative infrastructure to support student participation and collaboration and help the instructor manage large or distance classrooms using multiagent system intelligence. The system, called I-MINDS, has a host of intelligent agents for each classroom: a teacher agent ranks and categorizes real-time questions from the students and collects statistics on student participation, a number of group agents that each maintains a collaborative group and facilitate student discussions, and a student agent for each student that profiles a student and finds compatible students to form the student's "buddy group". Each agent is capable of machine learning, thus improving its performance and services over time. These agents also interact and collaborate among themselves to exchange information and form coalitions dynamically to better serve the users. We have pilot-tested I-MINDS in GIS lectures, deployed I-MINDS in an introductory computer science course (CS1)'s laboratory, and evaluated the impact of I-MINDS based on student assessment. The results showed that students using I-MINDS performed (and outperformed in some aspects) as well as students in traditional settings.

General Terms

Algorithms, Design, Experimentation.

Keywords

Multiagent, Cooperative Learning, Distance Education.

1. INTRODUCTION

Students in large or distance classrooms often do not enjoy the same level and quality of student-to-student and student-to-instructor interactions during the class (synchronously) or after the class (asynchronously) as in smaller classrooms. Such interactions are, however, important to foster group-based learning and student affinity in a class. To improve such interactions, educators have turned to technology such as personal response systems, online chat rooms, teleconferencing tools, and computer-supported cooperative learning (CSCL) environments. However, these systems do not adapt to diverse student and instructor needs and behaviors. These systems are passive participants in the process and students and instructors often resort to other modes of interactions (e-mail, phone, or face-to-face meetings) in order to address individual problems. Further, the advent of Internet and multimedia technology has meant potentially drastic changes in the teaching and learning process from the traditional classroom setting to a more geographically distributed, virtual but still interactive one. Hence, there are both motivation and opportunity to develop intelligent CSCL systems.

The long-range goal of our research is to improve teaching and learning through technology, where intelligent agents actively support *cooperative learning* among students and support teachers in managing real-time classroom activities. A secondary goal is to bring the same quality of interaction and team building that invigorates the traditional classroom to distance education for both synchronous and asynchronous student learning. Note that "cooperative learning is instruction that involves students working in teams to accomplish a common goal" [4].

Our research has designed and developed an infrastructure called the Intelligent Multiagent Infrastructure for Distributed Systems in Education (or I-MINDS). I-MINDS consists of different intelligent agents working together to actively support student-student and student-instructor interactions. Specifically, there are agents that rank and categorize questions, and profile students to help the instructor manage a classroom in real-time; agents that find compatible agents to form "buddy groups" for students; and agents that form and maintain structured cooperative learning groups.

We have pilot tested I-MINDS and further deployed the software in the laboratory of an introductory computer science course at the Computer Science and Engineering Department of the University of Nebraska. Tests based on student assessments and control-treatment groups showed that I-MINDS, though still needing better graphical user interfaces and further development, could support and improve student performance and instruction in several pedagogical aspects.

In the following, we first present I-MINDS' architecture in Section 2. Section 3 discusses I-MINDS' agents as well as their roles and relationships. We then describe the suite of features that allow the agents to actively support classroom interactions in Section 4. Section 5 gives an overview of the implementation of I-MINDS. In Section 6, we discuss the results of the pilot test and the deployment. Finally, we conclude with some future directions.

2. ARCHITECTURE

I-MINDS is built using a loosely-coupled layered architecture [7] (Figure 1), which makes I-MINDS flexible and usable in heterogeneous environments.

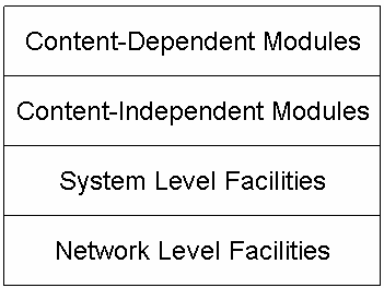

Figure 1: I-MINDS Agents and Topology

The bottom layer (i.e., the network layer) in I-MINDS provides the basic communication functionalities by using sockets. Since sockets are available in a variety of platforms across the network, this layer allows I-MINDS to communicate in heterogeneous situations.

The second layer provides system-level protocols and encapsulations with necessary abstraction to provide convenient communication and deployment functions to the upper layers. This level includes a Relational Database Management System (RDBMS)-type database (MySQL) and an audio/video server (Macromedia Flash© Communication Server). The database is used by the agents for fast storage and retrieval of information and the audio/video server helps establish audible and visual communication between the teacher and the students.

Finally the topmost two layers of I-MINDS contain the intelligent agents i.e., teacher agents, student agents, and group agents. Each intelligent agent has two sets of modules: content dependent and content independent. The content independent set provides the definitions and processes for general education-related services, while the content–dependent module handles specific course-related information and knowledge base, providing the required data and the heuristics used to gather, analyze, disseminate and process the generated data.

3. AGENTS and TOPOLOGY

Figure 2 shows an example of the topological infrastructure of I-MINDS [8]. The manager manages the ongoing classroom sessions. It manages system level information such as the list of ongoing classes, list of courses and teachers, the login names and passwords for the students for each of the classrooms, etc. I-MINDS is capable of holding multiple concurrent classroom sessions. In each I-MINDS classroom session, the teacher, students and student groups are assigned the teacher agent, student agents and group agents, respectively. These agents support the person/group that they serve.

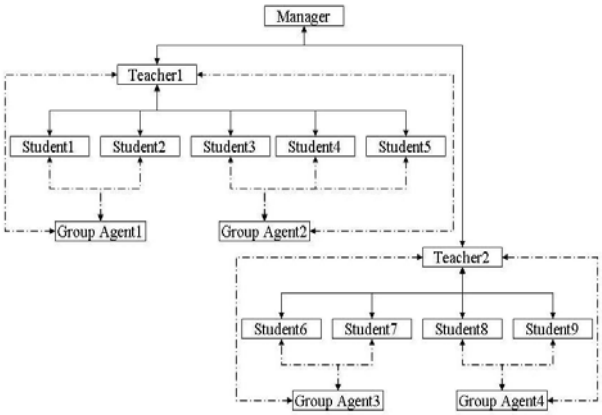

Figure 2: I-MINDS Agents and Topology

Intelligent agents are autonomous and can operate robustly in rapidly changing, unpredictable, or open environments. With these intelligent agents serving and catering to students' unique needs and behaviors, students will be able to participate in a computer-supported cooperative learning (CSCL) environment actively rather than listening to the lectures passively as in a traditional large or distance classroom. Currently, I-MINDS has three types of intelligent agents: (1) teacher agents, (2) student agents, and (3) group agents. A teacher agent, interacting with a teacher, is responsible for disseminating information streams to student agents, maintaining profiles for all students, assessing the progress and participation of different students, ranking and filtering of the questions asked by the students, and managing the progress of a classroom session. A student agent, on the other hand, mainly works as a personal helper to the student. The student agent manages the communication channels among students and between the teacher and the students. The student agent also presents the learning material to the student and forms coalitions with the other students for collaborative learning. The group agent forms and conducts structured cooperative learning such as the Jigsaw model [1], monitors and facilitates group activities.

3.1 Teacher Agent

In I-MINDS, a teacher agent has a graphical user interface (GUI) front-end, two sets of modules, and a database, as shown in Figure 3. A teacher agent interacts mainly with an instructor. It also sends instructions to the student agents, maintains student profiles, and receives questions from the student agents.

The GUI is equipped with various tools to create a classroom environment. For example, an instructor can capture and transmit desktop screenshots/slides to the class in real-time. An instructor can also communicate through the GUI with the students using text or audio/video using the message passing interface and video channel respectively [14].

The content-dependent module set of the teacher agent has a list of weighted keywords for a particular subject topic, rules and heuristics for ranking student questions for a particular course, and student profiles for a particular classroom. The content-independent module set of the teacher agent has a repository

mechanism to allow the storage and access of the knowledge bases used in the content-dependent module set. It also has reinforcement learning mechanism, associated with question processing,, to allow an instructor to implicitly "teach" the teacher agent how to rank questions better, as will be discussed in Section 4. There is also a Jigsaw support module that supports the structured cooperative learning Jigsaw model [1, 2], to be discussed as well in Section 4.

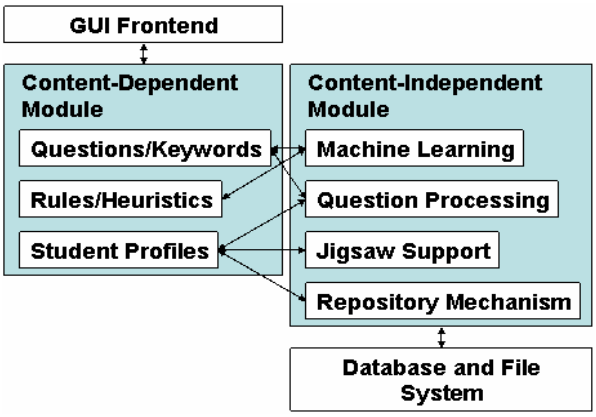

Figure 3: Teacher Agent

3.2 Student Agent

In an I-MINDS supported classroom, a student agent serves a unique student, and, similar to a teacher agent, it also has a GUI front-end, two module sets and a database as shown in Figure 4. A student agent primarily interacts with a student. It also exchanges information with the teacher agent and the group agents.

The student agent first allows for student login and course registration through communicating with the manager and the teacher agent, respectively. The student agent then acts as a medium: displaying the instructional materials received from the teacher agent to the student and relaying information from the student to the teacher agent.

In the content-dependent module, there are locally archived course materials and questions asked by the student and received from collaborative buddies [16]. Each student agent keeps a copy of profiles of all other students in the same class and synchronizes these profiles in real time with the teacher agent. The profiles are used as an important criterion by the student agent to automatically construct and refine the buddy groups. A student's buddy group is one that the student relies on to collaborate in forums and "idea sketching". This capability [15] can be turned on/off by the student.

When a student asks a question or performs some kind of collaborative activities (e.g., initiates a forum discussion or participates in sketching out ideas), his or her profile is changed and subsequently updated with the teacher agent and other student agents. The change might trigger other student agents to recruit the student to join their buddy groups. Thus, a buddy group is dynamic. Further, if a student is not responsive to a buddy group that he or she is a member of, he or she can be dropped from the group. Hence, more responsive students will be approached more frequently than the others. The student agent also adjusts its heuristic rules according to the current classroom environment. For example, in a course in which students are very active in collaborative learning in every classroom session, a buddy who has not been active for the entire session may be dropped.

Error! Objects cannot be created from editing field codes.

Figure 4: Student Agent

In the content-independent module, the tracking component tracks all activities and progresses of the student's learning and collaboration. For example, I-MINDS provides a digital forum and a digital white board for students to communicate and collaborate. The digital white board facilitates "idea sketching". All messages posted in the forum and activities on the digital white board are tracked and analyzed by the student agent. The tracking component also tracks the student's attendance. If the student misses part of a class session, the student agent contacts the teacher agent, finds the archived course materials for the missed time period according to the timestamps and the syllabus, and reminds the student about the missed lectures. All the tracking results are sent to the teacher agent and factored into the student's profile.

3.3 Group Agent

In I-MINDS, a group agent is activated when there are structured cooperative learning activities. Structured cooperative learning involves specified activities that explicitly require students to cooperate. Currently, I-MINDS implements the Jigsaw model [1], as will be discussed in Section 4. Since a group agent works behind the scene, it does not have a GUI front-end. Like the teacher and student agents, it has two content module sets and a database, as shown in Figure 5.

To support structured cooperative learning, the content-independent module set is capable of forming groups (or coalitions) of students based on their profiles, evaluating student perception of teamwork and other members through online surveys, tracking student participation, and improving its heuristics in monitoring and forming better groups. More will be discussed about the coalition formation module in Section 4.

The content-dependent module performs similar tasks as those discussed in previous sub-sections, archiving group activities (tasks and subtasks), and storing specific rules, heuristics and student profiles.

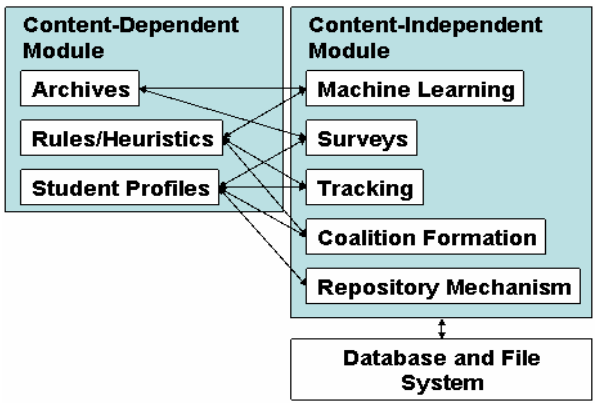

Figure 5: Group Agent

4. Intelligent and Multiagent Modules

In this section, we will discuss several key modules that makes our I-MINDS intelligent: automated question ranking that scores each question in real-time and ranks them, question grouping that classifies questions into similar groups based on their utterance classification and keywords, student profiling that keeps tracks of how each student performs in the classroom, cooperative student learning support implementing the Jigsaw process, and coalition formation that builds and refines the "buddy group" of each student.

4.1 Question Ranking

Question ranking is a key feature of the Question Processing module shown in Figure 2 that allows the teacher agent to manage large or distance classrooms for the instructor. When questions are asked, the teacher agent scores each question based on a set of keywords and heuristics. Keywords are subject-topic specific and weighted. Heuristics are course-specific. For example, a question asked by a student with a high-score profile will be given a high score; a question asked by a student who has never asked a question before will also be given a high score to encourage the student to ask more questions in the future; and a "why?" question is scored higher than a "what?" question. After scoring, the questions are ranked and displayed to the instructor. The instructor may choose to answer or discard a question. This is how the instructor's actions trigger the reinforcement learning mechanism of the module. When the instructor chooses a lowly-ranked question over a highly-ranked question to answer, the teacher agent takes this as an indication that it has ranked the question incorrectly. It thus traces back to the heuristics and keywords that have contributed to the high score of the question and lower their weights; likewise, it increases the weights of the heuristics and keywords that have scored the question low in the first place. Thus, by answering and discarding ranked questions, the instructor implicitly teaches the teacher agent how to better score and rank the questions. Further, the Question Ranking feature also parses and extracts keywords from the questions. Questions that are answered trigger the learning of these keywords. As a result, the teacher agent is able to add new keywords to the list of keywords, effectively building and refining important keywords for specific courses and subject topics. Details of this module can be found in [9].

4.2 Question Grouping

Question grouping is a key feature of the Question Processing module shown in Figure 2 that allows the teacher agent to address multiple similar questions together and profile students who ask similar questions. Future applications of this feature include automatically generated and answered Frequently Asked Questions (FAQs).

Question grouping is based on question classification and keyword matching. To achieve question classification, we adopt the *utterance classification* approach in the AutoTutor [3]. We use the ApplePie parser [11] and the utterance classifier program of AutoTutor [10] to classify a question into one of twelve classes such as Contribution, Discovery, and so on. This classification feature also allows the group agent to monitor the roles of group members in group discussions. Two questions are also considered similar if they share a high percentage of keywords.

4.3 Student Profiling

A student is profiled by I-MINDS' agents in several ways. First, student-instructor interactions are profiled mainly based on the quality of questions that a student asks. Based on the grouping of these questions, students can also be profiled relative to others in terms of compatibility. Second, student-student interactions are profiled through the monitoring of a buddy group. This profiling process is carried out by a student agent from the viewpoint of the student it serves. That is, the student agent keeps a profile of its student's buddies in terms of their responsiveness in collaborative activities (forums and digital whiteboard). These include the number of messages sent, type of messages, frequency of messages being sent, time spent on "idea sketching", the number of times a student is dropped from a buddy group, and so on. Third, group interactions are monitored by the group agents during structured cooperative learning. These include the number of messages sent, types of messages, self-reported teamwork capabilities, peer-based evaluations as a team member, and so on. The teacher agent collects the student-student and group profiles from the student and group agents. The group agent does make use of the student-student profiles to help form coalitions.

4.4 Coalition Formation Module

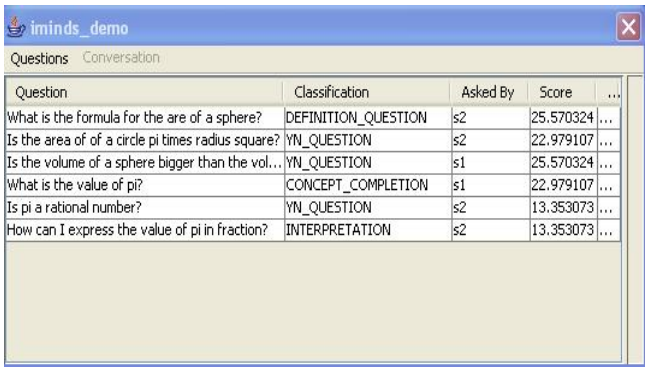
To support the Jigsaw learning model we have designed an auction-based learning-enabled coalition formation algorithm called VALCAM that combines automatically tracked collaboration activities with subjective peer-based evaluations of a student's performance in structured cooperative learning.

In VALCAM, the teacher agent acts as a coordinator or the coalition formation process and makes global decisions, such as, what should the least number of members in a coalition be, how long should the coalitions last, how the performance of each coalition should be evaluated, etc. The group agents then manage the coalitions. Each group agent monitors the performance and activities of the members of its assigned group. After the coalition has completed their tasks, the group agent also evaluates the performance of each student agent as a group member.

VALCAM algorithm is based on reinforcement learning of the student agents. In the beginning of every session the teacher agent chooses a few students and then initiates the group formation. During the group formation process, each student agent bids—an iterative Vickrey auction—to join its favorite group based on

virtual currency earned from previous Jigsaw activities. Once the groups are formed, the student agents work with their group members to complete tasks assigned by the instructor. Finally, when the assigned task is completed, the student agents are rewarded with virtual currency based on their individual performance and their performance as a group member through surveys of their peers' evaluation of the student. Students who performed well will receive more virtual currency, allowing them to more successfully bid for their favorite groups in future sessions. Details of this algorithm can be found in [5].

5. REALIZATION of I-MINDS



We have implemented I-MINDS in Java (SDK 1.4.2). We have used Java's socket functionalities to establish communication among agents, Java's swing class to create interfaces. Furthermore, we have used Java's JDBC technologies to connect to our MySQL database repositories to store and retrieve all data. We have also used the Macromedia Flash© Communication Server to establish audio/visual link between the teacher and the students. Figures 6 and 7 show the interfaces of the teacher and student agents.

Figure 6(a) shows the teacher agent interface. The basic buttons allow the teacher to send a page (basically a snapshot of what is on the desktop of his or her computer), modify a page with full editing capabilities (draw, write, etc.), create a blank page and build one from scratch, to bring up statistics on the students ("stuMng"), to log out, and to bring up or close the Q&A interface (QuestionList). It also has two menu groups. The "Jigsaw" menu group allows the instructor to oversee the Jigsaw process, such as creating a task and its subtasks, specifying the times allotted for each Jigsaw phase, and making sure that all phases are started and terminated correctly. The "Jigsaw Group" menu group allows the instructor to oversee each group's activities and monitor how group members are interacting (via the forums and digital whiteboards).

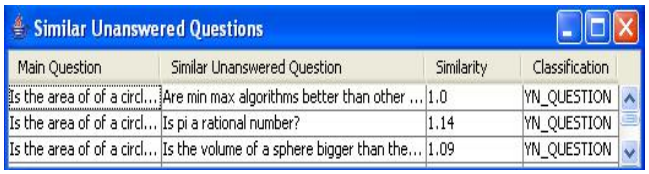


Figure 6(b) shows the popped up Q&A interface for the teacher agent. Each question is displayed with its type classification, the student who asked the question, and a score. The instructor then could sort the questions by clicking at a specific column heading. In Figure 6(b), the questions are sorted by their "scores", where the scores are computed using the design as discussed in Section 4.1. The instructor may also click on each question to bring up a detailed information window that displays the entire question and the profile of the student who asked the question. The instructor may also click on each question to "discard" or "answer" it, effectively "teaching" the teacher agent to learn about the inappropriate or appropriate questions. The Q&A interface also has a menu group "Questions" that allows the instructor to bring up "similar unanswered questions" of a question. Figure 6(c) shows the graphical user interface of this component. It lists the main question, the similar unanswered questions, the similarity scores, and the type classification. This is done through the question grouping design previously discussed in Section 4.2.

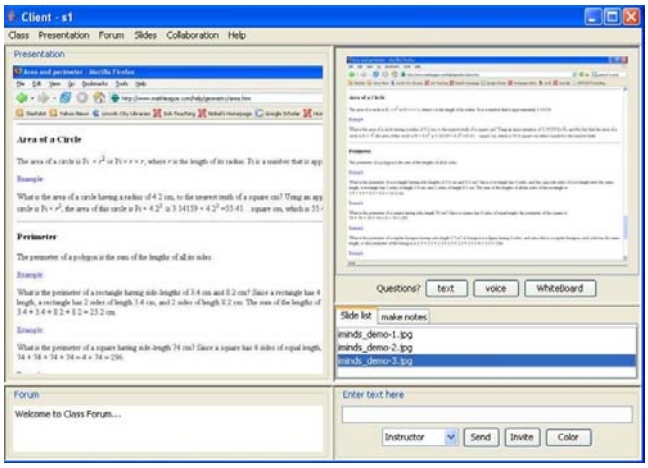
(a)

(b)



(c)

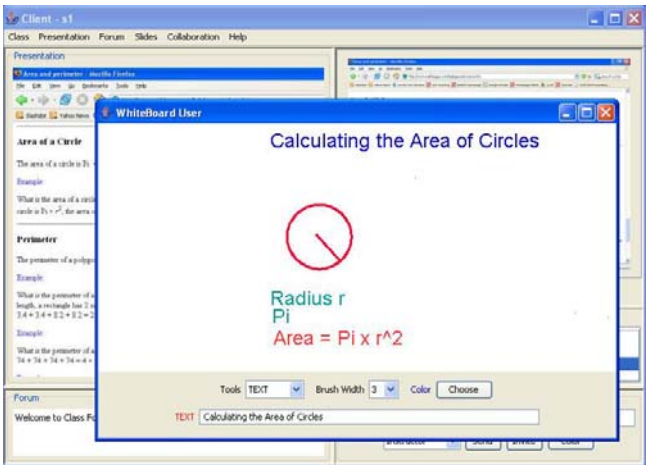


Figure 6: Teacher agent interface (a) the teacher agent interface, (b) the teacher agent's popped up Q&A interface, and (c) the teacher agent's popped up Q&A interface component that deals with question similarity

Figure 7(a) shows the full-feature student agent interface. It has four quadrants. The size of each quadrant is adjustable by moving the borders. The top-left quadrant is the "presentation quad" that displays any document (e.g., a presentation slide, a web page, or a text file, an image, or even a snapshot of the computer desktop) that the instructor sends to the students. The top-right quadrant is the "housekeeping quad" that allows a student to bring up a particular archived document, ask a textual or audio question to the instructor, and invoke a digital whiteboard. It also has a list of archived presentation pages. The bottom-right quadrant is the "text entry quad" that allows a student to type and send messages to various groups of recipients. It also allows a student to invite another student agent to be in the "buddy group" and change the color of the student's messages. Finally, the bottom-left quadrant is the "forum quad" that displays all the messages received by the student and the student agent, in color-coded texts.

Figure 7(b) shows the student agent interface with the invoked digital whiteboard. It allows students to draw and write on the board simultaneously through their student agents. Further, it has a "control token" that a student may grab such that he or she can draw and write on the board while the others cannot. This allows a student to be an active contributor while others in the buddy group "watch" or "listen" to what the student is going to contribute. The student may then release the token to allow for group contribution to resume.

6. Results

6.1 Pilot Study

To determine the potential impact of I-MINDS on student learning, a pilot study [12] was conducted in May 2003 where the tool was used by subjects in a controlled experiment to assess what impact it had on student learning of Global Information Systems (GIS) content. GIS technology can be used for scientific investigations, resource management, and development planning.

In this study, all sessions were taught by the same instructor. There were 20 undergraduate and graduate student participants, divided into two groups. The *control* group was conducted like a traditional classroom, with the instructor and the students in the same room. The *treatment* group was conducted as a distance classroom where the instructor and the students were in separate rooms and their only communication channel was through I-MINDS.

All students took a pretest that would serve as a baseline score. Then, each group was given two 1-hour sessions. Session 1 discussed basic GIS topics and session 2 discussed advanced GIS topics. After each session, each student was required to take a post-test. The instructional content was the same for both groups.

Results from the two testing sessions were encouraging. Here we outline the results as reported previously in [12].

Although there was a slight difference in the means of the experiment and control groups for Test 2, this difference was not statistically significant ($p > .05$), and *the amount that the treatment group improved from the pretest to the posttest was nearly twice that of the control group.*

Comments from the university professor who used I-MINDS in teaching both of the content lessons were also encouraging. He indicated that the teaching tool was very easy to learn and use. He also said that the tool could enhance distance learning, especially by making it possible for building an archive of information that could be accessed "on-demand" by students. The instructor also noted that questions asked of him via I-MINDS tended to have higher quality, reflecting a deeper understanding, and demand a richer response than those questions posed during the control sessions.

Details of this pilot study can be found in [12].

6.2 Deployment with Jigsaw

In Spring 2005, we deployed I-MINDS in the laboratory of an introductory computer science course at the University of Nebraska. The course is CS1, the first core course for computer science and computer engineering majors in the Computer Science and Engineering Department. The course had three 1-hour weekly lectures and one 2-hour weekly laboratory sessions. In each lab session, students were given specific lab activities to experiment with Java and practice hands-on to solve CS problems. In Spring 2005, there were three different lab sections, each with about 20 students.

Our study utilized two sections. In the control section, students worked in Jigsaw cooperative learning groups without using I-MINDS. Students were allowed to move around in the room to join their Jigsaw groups to carry out face-to-face discussions. In the treatment section, students worked in Jigsaw cooperative learning groups using I-MINDS. Students were told to stay at their computers and were only allowed to communicate via I-MINDS. With this setup, we essentially simulated a distance classroom environment.

For each lab, the students were given a lab handout with a list of activities—thus, a lab is a task and its activities are the subtasks. We conducted the study for three weeks, covering topics in debugging and testing, Unified Modeling Language (UML), and recursion.

The students of both the control group and treatment group were required to complete the tasks and subtasks in the four Jigsaw Phases. Table 1 shows the four Jigsaw phases with the allocated amount of time.

In each section, the instructor announced the main groups. In the control section, this was done manually. In the treatment section, I-MINDS automatically performed this using its VALCAM algorithm (Section 4.5). Once the main groups were formed, the teacher agent formed the focus groups by randomly selecting students from the main group. After the focus groups were formed, every focus group was assigned one subtask randomly.

After the subtask assignment the focused exploration phase was started. In this phase the three Jigsaw Phases were carried out in order. During these three phases the student agents and the group agents monitored and controlled the activities of the students and the student groups respectively. After the three Jigsaw Phases were executed, all the students filled out the Peer Rating Questionnaire and Team Based Efficacy Questionnaire and took a 10-minute post-test. This 10-minute post-test score was used as the measure of student performance in terms of understanding the topic of the lab. Details of this process can be found in [13].

Table 1: Time allocations of Jigsaw phases

Jigsaw Phase	Time (min)
Introduction	15
Focused Exploration	30
Reporting and Reshaping	20
Integration and Evaluation	20

Table 2 shows the post-test scores of the three sessions for the "Control" (i.e., Jigsaw without I-MINDS) and "Treatment" (i.e., Jigsaw with I-MINDS) sections. The results indicate that students using I-MINDS for the Jigsaw activities were able to obtain comparable and even better post-test scores. We had initially hypothesized that the students in the control section would perform better than the students in the treatment section simply because the students in the former would have a chance to discuss face-to-face and were able to use paper and pencil to draw and share the same computer screen during the stages 2 and 3 of the Jigsaw process. On the other hand, I-MINDS, still lacking user-friendly GUI, had been expected to hinder such free, natural interactions among students, leading to ineffective collaborations. Thus, the result had not been expected. Students in the Treatment section performed better than the students in the Control section in the later two sessions. Further, students in the Treatment section also achieved better standard deviation—meaning that these students' post-test scores were more tightly clustered than those of the Control section. Upon closer analysis, we suspect that the act of typing and communicating through the forum and digital whiteboard of I-MINDS forced the students to articulate explicitly their thoughts and focused their attention to the tasks at hand. This in turn improved student understanding of the subject matter.

Table 2: Student performance for the Control (Jigsaw only) and Treatment (Jigsaw w. I-MINDS) sections

Peer Rating Questionnaire Results				
Week	Control Section		Treatment Section	
	Mean	Std. Dev	Mean	Std. Dev
1	42.02	2.68	35.60	5.97
2	39.06	7.05	33.30	8.65
3	39.90	4.80	38.59	6.34

The results were very encouraging: without face-to-face interactions, students carried out their I-MINDS-supported Jigsaw tasks and performed relatively well in individual post-tests.

Next, we look at the surveys in terms of peer rating and team-based efficacy. These surveys were conducted in both sections after each lab session. Tables 3 and 4 show the results. The *peer rating* average is the average peer rating scores that each student gave to his or her group members. As evidenced in the scores, students in the Control section rated their peers better than the students in the Treatment section. This is possibly due to the face-to-face interaction. After all, students interacting through I-MINDS could not enjoy the advantages of face-to-face interactions such as facial expressions, the spontaneous free-flowing of ideas, and more immediate feedback in their discussions. This observation indicates that I-MINDS still lacks sufficient graphical user interface and multimedia capabilities to fully capture real-time characteristics.

The team-based efficacy was collected after each lab based on a set of questions. It measured how a student viewed how well its group had performed. Once again, students in the Control section approved of their team-based activities more than the students in the Treatment section. Since there was no difference in the scores in tasks for the Control and Treatment sections, and that students in the Treatment section had more similar post-test scores, that means this perception had been likely biased by the ease-of-use (or the lack thereof) of I-MINDS.

Table 3: Peer Rating Questionnaire Results

Peer Rating Questionnaire Results				
Week	Control Section		Treatment Section	
	Mean	Std. Dev	Mean	Std. Dev
1	42.02	2.68	32.45	5.78
2	39.06	7.05	37.72	4.60
3	39.90	4.80	34.63	8.08

Table 4: Team Based Efficacy Questionnaire Results

Team Based Efficacy Questionnaire Results				
Week	Control Section		Treatment Section	
	Mean	Std. Dev	Mean	Std. Dev
1	29.87	2.51	27.72	5.08
2	31.86	3.48	29.20	2.78
3	30.08	3.02	28.25	4.02

Looking at the data tracked by the I-MINDS agents and comparing them to post-test scores, we observe the following. First, students rate their peers subjectively: average peer rating that a student gave to his or her peers is negatively correlated to his or her post test score with a correlation of -0.63. Second, students who do well in the post-tests tend to send long messages with a correlation of 0.51.

7. CONCLUSION

We have described a computer-supported cooperative learning system called I-MINDS that uses multiagent intelligence. We have discussed the structure and functionalities of the different agents in I-MINDS. Then we have described the intelligent and multiagent modules that allow the teacher, group, and student agents to collaborate to actively support student-student and student-instructor interactions. To demonstrate the effectiveness of I-MINDS, we have presented the results of our pilot study and also the results of incorporating Jigsaw Framework in I-MINDS in real-time classroom situations.

The results of the pilot study shows that the instructor and the students can both use I-MINDS effectively as a framework for delivering distance education.

Furthermore, the results of our CS1 lab deployment shows, although face-to-face activities were perceived to be better by the students, I-MINDS-supported activities were able to produce better or comparable post-test scores and were able to yield more similar scores among the students.

Future work includes continued deployment of I-MINDS in the classroom, improvement of the GUI front-end for the teacher and student agents to better support collaborative, real-time programming, and extension of I-MINDS to work more seamlessly with existing Interactive Design Environments (IDEs). Additional research includes the refinement of the VALCAM algorithm to more fairly synthesize subjective peer-based evaluation and agent-tracked empirical data in determining the amount of virtual currency rewarded to each student.

8. ACKNOWLEDGMENTS

The I-MINDS project was first developed with a seed grant from the National Center for Information Technology in Education (NCITE). It was later sponsored partially through an NSF SBIR grant DMI-044129. The authors would like to thank Phanivas Vemuri, Suresh Namala, and Xuesong Zhang for their programming work.

ABSTRACT

We report on our ongoing practical experience in designing, implementing, and deploying PTIME, a personalized agent for time management and meeting scheduling in an open, multi-agent environment. In developing PTIME as part of a larger assistive agent called CALO, we have faced numerous challenges, including usability, multi-agent coordination, scalable constraint reasoning, robust execution, and unobtrusive learning. Our research advances basic solutions to the fundamental problems; however, integrating PTIME into a deployed system has raised other important issues for the successful adoption of new technology. As a personal assistant, PTIME must integrate easily into a user's real environment, support her normal workflow, respect her authority and privacy, provide natural user interfaces, and handle the issues that arise with deploying such a system in an open environment.

1. INTRODUCTION

Over the past two-and-a-half years, we have been developing the Personalized Time Manager (PTIME), an agent with the goal of helping a human user manage her temporal commitments in a consistent, integrated manner over an extended period of time. While automated meeting scheduling has been well studied in the research community [8, 25, 23, 17], the resulting systems have rarely been adopted. We can point to two main reasons. The first is a failure to take into account the intensely personal nature of the human time management problem. Most individuals, even the busiest knowledge workers, are reluctant to relinquish control over the management of their own time. Further, people have different preferences and practices regarding how they schedule their time, how they negotiate appointments with others, and how much information they are willing to share when doing so. To be successful, a time management solution must thus address these basic issues of authority, privacy, and preferences. The second reason is that adoption of such a system is contingent on its practical usability—including important user interface issues—within a real-world deployment. While we do not claim to have fully resolved either one of these obstacles, this paper describes our experience and progress in overcoming these challenges.

Each PTIME agent is an autonomous entity that works with its user, other PTIME agents, and other users, to schedule meetings and commitments in its user's calendar. It can negotiate with other agents on behalf of its user, provide her with useful information about upcoming events while protecting her privacy, and learn her preferences. To achieve these goals, PTIME integrates commercially available calendaring tools and user interface technology with state-of-the-art algorithms for constraint satisfaction (to solve the underlying scheduling problems and find preferred schedules), goal-directed process management, and preference learning.

PTIME is part of the CALO project, a large-scale effort to build an adaptive cognitive assistant situated in the office environment [15]. A CALO agent is designed to support its user in various ways, including project and task management, information collection and organization, and meeting preparation and summarization. In October 2005, the CALO project started its third year of research and development. In Year 1, the theme was *integration*—assembling a large collection of independently developed pieces of software into a single system. CALO 1.0 was highly distributed, with the CALO modules implemented on top of the Open Agent Architecture (OAA) [4] and with integration primarily at the level of communication. CALO 1.0 required multiple computers to run and provided only the most rudimentary desktop functions. In Year 2, the theme was *usability*—integrating the applications within a common architecture that could run on a single laptop computer. CALO 2.0 was reborn within the IRIS desktop environment [5], which featured a semantic knowledge base, based on the CALO ontology, and shared by a suite of common desktop applications, including email, calendar, web, file system, and chat. Through the shared knowledge base, IRIS supported the sharing of information between the disparate applications, enabling CALO to better control and coordinate its assistive behavior. With CALO 2.0, users could read email, file documents, schedule meetings, organize bookmarks,

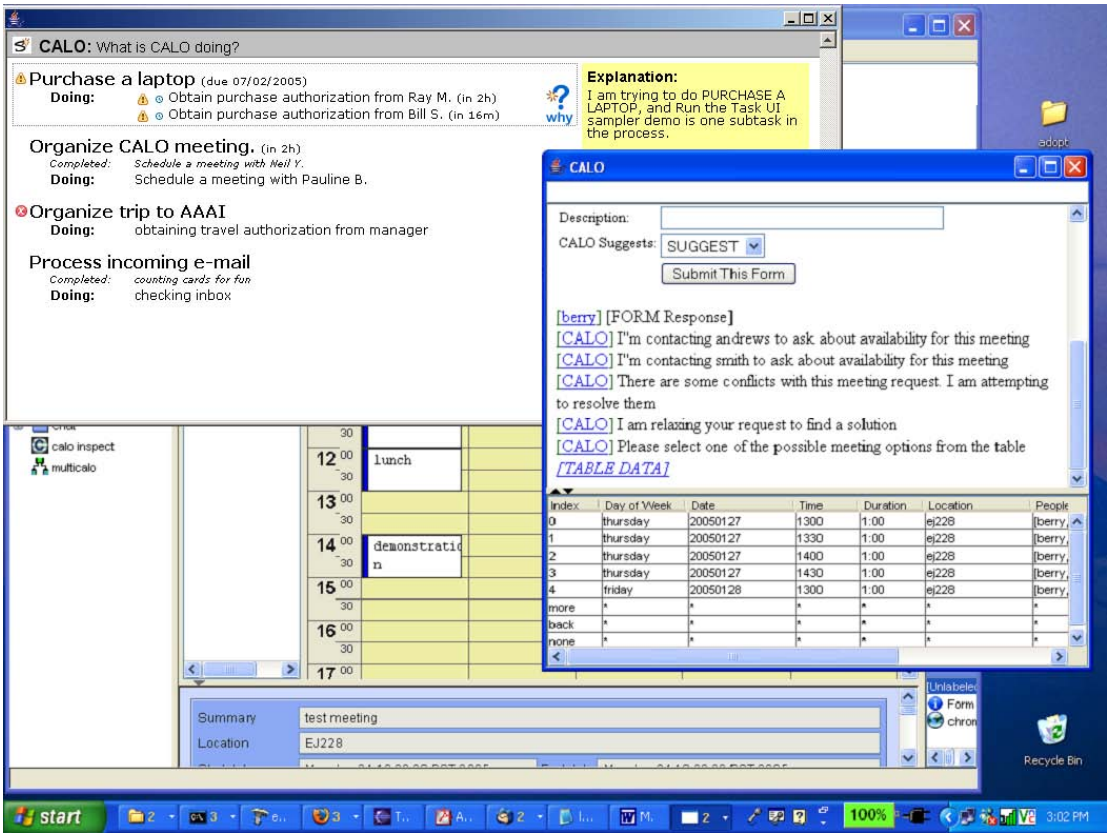

Figure 1: Screenshot of Year 2 PTIME interface

and perform various other everyday office activities. However, there remained obstacles to its widespread use, such as cumbersome user interfaces and computational inefficiency. The theme for Year 3 is *usefulness*—providing users with a CALO that is not only usable but can also truly help make busy office workers more efficient and effective in their everyday lives.

This paper describes lessons learned from the development and deployment of PTIME within the CALO project. We begin by presenting the PTIME system, its local agent architecture, and its deployment in a multi-agent setting (Section 2). Next, we present the challenges we faced and the solutions we implemented to successfully field a PTIME agent in CALO 1.0 and 2.0 (Section 3). Then we discuss other issues that arose post-deployment, through actual use by real users, and we present the modifications we made to address these issues prior to the final, annual release (Section 4). We then discuss our plans for CALO 3.0, including the modifications to existing features and implementation of new features designed to address known issues as well as new challenges (Section 5). We conclude with a discussion of related work and a summary of lessons learned (Sections 6 and 7).

2. PERSONALIZED TIME MANAGEMENT

Despite the proliferation of calendar tools to organize, display, and track commitments, most individuals still expend a considerable amount of effort managing their schedules.

The research community has primarily focused on automated meeting scheduling: finding feasible timeslots for meetings given a set of requirements on participants, times, and locations. Work in this area can be generally divided into *open* and *closed* scheduling systems [8]. In an open system, individuals are autonomous, responsible for creating and maintaining their own calendars and meeting schedules. They generally operate in an unbounded environment, without any obligation to a single organization. In a closed system, by contrast, a consistent and complete global calendar is maintained. While closed systems are more commonly studied and marketed because they provide a controlled and known setting, they are rarely adopted in a uniform way because users seldom live in a completely closed environment. However, open scheduling systems pose challenges of their own. An individual may not wish to share all of her schedule, or may choose not to participate in a meeting. Different individuals will have different scheduling preferences. Without centralized control to balance the constraints and preferences of all involved parties, how does an open system respect individual preferences without devolving into completely selfish agents that result in greatly suboptimal schedules? Further, while users may not wish to cede all control to an autonomous assistant, they may let their agent automate some processes.

CALO exists in such an open, unbounded environment, where these issues of privacy, authority, adjustable autonomy, cross-organizational scheduling, and uncertain availability of participants abound. PTIME is an autonomous agent integrated within a larger CALO agent [15]. Each CALO/PTIME agent is itself composed of a set of internal agent components linked within the OAA agent architecture; we will refer to these as CALO/PTIME components.

2.1 The Distributed Scheduling Task

The distributed scheduling task that PTIME addresses fits into the continuum between fully competitive and fully cooperative agents. PTIME agents in collaboration with their users are autono-

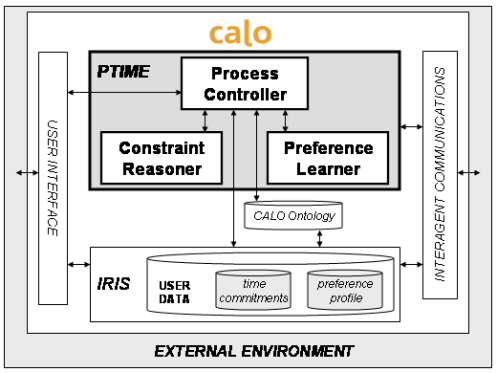

Figure 2: Architecture of Year 2 PTIME agent

mous, self-interested entities that manage their user's own calendars. They are in effect single-calendar schedulers dependent on other agents to coordinate shared calendar entities. The scheduling task is viewed as a shared goal of the user and the agent. For a PTIME agent, global utility is thus secondary to maximizing the local utility of its user, which typically does include a component valuing cooperation with others [22]. This is in contrast to most distributed scheduling systems [25], which aim to maximize some notion of global schedule quality (e.g., [16]).

Thus, PTIME supports two forms of collaboration: between itself and its user and between itself and the PTIME agents of other users. The collaborative scheduling process is separated from the scheduling algorithms, to enable interaction with the user and other PTIME agents. This interaction forms the framework for learning and adjustable autonomy.

The collaboration between PTIME and its user is illustrated in Figure 1, which is a screenshot of the PTIME interface for the deployed CALO 2.0 system. The collaboration is seen in the "CALO Chat" window in the foreground (right). In the top-left window, CALO is reporting on its activities in response to a user request for explanation. In the background, the calendar view of the IRIS desktop environment can be partially seen. In addition to a traditional form-based input mechanism, CALO has a restricted natural language (NL) input that allows the user to interact by means of spoken or typed input, for instance "meet with Alice about integration next week". CALO also has multi-modal output, including leaving spoken messages on the user's cellphone.

2.2 Local Agent Architecture

Figure 2 depicts the architecture of PTIME in relation to the relevant components in IRIS and CALO. We limit our discussion to the three PTIME components this paper primarily involves; for a more complete discussion of the various components of PTIME, see [3].

- At the heart of PTIME is its *Process Controller*, a SPARK agent that captures possible interactions between the user and other agents in the form of structured decision points. SPARK [19] is a Belief-Desire-Intention agent framework that supports both goal-directed and reactive behavior. The Process Controller manages PTIME's processes, tasking and coordinating the activities of the Constraint Reasoner and Preference Learner, and managing interactions with the rest of CALO and the external environment. Alternative processes reflect different scheduling strategies, preferred by users or organizations, or applicable in different contexts. For example, different processes would correspond to scheduling a set of interviews with available interviewers versus allowing interviewers to sign themselves up. The SPARK framework supports agent advisability [20], and users can give advice to PTIME regarding preferred actions as well as explicit scheduling preferences. SPARK also supports adjustable autonomy, and users can explicitly or gradually delegate certain decisions to PTIME for autonomous execution.

- The basic scheduling process employs a unified representation for temporal and nontemporal constraints, and preferences. Unlike standard calendaring systems, as part of CALO, PTIME has access to rich information about the user's other activities. Thus, even when scheduling simple meetings, the Constraint Reasoner considers such issues such as workload and task deadlines, to ensure, for instance, that the user is not over-committed. The Constraint Reasoner can also explore alternative conflict resolution options using relaxation, event bumping, and explanation techniques [14].

- A core design goal of CALO is personalization. PTIME evolves by learning preferences through its *Preference Learner*. The Preference Learner in PTIME is an unobtrusive, online learner where the user's selections from suggested alternatives provide feedback to the learning algorithm. Learning has so far focused on temporal scheduling preferences over when meetings should be scheduled (e.g., time of day, day of week) and over the nature of the resulting calendar (e.g., degree of fragmentation). PTIME learns these preferences for under-constrained problems. We have showed how active learning with support vector machines (SVM) can be used to improve performance [11]. Learning a user's preferences enables PTIME to suggest increasingly desirable schedules to the user, thus providing more effective assistance.

The components of a PTIME agent utilize a variety of programming languages: the Process Controller is implemented in SPARK, the Constraint Reasoner in SICStus Prolog [27], and the Preference Learner in Java, with its underlying SVM learner being SVMLight [13], which is implemented in C. The different components, deployed as OAA agents, communicate with each other through the mechanisms provided by the OAA architecture [4].

3. DEPLOYMENT CHALLENGES

Deployment of the PTIME calendaring system required overcoming several multi-agent integration issues. We discuss them in this section, together with some of the deployment constraints imposed by the CALO personal assistant system.

3.1 Calendar Integration

Most fundamentally, a calendar scheduling system must be able to update and maintain a user's calendar. PTIME uses the *iCalendar* specification [7] for compatibility with other calendar tools on the market. An initial implementation used Microsoft Outlook, which was instrumented so that PTIME could query information from the calendar; add, delete, or modify calendar events; and listen to calendar actions performed by the user. Initial experiments with test users indicated this was a workable integration. One problem with this implementation, however, was that availability information was inaccessible when one or more users did not have their desktop environments connected.

A second integration was required with the introduction of the CALO user environment, IRIS [5], which includes a calendar application for accessing a centralized commercial calendar server.

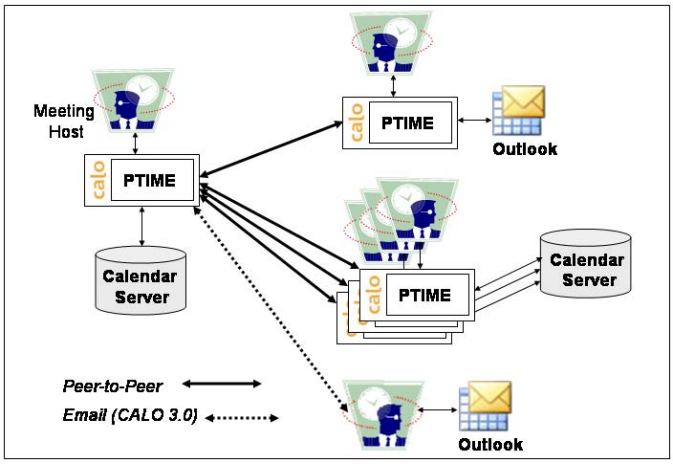

Figure 3: Communication modes between PTIME agents

The IRIS calendar application allowed PTIME to query user calendar information using the Glow API [1], but many users preferred to continue using their familiar calendaring tools, such as Outlook or Mozilla, that do not store their data on the centralized calendar server. There were also data synchronization issues, since PTIME could query the server for a participant's calendar status even when that user's CALO was unconnected.

One particularly challenging architectural constraint was that we could not make modifications to the calendaring user interface in IRIS. A core CALO 2.0 design decision was to keep "CALO actions" completely separate from the regular operations of the IRIS applications. Instrumentation of existing dialogs and development of external user interfaces were allowed. The result of this architectural constraint was two separate interfaces for adding meetings to the calendar: the standard "Add meeting here" Outlook-style dialog within the IRIS calendar application, and a separate CALO interface for scheduling through PTIME.

3.2 Multi-Agent Integration

A PTIME agent must communicate with other people's calendars to gain availability information, and negotiate with other agents to resolve conflicts and commit to calendar changes. Calendars are private; we assume that direct interrogation of other users' calendars is restricted to free/busy timeslots. Other calendars cannot be updated directly without adequate permission. PTIME agents communicate using peer-to-peer messaging or using email (Figure 3). The initial deployments (CALO 1.0 and 2.0) relied only on peer-to-peer communication via message passing. The next deployment will also offer email communication peer-to-peer as well as with the user. Thus, PTIME will be able to schedule with any online participant, whether or not she is running CALO. The protocol adopted for inter-agent negotiation is the following:

- Use direct agent-to-agent communication: resulting action would be governed by the destination's own agent.
- Agent not answering: for availability requests, ask the calendar server for a recent (possibly outdated) free/busy estimate.
- Otherwise: send an email query that could be answered by the human user or the other (PTIME) agent.

This communication protocol exists in a deployed and unbounded environment where not all participants in a meeting may be using PTIME, the shared calendar server, or indeed any automated calendar. In addition, we cannot assume that the participant's contact details exist in the user's address book. During the initial deployment of the system, a simple name resolution system asked the user for clarification of a participant's email address. However, we encountered a problem when a person had multiple email addresses and thus PTIME would duplicate messages. Although we did work around this problem, for current and future deployment we have a two-pronged solution:

- When a CALO agent (of which PTIME is a component) is initialized it sends information to a common name server. This name server stores the contact information for other agents, and this information may be queried by any agent.
- The CALO agent also provides a name resolution capability that allows a participant's name to be resolved to a known person on the name server, in the personal CALO address book, or an email address typed in by the user.

3.3 Knowledge Integration and Advisability

In addition to personal and shared 'contact' information, a personalized time management assistant must also have access to a user's organizational information, institutional rules, and personal preferences. For example, a PTIME agent may schedule a meeting with the user's superior or subordinate using different strategies. PTIME can store locally some of this information, such as scheduling preferences, but it must access other information, such as organizational relations, from the wider CALO knowledge base. PTIME adopts the CALO-wide ontology and query standards.

A foundational requirement for deployment was user–PTIME interaction. Not only must PTIME serve the user's needs in a mixed-initiative fashion [3], but it must also become a more effective assistant over time. It must build trust through its interaction with the user. Thus, PTIME permits the user to provide advice [20] that adjusts the level of autonomy, and permits her to override decisions made by the agent. A specific problem with these simple mechanisms to adjust autonomy was that the users were reluctant to change settings if the system did not provide an adequate explanation of their effects. For example, the user might advise the agent about preferred days of the weeks for meetings, but PTIME did not have the ability to illustrate to the user the resulting preference profile or to explain decisions with respect to those preferences.

4. LESSONS FROM TESTING AND USE

The CALO program is evaluated annually through a SAT-style test administered on a number of CALOs that assist users over some designated period of time. In Year 2, the test involved fifteen users, including some of the authors of this paper, using their CALOs over the period of a week to perform a variety of everyday office tasks, including tending to email, scheduling and preparing for meetings, editing documents, and performing web searches.

In preparation for the test, CALO underwent a standard software development cycle involving a series of releases each featuring increased and more robust functionality. As part of this process, CALO underwent quality assurance testing, including regression and unit tests. Each release was vetted through "dry runs" with real users. The process provided valuable feedback to the research and development teams, validating some design decisions while raising new problems, allowing time to address them before the actual test.

4.1 Different Modes of Use

PTIME was initially designed to schedule meetings on behalf of the user, including accepting or declining meetings scheduled by

other users. However, users turned out to desire PTIME support for at least two other usage modes as well.

First, users often simply wanted to add fully-specified events (e.g., seminars, weekly group meetings) to their calendars regardless of overlaps with existing events. PTIME's standard scheduling interface could be used to add such meetings, resulting in a single alternative being presented for acceptance by the user, with the option to reschedule in the case of conflicts. However, with this solution, what should have been a one-step procedure turned into a multi-step process, because of the verifications required from the user. The offer to reschedule in case of a conflict was also inappropriate for these types of events, which were already scheduled.

The second situation involved scheduling a complete agenda or related set of meetings centered on another person, for example, scheduling an interview for a job candidate. Here, the user's preferences are of no special import, since the schedule is for someone else. There may also be constraints and preferences not just on individual meetings but between meetings: for example, minimizing the free time between meetings so that the visitor is not left idle. We handled this scenario by implementing a separate set of SPARK processes for visitor scheduling, including separate facilities for obtaining the scheduling constraints from the user, and presenting agenda options. This worked reasonably well, and we will continue to do this for CALO 3.0.

This second usage mode also revealed inefficiencies in the Constraint Reasoner. While efficient enough to find alternatives for scheduling one or a few new meetings at a time, the Constraint Reasoner was often unable to efficiently find a solution in the significantly larger search space generated by visitor scheduling scenarios, consisting mostly of temporal constraints. Our solution to the search inefficiency problem was less than desirable: we modified the constraints formulated by the agenda scheduling problem to reduce the size of the search space sufficiently so that the Constraint Reasoner could find a solution if one existed. Clearly, this is only a stopgap solution since it forces users into unnatural and inexact problem formulations. We have solved this problem for CALO 3.0 by using constraint-solving techniques specifically designed for temporal constraints (discussed in Section 5.3).

4.2 Visibility into the Scheduling Process

Scheduling a meeting involving multiple participants can be a somewhat involved process, as it requires gathering availability information for all participants, finding valid solutions or—possibly—relaxing unsatisfiable constraints, before presenting the user with candidate solutions. Early on, it became clear that we needed to give users some method of tracking the scheduling process. Thus, as it undertakes the various tasks involved in scheduling a meeting, PTIME prints simple status messages in the CALO chat window to inform the user of its progress, as seen in Figure 1.

This feedback proved valuable in letting the user track PTIME's progress, particularly when unexpected situations arose. For example, obtaining another person's availability information typically takes a few seconds. In the case of delayed results, whether due to the other person wanting to personally approve all requests or due to inter-CALO communication failure, PTIME could notify the user accordingly, letting her take action if desired.

A related issue is CALO's ability to explain its scheduling decisions. Often, users want to know why CALO is unable to schedule a meeting. We addressed this by providing a minimal set of unsatisfiable constraints [14] when informing the user that a particular meeting request was unsatisfiable. This explanation mechanism also turned out to be particularly useful when debugging the system, exposing, for example, the Constraint Reasoner's flawed expectation that all events have non-zero durations. Similarly, when CALO suggests relaxed alternatives, users often want to know what constraints have been left unsatisfied so that they can make well-informed decisions. We will be extending the explanation mechanisms in CALO 3.0 to cover this situation as well, and linking PTIME's explanations with the broader CALO-wide explanation capability seen in the left-most window in Figure 1.

4.3 Qualitatively Different Schedules

Since our learned schedule evaluation was based on simple weighted sums, the best schedules tended to be clustered together. One of the factors we investigated in our active learning experiments was the presentation of qualitatively different schedules to the user, motivated by the intuition that users would be interested in seeing a variety of schedules and that the resulting feedback would also improve learning. However, as our experiments showed, the greedy approach of showing the best solutions according to the current learned model resulted in the fastest learning [11]. As a result, the fielded system used this approach to select candidates to present.

While most successful for learning, this scheme often resulted in highly similar schedules being presented to the user. For example, it was not uncommon for PTIME to present alternative candidates that began at 9:00, 9:30, 10:00, 10:30, and so on. This was particularly problematic early on, when PTIME had not yet sufficiently learned the user's preferences and was thus unable to present any good schedules within its default presentation set of 15 candidates. In our experiments with synthetic users we had relied on the user's ability to override bad solutions by scheduling the meeting manually. However, user interface limitations (see Section 3.1) prevented such a solution: users could schedule the meeting manually through the regular IRIS calendar interface, but in bypassing PTIME, the learning algorithm could receive no feedback on its suggestions. We believe a second issue is that our synthetic users did not fully represent the different kinds of preferences real users have; in particular, preferences between criteria. We are currently developing a richer, multi-criteria evaluation approach (Section 5.4) that we expect will lead to better adaptation.

4.4 User Interface Issues

Our primary focus for CALO 2.0 was scheduling functionality: encoding the procedures controlling user interaction and the scheduling process, implementing the constraint solver to generate solutions, and developing the learning module to provide personalized scheduling assistance. As a result, PTIME's user interface was functional but not particularly effective. Besides being hard to use, it prevented us from exposing all of PTIME's functionality.

First, PTIME provided a single dialog form through which users could specify a meeting request. This was a particularly poor fit to other scheduling situations. Moreover, it was also a poor fit to basic meeting scheduling, as it required users to specify constraints differently to their normal way of specifying meeting requests.

Second, while users could explicitly state general scheduling preferences to bootstrap the learning process, the mechanism was both cumbersome and unable to handle fine-grained preferences.

Third, PTIME presented its candidate schedules in a table (as seen in Figure 1), completely separate from the IRIS calendar interface. This was primarily due to the architectural constraint of keeping CALO actions distinct from the regular operations of the desktop applications. However, it turned out to be problematic in this case as it not only confused users, but also presented the candidate schedules almost completely devoid of context. Without knowing their existing schedules, users often found it difficult to select an appropriate candidate schedule.

5. ONGOING/FUTURE DEPLOYMENT

The third annual release of the CALO agent system, CALO 3.0, will deploy a new version of PTIME that will address the lessons learned from CALO 2.0 and add new capabilities to the agent. The ultimate goal is to advance the capabilities and interface to a point where people other than PTIME developers and CALO testers find value in using their CALO agent on a daily basis. Below we outline five improvements designed to bring us closer to this goal. CALO 3.0 will be evaluated similarly to CALO 2.0; the increased usability will facilitate the next round of user studies, which, along with daily use, will surely uncover new lessons about developing and deploying user-assistive agents in unbounded environments.

5.1 Multiple Modes of Use

Recall that the PTIME user interface in CALO 2.0 enabled the interactions necessary for PTIME's advanced functions, at the expense of encumbering the user with extra steps for the simple, more common, scheduling scenarios. We are addressing this issue in CALO 3.0 by defining distinct use cases and implementing a different SPARK process for each case, including different input and output facilities in the user interface.

The new version of PTIME will allow users to simply add meetings to their calendars, with or without checking for overlap and communicating meeting information to participants. In the case of overlap checking, PTIME's course of action is still an open issue. Ideally, if the user is looking at the appropriate portion of her calendar, then an overlap should be obvious and the user would not want to be bothered by superfluous confirmation requests or warnings. Instead, a simple highlighting may occur. In the more complex case of multiple participants, we must determine whether PTIME should check for participant conflicts and whether PTIME should pass on the commitment to the participants. PTIME may do background checks for such changes in the user's calendar and warn the user about conflicts with or rejection by other participants.

5.2 Multi-User Scheduling

Our informal user studies confirm that other participants' constraints and preferences often influence the meeting organizer's decisions [22]. When deciding which of many possible candidate schedules to present to the user, PTIME must reason about how each candidate schedule will affect others. This requires PTIME to retrieve from each affected party that person's schedule (as in CALO 2.0), preferences, and probable effects of the proposed schedule. Moreover, reasoning about other participants is required even when communication with another user's agent (CALO) is not available—and hence, should a shared calendar server be in use, even when the information it contains is unreliable (recall Section 3.1). Once a PTIME user selects a schedule from those presented, PTIME must negotiate with the agents of the other parties to resolve conflicts within each schedule. The goal is to remove the burden of much of this reasoning and negotiation from the user, while keeping her informed about the state of the process.

To determine the effect of a particular schedule on others, we are currently integrating a distributed querying mechanism, based on the ADOPT protocol [16], that will obtain a cost reflecting the rescheduling effort required as a result of a proposed schedule. The cost for users who do not respond (i.e., communication with their CALO fails) is estimated using the most recent knowledge about their schedules and their negotiation history.

When the user organizing a new meeting selects a candidate schedule, PTIME invites all other meeting participants, with a justification for the request. All conflicts are then addressed by other users, who will either resolve the conflicts with other CALOs or choose to not attend. Negotiation with the meeting organizer to counter-propose an alternate time is planned for CALO 4.0.

5.3 Improved Constraint Reasoning

Section 4.1 described some of the limitations of the constraint reasoning in the CALO 2.0 system. The current technology will be replaced with a Constraint Reasoner efficient for both finite-domain and temporal constraints [26, 18]. Increased performance improves the user's interaction experience with CALO, and allows PTIME to present more varied candidate schedules (Section 4.3). For instance, in the scenario of scheduling a complete agenda (e.g., for an interview visit) described earlier, preliminary experiments show that computation time can be reduced by orders of magnitude, putting larger multi-event scheduling problems within reach.

Further, the new technology will allow representation of soft constraints, enabling the user to specify, for example, preferred times for meetings, the relative importance of each participant, and events that may partially or fully overlap. In the case where many schedules satisfy all hard constraints, the soft constraints allow computation of schedules that best satisfy the user's preferences. In the case where no schedule satisfies all hard constraints, the soft constraints provide instruction for how to best relax constraints. For example, knowing the relative importance of each meeting participant would guide the Constraint Reasoner to first try omitting an unimportant participant before relaxing other constraints.

5.4 Schedule Evaluation Criteria

For meeting requests other than the simple "Add meeting here" type, PTIME presents multiple candidate schedules to its user. As stated earlier, in CALO 2.0 the candidates were ranked according to the learned schedule evaluation function, a simple weighted sum over schedule features, and a subset was selected for presentation by an active learning mechanism. Based on the results from actual use, informal user studies, and interviews of subjects from the CALO 2.0 test, we determined that this approach was inadequate for a number of reasons. The most important is its inability to express tradeoffs users have in practice: for instance, Pareto optimal schedules that balance two criteria [2].

Based on those same studies, we have identified key criteria that contribute to the user's evaluation of a schedule. These features include satisfaction of the user's general preferences on schedules, specific meeting-request constraints (both hard and soft constraints), perturbation from the previous schedule, and, as noted, the goodness of the schedule according to others. We will use these criteria in a multi-criteria evaluation framework [2] in which the relative importance of each criterion is learned.

When deciding which solution candidates to present, PTIME has multiple objectives: present desirable schedules that the user is likely to accept; present qualitatively different schedules to help the user explore the space of possibilities; and support faster learning of preferences over criteria. The second point is particularly important if the user has not yet formulated what is a 'good' solution to a specific meeting request. Only after the user has elicited in her own mind what is 'good' can we address the other two points, presenting desirable schedules and learning preferences. We are now exploring search techniques that can produce not only a single optimal solution, but also a good set of qualitatively different solutions to meet these objectives. Based on an example critiquing approach, in which solutions are presented to the user to prompt her decision process, we will present schedules designed to maximally stimulate expression of the user's preferences [28]. In conjunction, we are exploring how to vary the diversity of the solutions chosen for presentation based on a measure of entropy of the solution set.

Figure 4: Concept of future PTIME interface

5.5 Collaborative Interface

User feedback from CALO 2.0 reinforces the point that an intuitive and visually appealing user interface (UI) not only enhances human–agent collaboration, but strongly influences whether users are willing to adopt the underlying agent technology. To encourage adoption of PTIME in CALO 3.0, we will redesign the UI to improve the two main tasks: defining a meeting request and viewing/selecting candidate schedules for that request. This new UI is being designed and developed in collaboration with human-computer interaction professionals.

When defining a meeting request, PTIME's interface will allow more expressive, albeit restricted, natural language input. Although specifying preferences such as "prefer Tuesday at 2pm", "Bob is optional", and "can overlap" is possible with dialog form widgets, to include the appropriate widgets for all possible constraints and preferences would result in an overly complex interface, and such interfaces have been found to elicit untrue preferences [28].[1]

When candidate schedules are presented to the user, PTIME will display a collaborative, graphical interface to help the user rapidly understand the key differences among the set of schedules, refine or relax her input constraints, explore alternative solutions, and select a preferred candidate. This will replace the generic text-based table used in CALO 2.0.

Figure 4 shows a mockup of the future interface, including the visualization for presenting candidate schedules. "Overlaps with Coffee" (lower left-corner) indicates to the user that some hard constraints were not fully satisfied; red underlines indicate portions of the user's schedule that had to be rearranged. In a separate editing mode, PTIME will show what rearrangements are compatible with other users' schedules. The top half of the interface displays past actions of both the user and CALO to provide additional context.

[1]Users often fill out all the widgets on the form, even those marked as optional: simply asking whether the user has a preference for a feature can lead to the user having a preference for it.

6. RELATED WORK

While both commercial (e.g., Outlook/Outlook Exchange Server, Sun Java System Calendar Server) and open source (e.g., Zimbra, UWCalendar) calendaring systems abound to support centralized solutions within an institution, as closed systems [8] they suffer from the issues discussed earlier, including resistance to adoption due to loss of control and privacy. Unlike PTIME, they offer a one-size-fits-all solution that does not readily support different calendars, different modes of interaction, and different user preferences—often exhibited in the necessity of an institution-wide mandate to standardize on a particular tool. Also, unlike PTIME, which is part of a much larger cognitive assistant (CALO), these tools are dedicated calendar scheduling solutions that cannot utilize other types of information—such as workloads and deadlines—to better manage the user's schedule. Similarly, tools such as OfficeTracker and GroupReady focus on visualization and facilitating a scheduling process actually performed by a human.

In the applied research community, scheduling agents have been developed for fragments of the tasks with which a PTIME agent assists a user (e.g., [12]). Examples of other scheduling systems that operate in open environments include RCal [23] (arguably the first agent work for this scheduling task), CMRadar [17], and work in preference-aware constraint programming, such as [10].

The CMU scheduling agents RCal [23] and CMRadar [17] both distribute the scheduling problem in a similar way to that of PTIME, and the more recent CMRadar embodies a spirit similar to PTIME. A CMRadar agent helps its user schedule meetings by parsing out meeting information from email. It generates schedule options using a constraint-based scheduler that takes into account user preferences; presents candidate schedules with a graphical visualization; and enters into multi-agent negotiation. CMRadar is designed as a standalone scheduler and is tightly integrated into Microsoft Outlook, while PTIME is integrated into CALO and primarily uses the IRIS interface to access external calendar servers. PTIME is also able to support other individual calendar tools, and schedule meetings with non-CALO-related individuals. In a further architectural difference, CMRadar relies solely on email for inter-agent communication, while PTIME uses multiple modalities, with direct inter-CALO communication as its primary modality. CMRadar uses a passive learning approach to learn user preferences [21], which contrasts with PTIME's online, active learning.

Another mixed-initiative, multi-agent scheduling system is currently deployed in a closed environment to schedule nightly maintenance operations for the Hong Kong metro system [6]. The system provides core scheduling abilities and visualizations that facilitate both the scheduling of operations and the negotiation of resources between managers. Like PTIME, the UI for this system allows a window into the workings of the automated scheduler.

The CALO 3.0 UI offers multi-schedule comparison similar to RhaiCAL [9] and several non–agent-based commercial calendaring tools (e.g., GroupReady), although PTIME's visualization is part of a larger collaborative user–agent dialogue paradigm. Nonetheless, the independent development of such UIs underlines key interaction challenges, which include how an agent can ask a user to check and correct its understanding of NL input, and how it can iterate with a user to approve, reject, or modify proposed actions. Explanation in the context of collaborative and semi-autonomous assistive agents has been explored in frameworks such as Collagen and the (prototype) deployed systems built with it [24].

7. CONCLUSION

The CALO project presents a combined challenge, being both a research effort into intelligent, adaptive, personal assistants and a large-scale deployable software system. This paper has described the PTIME system, the Personalized Time Manager of a CALO agent. PTIME is designed to assist a human user in managing her time commitments, a large part of which involves managing the communication and negotiation intrinsic in scheduling meetings. We have presented the motivations behind our design decisions, the deployment challenges we faced, the issues that arose with actual usage, and our current work on addressing them.

Our experience in developing PTIME has led to the following lessons that now inform our current research and development:

- *Scheduling technology is only one part of a personalized time management solution*. To be useful, an assistive agent must address issues of privacy and authority while providing support in solving the user's most important problems. To be usable, the agent must be deployed in the real world, an open environment not fully under the user's or agent's control.
- *Multiple modes of communication and operation are critical to successful scheduling*. An open system must be able to function within the real world. For a scheduling system, this means the ability to communicate and negotiate with other agents, be they CALOs with complementary PTIME components, CALOs or human users with email, or human users with voicemail. Crucially, it also means being able to function in spite of incomplete or uncertain information.
- *A well-designed user interface is key not only to making a system usable but also to promoting the use of new functionality*. Design flaws of the initial user interface hindered adoption and masked the full set of PTIME capabilities. Strong usability allows users to explore advanced capabilities and leads to more frequent use of the overall technology.
- *A personal assistant must build trust*. Until users understand the benefits of a new technology, they will be reluctant to abandon their tried-and-true practices. An assistant can facilitate this transition by providing users with visibility into its reasoning process—for example, by providing progress reports, and explanations, especially of problems or failures.
- *An assistive agent must aim to support, rather than replace, the user's natural processes*. Since users are often unwilling to relinquish full control of their time management, an assistive agent must be designed primarily to facilitate rather than automate the user's scheduling processes. This means implementing a process that closely follows the user's own practices (including her evaluation criteria for a candidate schedule) and making explicit the various decision points to support adjustable autonomy.

Acknowledgments. We thank all the members of the CALO project, especially our collaborators at SRI, University of Michigan, and USC. This material is based upon work supported by the Defense Advanced Research Projects Agency (DARPA) through the Department of the Interior, NBC, Acquisition Services Division, under Contract No. NBCHD030010.

ABSTRACT

Autonomic computing, a proposed solution to the looming complexity crisis in IT, is a realm in which software agents and multi-agent systems can play a critically important role. Conversely, given its importance to a multi-billion dollar industry, it is fair to say that autonomic computing is a *killer app* for agents. Two years ago, we introduced Unity, an agent-based autonomic data center prototype that demonstrated the virtues of agency in autonomic computing applications. We discuss the road to commercialization of Unity, which entails infusing agent concepts into well-established lines of software and middleware, and discuss experiments that establish the commercial viability of utility-based resource allocation. Furthermore we examine the practicality of framing resource allocation in data centers as a collaboration between two agents, each of which is based on a commercially available product.

1. INTRODUCTION

The complexity of modern-day corporate computing infrastructures makes them very difficult for administrators to install, configure, maintain, and tune. A typical medium- to large-scale enterprise may employ hundreds of applications from half a dozen different vendors running on a combination of mainframes, Linux, and Windows systems. Often, software compatibility issues necessitate running different versions of one vendor's middleware or database management systems within the same IT (Information Technology) environment. The data flows among the applications are often so complex that visualizations of them are too dense with lines to discern the interdependencies, let alone comprehend them.

IT complexity has several unfortunate consequences, of which we cite just three. First, it significantly raises the cost of making a change once the infrastructure is in place. Even after taking many precautionary measures, administrators frequently make mistakes in adding a new component or in upgrading the middleware on one of the applications with resulting costs that range from thousands to hundreds of thousands of dollars per hour. The high cost and risk of change makes IT systems ponderous—in contradistinction to the increasing call by customers for On Demand computing, which promises flexible and resilient IT systems that support nimble response to new business threats and opportunities. Second, the complexity of individual system components and their interdependencies makes it difficult for administrators to localize, diagnose, and fix problems. Often, the supposed fix does not work, or creates new problems. Third, administrators are finding it ever more difficult to keep pace with the flood of new parameters that get introduced with each new release of products. New books on database management systems from IBM, Oracle, or Microsoft are literally out of date before they are printed. Under such circumstances, it is very difficult to extract the best performance from the system, and system administrators dare not tweak knobs too much for fear of degrading performance or creating other problems.

Most major IT vendors agree that the rapidly growing complexity of IT is a looming crisis that can be averted only if systems become more self-managing. IBM coined the term "autonomic computing" in 2001 to describe its vision of a future in which large-scale IT systems would manage their own behavior in accordance with high-level objectives specified by administrators[4]. Other vendors like Hewlett Packard and Microsoft may use somewhat different terminology, but they agree generally on the importance and urgency of making systems more self-managing.

In short, realizing the vision of autonomic computing is of fundamental importance to the future of the multi-billion dollar IT industry. Moreover, there is every reason to believe that software agent and artificial intelligence technology will play a strong, multi-faceted role in achieving autonomic computing [4]. Inverting the last statement, autonomic computing appears destined to be the long-sought *killer app* for software agents and multi-agent systems [3].

In previous work[10, 13], we discussed and illustrated how an agent-oriented architecture can provide an excellent basis for autonomic computing. Individual self-managing compo-

nents can be framed as agents that are responsible for managing their own behavior in accordance with agreements established with other agents. The self-management of the system as a whole (including self-optimization, self-healing, self-configuration, and self-protection) arises from more than just the individual self-managing capabilities of the agents; it is an emergent property of the mutual interactions that occur within the multi-agent system. We demonstrated the advantages of an agent-oriented approach in the context of a simple prototype data center called Unity. Middle agents [9] such as registries and sentinels were used to attain a measure of self-configuration and self-healing. Utility functions expressed in terms of service-level attributes such as response time, used in conjunction with models and optimization techniques, drove efficient allocation of server resources across multiple large-scale applications.

Unity proved to be no exception to the general rule that the flow of ideas from research prototypes to real commercial products is fraught with barriers that are not just technical in nature. One cannot ignore the strong legacy of a successful product line and abandoning it in favor of productizing a multi-agent system designed from scratch. To do so would not just be difficult for the vendor; it would risk alienating an existing customer base that is reluctant to accept radical departures from legacy solutions. The only practical course is to infuse agency gradually into existing products, demonstrating value incrementally at each step along the road towards full agency.

Therefore, during the last year, we have worked with colleagues at IBM Research and with IBM product development teams to implement some of the Unity ideas in two commercially-available products: WebSphere Extended Deployment and Tivoli Intelligent Orchestrator. WebSphere Extended Deployment (henceforth denoted WXD) is an IBM middleware offering that is used to manage routing, CPU and memory allocation, and software module placement in a large-scale multi-tiered application environment given a fixed set of server resources. Tivoli Intelligent Orchestrator comprises a couple of management components, including the Global Resource Manager (henceforth denoted TIO-GRM). TIO-GRM decides how to allocate server resources across multiple application environments, and communicates its decisions to another management component, the Tivoli Provisioning Manager, which provisions, configures, and redeploys server resources in accordance with the re-allocation decisions made by TIO-GRM.

The remainder of this paper is structured as follows. Section 2 sets the stage for our current work by providing a historical perspective of our past efforts in getting WXD and TIO-GRM to interact with each other. In section 3, we discuss WXD and TIO-GRM and our modifications to them for utility-based collaboration in greater detail. Then, in section 4, we describe two experiments designed to show that, in practical usage scenarios, our scheme allocates server resources in accordance with an administrator's service-level objectives in the face of dynamically changing workloads and objectives. Finally, in section 5, we summarize our main points and provide thoughts on future directions.

2. BACKGROUND

Conceptually, the capabilities of WXD and TIO-GRM are complementary, with WXD managing to service-level objectives as well as possible within fixed resource constraints, and TIO-GRM operating one level above, deciding how to allocate resources across multiple independent large-scale application environments as outlined in Figure 1.[1]

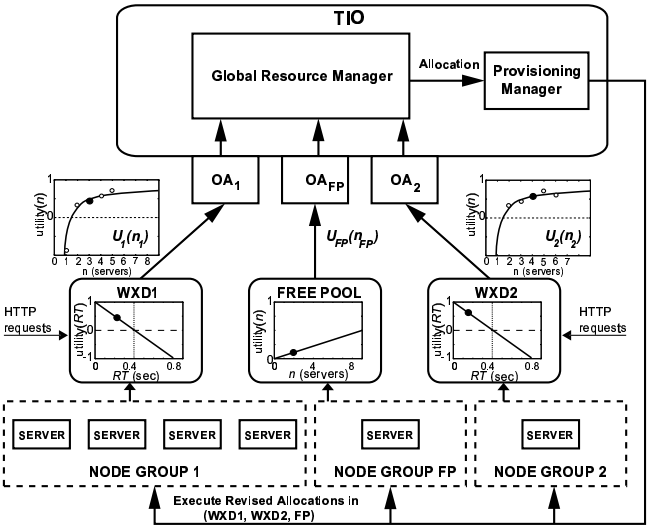

Figure 1: WebSphere Extended Deployment (WXD1 and WXD2), Tivoli Intelligent Orchestrator (TIO), the Objective Analyzers (OAs), and their mutual interactions.

Yet the products as originally conceived did not dovetail very well. This is not surprising, as WXD and TIO-GRM were developed completely independently of one another (indeed, the TIO-GRM technology was obtained by IBM via acquisition) with very different assumptions about environments, span of control, and the nature of the objectives to which they would manage. Therefore there was a great desire on the part of IBM to get these two independently-developed software entities, each capable within their own realm of expertise, to collaborate effectively to achieve system-wide performance optimization.

In recent work [1], we reported early progress in getting WXD and TIO-GRM to interact fruitfully with minimal changes to the existing products. One particularly daunting challenge was the mismatch between the way objectives were expressed by WXD and TIO-GRM. WXD drives its internal behavior using a simple form of service-level utility function expressed in terms of average response time of the various service classes. In other words, an administrator creates a function that describes the value of achieving a given average response time target. This is entirely consistent with the utility-based approach used by Unity. In order to have adopted the Unity approach, WXD should then have computed a resource-level utility $U(n)$ expressing the value of having a given number of server resources at its disposal, and sent this curve to TIO-GRM. TIO-GRM would then have combined similar estimates from other application environments (managed by WXD, or possibly some similar entity) to compute a best overall server allocation that maximized total system utility in each allocation-decision period.

However, the hitch is that TIO-GRM does not view the

[1]An application environment might contain a set of applications running on behalf of one customer within a data center, for example.

world in terms of utility. Rather, TIO-GRM expects to receive "Probability of Breach" (PoB) curves, which describe the estimated probability for the application environment to breach its contract as a function of the number of servers with which it is provided. The resource-level utility curves required by Unity and the Probability of Breach curves expected by TIO-GRM are similar in form, but completely incompatible. WXD is similarly incompatible with TIO-GRM—there is no *breach* of contract in WXD; there is only lower or higher utility.

The approach used in [1] was for WXD to output "speed" numbers that hinted at how urgently it needed additional resources. Then, an *Objective Analyzer*—an extension of WXD designed to mediate interactions with TIO—did a highly heuristic transformation of the speed numbers into a probability of breach. The resulting system was shown to work in a qualitative sense, with more resources being supplied to a single application environment when the load was increased. However, it was difficult to quantify the extent to which WXD was receiving the right amount of resource.

In [12], a follow-on to [1], the form of communication between WXD and TIO-GRM was improved. With help from our colleagues at IBM Research, WXD was instrumented to produce from its internal queuing models the information needed to construct the resource-level utility curves $U(n)$. This achievement required WXD's internal model to operate in a what-if mode, by which it would express the utility it thought it would experience if there were n servers. This is a fairly sophisticated analysis, as it entails some computation of how internal control parameters would be changed if more or less resource were made available. However, a problem remained. Although WXD was now articulating its resource-level utility curve $U(n)$, TIO-GRM was incapable of consuming it: it still expected to receive PoB curves. Accordingly, we developed a heuristic for converting from $U(n)$ to PoB(n) by mapping extrema and midpoints of these curves to one another on the basis of intended behavior. While this scheme was somewhat better at conveying the true intent of the WXD objectives, it was still difficult to quantify the degree to which this was so.

In this paper, we bring our product implementation significant steps closer to the original agent-based vision of the Unity prototype. As we shall describe, we have worked with IBM product developers to create an experimental version of TIO-GRM that accepts utility input directly, eliminating the need for heuristic conversions from utility to PoB. Now TIO-GRM can allocate resources in a manner that truly reflects the intent of the WXD administrator. Thus utility information—and information derived from it via models and optimization—serves as a clean, consistent, universal means for expressing objectives and managing the system to those objectives automatically. Furthermore, we go beyond the original Unity prototype in that we use utility to represent the relative importance of retaining servers in the free pool, a point that will be further explored in section 4.

3. THE COLLABORATING AGENTS

In this section we discuss the two main collaborating agents, based on WXD and TIO-GRM—both of which are commercially available IBM products. Specifically, we use WebSphere Extended Deployment v6.0, which includes the extensions to WXD that supply utility estimates, and we use an experimental version of Tivoli Intelligent Orchestrator that is based upon TIO v3.1, but extended to support utility functions. As will be discussed, each of these agents is itself composed of multiple autonomous interacting entities that have agent-like properties.

3.1 WebSphere Extended Deployment

WebSphere Extended Deployment (WXD) is an advanced middleware application server environment. While a full enumeration of the capabilities of WXD is beyond the scope of this paper, we will discuss here those features of the environment that are most relevant to the paper.

WXD provides the ability for administrators to set service-level objectives (in the form of performance targets) for the web applications installed within the environment. It provides a load balancing reverse proxy (called the "On Demand Router", or ODR) that directs requests to individual application servers such that the specified service-level objectives are met. WXD also starts and stops instances of individual application servers as the extant load changes.

A WXD installation consists of a central management server (called the "Deployment Manager"), one or more ODRs, and several backend nodes (physical machines) that run the applications themselves. Administratively, the backend nodes are grouped into one or more "Node Groups". Each node can be in multiple Node Groups. The user's applications are installed into "Dynamic Clusters", which are in turn backed by the Node Groups—each application is installed into one Dynamic Cluster (although each Dynamic Cluster can host many applications), and each Dynamic Cluster is backed by one Node Group.

Each backend node can run multiple instances of WebSphere Application Server. WXD makes decisions at runtime concerning which instances to start and when. The user's applications are hosted in these individual instances.

The ODR determines the appropriate application for each inbound request by examining the URI. Then, from the set of servers running the application, it selects a server to process the request, taking into account session persistence, etc. The server handles the request in the usual way, and sends the response to the ODR, which relays it to the client.

Clearly, WXD would not be able to meet the service-level objectives if it merely mediated incoming requests. Sometimes, an application is flooded with so many incoming requests that it cannot meet its service-level objectives. Consequently, WXD is also able to start and stop server instances. Thus when the load for a given application is high, WXD can start additional instances of the WebSphere Application server created for the Dynamic Cluster containing the application.

3.1.1 WXD as agents

Rather than having all the management functionality and logic in WXD in a single place, it is distributed through the system as separate components. These components can be regarded as independent, yet inter-connected, agents. The performance management aspects of WXD are handled by three such agents.

The first such agent is the placement control agent—this determines which application server instances should be running at any given time on each node in the system. The approach taken to solving the placement problem is that discussed in [5].

The second such agent is the flow manager—this manages

the various service classes, trading one off against the other to obtain the highest overall system utility. The flow manager takes the current placement (which servers are available for each Dynamic Cluster) as a given, and calculates the concurrency limits for the various Dynamic Clusters that the ODR uses for request assignment. The algorithms used by the flow manager are essentially those described in [6].

The flow manager is particularly relevant to this paper, as it is the component that the TIO-GRM asks for system utilities. The flow manager is not only capable of considering the system as it currently stands, but also of considering possible future allocation changes. The value to WXD of these possible future allocations (in addition to the value of the current allocation) is expressed in terms of a utility function $U(n)$, where n is the node count.

The third such agent adjusts the load balancing weights used in request routing; its function is not pertinent to this paper, and it will not be mentioned further.

The three performance agents are inter-connected, in that information calculated by each agent is used by the other agents. For example, the flow manager agent computes "demand constraints" which the placement control agents uses as input to the placement decision.

3.1.2 The WXD Objective Analyzer

As discussed later in Section 3.2, TIO-GRM provides a mechanism by which components called "Objective Analyzers" (OAs) can be plugged in to provide performance information for specialized systems that TIO-GRM is managing.

WXD provides such an OA, in order that higher-level management and administration functionality can be carried out automatically. As TIO-GRM provides a flexible scripting and automation environment for system management, it can be used to carry out higher-level reallocations that WXD cannot do on its own—specifically, TIO-GRM is able to move nodes between Node Groups. In order to do this, as was discussed above, properties of the nodes other than those controlled by WXD need to be changed—for example, database clients might need to be installed or reconfigured so that a node is capable of running the applications that will be deployed upon it once it is a member of a certain Node Group or set of Node Groups.

A hierarchy of management can therefore be seen between WXD and TIO-GRM—WXD handles management within each Node Group, and is aware of low-level performance properties of the applications, whereas TIO-GRM handles management between Node Groups, and between WXD and other systems in the data center.

The OA that currently ships with WXD v6.0 obtains the $U(n)$ function discussed above from WXD for each Node Group (see Section 3.3 for more information on the communications between the various agents), and uses mechanisms discussed in [12] to convert those utility curves to probability of breach curves PoB(n). Some information is lost in the conversion because WXD's utility values are fit to negative exponential curves with a small number of parameters, which are then mapped very nonlinearly to parameters describing sigmoids that represent the PoB curves required by TIO-GRM. In addition, as is discussed in Section 4, the PoB values are themselves subjected to a nonlinear transformation to "fitness" values after being passed to TIO, which can distort and magnify any inaccuracies introduced by the OA conversion.

In order to support direct use of utility values by TIO, the commercial OA was modified to produce an experimental OA in which the mapping of $U(n)$ to PoB(n) was removed. This removal introduced a slight problem that is not an issue for the commercial OA. TIO-GRM requires input curves PoB(n) or $U(n)$ that cover a broad range of n (from 0 or 1 to some upper bound on the total number of servers). However, WXD does not compute $U(n)$ for all n; for a variety of reasons it computes $U(n)$ only for a small range of n that does not differ from the current allocation n_t by more than 2 in either direction. In the commercial OA, the partial range is not a problem because $U(n)$ is used as input to a curve-fitting procedure that yields a complete PoB(n) for all n. In the experimental OA, the problem of missing data values $U(n)$ for $n < n_t - 2$ and $n > n_t + 2$ is solved by extrapolating them from the $U(n)$ in the limited range computed by WXD. The resulting utility curve $U(n)$ for *all* n is input to TIO-GRM.

3.2 TIO Global Resource Manager

Tivoli Intelligent Orchestrator (TIO) is an automated resource management solution for corporate and Internet data centers. It allows automatic policy-based management of computing resources by automating three key data center processes: infrastructure provisioning, capacity management, and service level management. TIO allows system administrators to create, customize, assemble and store for further use a large variety of workflows that automate various data center processes from configuring and allocating servers, to installing, configuring and patching software.

The TIO component of interest for this paper is the TIO Global Resource Manager (denoted TIO-GRM), which is charged with making resource allocation decisions that are optimal and sufficiently stable. An optimization component in TIO-GRM performs a tree search over the possible combinations of server allocations and proposes an allocation with the highest overall system "fitness", taken to be the sum of the individual fitnesses of each application environment that is requesting resources from TIO.

In the commercially available version of TIO-GRM, the fitness $F(n)$ for an individual application environment is a nonlinear transformation of its PoB(n). While TIO-GRM supports any transformation function, the default transform assigns the highest fitness values to PoB values that are in middle range. Typically, this helps prevent underprovisioning and overprovisioning. However, since the fitness is defined strictly within TIO-GRM, there is no way to ensure that the fitness function reflects the intent of the adminstrator as expressed in the utility functions defined in WXD. Moreover, even if the administrator had access both to WXD and to TIO-GRM, the doubly compounded nonlinear transformations (from utility to PoB in the OA, and from PoB to fitness within TIO-GRM) would make it excessively difficult for an administrator to construct a fitness function that properly reflected his objectives.

Therefore, to allow the utility-based objectives defined in WXD to flow transparently to TIO-GRM, the commercially available TIO-GRM was extended to support utility functions directly. This was achieved by setting $F(n) = \text{PoB}(n) = U(n)$. In other words, aside from the extrapolation provided by the OA, the fitness function is no longer an independent, carefully engineered function that is separately defined within TIO-GRM. It is determined com-

pletely by (and essentially equal to) the utility estimates from WXD. The optimization component in the TIO-GRM is quite generic, and therefore required no changes; as always, it simply maximized the sum of the fitness functions of the individual application environments, which in this case is equivalent to maximizing the overall system utility.

3.3 Inter-agent communication

There are two distinct communication paths between WXD and TIO-GRM. The first path conveys utilities estimated by WXD to TIO-GRM. Periodically, when TIO-GRM desires utility estimates, it calls the OA (which is in the same JVM). In turn, the OA makes a JMX call[2] to WXD requesting from WXD's flow manager the current utility estimates.

The second communication path executes the resource allocation decisions made by TIO-GRM by adding or removing servers in the WXD environments and the free pool. There are two methods, each of which permit TIO to execute OS-level commands on the machines it wishes to modify. The first method involves use of the "Tivoli Common Agent" (TCA), a client-side agent used by various IBM management software. The second method, which was used in our experiments, does not require TCA, but uses SSH (Secure Shell) to execute the commands instead.

When TIO decides to add a node to a Node Group, it does so by first executing commands on the node to add that node to the WXD system ("federating the node"), and then executing commands on the WXD Deployment Manager to move the node into the Node Group. Conversely, when TIO decides to remove a node from a Node Group, it does so by first executing commands on the WXD Deployment Manager to take the node out of the Node Group, and then executing commands on the node to remove that node from the WXD system (this process is known as "unfederating the node").

4. EXPERIMENTS

In this section, we describe two experiments, each of which is based on what we anticipate will be a common usage pattern for the TIO-GRM and WXD agents in deployed systems. In different ways, the two experiments demonstrate efficacious collaboration between these agents to achieve service-level objectives specified by administrators—even in the face of dynamically changing workloads and dynamically changing objectives. First, we describe an experimental setup common to both experiments, and then we discuss each experiment and its results.

4.1 Experimental Setup

The following setup, which applies to both of the experiments, is illustrated in Figure 1. An installation of TIO-GRM was configured to manage two independent instances of WXD, each running its own application with time-varying workload on a single dedicated Node Group contained in a single dedicated Dynamic Cluster. Additionally, TIO-GRM was configured to manage a free pool of homogeneous servers from which the two WXD instances could be supplied. For each WXD instance, the Deployment Manager and the ODR were installed on separate dedicated servers, amounting to four servers in all. (i.e. four servers were used in all for the WXD management).

[2] [2] describes WebSphere's use of JMX.

We employed the same web-based application for both instances of WXD. Each application consisted of a single service class. For each service class, WXD permits an administrator to establish a simple utility function expressing the value of attaining a given average response time[3]. The utility function is elicited via a simple template: the administrator inputs a response time target RT_0 and selects one of seven importance levels ranging from very low to very high. These two parameters are mapped to a simple utility function $U(\mathrm{RT})$, in which the utility drops monotonically from 1 at $\mathrm{RT} = 0$ to 0 at the response time target RT_0. For response times greater than RT_0, the utility is negative and linearly decreasing with a slope governed by the importance level. In all of our experiments, the response target was $\mathrm{RT}_0 = 0.4$ sec, and the importance level was selected to be "very high", which translated to a constant slope for all response times. (For lower values of importance, the absolute value of the slope is reduced to reflect a lower penalty for response times above the target.) Thus the utility was given simply by $U(\mathrm{RT}) = \frac{\mathrm{RT}_0 - \mathrm{RT}}{\mathrm{RT}_0}$ for all possible values of RT, with $\mathrm{RT}_0 = 0.4$ sec.

The demand in each application, quantified by the number of clients sending requests to the ODR, was generated using a single closed-loop load generator [7] with an adjustable number of clients. In principle, each request required the same amount of CPU cycles. The think time for each client in the closed-loop load generator was drawn from an exponential distribution with a mean of 0.125 sec.

A total of six homogeneous server machines were available for our experiments. Each server machine was an IBM eServer xSeries 335 machine with two Intel Xeon 3.06GHz processors (with 512KB of Level 2 cache) configured with hyperthreading enabled. Each machine had 2.5GB of RAM. The properties of the application and the server machines were such that each machine could serve up to 30-40 clients and still meet RT_0 of 0.4 sec.

TIO was installed on a separate machine and the Global Resource Manager was configured to allocate server machines to the two WXD instances based on *resource utility* information $U(n)$ provided by the two OAs every 30 seconds. The free pool was placed on the same footing as the two WXD instances by ascribing a utility u_f to each server in the free pool, i.e. $U_f(n) = nu_f$. In our experiments, we typically set $u_f = 0.05$, although as reported below we also tried setting it to higher ($u_f = 0.4$) and lower ($u_f = 0.01$) values. While it would have been more elegant to represent the third pool by a third (very simple) OA, for the sake of expediency the free-pool utility was computed inside our modified version of TIO-GRM. From discussion with developers and TIO customers, it is clear that there is a good, solid grounding for the use of a free-pool utility. A server that is idling in the free pool may be less costly than one employed by WXD because some hardware contracts specify a lower rate for idle servers, or because multi-server applica-

[3]WebSphere Extended Deployment supports performance measures other than average response time, such as percentile response time. In these cases, utility functions are defined similarly to what is described here for average response time. We have conducted a similar series of experiments on percentile response time, and we have also experimented with heterogeneous applications and multiple service classes, but for reasons of clarity and space we focus only on the average response time results in this paper.

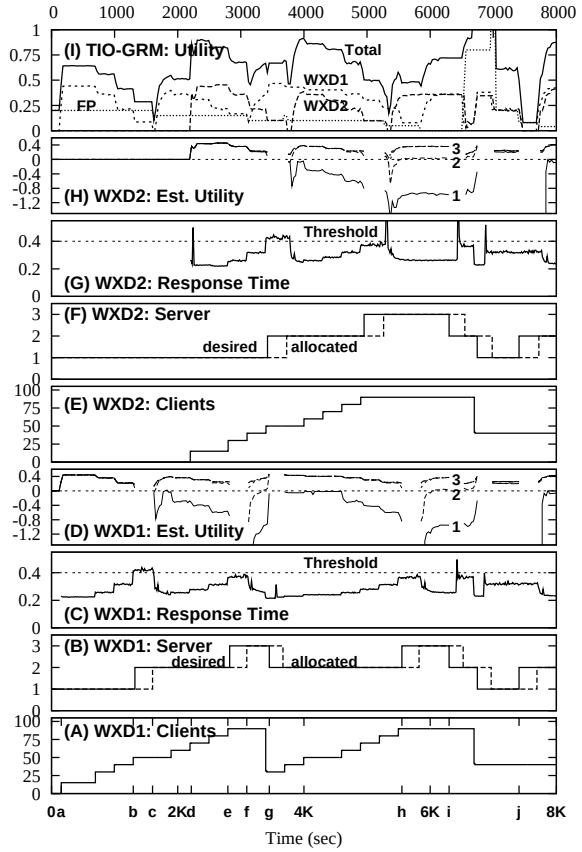

Figure 2: Summary of Experiment 1 in nine time series plots.

tion or middleware software licenses may take into account the number of servers on which the software is installed. An idle machine costs less in terms of power and money to run. Moreover, an idle server is advantageous because, if there is a sudden urgent need, it can be employed more quickly than one that is in currently in service, as there is no need for a potentially lengthy de-installation. Thus in many cases a data center administrator would like to ascribe a utility value to the size of the server free pool.

TIO-GRM guaranteed that at least one server machine would always be made available to each instance of WXD. Thus, based on the current level of load, each WXD was essentially competing with the other WXD instance and the free pool for the remaining four server machines. TIO-GRM's overall goal was to find the allocation that maximized the total system utility, which was taken to be the sum of the utilities derived from the two WXD instances and the free pool.

In all of our experiments, TIO was run in the *automatic* mode, allowing it to execute the resource allocation decisions with no manual intervention.

4.2 Experiment 1

Results from an experiment with TIO-GRM managing two WXD instances, denoted henceforth as WXD1 and WXD2, are summarized in Figure 2. The figure shows nine time series plots over a period of 8000 seconds (2 hours and 20 minutes). From bottom to top, they are:

(A) the number of clients requesting service in the application installed on WXD1,
(B) the number of servers scheduled to be allocated and the number of servers actually allocated to WXD1,
(C) the average response time achieved by WXD1,
(D) the utility values $U(n)$ reported by WXD1 to TIO-GRM,
(E) the number of clients requesting service in the application installed on WXD2,
(F) the number of servers scheduled to be allocated and the number of servers actually allocated to WXD2,
(G) the average response time achieved by WXD2,
(H) the utility values $U(n)$ reported by WXD2 to TIO-GRM, and
(I) the total actual system utility obtained by TIO-GRM from WXD1, WXD2, and the free pool (FP).

Notable times are indicated by labeled letters at the bottom of the figure.

At time 0, each WXD had one allocated server machine as per TIO-GRM's guarantee, and the number of clients for each application was zero. Hence all utility values reported by WXD1 and WXD2 were initially zero. The total system utility obtained by TIO-GRM was derived solely from the free pool, and since there were four machines in the free pool, this value was $0.05 \times 4 = 0.2$.

At time **a**, the number of clients in the application running on WXD1 suddenly jumped to 15. WXD1 already had a server in its Node Group, and after a small transient period the server provided an average response time of about 0.23 sec. The actual utility reported by WXD1 to TIO-GRM was 0.44. Note that WXD1 also estimated that there was virtually no increase in utility $U(n)$ with increasing n.[4] Because of the utility associated with the free pool, TIO-GRM correctly decided not to allocate any additional servers to WXD1.

From time **a** to **b**, the number of clients in WXD1's application increased in a series of steps. With each such step, it is possible to associate a corresponding increase in response time and a decrease in the utility values. At time **b**, when the number of clients increased to 50, the average response time sharply jumped to over 0.4 sec. This drop in performance also caused a drop in WXD1's utility, and since $U(2)$ was slightly more that $U(1)$, TIO-GRM began the process of allocating an additional server to WXD1. The allocation entails copying application software and other necessary infrastructure information to the new server machine, a process that may take more than 5 minutes.[5] However, once the server is finally made available to WXD1 at time **c**, there is a drop in response time and a corresponding increase in utility reported by WXD1 to TIO-GRM. The utility of the free pool on the other hand drops to 0.15. Interestingly, even after the server has been allocated to WXD1, there is a substantial transient period before the response time and utilities reached their corresponding near-asymptotic values.

Beyond time **c**, the number of clients associated with WXD1 continues to climb to 90, putting an increasing strain on the two servers in WXD1. In response to further decrease in the reported utility, TIO-GRM decides to allocate the third server to WXD1 at time **e**. A similar series of

[4]This is because the mean queue length was zero for this level of load on a single server. Thus additional servers would not have had any effect.

[5]In its current implementation, the OA stops reporting the estimated utility values to the TIO-GRM while an allocation (or de-allocation) process is in progress. Hence, we see the gaps in the utility values in Figures 2(D) and (H).

events ensues, and once the new server is online at time **f**, the response time drops accordingly.

At time **g**, the trend of increasing clients is reversed, with the client count dropping suddenly to 30. All of the estimated utility values in WXD1 rise dramatically, as a result of which TIO-GRM determines to take away one server from WXD1. In this case, once the server is returned to the free pool, XD1 is still able to provide a response time well below the threshold of 0.4 seconds.

While TIO-GRM and WXD1 were involved in this exchange of server machines, note that back at time **d**, the WXD2 application took on some clients for the first time, and the number of clients began to increase with the passage of time. Accordingly, beyond time **d**, when WXD2's performance begins to sag noticeably, TIO-GRM granted an additional server to WXD2. The allocation of a server to WXD2 and the de-allocation of a server from WXD1 overlap near time **g**, underscoring TIO-GRM's robust ability to handle multiple allocation processes at the same time.

Later, at time **h**, we stress-tested our experimental setup with very high load on WXD1 and WXD2. Soon after TIO-GRM's decision to allocate the last remaining server in the free pool to WXD1 at time **h**, both WXD1 and WXD2 make use of three servers each, enabling them to successfully meet their response time targets and obtain relatively high utility.

To illustrate the ability of the system to respond dynamically to changes in objectives, and to demonstrate the naturalness of the free pool utility, the free pool utility is increased at time **i** from its default value of 0.05 to 0.4. As discussed above, this may represent a change in the licensing structure, or in the perceived advantage of retaining machines in the free pool. Fig. 2 demonstrates that TIO-GRM is able to take this change in stride with no need for stopping and restarting. In this case, TIO-GRM decided to pull one server away from environments WXD1 and WXD2. While this action causes the response times of WXD1 and WXD2 to rise noticeably, and their utilities to fall somewhat, this is more than compensated by the increased utility of the two extra servers in the free pool.

Later, when the load on both WXD1 and WXD2 has dropped, a complementary series of steps is triggered at time **j**, when the system administrator chooses to decrease the value of each individual server in the free pool to 0.01. As a result, TIO-GRM now relinquishes an additional server from the free pool to each WXD.

This experiment demonstrates effective utility-based collaboration among three autonomous agents, resulting in robust, dynamic allocation and de-allocation of server machines that faithfully reflects service-level objectives that may themselves be dynamic in nature.

4.3 Experiment 2

The purpose of the second experiment was to explore the effectiveness and reliability of the collaborative agents in a more dynamic setting with more realistically time-varying workloads. The experimental setup was substantially similar to that of Experiment 1. The main difference was the use of a time-series model of measured web traffic developed by Squillante et al. [8], which provides a realistic emulation of stochastic bursty time-varying demand. The number of clients in the closed-loop load generator was reset every minute according to this model with hard lower and upper thresholds of 5 and 125 clients respectively. The time

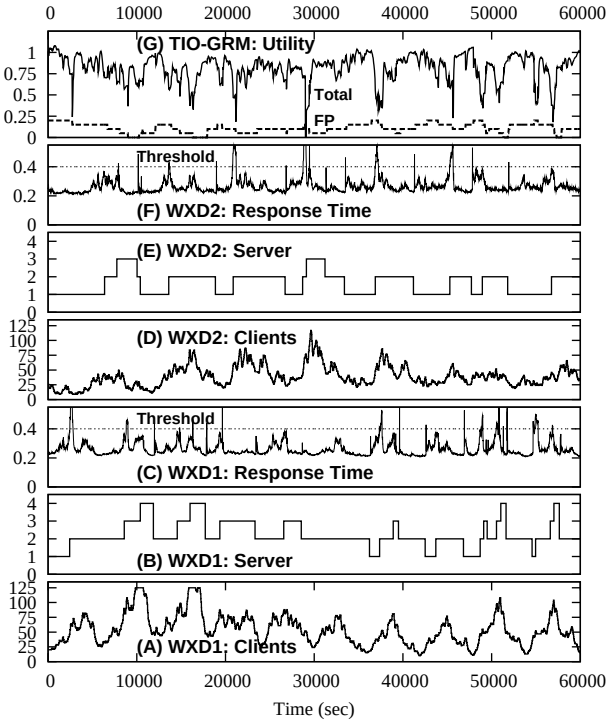

Figure 3: Summary of Experiment 2 in seven time series plots.

series of the workload on each application was generated independently, with the application on WXD1 experiencing slightly higher average load conditions than the application on WXD2.

TIO-GRM was again set in the "automatic" mode, and the experiment ran uninterrupted for a period of over 60000 seconds (16 hours and 40 minutes).

Results from Experiment 2 with TIO-GRM managing WXD1 and WXD2 are summarized in Figure 3. The figure shows seven time series plots; from bottom to top, they are:

(A) the number of clients requesting service in the application installed on WXD1,
(B) the number of servers set to be allocated on WXD1,
(C) the average response time achieved by WXD1,
(D) the number of clients requesting service in the application installed on WXD2,
(E) the number of servers set to be allocated on WXD2,
(F) the average response time achieved by WXD2, and
(G) the total actual system utility obtained by TIO-GRM from WXD1, WXD2, and the free pool (FP).

The results show that, over the course of over 16 hours, all the agents collaborated successfully. Through a harmonious exchange of servers, each instance of WXD was generally able to meet the response time threshold. Dynamic systems with delayed feedback often suffer from nonlinear effects such as hysteresis under time-varying conditions. The XD-TIO-GRM system studied here experiences long transients and allocation delays that can last for over 5 minutes—conditions which under some circumstances can induce thrashing behavior. However, for the time-varying workloads experienced by WXD1 and WXD2 in this experiment, rapid repeated allocation and de-allocation of servers by TIO-GRM was not observed in spite of the allocation delays.

5. CONCLUSIONS

In this paper and in prior work [1, 12], we have argued and demonstrated that software agents and multi-agent systems have a centrally important role to play in autonomic computing, and that, given that it may be the only answer to solving a major problem in the multi-billion dollar IT industry, autonomic computing is a *killer app* for software agents and multi-agent systems. One important proof point in that argument was Unity, an autonomic data center prototype that used an agent-oriented architecture to configure, heal, and optimize itself.

This paper focused on the road to productization for the self-optimizing portion of Unity, which entailed the elicitation, usage, transformation and propagation of utility functions. Direct productization of Unity was not feasible, given the considerable legacy of IBM products that occupy the space of automated provisioning and workload management. Instead, we set about to gradually infuse the most interesting and important elements of Unity into existing products. This paper describes an important breakthrough in that process, in which we have succeeded in implementing in two commercial products the main capabilities that are needed to produce and consume what-if utility information. Two experiments demonstrated effective utility-based collaboration between two products that formerly viewed the world in very different and incompatible terms, resulting in effective cooperative interactions between workload management and provisioning. Indeed, we were even able to take a step beyond the original prototype, showing that management of the free pool (which had not been present in the prototype, and which had been managed heuristically in the product) could be done elegantly, using the same utility-based methods that are used for managing application environments.

Of course, our work is hardly finished. WXD and TIO-GRM still lack features that one would expect in full-fledged agent systems. To cite just one desirable feature, it would be beneficial for the agents to exchange what-if information using more general, flexible semantics. For example, TIO-GRM might find it advantageous to ask for more detailed information on estimated utilities for individual service classes, rather than a single overall utility. We have begun to work on more flexible languages that allow agents to specify and describe hypotheticals. We are also exploring various uses for reinforcement learning techniques in this context [11]. Looking further beyond, we would like to incorporate in these products the other self-managing capabilities in the original Unity that gave rise to its self-healing and self-configuring properties. And looking beyond still further, there is practically infinite scope for employing agent concepts, architectures and technologies—not just for workload management and provisioning, but within autonomic computing systems quite generally.

6. ACKNOWLEDGMENTS

We thank our IBM Research colleagues Giovanni Pacifici, Malgorzata Steinder, Mike Spreitzer, and Asser Tantawi for much discussion and consultation on WebSphere Extended Deployment, without which this project would have been impossible. We are also indebted to U. Gopalakrishnan of IBM India for making several essential enhancements to the workload generator, giving us the flexibility we needed.

ABSTRACT

This paper describes the specification, design and development of ACTIVE, a testbed for the testing and simulation of large-scale agent-based systems. ACTIVE is being developed as part of DARPA's Coordinators program. The goal of the ACTIVE testbed is to support the simulation of large collections of distributed cooperating agents in solving constrained scheduling problems.

Categories and Subject Descriptors

I.2.11 {**Artificial Intelligence**}:Distributed Artificial Intelligence.

I.2.5 {**Artificial Intelligence**}:Programming Languages and Software.

I.2.8 {**Artificial Intelligence**}:Problem Solving, Control Methods and Search.

General Terms

Algorithms, Measurement. Performance. Design, Reliability, Experimentation, Languages, and Verification.

Keywords

Agent testbed, Scalable testbed, Test Harness, CTAEMS, GMASS, TAEMS, MASS.

1. INTRODUCTION

The Coordinators Program seeks to research, develop, and deploy agent-based systems in support of emergency responders in disaster relief scenarios as well as war-fighters in combat situations. The Coordinators Program is managed by Dr. Tom Wagner of the Defense Research Projects Agency (DARPA) — The purpose of this program is to support fielded units in adapting mission plans to changing situations. The problem involves distributed coordination over large interconnected mission structures that change dynamically. Once deployed, the units are physically distributed. Authority and information are also distributed. The Coordinators Program will use agents to interact and modify plans according to constraints and select the best options for modifying plans. It is a complex task involving a great deal of low level information exchange and analysis that is done better and more quickly by machines than humans and will free humans for high level tasks and decision making

The goal of the ACTIVE system is to provide the infrastructure to support the configuration, simulation, execution, monitoring and evaluation of teams of distributed agents that cooperate in solving large-scale scheduling problems that cannot be solved in a centralized fashion. The distributed nature of the problem, the sheer number of agents involved and the complexity of the tasks together with their constraints, invites new approaches to solving this problem

It is essential to automate the tests, in order to support the number of software agents needed to support these personnel. Large scale testing will be required. Hundreds or even thousands of tests must be run automatically and unattended. The Coordinators agents must be tested with numerous input scenarios and the tests must be repeatable and the results quantifiable. We at Global InfoTek, Incorporated are designing, building and testing the ACTIVE testbed to support three agent-based projects, each of which is specifying, designing, implementing and testing their own Coordinators agents. The performer teams are from Honeywell, Information Sciences Institute at USC, and SRI International.

The ACTIVE Testbed is designed to support both testing and evaluating the results of the tests. A Scenario Generator has been developed to generate scenarios based on input parameters. Developing the scenario manually would not be feasible given the scale of the testing. The Centralized Scheduler provides a baseline set of solutions for each input scenario that will be used to test the Coordinators agents. Chronos provides time management for the Centralized Scheduler.

The ambitious goals of the Coordinators Program, the size of the agent communities being fielded by the three teams, and the complexity of the problem space in which the agents operate, requires that the simulation testbed be both scalable and robust. Although we are aware of other testbeds for agent-based systems,

we feel that our approach is better in that it is modular, service-oriented, scalable, and able to operate "24/7" so as to support the vast number to tests needed to evaluate the performance of each performer team's solutions to the agent-based team scheduling and coordination problems.

1.1 Related Work

Several agent-based testbeds have been proposed and built. Examples are the ART Testbed (Agent Reputation and Trust) at the University of Texas at Austin [2], JADE [1] at Telecom Italia in Naples, the Autonomous Multi-Agent Testbed at the University of Washington [5], and the AgentCities Testbed [7].

The ART Testbed [2] has an international team of researchers whose focus is to coordinate game design, game specification, testbed development and competition administration. The competition testbed is designed to fulfill two roles: 1) provide a forum in which competitors can compare results using objective metrics, and 2) provide a suite of tools with flexible parameters to allow researchers to perform customizable and easily-repeatable experiments. The architecture consists of multiple agents connected to a simulation engine which accesses a database, a game setup interface and game monitor interface. The focus is to measure agent trust and reputation in the game-playing environment. This is different from the ACTIVE Testbed environment.

The Java Agent DEvelopment Framework (JADE) [1] has a large following in the FIPA agent community. It is designed to enable agent-based system development through middleware services. The framework provides for scalable messaging among agents.

The Autonomous Multiagent Testbed [5] at the University of Washington supports seven miniature robots, a global vision system and a custom-designed infrared communication structure. The wireless aspect of the testbed gives the agents real autonomy.

The AgentCities testbed [7] supports FIPA agents and is intended to handle a very general service-oriented architecture for the dynamic search, discovery and composition of Semantic Web Services. This testbed also runs in 24/7 mode. As we shall explain in this paper, the ACTIVE Testbed under development at Global InfoTek to support the DARPA Coordinators Program has unique features not found in other testbeds.

1.2 Organization of Paper

This paper is organized as follows. Section 2 provides an overview of the ACTIVE testbed architecture and the layered services approach. Also discussed in Section 2 are the subsystems for the testbed, infrastructure and benchmarking. Section 3 gives a brief description of the Testbed Lab. Section 4 outlines our future work for the ACTIVE system.

2. ACTIVE TESTBED ARCHITECTURE AND SYSTEM

Global InfoTek (GITI) is a company dedicated to providing intelligent systems and advanced middleware solutions to government and industry. It has a long history of successful projects with DARPA and other government agencies. The Coordinators program requires an industrial-strength testbed in which to load, initiate, run, monitor, and evaluate the agent-based schedules, execution traces, and overall quality of the performer team solutions.

2.1 The ACTIVE Testbed Architecture

The ACTIVE testbed is a robust, scalable and lightweight experimental framework to support scientific evaluation of Coordinators agents. It is a system-agnostic framework, which supports any Coordinators agent interface, and requires minimal effort to integrate with the testbed. It also provides agent-based tools to orchestrate Coordinators agents and supporting testbed services, rapidly set up experiments, and quickly reinitialize the baseline system to support repeatable experiments.

Figure 2 provides an overview of the ACTIVE services for testing and evaluation for the Coordinators Program. The Testbed consists of three service layers: Test Harness, Command and Control (C&C), and Evaluation/Experimentation utilities. The CoABS Grid [6] middleware is used for agent communication. The Command and Control module manages the complex, distributed environment for the Coordinators agents and controls and monitors experiments. Evaluation/Utility Services include a Scenario Generator and a Centralized Scheduler as well as collecting and archiving test outputs for analysis and evaluation.

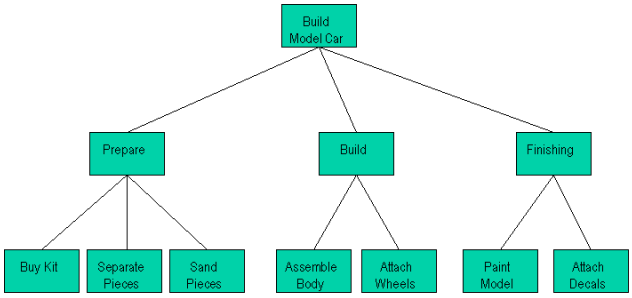

Figure 1. Hierarchical Task Structure

2.2 Test Harness

Figure 3 shows the ACTIVE layered services architecture, and Figure 4 shows the calling relationships among the services. Figure 5 presents an event-sequence diagram showing how the ACTIVE services interact in support of a test. The Test Harness layer encapsulates the agent tasking language, CTAEMS (Coordinators Task Analysis, Environment Modeling and Simulation) and the simulation engine, GMASS (GITI Multi Agent System Simulator). It also provides the interface for Coordinators agents to interact with the testbed services and with other Coordinators agents.

TAEMS (Task Analysis, Environment Modeling and Simulation) is a language designed to model tasks for software agents. TAEMS models the quantitative behavior of tasks, task activities and interactions between tasks [4]. CTAEMS was created by

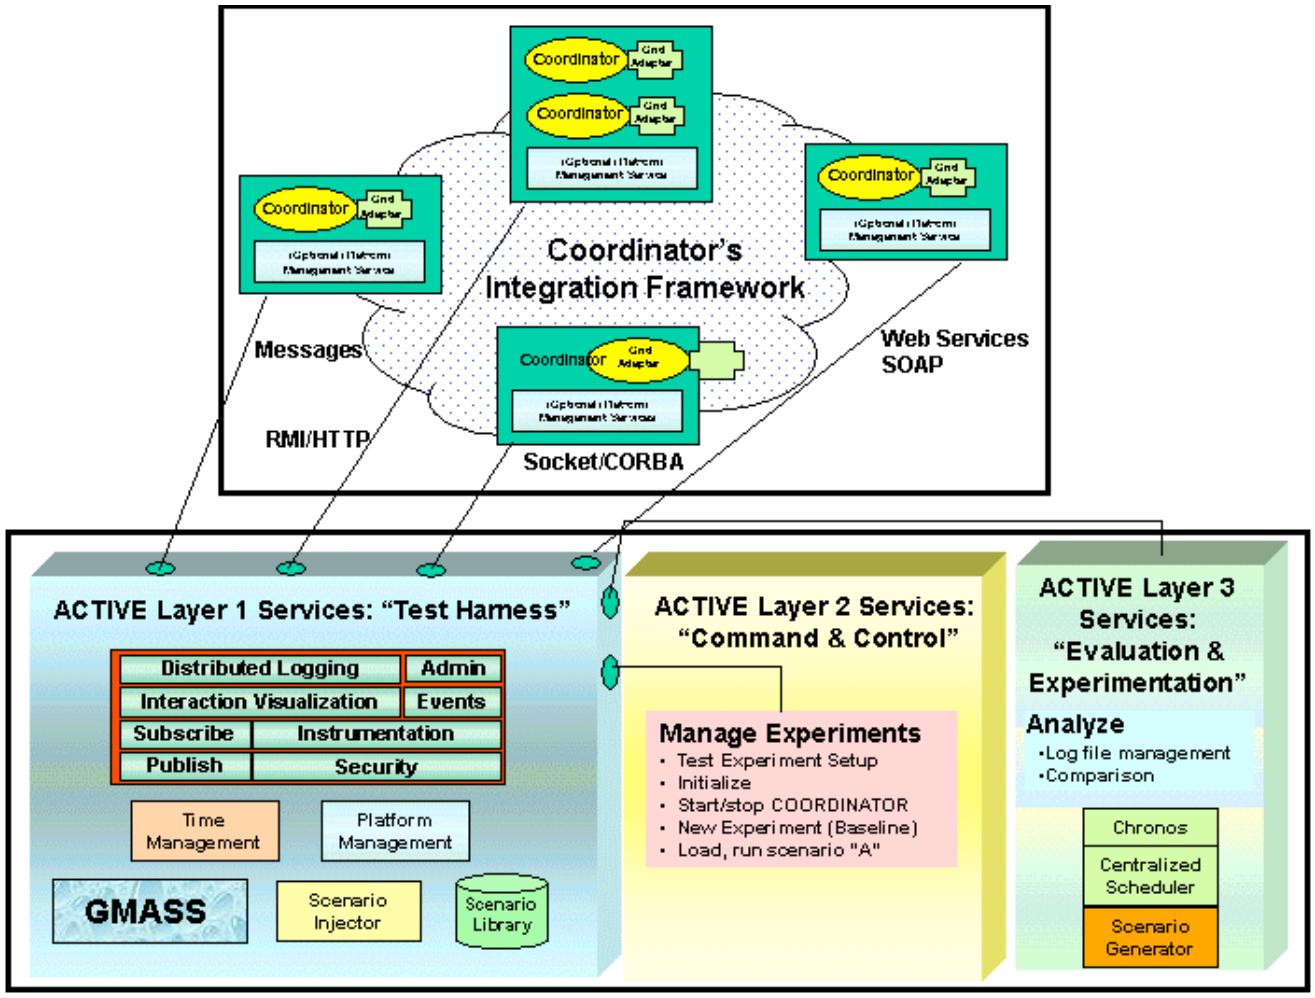

Figure 2. ACTIVE Services for Testing and Evaluation

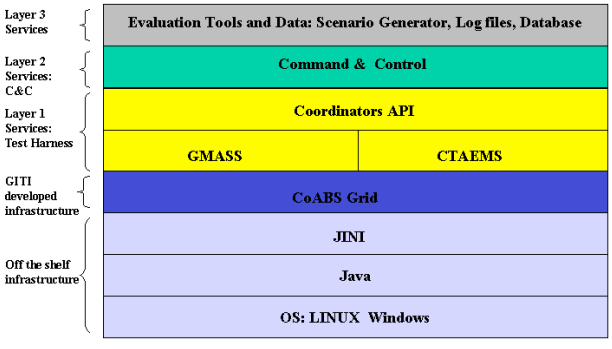

Figure 3. ACTIVE Layered Services Architecture

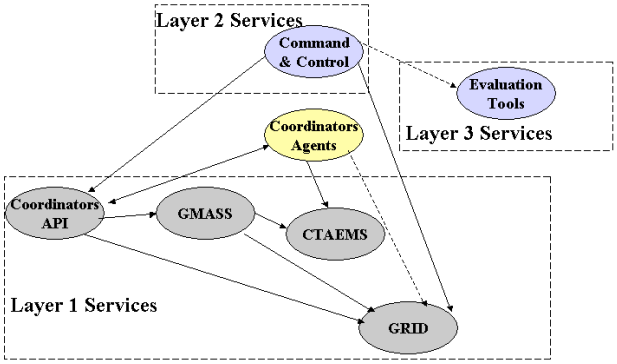

Figure 4. Relationships Among Services

modifying TAEMS to meet the unique needs of the Coordinators Program. The primary modifications are:

- Removal of GUI infrastructure, preprocessor, and commitments
- Changes to core data structures, virtual nodes and parser
- Addition of exogenous events

There are three types of CTAEMS Nodes: method, task, and task group. Methods are the leaf nodes of the graph and represent primitive executable actions. These actions are grouped together as tasks. A task can contain one or more methods and represents a goal that can be accomplished by its method(s). A task group represents a higher-level goal that is accomplished by the tasks in its structure. Figure 1 shows a simplified example of a task group for building a model car.

GMASS (GITI Multi Agent System Simulator) provides the simulation engine for testing coordination and negotiation among teams of Coordinators agents. GMASS was created by modifying MASS (Multi Agent System Simulator) to meet the unique needs of the Coordinators project. The primary modifications are:

- New Time Management model
- Rewrite of core event handling
- Communication changed from sockets to CoABS Grid

The simulator itself runs as a single process. All Coordinators agents involved in the simulation are connected to the simulator through the CoABS Grid [6]. This allows the simulation to monitor all Coordinators agent communication with the simulator and with other Coordinators agents. Each Coordinators agent has its own subjective view of the world and its own goals. The simulator has the objective view of the world containing information that the Coordinators agents do not see. These views are created by the Scenario Generator based on input parameters.

GMASS simulates the Coordinators agent's method execution. The actions of the simulator are directed by a queue containing a time-ordered list of events. The simulator receives two basic types of messages from agents: Method Abort and Method Start. Each message causes a method to be added to or deleted from the event queue. At each pulse the simulator selects the correct events and realizes their effects.

A CTAEMS Scenario for the Coordinators program contains a hierarchy of tasks assigned to each Coordinators agent along with deadlines and constraints. There are two types of views of a CTAEMS scenario, objective and subjective. The objective view contains the entire correct scenario. The subjective view does not include everything that is contained in the objective view. Agents only have access to a subjective view for their planning and interacting. The subjective view is different from the objective view because agents may have an imprecise model of what will actually happen, performance-wise when the method is executed. The objective view is created by the Scenario Generator. The objective views of the methods are managed by the simulator; the subjective views are created by the simulator and passed to the agents.

When an agent requests that the simulator start a method, the simulator retrieves the method from the objective CTAEMS structure. The first step of the simulator is to calculate the values of the quality, cost and duration that will be produced by this execution. A random number generator is used to calculate these values. Any event that occurs before a queued event is performed can affect the results of that event's execution

The simulator controls time simulation for the agents. A single unit of time is called a *pulse*. The simulator periodically sends a pulse to each of the agents. MASS manages time so that a pulse is complete after all agents have completed an action. The pulse time is not proportional to clock time or CPU time, but can be of varied length. A pulse ends when all agents have reported in. The MASS time management scheme has been altered for GMASS so that the pulse time is based on clock time and is the same length throughout a run. The length of a pulse is controlled by a setting in a configuration file.

GMASS time management provides a guarantee window that ensures that requests sent to the simulator within a time window in a given pulse will take effect within that pulse. Coordinators agents can run at any time they please and exchange messages within or outside the guarantee window. The simulator will process such requests within the given pulse period provided it can do so without delaying the next pulse. It will send a failure message to the requesting agent if it cannot do so.

The Coordinators API provides a single programming interface for accessing the simulator, representing the agent subjective view, communicating among agents, and communicating between agents and the simulator. The API is both a convenience for developers of Coordinators agents and a tool for observing and instrumenting the Coordinators agents. The Coordinators API serves as a wrapper for GMASS and CTAEMS.

2.2.1 Agent Startup

All Coordinators agents are required to implement the Coordinator interface, which allows them to receive messages from GMASS and from other agents. It also provides the capability to be started by the ACTIVE testbed.

The methods used during startup are initialize and begin. Initialize tells the agent to start any processes and perform all initialization that it can without having scenario-specific information. Begin notifies the agent that the simulation is starting. It passes the CTAEMS task structure and other information necessary for the agent to begin the simulation.

2.2.2 Agent to GMASS Communication

Agents send requests to GMASS using method calls defined in the Simulation interface. When an agent is started by the Testbed, it is given an object that implements this interface. The Simulation interface allows agents to start methods and abort methods in GMASS.

2.2.3 GMASS to Agent Communication

The Coordinator interface allows agents to receive messages from GMASS (with receiveMassMessage) and from other agents (with receiveMessage). The API defines different classes to represent different types of messages and events that agents may receive from GMASS. Agents are not permitted to communicate with one another until their begin methods have been called.

2.2.4 Agent Shutdown

When a simulation ends, agents will receive a disconnect message from the simulator. Upon receipt, the agent should shut down any external processes, close open files, etc. Once the agent is ready to exit, it should notify the Simulator by calling Simulation.bye. If

another simulation is to be run, the command and control infrastructure will initialize and restart a new instance of the agent.

2.3 Command and Control

The primary requirement for the C&C system is to provide completely automated unattended testing on a large scale of up to thousands of tests. In addition, tests are to be run simultaneously on multiple subnets.

C&C provides services to manage the large-scale experiments using the Test Harness and collecting data for evaluation. Features include automation and remote control, installation and configuration, test definition and management, preflight check, control of test results, instrumentation, logging and data capture. Services include experiment setup, initialization, load and run a scenario.

C&C monitors the full execution of a trial, which is one execution of a test or group of tests. A test refers to a test specification that can be repeated many times and run for different teams. A trial refers to a specific test run at one particular time for one particular team.

The test lab configuration consists of a simulation host that runs the simulation engine, a C&C host that runs the C&C software and logging database, and one or more client workstations that run the Coordinators agents.

2.3.1 Preparation for Testing

There are several steps which must take place prior to testing:

- Create the .xml file with input parameters for generating the CTAEMS scenario file.
- Run the Scenario Generator to create the CTAEMS file containing the objective view.
- Create an initial schedule for the scenario by running the Centralized Scheduler on the objective view.
- Run a utility to extract the simulator parameters and other info from the Scenario Generator input and output files.

2.3.2 Configuration and Initialization

In order to minimize time and effort required to prepare test hosts, C&C requires very little software on each test system. Only Java, Ant, and Bash Shell are required on each machine. All other software is pushed out by C&C just prior to running each trial. This software is prepared once for each type of system and is called a "mold." A mold consists of the baseline home directory and all files required for a Coordinators agent or the simulator to run. This includes software, data, configuration files, scripts, and utilities. For each trial, the software is essentially reinstalled. This ensures that the software is always up to date and that each test is run from a consistent clean initial state. When the software to be tested is modified or updated, it only needs to be delivered and installed once - to the C&C host. Installation on all other systems will be done automatically at the time of testing by the C&C services.

The techniques used by C&C ensure that test results are reliable and not invalidated by files or processes left behind by previous tests or by failure to keep software up to date and consistent between systems. C&C also supports distribution of other software packages to all machines in the lab, or specific subsets of machines. This facilitates the process of updating machine software, and will be used to ensure software consistency between all machines in the lab.

When C&C is invoked, it loads the Test Definition and other configuration information. For each trial, C&C verifies that all required hosts are available and running. Each trial will require one simulation host and one client workstation for each Coordinators agent to be run. C&C then baselines each host, by clearing the home directory and copying over a "mold" for each type of system. .

2.3.3 Monitoring Network Status

C&C monitors the network and all nodes to verify that all agents are running, GMASS is properly registered with the CoABS Grid, and that the test has started. If a required service is not running, C&C will attempt to restart it.

2.3.4 System Preflight Check

C&C's System Preflight Check utility verifies that the test environment is operating properly prior to execution of a test or experiment. It checks network connectivity and verifies that all required processes are running on the systems involved in the test. It checks for sufficient available disk space and system memory to execute the test and store logs.

2.3.5 Execution of a Test

The test definition files consists of a CTAEMS scenario file and a properties file. The properties file contains simulator parameters, the names of other configuration files, and the name of the CTAEMS file, generated by the scenario generator, contains the scenario (both the objective and subjective views). These files will be queued for processing by placing them in a specified directory. The CTAEMS file will be passed to the simulator by C&C and the simulator will provide the Coordinators agents with the subjective views only.

C&C will begin each trial by starting the CoABS Grid and then starting the simulator.

The C&C will use the Test Harness API to communicate with the Agent Conductor to initialize and start up all the s agents.

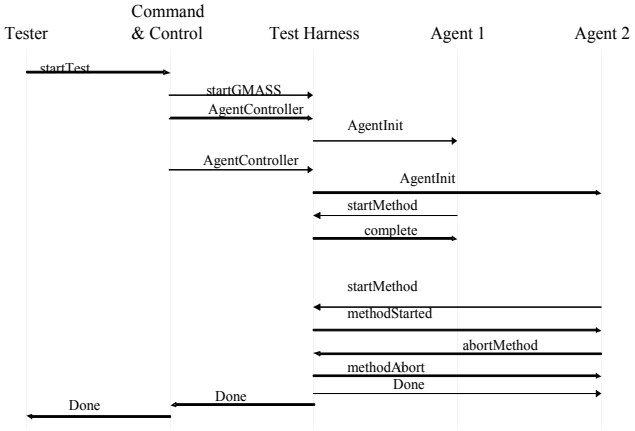

Figure 5. Single Test Event Sequence Diagram

2.3.6 Data Collection

Data is collected into logs during execution of each test. In order to minimize network traffic, logs are written to the local systems during the execution of the tests. After the test run is completed,

the logs are collected, compressed, and moved to the C&C host. The original CTAEMS scenario files, property files and other configuration files are stored with the log files for use in evaluation. In the event of a failed test, the logs are still moved to the C&C host for analysis..

2.4 Evaluation

The ACTIVE Evaluation layer includes tools used to support evaluation of performance of Coordinators agents.

2.4.1 Scenario Generator

The Scenario Generator automatically generates scenarios based on the input parameters. The scenarios are expressed as CTAEMS structures. A scenario consists of 1 to 10 concurrent problems linked by a top-level SUM task. The input parameters determine the number of problems in the scenario and specifications for window or deadline tightness and overlap, number of agents, nonlocal events, and uncertainty. Input parameters can be specified exactly, or can be randomly generated within a specified range. From the input parameters, the Scenario Generator produces a template file that includes all parameters and their default values and a CTAEMS text file that describes the scenario generated according to the input parameters.

2.4.2 Centralized Scheduler

The Centralized Scheduler is a program that solves a centralized coordination problem. It computes a set of solutions via an exhaustive search (or heuristic search for large problems) for experimentation and evaluation. The Scheduler operates on the same scenarios as the Coordinators agents. However, the Scheduler does not operate under the same time constraints as the Coordinators agents – it has unlimited time to create solutions. The results from the Centralized Scheduler will be used as a baseline for evaluating Coordinators agents.

2.4.3 Chronos

Chronos provides the time management for the Centralized Scheduler. The Centralized Scheduler can be used to determine whether a feasible initial schedule exists for a static scenario. However, in general, scenarios are dynamic – during the course of a scenario execution, several types of "unexpected" events may occur, such as method failures, new task arrivals, and deadline changes. Chronos integrates the centralized scheduler and GMASS, resulting in a centralized agent capable of handling these exogenous events. As with the distributed Coordinators agents, Chronos cannot see the future – dynamics are not known ahead of time, and past decisions (actions or non-actions) cannot be reversed. However, unlike the distributed agent teams, Chronos is not subject to time constraints between clicks, and Chronos is given the objective (rather than subjective) scenario view.

2.5 Infrastructure

2.5.1 CoABS GRID

The CoABS Grid [6] is middleware that integrates heterogeneous agent-based systems, object-based applications, and legacy systems. It includes a method-based application programming interface to register services, advertise their capabilities, discover services based on their capabilities, and send messages among those services. The Grid also provides a logging service, to log message traffic and other information, a security service to provide authentication, encryption, and secure communication; and event notification when agents register, deregister, or change their advertised attributes.

The Grid is built using Jini™ Network Technology developed by Sun Microsystems. Jini is a specification for service discovery and provides the robust and dynamic nature of the CoABS Grid. The Grid provides helper utility classes that are local to an agent and that shield the Grid user from the complexity of Jini. It also provides Jini services to facilitate agent communication and logging. Although on the one hand, the Grid shields the user from Jini, on the other, it exposes the underlying Jini classes, so that the programmer can use Jini directly, if desired.

2.5.2 Labmin

Labmin, the GITI Lab Manager, is a set of tools for managing a dynamic test lab environment. Labmin was developed with open source software and utilities. The primary utilities are SSH, partimage, Python, GRUB bootloader, and the PXE framework.

Labmin provides for remote reboot, restart, and shutdown. Systems can be turned on using the PXE framework. Running machines can be rebooted or shut down using secure channel commands. Remote change of operating system is also supported by this utility. Individual partitions can be re-imaged either from a network store, or a file on the local drive. This feature can be used for a return to baseline to ensure identical initial states for test runs.

For system integrity, Labmin commands are authorized only after they have been authenticated using public key cryptography. All Labmin communication is encrypted using asymmetric key algorithms such as RSA and DSA.

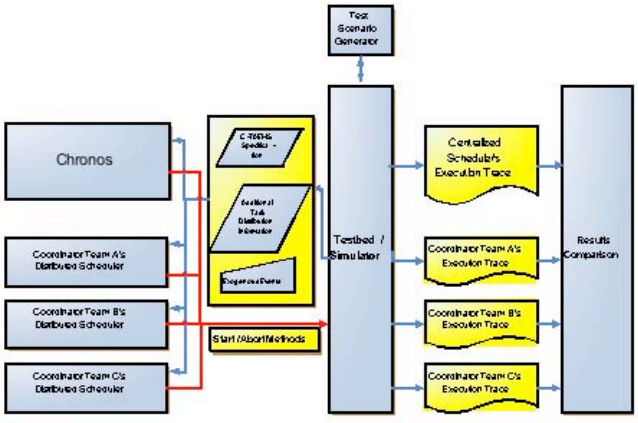

Figure 6. Centralized Scheduler in Context

2.6 Benchmarking of Coordinator Teams

Benchmarking of the Coordinators teams is done with the help of Chronos. The conceptual benchmarking scheme is depicted in Figure 2. Multiple scenarios are prepared for evaluation by the evaluation team. Each scenario contains (1) CTAEMS specification of the requested distributed tasks/methods, (2) information on specific probabilistic outcomes of methods in terms of duration and quality, and (3) exogenous events. The input (1) is given as input in the beginning of each test to both the Coordinators teams and Chronos. The inputs (2) and (3) are released to the Coordinators teams later, in real time, during the testing process. Chronos utilizes the centralized scheduler for

scheduling, which runs off-line. However, similar to the Coordinators teams, Chronos is not allowed to use inputs (2) and (3) to schedule tasks/methods that occur before the information (2) and (3) becomes available on the simulated timeline. The Coordinators teams and Chronos submit start/abort method instructions to the Testbed simulator. The simulator executes the instructions which results in producing an execution trail for each of the Coordinators teams and Chronos. Each of the execution trails are assigned the total Quality measurement according to the CTAEMS specification. The Quality measurement of the Chronos execution trail serves as the benchmark for the Coordinators teams. Chronos has the advantage of knowing the *objective view* in the CTAEMS specification, whereas the Coordinator teams know, at least initially, only the *subjective views*, i.e., parts of the CTAEMS specifications relevant to individual agents, and their environment. Also, the Coordinators teams need to produce decisions on starting/aborting tasks/method within strict time-limits, dictated by real-time constraints (enforced by the simulator), whereas Chronos has more time to make its scheduling decisions. However, due the volume of computations necessary in the testing process, the Centralized Scheduler is using a simple combinatorial algorithm, that sacrifices optimality for computational time. Thus, the quality of execution trails of Chronos may either outperform or under-perform the Coordinators teams' execution trails. In either case, the quality of execution trails produced by Chronos is used as a benchmark.

3. TESTBED LAB

The current Testbed Lab is configured with a separate subnet for each Coordinators Performer team, each of which contains 11 workstations. One of the machines on each subnet is a reserved host used for simulation execution and contains a 200 GB disk that will be used as a software and data repository. The 10 remaining machines are reserved for Coordinators agent execution. The current scenarios do contain not more than 10 agents, each agent on a Coordinators team can execute on its own machine. Figure 7 shows a diagram of the Lab Design. These machine clusters give high system/agent efficiency, enabling all three teams to execute scenarios independently in parallel, while the subnet topology ensures inter-team security. The ACTIVE Testbed software can support additional subnets, which may be required in later phases of the Coordinators program.

A server outside the individual subnets will serve as the C&C host to run the C&C services and host archived log data for evaluation. The C&C host is used to monitor the progress and operation of each cluster, manage the clusters, and manage large-scale experimentation and evaluation.

4. FUTURE WORK

The ACTIVE testbed will be advanced to support the continuing development of Coordinators agents. CTAEMs will be extended to include more non-local effects such as Disables and Hinders. The capability may be added to modify the task structure by adding exogenous events, removing nodes from the task structure, and reparenting nodes in the task structure. Currently the communications model for the agents is completely reliable; it may be changed in future to be unreliable in order to more realistically model the environment. GMASS may be modified to support a different timing model. All software components will be enhanced as needed to support testing on a larger scale.

5. ACKNOWLEDGMENTS

This work is supported by the Defense Research Projects Agency in the Coordinators Program.

We also thank the performer teams for their helpful comments and suggestions.
